Identification of cSNPs in environmental response genes contributing to breast cancer etiology. *R. Ellsworth[1], J. Weyandt[1], H. Patney[1], K. Anthony[1], C. Shriver[2]* 1) Clinical Breast Care Project, Windber Research Inst, Windber, PA; 2) Clinical Breast Care Project, Walter Reed Army Medical Center, Washington, DC.

Sporadic cancer is likely caused by a number of DNA variants, each making a small contribution to overall cancer risk. The Environmental Genome Project has identified 57 potentially deleterious cSNPs in 40 genes involved in metabolism of toxins, drug clearance, and DNA repair with population frequencies ranging from 0.01 - 0.38. To determine whether these cSNPs contribute to breast cancer etiology, we examined the prevalence of these variants in women with invasive breast cancer (n=212) and age- and ethnicity-matched (n=212) female controls enrolled in the Clinical Breast Care Project (CBCP). The patient population was comprised of 21% African American and 79% Caucasian women; other minority populations were excluded due to small sample size. Genotypes were determined by RFLP assays or by direct sequencing. Minor allele frequencies (MAFs) in controls were in agreement with published values; most cSNPs had MAFs <0.01, while SNPs in GSTZ1 (rs3177427), GCKR (rs1260326), MTHFR (rs1801133 and rs1801131) and ERCC5 (rs17655) had relatively high minor allele frequencies (>0.20). Overall allele frequencies differed significantly ($P<0.05$) between cases and controls for SNPs rs1799950 (BRCA1), rs1799853 (CYP2C9), and rs3218778 (POLI). Examination of the data by ethnic group revealed that a number of the cSNPs differed between cases and controls within a single population: the Q356R BRCA1, A232V RFC2 and R71G POLI variants in Caucasians, and the W452C ERBB2 variant in African Americans. Altered expression of ERBB2 has been associated with poor prognosis in women with breast cancer and African American women frequently have aggressive tumors with poor clinical outcomes. CYP2C9 is involved in estrogen metabolism, and BRCA1, POLI, and RFC2 are largely involved in proper DNA synthesis and thus deleterious SNPs may contribute to increased risk of DNA damage, genomic instability and disease pathogenesis. Functional variants in environmental response genes may, therefore, impair the ability to respond to exogenous exposures and increase the risk of developing breast cancer.

Cryptic deletions are a common finding in balanced reciprocal and complex chromosome rearrangements: a study of 43 cases. *M. De Gregori[1], R. Ciccone[1], F. Cifuentes[2], P. Magini[1], S. Gimelli[1], J.R. Vermeesch[3], J. Messa[1], O. Zuffardi[1,4]* 1) Patologia Umana ed Ereditaria , Università di Pavia, Pavia, PV, Italy; 2) Agilent technologies Santa Clara, California 95051, USA; 3) Center for Human Genetics, University Hospital Gasthuisberg, Leuven, Belgium; 4) IRCSS Policlinico San Matteo, Pavia, Italy.

We report array-CGH findings (44B Agilent kit, resolution of 100 kb) in 26 cases of de-novo reciprocal translocations and 17 complex chromosome rearrangements (CCRs), all but one interpreted as balanced through conventional cytogenetic examinations. Thirteen CCRs were detected in individuals with abnormal phenotypes, two in females with repeated abortions and the remaining two in fetuses investigated for advanced maternal age. Fifteen (twelve patients with chromosomal phenotype, one of the women with abortions and the two fetuses) resulted unbalanced with up to four deletions present either at the breakpoints or elsewhere. Thus, genome-wide array is recommendable in patients with a phenotype and a balanced CCR. Regarding the reciprocal translocations, seventeen were detected in patients with abnormal phenotype and six resulted unbalanced after array-CGH screening with three having a deletion at one derivative and three having a deletion elsewhere with one case having three deletions. All twenty-one imbalances originated at the paternal meiosis. Thus, among patients with a chromosomal phenotype and an apparently balanced translocation 35% is unbalanced. We analyzed nine fetuses with an apparently balanced translocations that resulted normal at the array-CGH screening. The size of all imbalances ranged from 0.37 Mb to 35 Mb. Using a customized array for seven CCRs we narrowed the deletion breakpoints to few hundreds of bp and no peculiar motif of DNA sequences associated to the imbalance was detected. Our findings demonstrate that phenotypic abnormalities, reported in half of the cases of apparently balanced de novo rearrangements, are mainly due to cryptic deletions not exclusively at the breakpoints and that male gametogenesis is more prone to create chaotic multiple chromosome imbalances and reciprocal translocations than female one.

Vitiligo and hearing loss: Report of a new case. *L.Hdez Gomez[1], G.Juarez Garcia[2], D.Gomez Torres[3], M.Izqdo. Ortiz[4], E.Hdez Gomez[5]* 1) Dept. Genetics and Audiology, Instituto Nacional Rehabilitacion, Mexico, DF; 2) Dept. Genetics and Neuropsicologia, Instituto Nacional Rehabilitacion, Mexico, DF; 3) Dept. Investigación, Instituto Nacional Rehabilitacion, Mexico, DF; 4) Dept. Neurotology, Instituto Nacional Rehabilitacion, Mexico, DF; 5) Facultad de Estudios Superiores Iztacala. Universidad Nacional Autonoma de Mexico Biologia.

Vitiligo is a common, often inherited, acquired disorder resulting from destruction of functional melanocytes (MCs). It affects all ethnic groups and has a worldwide occurrence of 0.3-1.0%. Functional MCs in patients with vitiligo disappear from the involved skin by a mechanism(s) that has yet to be identified. Traditionally, there have been three hypotheses to explain vitiligo: the immune, the neural and the autocytotoxic hypotheses A number sign is used with this entry because of evidence that susceptibility to vitiligo, like a number of other autoimmune disorders, is associated with more than 1 gene, loci for susceptibility to autoimmune disease, particularly vitiligo, have been mapped to chromosomes 17p13, 1p31,7,8,and 4. There is convincing evidence that vitiligo is a systemic disorder influencing the whole pigmentary system, including melanocytes in the inner ear. Cochlear melanocytes and also melanin-containing cellular elements of the auditory system may be affected in vitiligo and interfere with the conduction of action potentials. We report a Mexican woman affected with hearing loss and vitiligo. Female patient 62-year-old, hearing loss and vitiligo onset at 59-year-old. Audiometric test showed sensorineural bilateral middle hearing loss. Speech audiometric test showed neural deficit. Timpanogram: curves A bilateral. Stapedial reflex: absent bilateral. ABR performed reported without response at 100 dB. Trascient evoked otoacoustic emissions absent bilateral. Vestibular response to caloric is markedly reduced. Posturographic testing sensory analisys and motor control test abnormal.

BRCA1:5382insC in Individuals of Eastern European Heritage. *D. Gilchrist* Medical Genetics, Univ Alberta, Edmonton, AB, Canada T6G 2H7.

Introduction: In 10 years of BRCA testing, our most common mutation is BRCA1:5382insC. This is commonly identified as an Ashkenazi mutation. The prevalence of the three common AJ mutations is: 0.8-1.1% for BRCA1:185delAG, 0.9-1.5% for BRCA2:6174delT and 0.13-0.3% for BRCA1:5382insC.

Method: We reviewed all charts with mutations in BRCA1:5382insC, BRCA1:185delAG and BRCA2:6174delT for geographic/ethnic heritage. We then compared our results to the total number of index cases, cases with an identified mutation, and demographic information for Edmonton.

Results: 568 index cases were clinically selected for high likelihood of HBOC. Of these, 110 had a BRCA1 or BRCA2 mutation. There were 24 BRCA1:5382insC, 3 BRCA1:185delAG, and 1 BRCA2:6174delT mutations. Of the latter four, three gave a clear history of Ashkenazi heritage. The remaining 185delAG family did not have heritage recorded on the chart. Of the 24 BRCA1:5382insC mutations (19% of the total), NONE were Ashkenazi in heritage.

The 5382insC families gave a heritage of: Ukrainian (11), German (7), Russian (2) and one each of Polish, Dutch, Croatian and Estonian. Publications from Poland, Ukraine, Russia, Latvia and Germany have reported BRCA1:5382insC to be common in their non-Jewish nationals.

The population of Edmonton is approximately one million. Over half of this population identify themselves as United Kingdom in origin. Over 30% identify themselves as being from Germany or the Ukraine. There are about 10,000 individuals of Ashkenazi heritage in the area. Referrals to our clinic roughly parallel city populations.

Conclusion: BRCA1:5382insC is not only a common Jewish mutation. Rather it is a common mutation from Eastern Europe - particularly the areas of Ukraine, Eastern Germany, Western Russia, Poland and the Baltic states. BRCA1:5382insC should be considered at high likelihood in a patient from these areas.

Juvenile Hyaline Fibromatosis, a Genetic Disease. Three Mexican Cases Report. *J. Aparicio[1, 10], P.M. Barrientos[2], M.V. Chong[3], H.M.A. Garrido[3], L.A. Luis[4], H.G. Lopez[4], M.L. De la Torre[5], R.N. Balbuena[6], H.M.L. Hurtado[7], S.S. Monroy[1], O.N.C. Gil[8,10], B.W. San Martin[8], H.F. Lara[9]* 1) Genetics; 2) Endocrinology; 3) Oncology; 4) Hematology; 5) Pediatric surgery; 6) Dermatology; 7) Cytogenetics; 8) Estomatology; 9) Pathology, Hospital para el Nino Poblano; 10) Estomatology, Benemerita Universidad Autonoma de Puebla, Mexico.

INTRODUCTION. Juvenile hyaline fibromatosis (JHF) is a rare genetic disease of the connective tissue. It is characterized by papulonodular skin lesions, soft tissue masses, gingival hypertrophy, osteolytic bone lesions and flexion contractures of the large joints. JHF is caused by mutation in the gene encoding capillary morphogenesis protein-2 (CMG2, or ANTXR2) on chromosome 4q21. JHF is also considered an autosomal recessive genetical condition. CLINICAL CASES. In this study three male patients, 1 , 7 and 8 years old were studied. All the patients with characteristic clinical features of JHF as nodular/papular skin lesions and gingival hypertrophy. The skin lesions was observed on the hands, scalp, ears, and around the nose and head. It require recurrent excision. Progressive joint contractures and osteopenia was also showed and severe limitation of mobility was observed. CONCLUSION. The three patients presented multiple subcutaneous tumors, particularly of the scalp and slowly growing, causing deformities, gingival fibromatosis and large tumors were found on the scalp and whitish nodules on the nape and sides of the neck. Hypertrophic gingivae and tumors at both commissures of the lips were found. The diagnosis is confirmed by demonstration of hyaline deposition in the dermis, since pathology studies showed a mesenquimotosa lession with a lower celullarity made of fibroblastic cells with a high hyaline matriz. Celular atipia nor mytosis was idenftified. Therefore, histologically I was demonstrated an abundance of homogeneous, amorphous, acidophilic ground substance. Early diagnosis and treatment is important for a better function and quality of life. REFERENCES. 1.Aldred, M. J.; Crawford, P. J. M. : Juvenile hyaline fibromatosis. Oral Surg. Oral Med. Phenotipic Variability of Diphalia. Three cases report from the Hospital para el Niño Poblano. México. *L. Cuellar[1], J. Aparicio[2,6], P.M. Barrientos[3], H.M.L Hurtado[4], G.R. Vargas[5]* 1) Urology and Pediatric Surgery; 2) Genetics; 3) Endocrinology; 4) Cytogenetics; 5) Pathology, Hospital Para El Nino Poblano; 6) Estomatology, Benemérita Universidad Autónoma de Puebla, México.

Code Words: Diphallia, hipospadias, homebox genes. INTRODUCTION. Diphallia, or penile duplication (PD), is a medical condition in which a male infant is born with two penises. It has been estimated that one out of 5 million live births in the United States results in a diphallic birth defect. When diphallia is present, a different kind of other congenital anomalies such as renal, vertebral and anorectal duplication are observed. There is also a higher risk of spina bifida. Infants born with PD and its related conditions have a higher death rate from various infections associated with their more complex renal or colorectal systems. CLINICAL CASES. A study was performed in three male patients 2 months, 4 and 16 years respectivelly. All patients were diagnosed with real diphallia, well developed with urinarious meatus, and both testicles, one of the case a vessel duplication was observed, all of the patients has a normal cariotype, 46XY. Pathology studies were performed to the surgered penises. CONCLUSION. It is thought diphallia occurs in the fetus between the 23rd and 25th days of gestation when an injury, chemical stress, or malfunctioning homeobox genes hamper proper function of the caudal cell mass of the fetal mesoderm as the urogenital sinus separates from the genital tubercle and rectum to form the penis. This rare condition has been documented in pigs and other mammals. It is commonly mistaken that all sharks have this condition, but in reality they have a pair of "claspers" which serve a reproductive function. REFERENCES. 1. Sergio F. Camacho-Gutierez y cols. Molecular relationship between HER2 and BRCA1 in invasive breast carcinoma. *B. Deyarmin[1], R.E. Ellsworth[1], C.D. Shriver[2]* 1) Clinical Breast Care Project, Windber Reseaerch Institute, Windber, PA; 2) Clinical Breast Care Project, Walter Reed Army Medical Center, Washington, DC.

Background: Deletion of 17q is one of the most common alterations found in sporadic breast cancers and often results in inactivation of the BRCA1 tumor suppressor gene, rendering cells susceptible to additional DNA damage. In contrast, the HER2 gene, located within 5 Mb of the BRCA1 gene, is found to be amplified in ~20% of breast tumors. Although efforts have sought to identify the smallest common region amplified in patients with HER2 amplification, the status of BRCA1 in these patients, whether co-amplified or deleted, is unknown, thus FISH analysis of BRCA1 was performed in breast tumors with documented HER2 amplification and/or allelic imbalance at 17q12-q21. Methods: HER2 status was determined for 77 invasive breast tumors using the PathVysion HER2 kit. For BRCA1 analysis, DNA probes were generated by nick translation from BAC clone RP11-831F13 in conjunction with a CEP 17 probe. Chromosomal content was defined using copy number values of the CEP17 probe: monosomy = <1.75, disomy = 1.76-2.25, and polysomy = >2.25. Chromosomal gains and losses for HER2 and BRCA1 were defined as copy number ratios of >3.0 and <1.75, respectively. Results: The majority (73%) of breast tumors were aneusomic (42% polysomy, 31% monosomy) for CEP17. Frequency of HER2 gains and losses was 73% and 4%, respectively. For BRCA1, 56% of specimens had a loss of BRCA1, but no tumors showed a gain of BRCA1. HER2 and BRCA1 status were discordant in 35% of specimens and were divided equally between polysomy, disomy, and monosomy. Conclusions: The high frequency of BRCA1 deletion tumors selected for HER2 amplification suggests that amplification and deletion occur independently within a 5 Mb region. 20% of samples had copy number <1.75 at CEP17 and BRCA1 with normal or amplified chromosomal content at HER2 suggesting an early large deletion of 17q followed by targeted amplification of the HER2 region. This data, in conjunction with the high levels of repetitive elements within the BRCA1 gene region, suggest that genomic instability of BRCA1 may influence HER2 amplification.

Rapid and accurate haplotype phasing and missing data inference for whole genome association studies using localized haplotype clustering. *S.R. Browning, B.L. Browning* Department of Statistics, The University of Auckland, Auckland, New Zealand.

Whole genome association studies present many new statistical and computational challenges due to the large quantity of data obtained. One of these challenges is haplotype inference: methods for haplotype inference designed for small data sets from candidate gene studies do not scale well to the large number of individuals genotyped in whole genome association studies. We present a new method and software for inference of haplotype phase and missing data that can accurately phase data from whole genome association studies. Our method is based on fitting a localized haplotype cluster model[1,2], to initial estimates of haplotype phase. The localized haplotype cluster model is extended to give a hidden Markov model, from which revised estimates of haplotype phase can be sampled. This process is iterated, with most likely haplotype phase inferred at the last iteration. Our method is compared with existing haplotype inference methods, including fastPHASE and HaploRec, on real and simulated data sets with thousands of genotyped individuals. We find that our method outperforms existing methods in both speed and accuracy for large data sets with thousands of individuals and densely spaced genetic markers, and we use our method to phase a real data set of 3002 individuals genotyped for 490,032 markers in 3.1 days computing time, with 99% of masked alleles imputed correctly. Our method is implemented in the Beagle software package which is available at http://www.stat.auckland.ac.nz/~browning/beagle/beagle.html

Association of insertion-deletion polymorphism of the angiotensin-converting enzyme gene with rheumatoid arthritis. *M.Z. Haider[1], S.S. Uppal[2], G.S. Dhaunsi[1]* 1) Dept Pediatrics, Fac Medicine, Kuwait Univ, Safat, Kuwait; 2) Dept Medicine, Fac Medicine, Kuwait Univ, Safat, Kuwait.

Rheumatoid arthritis is a multifactorial disease in which environmental agents interact with genetic factors that influence susceptibility. Only 30% of the genetic contribution to RA can be attributed to HLA genes and it is suggested that other non-HLA genes may play a relevant role in RA susceptibility. Recently, Angiotensin converting enzyme (ACE), a key player in inflammatory signal transduction pathways, has been reported to be involved in pathogenesis of RA, and high levels of ACE have been documented in RA synovial fluid and RA pleural effusions. Plasma and tissue levels of ACE are regulated at the transcriptional level, we hypothesize that the genotype of ACE in RA patients may be a determining factor in the pathogenesis of this inflammatory disease. So far no studies have assessed this possibility. Sixty RA patients were recruited and clinically characterized according to disease duration, disease severity, disease activity and ACR functional class. Thirty five healthy controls (HC) were also enrolled in the study. ACE gene I/D polymorphism genotypes were determined in patients and HC. We found a significant over-representation of the DD genotype and the D allele in RA patients when compared to HC. Additionally, we also found that gender correlates significantly with genotypic and allele frequencies, with RA males exhibiting a higher frequency of the DD genotype and D allele compared to HC males. Furthermore, Arab patients show a higher frequency of D allele when compared to Arab HC. By logistic regression analysis the DD genotype confers a relative risk for development of RA of 3. Thus, our data indicate that the worst case scenario for the development of RA would be an Arab male with DD genotype. Our results also suggest a possible influence of the ACE gene on the RA disease activity, severity and functional class.

Constitutional telomere shortening may be a predisposition to young onset microsatellite stable colorectal cancer.

L.A. Boardman[1], D.L. Riegert-Johnson[1], R.A. Johnson[2], S. L. Slager[3], S. J. Achenbach[3], S.N. Thibodeau[2], G.M. Petersen[4] 1) Dept Internal Medicine, Mayo Clinic Colege of Medicine, Rochester, MN; 2) Dept of Laboratory Medicine and Experimental Pathology, Mayo Clinic College of Medicine, Rochester, MN; 3) Division of Biostatistics,Department of Health Sciences Research, Mayo Clinic College of Medicine, Rochester, MN; 4) Division of Epidemiology,Department of Health Sciences Research, Mayo Clinic College of Medicine, Rochester, MN.

Background and Significance: Telomeres are repetitive base pairs sequences that cap linear chromosomes and protect them from unraveling. With progressive cell division, telomeres will shorten; leading to regulated cell senescence and apoptosis in healthy cells. A phenomenon associated with aging, telomere shortening has been associated with many diseases of aging, including cancers. Though telomere shortening has been documented in colorectal cancer (CRC) tumor cells, constitutional telomere shortening has not been rigorously studied in CRC patients. Methods: We evaluated telomere length by quantitative PCR in peripheral blood lymphocytes DNA from 114 CRC patients and compared to telomere length in 98 individuals serving as healthy controls on the basis of having no current or prior history of cancer. Statistical analysis: Results are presented using medians and interquartile ranges (IQR). The Wilcoxon Rank Sum Test was used to perform between group comparisons. All tests were two-sided and p-values <0.05 were considered statistically significant. Results: Peripheral lymphocyte telomere length was statistically significantly shorter in patients with CRC than in age matched controls ($p< 0.001$). Men with CRC had significantly shorter telomeres than women with CRC ($p=0.003$). There were no significant differences seen in telomere lengths between CRC patients or healthy controls on the basis of tobacco exposure. Conclusion: Constitutional telomere shortening is associated with an increased risk for MSS colorectal cancer in patients 50 years of age. Men with CRC had a higher degree of constitutional telomere shortening than did women with cancer.

Syne1 mutations cause a novel form of autosomal recessive pure cerebellar ataxia. *F. Gros-Louis[1], N. Dupré[3], P. Dion[2], M. Fox[4], S. Laurent[2], J.R. Sanes[4], J.P. Bouchard[3], G.A. Rouleau[2]* 1) CHUL Research Centre, Universite Laval, Quebec, PQ, Canada; 2) Centre for the Study of Brain Diseases, CHUM and Ste-Justine Hospital Research Centre, Université de Montréal, Montréal, QC, Canada; 3) Department of Neurological Sciences, CHAUQ - Enfant-Jesus Hospital, Quebec City, QC, Canada; 4) Department of Molecular and Cellular Biology, Harvard University, Cambridge, MA, 02138, USA.

BACKGROUND: The recessive ataxias are a heterogeneous group of disorders comprised mainly of Friedreich ataxia, ataxia telangiectasia, ataxia with vitamin E deficiency, ARSACS, abetalipoproteinemia, AOA1, and AOA2. We have recently identified a cluster of families with a new recessive pure cerebellar ataxia phenotype that we named ARCA1. METHODS: (1) Clinical history and neurological examination was performed on each affected members of 27 families who originate from Quebec. 2) We conducted a genome-wide scan with 5 families of which 20 individuals were affected. (3) We screened candidate genes within the mapped area. RESULTS: (1) Based on the cases examined, ARCA1 is characterized mainly by: middle-age onset and slow progression; a cerebellar syndrome with dysmetria and wide-based gait; normal nerve conduction studies and severe cerebellar atrophy. (2) Genome-wide scan revealed one marker (D6S476) with a LOD score higher than 3. This linkage was followed up with additional markers and the maximum two-point LOD score was 6.84. (3) Sequencing analysis allowed us to uncover 5 different mutations within SYNE1, one of the biggest genes in the human genome. 4) We have identified 2 additionnal mutations detected amongs a cohort of unlinked recessively inherited ataxias. CONCLUSION: We report a novel form of recessive ataxia in a French-Canadian cohort and show that SYNE1 mutations are causative in all of our kindreds, making SYNE1 the first gene responsible for a recessively inherited pure cerebellar ataxia. Since 7 different mutations have been identified in a relatively homogenous population, we predict that mutations in this gene may be responsible for a significant fraction of all adult-onset autosomal recessive ataxia syndromes with cerebellar atrophy.

Polymorphism at the Sp1-binding site in the collagen type I COLIA1 gene in women with pelvic organ prolapse.
S. Kim, H. Cho, M. Jeon, H. Jung, J. Choi, N. Cho, S. Bai OB/GYN, Col Med, Seodaemun Ku, Yonsei Univ, Seoul, Korea.

We examined the possible influence of polymorphism at the transcription factor Sp1-binding site in the gene encoding -1 chain of type I collagen (COLIA1) on the risk of pelvic organ prolapse. From May 2006 through September 2006, 15 patients were treated for pelvic organ prolapse at Yonsei University Medical Center. Fifteen control subjects with benign gynecological condition were selected by matching with age, postmenopausal status, and body mass index. DNA was obtained from peripheral blood leukocytes. The fragment of the first intron of the COLIA1 gene of type I collagen containing the Sp1-binding site was amplified by real time polymerase chain reaction. The polymorphism was identified with LightCycler Technology with hybridization probes. The melting curve analysis represented detection and visual discrimination based on the melting temperatures of normal and mutant alleles. Sequencing reactions were performed on each template using primer. The groups were similar with respect to parity, medical history, surgical history, and smoking. The homozygous peak was noted on the melting temperature of 57C curve analysis. Sequencing reactions confirmed the G/G alleles in the 30 specimens tested. We could not find any polymorphism at the Sp1-binding site in COLIA1 gene of type I collagen in patients with both pelvic organ prolapse and control group. Our results suggest that the polymorphism at the transcription factor Sp1-binding site in the gene encoding -1 chain of type I collagen is unlikely to be of clinical value in identifying Korean women who are at risk of pelvic organ prolapse.

Identification of genes regulated by the Extracellular Signal-Regulated Kinase (ERK1/2) in primary mouse astrocytes. *L.S. Correa-Cerro[1], D. Heffron[1], Y. Zhang[2], G. VandeWoude[2], J.W. Mandell[1]* 1) Dept of Pathology, Univ Virginia, Charlottesville, VA; 2) Department of Molecular Oncology, Van Andel Research Institute, Grand Rapids, MI.

Astrogliosis is defined by cellular hypertrophy and process extension, increased glial filament production, and some degree of proliferation. Astrogliosis has been identified in Parkinsons and Alzheimers diseases as well as in several others human brain injuries. Increasing evidence points to neuroprotective roles of astrogliosis in the setting of brain injury. We used Affymetrix Mouse 430 2.0 Arrays to test the hypothesis that FGF2 acting via the MEK-ERK intracellular signaling pathway, leads to pathway-specific gene expression changes in astrocytes which promote the morphological plasticity of reactive astrocytes. Astrocyte cultures were prepared from 1-day-old mouse brains and treated with human recombinant FGF2 and the specific MEK inhibitor U0126 or DMSO (vehicle control) for 24h. Array data identified 89 up-regulated and 179 down-regulated genes (>2-fold change). Six of the upregulated genes were confirmed by real time PCR: Tgfbi, Rasgrf1, Rgs16, Esm1, Errfi1, and Spp1. Eight known negative feedback signaling genes were induced by FGF2: Rgs16, Dusp6, Dusp4, Spry4, Spred1, Spred2, Spred3, and Errfi1. Errfi1 (ERBB receptor feedback inhibitor 1), gene encodes a cytoplasmic protein known to be upregulated with cell growth and cell stress. To test the role of ERRFI1 in regulation of astrogliosis we performed histological and immunohistochemical studies of brain tissue from adult Errf1/, and control wild types mice. We found no evidence of brain malformation in four Errf1/ mice studied. Phosphorylated ERK levels were not qualitatively changed as determined by immunohistochemistry. Astrogliosis markers, including GFAP, Vimentin, and PCNA did not differ in knockout mice compared to controls. Although baseline astroglial activation appears unaffected by loss of Errfi1 the possibility that injury or stress-induced astroglial activation will be exaggerated in Errf1/ mice remains to be tested.

GMDR: A new software for detection of gene-by-gene and gene-by-environment interaction in the population-based study. *G.B. Chen[1, 2], X.Y. Lou[1], L. Yan[2], J. Zhu[2], M.D. Li[1]* 1) Dept Psychiatry & NB Sciences, Univ Virginia, Charlottesville, VA; 2) Institute of Bioinformatics, Zhejing University, PR China.

A user-friendly computer program is developed to implement the generalized multifactor dimensionality reduction (GMDR) method, a newly proposed approach for detecting gene-by- gene and gene-by-environment interactions underlying complex traits. This software consists of two main components: choosing and computing appropriate statistics and conducting GMDR analysis based on the selected statistic. Within the program, it includes built-in logistic regression and linear regression modules to compute the score statistic for categorical and quantitative phenotypes. As an alternative, user can import self-defined other statistic or score into the program. Furthermore, the program allows adjustment for covariates when using the built-in modules to calculate the score statistic. The output of the program can be in text and visual formats and save as different types of files such as JPG, JPEG, PNG, BMP or EPS. This java-based software is platform-free and can run on different operation systems including MS Windows, Linux and Mac OS. It can also run in the console form for advanced users to efficiently perform large-scale data analysis. The software is available at our website: http://www.healthsystem.virginia.edu/internet/addiction-genomics/. The source code is open to the whole scientific community and allows the user to further extend it. The project is supported by NIH grant DA-12844.

The NIDDK Central Repository. Using legacy data & samples to address new questions. *P.C. Cooley[1], C. O. Scheper[1], Y. Qin[1], C.F. Turner[1], S. Cantor[1], H. Ray[1], R. Rasooly[2]* 1) RTI International, Durham, NC. Research Computing Division, Bioinformatics; 2) NIH/NIDDK.

The National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) conducts and supports research on many of the most serious diseases affecting public health, including diabetes, liver and kidney diseases. In many cases, the study has collected genetic samples that can be linked to phenotypic data from the subjects; therefore, it is possible to match genotypes to phenotypes and perform many genetic analyses. As high-density genotyping becomes increasingly available, the ability to relate the genetics of patients to results of previous NIDDK-sponsored clinical trials becomes timely. Several NIDDK-supported studies have focused on diabetes and diabetic complications. If consistent phenotypes can be identified across studies and their observations pooled, it might be possible to assemble a dataset with sufficient power to support studies that are not possible from any one individual study. Entirely new studies could be conducted with no additional data collection. To help accomplish that goal and to preserve and distribute valuable resources, NIDDK has established a Central Repository to collect and distribute the data and samples collected by NIDDK-sponsored studies. The Repository co-locates multiple databases to make the data and the associated biological and genetic samples available to the scientific community. The repository also catalogues, retrieves and checks the integrity of study data, manages data requests, and answers researchers questions. It currently houses publicly available data and samples from 12 studies, including four genetics-based diabetes studies, and is collecting data and samples from more than 40 other ongoing studies for future distribution. The NIDDK Central Repository is a powerful tool for performing in-depth secondary analysis of previously collected data. It will be key in increasing the impact of diabetes studies and, ultimately, will make it possible for researchers to conduct entirely new studies without having to collect data or additional biological samples.

Sequence Analysis of the SCN9A Gene in a Familial Form of Adult-Onset Erythromelalgia. *T.Z. Fischer[1,2,3], S.D. Dib-Hajj[1,2,3], L. Tyrrell[1,2,3], F.M. Hisama[4], S. Novella[1], L. Marshall[1], S.G. Waxman[1,2,3]* 1) Dept Neurology, Yale Univ, New Haven, CT; 2) Center for Neuroscience & Regeneration Research, Yale Univ, New Haven, CT; 3) Rehabilitation Research Center, VA CT Healthcare System, West Haven, CT; 4) Dept Genetics, Children's Hospital Boston, Boston, MA.

Voltage-gated sodium channels play a major role in the pathogenesis of chronic pain in peripheral neuropathies. Alterations in the expression and targeting of specific sodium channels within the DRG neurons appear to predispose the neurons to abnormal firing in acquired channelopathies, and mutations in one channel, Nav1.7, have been linked to inherited painful neuropathies. Early-onset primary erythromelalgia is an autosomal dominant disorder that is characterized by episodic burning pain associated with redness and warmth of the affected extremities, often relieved by cooling. The etiology of this disease was unknown until recently when mutations were identified in the SCN9A gene, encoding the Nav1.7 voltage-gated sodium channel, indicating that erythromelalgia is a neuronal channelopathy. Mutations in Nav1.7 from erythromelalgia patients lower the threshold for single action potentials and induce higher firing frequency of nociceptive DRG neurons. The molecular basis of familial adult-onset erythromelalgia is less well understood, however. We enrolled a large family who met the clinical criteria for this disease, and screened for mutations within SCN9A by direct sequencing of PCR amplicons of exons and the immediately flanking intron sequences. A polymorphic substitution, R1150W, was identified in the proband. This allele was previously identified in sporadic cases of early- and adult-onset erythromelalgia, but importantly, it is present in 14% of a control sample. Thus, the disease-causing potential of this substitution is not clear. The chromosomal localization of a potential disease locus for adult-onset erythromelalgia is being investigated by genome-wide SNP analysis. Increasing the database of mutations in SCN9A will enable us to establish a genotype-phenotype relationship, and the identification of a new locus will hopefully permit the design of mechanism-based treatment for these painful neuropathies.

Penetrance of dementia in male carriers of the FMR1 premutation. *S. Jacquemont[1], M. Sevin[2], Z. Kutalik[3,4], P. Damier[2], M. Verceletto[2], P. Renou[2], P. Boisseau[5], S. Bergmann[3,4], J.M. Rival[5], J.S. Beckmann[1,3]* 1) Service de génétique médicale, CHUV, Lausanne, Switzerland; 2) Centre dInvestigation Clinique, CHU de Nantes, France; 3) Departement de Génétique Médicale, UNIL, Lausanne, Switzerland; 4) Swiss Institute of Bioinformatics; 5) Service de Génétique Médicale, CHU de Nantes, France.

The Fragile X-associated tremor ataxia syndrome (FXTAS) is a newly recognized neurodegenerative disorder found among carriers of the FMR1 premutation. Core clinical features are progressive cerebellar ataxia and intention tremor. Several studies have also reported cognitive decline/dementia in these patients, however, there is no data on the penetrance of this debilitating symptom. 67 males aged 50 years or older were recruited from fragile X families, regardless of their medical history or genetic status. The Mattis Dementia Rating Scale (MDRS) was used to quantify global cognitive capacities. Other tests assessed executive functioning, verbal and non-verbal working memory, visuospatial skills, and reasoning capacities. The evaluator was blinded as genetic status was obtained after evaluation. Molecular testing revealed 30 premutation carriers and 37 intrafamilial controls. Based on a cut-off score of 129 for the MDRS and an education level corrected at 9.5 years, the frequency of dementia at age 70 among individuals with large premutation (90 CGG), small premutation (60 CGG) and controls was 80%, 50%, and 4%, respectively. At age 60 these frequencies were 42%, 1%, and 0%, respectively. Multiregression analysis accounting for age and education found a significant correlation between CGG repeat length and the following: MDRS, tests of executive functions, visuospatial performances, and reasoning capacities ($p<0.001$). The penetrance of dementia among carriers of large premutation is particularly high. There is also a sizeable effect for smaller alleles which is of importance due to their higher prevalence in the general population. These data will greatly contribute to genetic counseling as this multiregression model is now able to provide estimates for the penetrance of dementia for any given allele size, age and education level.

Evidence of a quantitative trait locus for energy and macronutrient intakes on chromosome 3q27.3 in the Quebec Family Study (QFS). *A. Choquette[1,2,4], S. Lemieux[3,4], A. Tremblay[2,4], Y.C. Chagnon[5], C. Bouchard[6], M.C. Vohl[1,3,4], L. Perusse[1,2]* 1) Lipid Research Center, CHUQ-CHUL Pavilion, Québec, Canada; 2) Social and Preventive Medicine Department, Division of Kinesiology, Laval University, Québec, Canada; 3) Food Science and Nutrition Department, Laval University, Québec, Canada; 4) Institute of Functional Foods and Nutraceuticals, Québec, Canada; 5) Robert-Giffard Research Center, Québec, Canada; 6) Pennington Biomedical Research Center, Baton Rouge, Louisiana, USA.

Background: Poor dietary habits are associated with an elevated risk of obesity. Little is known about the genes influencing dietary energy and nutrient intakes, despite evidence that they are influenced by genetic factors. Objective : To identify chromosomal regions harboring genes affecting energy, carbohydrate, lipid and protein intakes through a genomewide linkage analysis. Design : Energy intake (EI) as well as intakes of carbohydrate (CHO), lipid (LIP) and protein (PROT) were assessed in 836 subjects from QFS using a 3-day dietary record. A total of 443 markers were genotyped and tested for linkage with age- and sex-adjusted dietary intakes and macronutrient intakes expressed as percent (%) of total energy intake using the Haseman-Elston method. A maximum of 454 pairs from 217 nuclear families were available for analysis. Results : The strongest evidence of linkage was found on chromosome 3q27.3 at marker D3S1262 for EI ($p = 0.0000003$). This marker was also linked with CHO ($p = 0.00083$) and LIP ($p = 0.000029$). The peak linkages for CHO, LIP and PROT were found on chromosomes 18q22.3 ($p = 0.000074$), 5q15 ($p = 0.000009$) and 10p14 ($p = 0.000003$), respectively. Evidence of linkage was also found on 20q11.21 for %CHO ($p = 0.00036$), 20q13.12 for %LIP ($p = 0.00091$) and 19q12 for %PROT ($p = 0.00086$). Conclusion : These results provide evidence for the presence of a QTL influencing total caloric intake as well as CHO and LIP intakes on chromosome 3q37.3. This region of the human genome has been shown to be linked to obesity in previous studies, which suggests the presence of a gene involved in the etiology of obesity through its influence on dietary intake.

Interleukin-10 Promoter Polymorphisms and Breast Cancer Risk in Iranian Women. *R. Asadollahi[1], N. Hakakian[1], E. Kamali-Sarvestani[1], A. Talei[2]* 1) Immunology department, Shiraz Medical School, Shiraz, Fars, Iran; 2) Department of surgery of Shiraz Medical School,shiraz, Fars, Iran.

Background: IL-10 is an anti-inflammatory cytokine which is involved in tumorigenesis. Over production of IL-10 and elevated number of IL-10 generating mononuclear cells in breast tumor tissue has already been shown. Objective: To determine the association of IL-10 promoter polymorphisms with increased risk of breast cancer and its association with breast cancer prognostic factors. Methods: Peripheral blood samples from 275 female breast cancer patients and 320 cancer free controls were used to detect three single nucleotide polymorphisms in IL-10 promoter region (-1082, -819, -592) by PCR method. Results: The frequency of genotypes and alleles of three mentioned regions of IL-10 promoter and their haplotypes (GCC, ATA, and ACC) showed no statistically significant difference between patients and controls. In the case of prognostic factors, progesterone receptor (PR) status exhibited significant relation with -1082 genotypes (P= 0.03) and haplotypes (P=0.02). -1082 AA genotype was associated with negative PR expression whereas AG and GG genotypes of this site were positively associated with PR expression. Similarly GCC haplotype correlated with positive PR expression and ATA and ACC with negative PR expression. Conclusion: The data of this study showed that IL-10 promoter gene polymorphisms may not be considered as one of the risk factors for breast cancer in Iranian patients.

The CIDR AutoCall Pipeline: An automated analysis pipeline for Illumina Infinium Products. *M.W. Barnhart, K. Hetrick, C.W. Bark, D.R. Leary, G. Lowe, E. Hsu, J.L. Goldstein, K.F. Doheny, L. Watkins, Jr.* Center for Inherited Disease Research, Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD.

The Center for Inherited Disease Research (CIDR) is a centralized facility established to provide genotyping and statistical genetics services for investigators seeking to identify genes that contribute to human disease. The large volume of data produced by genotyping products such as Illuminas Infinium group poses immense challenges for data storage, analysis, and retrieval. The CIDR AutoCall Pipeline, a Java application tightly integrated with the CIDR Infinium LIMS, is an automated analysis pipeline for data produced by Illuminas AutoCall utility for the HumanHap300, 550, and 650Y products. The tiny percentage of data that may be problematic is identified for human scrutiny; the rest is and archived for downstream data analysis and release. For a setof beadchip scans, the pipeline gathers and stores scanner information; generates a binary genotype call (GTC) file using Illuminas AutoCall utility; parses the GTC file to produce human-readable output; analyzes beadchip data quality; and archives the data. The pipeline first parses the final XML file produced by the scanner for each chip and uploads the data to the CIDR LIMS database. Next, AutoCall is used to generate a GTC file for each chip using the bead pool manifest (BPM) file, the cluster (EGT) file, and the chip intensity data (IDAT) files. Each GTC file is then read using CIDRs GTC file parser, a stand-alone software tool (available upon request) that retrieves detailed SNP data, computes normalized coordinates and theta, and writes a human-readable flat file. Overall data quality is calculated from the information in these files, and a BeadStudio R SNP table is used with it to generate Log R ratios across chromosome one. Finally, all the data is archived. Each chips GTC file, its flat-file representation, and the metrics file containing QC data for each chip are written to project-specific folders for easy retrieval. This GTC archive provides all the data needed to perform a genetic analysis across a project.

Advances in single copy hybridization technology for FISH and Quantitative Microsphere Hybridization (QMH).

J.H.M. Knoll[1], J.M. Cowan[1], P.K. Rogan[1, 2] 1) Pediatrics, Tufts-New England Medical Center, Boston, MA; 2) Phylogenetix Laboratories Inc., Overland Park, KS.

Single copy (sc) genomic probes, which are prepared from short, unique genomic sequences with precisely-defined chromosomal locations, have been used for high-resolution, genetic hybridization analysis of congenital abnormalities and cancer. We have previously described the development of sc probes for FISH (to detect chromosome rearrangement, deletion and duplication) and in QMH flow cytometry (to detect copy number differences). For these probes to be used clinically, hybridization efficiencies and signal intensities need to be comparable to or better than other commonly used reagents. We introduce new approaches for sc probe derivation and corresponding technical improvements in FISH and QMH methodologies using specimens previously characterized by cytogenetics and conventional FISH.

Sc probes can be developed either from repeat-masked genomic sequences or with other bioinformatic methods. We find that these different bioinformatic approaches identify the same single copy intervals with similar computational overhead, and that probes designed from these methods exhibit comparable laboratory results. Modifications of FISH protocols for cell processing, hybridization and post-hybridization wash conditions have resulted in simplified, accelerated experiments and increased hybridization efficiencies with brighter signals. Multiple probe labeling methods were also compared. For QMH, we have optimized procedures to expedite data collection and improve the statistical analysis of genomic hybridization of microsphere-conjugated sc probes. This increases the accuracy of copy number genotypes determined from mean fluorescence intensities. We demonstrate that optimization of multiple parameters in scFISH and QMH will significantly advance our goal of producing clinical assays based on sc technology.

A multiple testing correction method for genetic association studies using correlated single nucleotide polymorphisms. *X. Gao[1], J. Starmer[2], E.R. Martin[1]* 1) Miami Inst Human Genomics, Univ Miami Miller Sch Medicine, Miami, FL; 2) University of North Carolina at Chapel Hill, Chapel Hill, NC.

Multiple testing is a challenging issue in genetic association studies using large numbers of single nucleotide polymorphism (SNP) markers, many of which exhibit linkage disequilibrium (LD). Failure to adjust for multiple testing appropriately may produce excess false positives or overlook true positive signals. The Bonferroni method of adjusting for multiple comparisons is easy to compute, but is well known to be conservative in the presence of LD. On the other hand, permutation-based corrections can correctly account for LD among SNPs, but are computationally intensive. Recent attempts to quickly and accurately adjust for multiple testing have lead to advances in both areas. However, given information about the degree of LD, these methods remain unnecessarily conservative or difficult to compute. In this work, we propose a novel multiple testing correction method for association studies using SNP markers. It is shown to be simpler and more accurate than the recently developed methods and is comparable to permutation-based corrections using both simulated and real data. It can also be applied to genome-wide association studies. The efficiency and accuracy of the proposed method make it an attractive choice for multiple testing adjustment when there is high intermarker LD in the SNP dataset.

Alterations in family planning in female reproductive-aged BRCA mutation carriers. *A.M. Bakke[1], M. White[2], S. Ross[3], L.P. Shulman[4], A.P. Trivedi[4]* 1) Center for Genetic Medicine, Graduate Program in Genetic Counseling, Northwestern University, Chicago, IL; 2) Cancer Risk Clinic, University of Chicago, Chicago, IL; 3) Department of Psychiatry, Northwestern University Feinberg School of Medicine, Chicago, IL; 4) Division of Reproductive Genetics, Department of Obstetrics and Gynecology, Northwestern University Feinberg School of Medicine, Chicago, IL.

Objective: We investigated if and how reproductive-age female BRCA mutation carriers alter reproductive decisions after BRCA result disclosure. **Methods**: 41 out of 126 eligible mutation carriers completed surveys regarding whether or not their and their partners attitudes regarding family planning changed after receiving their test results. **Results**: 56% of participants desired additional children at the time of testing. Of this subgroup, 52% reported a change in their reproductive planning. 26% reported they desired fewer children after testing, and 17% desired more children than before testing. 26% wanted to start childbearing earlier, and 48% wanted to stop childbearing earlier than planned due to the desire to pursue oophorectomy. 22% of participants indicated other BRCA positive women in their family altered their family planning due to carrier status. Compared to their partners, participants perceived themselves to be more concerned about the chance of passing the BRCA mutation on to their children ($p<0.001$) and their own mortality ($p=0.013$). Of the three participants who designated they were single at the time of the survey, two indicated that their BRCA status affected their ability to have a committed relationship. More than one-third of participants indicated they would like to have family planning issues specifically discussed in a genetic counseling session. **Conclusion**: Young BRCA mutation carriers frequently alter their reproductive plans after learning their carrier status. Participants were more concerned about their own mortality and passing on their BRCA mutation to their children than they believed their partners to be. A subset of women would likely find value in discussing family planning issues in the genetic counseling session.

Phenotyping a *Magel2* knockout mouse: a model for Prader-Willi Syndrome. *E.M. Kwolek, R.E. Mercer, J.M. Bischof, R. Wevrick* Dept. of Medical Genetics, University of Alberta, Edmonton, Alberta, Canada.

First described in 1956, Prader-Willi Syndrome (PWS) is a polygenetic condition resulting from the loss of paternal expression of imprinted genes located at 15q11-15q13. While multiple genes have been implicated in PWS, the specific role of each gene is unknown and further investigation is warranted. PWS is one of the most common syndromic causes of obesity and major diagnostic criteria include neonatal hypotonia and failure to thrive, developmental delays, hypogonadism, dysmorphic facial features, hyperphagic behaviors that ultimately lead to obesity, and abnormal sleep and respiration. One of the genes identified within the implicated chromosomal region is *MAGEL2* - the expression of which is limited to the paternal allele as a result of its imprinted nature. This gene is developmentally regulated and expression in embryos is mostly in the hypothalamus and to a lesser extent in other nervous system tissues. In adults *Magel2* is expressed almost exclusively in the hypothalamus - specifically to the suprachiasmatic nucleus, which modulates circadian rhythm in mammals.

We have developed a *Magel2*-null knockout mouse to study the impact of loss *Magel2* expression in an *in vivo* system. Like neonates with PWS, the knockout mice are underweight compared to their wild-type counterparts prior to weaning; they ultimately gain more weight and have higher adiposity during adulthood than control littermates. Behavioral analyses show that *Magel2*-null mice have decreased basal activity and interruption of the wild-type circadian rhythm. We now report that the *Magel2*-null mice have abnormal locomotor function and reproductive deficits that worsen with ageing. As increased anxiety, repetitive behavior, and learning deficits are cardinal features of PWS, we are examining these traits in adult *Magel2*-null mice. This research aims to provide an appropriate in vivo model for studying Prader-Willi syndrome and the impact of *Magel2* dysregulation in hypothalamic dysfunction.
.

Pallister-Killian syndrome: tetrasomy of 12pter ->12p11.22 in a boy with an analphoid, inverted duplicated marker chromosome. *X. Huang[1], M. Michelena[2], E. Leon[2], T. A. Maher[1], R. McClure[1], A. Milunsky[1]* 1) Center for Human Genetics, Boston University School of Medicine, Boston, Massachusetts USA; 2) Centro Médico Genetica and Universidad Peruana Cayetano Heredia, Lima, Peru.

Abstract Supernumerary marker chromosomes (SMCs) without detectable alphoid DNA are predicted to have a neocentromere and have been referred to as mitotically stable neocentromere marker chromosomes (NMCs). Here we report the molecular cytogenetic characterization of a new case of Pallister-Killian syndrome (PKS) in a boy with an analphoid, inverted duplicated NMC derived from 12pter 12p11.22 by using High Resolution CGH (HR-CGH), multiplex FISH and BAC-FISH mapping analyses with various alpha-satellite DNA probes, subtelomere probes, and BAC-DNA probes. Precise identification of SMCs and NMCs is of essential importance in genetic counseling. HR-CGH is a more informative and often a faster way of precisely identifying the origin of SMCs. This case is the third report of PKS with a neocentromere marker chromosome containing an inverted duplication of partial 12p with available clinical data. These observations may help to determine the critical region for PKS and the mechanisms leading to the origin of the NMC derived from 12pter 12p11.22 - a region which appears to be susceptible to the formation of neocentromeres. The use of subtelomeric probe PCP12p in buccal cells appears superior to the use of the centromere probe D12Z3 for the diagnosis of the PKS. Key Words: High Resolution CGH (HR-CGH); Neocentromere Marker Chromosomes (NMCs); Pallister-Killian Syndrome (PKS); Supernumerary Marker Chromosomes (SMCs).

Psychiatric and substance abuse disorders in relatives of probands with schizophrenia and bipolar disorder utilizing a family history approach. *C.A. Bousman[1], L. Madlensky[2], M. Staton[1], S.J. Glatt[3], I.P. Everall[1], M.T. Tsuang[1]* 1) Center for Behavioral Genetics, Dept Psychiatry, Univ California, San Diego, San Diego, CA; 2) Cancer Prevention and Control Program, Moores UCSD Cancer Center, University of California, San Diego, San Diego, CA; 3) Dept Psychiatry and Behavioral Sciences, SUNY Upstate Medical University, Syracuse, NY.

Previous family, adoption and twin studies have demonstrated that many adult psychiatric disorders, including schizophrenia and bipolar disorder, have a clear genetic component. To estimate this genetic component the family history approach is often utilized in psychiatry due to its simple application, low financial and time burden and exceptional reliability and validity. This study was designed to (1) examine differences in psychiatric and substance abuse family history in biological relatives of probands with schizophrenia and bipolar disorder and, (2) estimate the utility of the family history approach with schizophrenia and bipolar patients. Psychiatric and substance abuse disorders were collected utilizing a family history approach in a sample of schizophrenia (n =10) and bipolar (n =10) probands diagnosed using the Diagnostic Interview for Genetic Studies (DIGS). Results show that relatives of bipolar probands had significantly higher rates of bipolar and alcoholism than relatives of schizophrenia probands. In addition, results reveal that probands with schizophrenia were unable to provide history on 31% of their parents and grandparents, and bipolar probands were unable to provide history on 18% of these relatives. Implications of these findings for the utilization of family history and the potential shared heritability of bipolar and alcoholism are discussed.

Antisense-mediated exon 51 skipping restores local dystrophin expression in muscle of Duchenne muscular dystrophy patients. *A. Aartsma-Rus[1], J.J.G.M. Verschuuren[2], A.A.M. Janson[3], G. Platenburg[3], G-J.B. van Ommen[1], J.C.T. van Deutekom[1,3]* 1) Department of Human Genetics, Leiden University Medical Center, Leiden, the Netherlands; 2) Department of Neurology, Leiden University Medical Center, Leiden, the Netherlands; 3) Prosensa B.V. Leiden, the Netherlands.

Antisense-mediated reading frame restoration is currently one of the most promising therapeutic approaches for Duchenne muscular dystrophy (DMD). In this approach, antisense oligoribonucleotides (AONs) induce specific exon skipping during pre-mRNA splicing. They have been successful in repairing the disrupted open reading frame accompanied by the generation of internally deleted, partially functional Becker-like dystrophins. Proof of concept has been achieved in cultured muscle cells from patients, as well as in the *mdx* mouse model. As an essential step towards broad clinical studies and future applications, we here evaluated the effect of a single, intramuscular dose of DMD AON PRO051. Four DMD patients with different mutations were included on basis of eligible mutation, adequate condition of the target muscle, and positive *in vitro* PRO051 skip-response. A dose of 0.8 mg PRO051, without any excipient, was injected locally into tibialis anterior muscle and a biopsy was taken after 4 weeks. Exon 51 skipping on RNA level and restoration of dystrophin expression was confirmed for each patient, as demonstrated by RT-PCR, immunohistochemical and western blot analyses. Dystrophin levels were ~10% of wild type levels, except for one patient who suffered from a severe loss of muscle fibers and profound signs of dystrophy in his tibialis muscle . The AON was well tolerated and did not provoke serious adverse events in any of the patients. Our results provide a strong basis for subsequent studies on systemic treatment of DMD patients.

Mutation spectrum of the Iduronate-2-Sulfatase gene and its implications for the molecular diagnosis of Mucopolysaccharidosis Type II in Korean patients. *Y. E. Kim[1], C. S. Ki[2], E. K. Kwon[3], M. J. Kwak[3], S. J. Kim[3], K. H. Paik[3], K. M. Pyun[3], M. J. Lee[1], S. H. Chu[1], A. H. Kim[1], D. K. Jin[3]* 1) Clinical Research Center, Samsung Biomedical Research Center; 2) Departments of Laboratory Medicine and Genetics Samsung Medical Center, Sungkyunkwan University School of Medicine; 3) Departments of Pediatrics, Samsung Medical Center, Sungkyunkwan University School of Medicine.

Mucopolysaccharidosis type II (MPS II) or Hunter syndrome is a rare X-linked lysosomal storage disorder caused by the deficiency of iduronate-2-sulfatase (IDS) that is required for the catabolism of dermatan and heparan sulfates. MPS II is caused by heterogeneous mutations that occur in the IDS gene ranging from point mutations to gross deletions and recombinations. We have previously identified IDS gene mutations in 23 out of 25 Korean patients with MPS II. In the present study. We attempted to elucidate the presence of mutations in 21 additional patients with MPS II as well as in 2 patients in whom mutations had not been detected in a previous study. Bidirectional sequencing analysis identified 17 mutations in the 23 patients: 7 missense, 1 nonsense, 4 deletion, and 5 splicing mutations. Among these, 7 were novel mutations including 3 missenses (Ser61Pro, Pro197Arg, and Pro261Ala), 3 deletions (c.344delA, c.420delG, and c.1112delC), and 1 splicing mutation (c.1180-1G/C). This data along with the data from a previous study has lead to the complete identification of the causative mutations in 46 Korean patients with MPS II.

Functional model systems for congenital ichthyosis: Basic and long way to therapy. *K.M. Eckl[1], S. Torres[1], S. de Juanes[3], D. Metze[2], P. Krieg[3], H.C. Hennies[1]* 1) Cologne Ctr Genomics, Univ Cologne, Div Dermatogenetics, Köln, Germany; 2) Univ Muenster, Dermatology, Münster, Germany; 3) DKFZ, Div Eicosanoids, Heidelberg, Germany.

In the last four years several new genes for autosomal recessive congenital ichthyosis (ARCI) were identified. However, still only little is known about the pathophysiology of this clinically and genetically heterogeneous group of severe disorders of keratinization. To investigate the role of proteins involved in the development of ARCI, we have established 3D organotypic skin models (epidermis equivalents) with primary keratinocytes and fibroblasts. Here we were able to analyse histopathologically and immunohistochemically the structure of the 3D model, especially the suprabasal layers including the stratum corneum. To stratify the effects of inactivation of different genes involved in ARCI, primary keratinocytes from healthy donors were transfected with siRNA to knock down specific genes. This was done for *TGM1*, *ALOX12B*, *ALOXE3*, *ABCA12*, *Ichthyin,* and *FLJ39501*. We found the typical histopathologic features seen in patient samples. Quantitative RT-PCR analysis was performed in samples from transfected keratinocytes and 3D models showing knock-down rates of 95% on average. Analysis of keratinocytes from patient biopsies demonstrated the impact of passage number, mutation type etc. We used double knock downs for *ALOX12B* and *ALOXE3*, which code for subsequent members of the same pathway, to investigate the effect of intermediate products. Importantly, these samples showed still knock-down efficiencies of 80% and 99%. We compared our results in humans (patients and 3D models) with those from 12R-LOX-deficient mice by expression profiling and qRT-PCR analyses. Knock-down efficiency did not always reflect phenotypical/histological findings. Since knock-down efficiencies were high even after seven days, we are increasing the differentiation period to study time-dependent changes in hyperkeratosis and forming a marked stratum corneum. Our models clearly mimick congenital ichthyosis and give us the chance to establish approaches for therapy under controlled and identical, patient independent conditions.

Efficient and Flexible Testing of Untyped Variants in Case-Control Studies. *M.P. Epstein[1], A.S. Allen[2], G.A. Satten[3]* 1) Dept Human Genetics, Emory Univ, Atlanta, GA; 2) Dept of Biostatistics and Bioinformatics, Duke University, Durham, NC; 3) Centers for Disease Control and Prevention, Atlanta, GA.

Candidate-gene and genomewide association studies of disease typically avoid the examination of all existing polymorphisms (for economical reasons) and instead focus inference on a reduced set of tag single-nucleotide polymorphisms (SNPs) that efficiently capture all relevant genetic variation. While investigators subsequently consider only such tagSNPs in association analyses, recent literature has proposed novel statistical methods for testing untyped variants using the sample tagSNP data coupled with external information from databases describing linkage-disequilibrium (LD) patterns across the genome. Here, we consider a flexible likelihood-based approach for testing untyped variants in case-control studies of disease using supplemental LD data from the International HapMap Project. Compared to existing approaches, our method is novel in that it permits estimation of the effects of the untyped variants and further allows for covariates and interactions (between different untyped variants, as well as between untyped variants and environmental covariates). Using both simulated and real data, we demonstrate our approach provides an attractive test to gain additional knowledge in association studies without incurring any additional genotyping cost.

Novel clinical manifestations in Pallister-Killian Syndrome: Comprehensive evaluation of 18 affected individuals and review of all previously reported cases. *L.B. Campbell[1], K. Park[1], M. Jackson[1], A. Kostanecka[1], M. Pipan[1], P.D. Pallister[2], I.D. Krantz[1]* 1) Department of Clinical Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Medical Genetics, Shodair Children's Hospital, Helena, MT.

Pallister-Killian Syndrome (PKS) is a multisystem developmental disorder caused by tetrasomy of chromosome 12p that exhibits tissue-specific mosaicism. The spectrum of clinical manifestations in PKS is wide and includes craniofacial dysmorphia, clefting, ophthalmologic, audiologic, cardiac, musculoskeletal, diaphragmatic, gastrointestinal, gentinourinary, and cutaneous anomalies in association with cognitive retardation and seizures. Growth parameters are often normal to elevated at birth with deceleration of growth postnatally. The prevalence of PKS has been estimated to be approximately 1 in 20,000 live births but is likely under-ascertained since tetrasomy 12p is often not present in the blood and requires fibroblast or other tissue sampling to identify. We report the clinical findings in 18 individuals with PKS who were all evaluated at the first family meeting of the PKS Foundation held at The Childrens Hospital of Philadelphia in the summer of 2006. This meeting represented a unique opportunity to report on a large cohort of individuals who were comprehensively evaluated by clinicians trained in dysmorphology (including Dr. Pallister) as well as consistently performed developmental assessments. The findings in this cohort were compared to findings summarized from 145 previously reported cases described in the literature. Several novel clinical characteristics were consistently identified in this cohort and will be described. Reassertion of a mild variant is documented and underscores the need for careful physical examination and consideration of skin biopsy in higher functioning individuals with less striking clinical findings. This report expands the clinical manifestations of PKS and highlights the highly variable expressivity of this disorder with important implications for diagnosis and counseling.

Compound heterozygosity of glucose-6-phosphatase results in glycogen storage disease type Ia in a Chinese family. *M.M. Gu[1], X.L. Wu[1], Y. Hu[2], D.G. Li[2], Z.G. Wang[1]* 1) Department of Medical Genetics, Shanghai Jiao Tong University School of Medicine, Shanghai, ChinaMedicine, Shanghai, China; 2) Xinhua Hospital Affiliated to Shanghai Jiao Tong University School of Medicine, Shanghai, China.

Glycogen storage disease type Ia (GSD Ia; MIM 232200) is an autosomal recessive inherited disorder resulting from a deficiency of glucose-6- phosphatase (G6Pase). Since the cloning of the gene coding for G6Pase, more than 80 mutations have been identified. Several common G6Pase mutations have been found in different ethnic groups. Here, we report a three-generation family with typical features of GSD Ia from Jiangsu Province, China. The genomic DNA was extracted from peripheral blood samples of two patients and 18 normal relatives. The coding regions of G6Pase were amplified and directly sequenced. The analysis revealed that the patients had a mutation of compound heterozygosity, one mutation from paternity is G to T transversion at the nucleotide 727 (727GT), another mutation from maternity is alanine (A) to glutamic acid (E) at the amino acid 331 (A331E). Mutation of 727 GT in exon 5 is a prevalent mutation causing glycogen storage disease Ia in Chinese population. Mutation of A331E is novel and is firstly reported. At the same time, we detect 5 relatives who carry a heterozygote mutation. This finding enrichs G6Pase mutation spectra and confirms that exon 5 may be a hot spot mutation. This character makes possible for mutation screening in Chinese population.

Progressive mitochondrial degeneration leads to neuropathology of the somatosensory-motor system in the Harlequin mouse: a model for mitochondrial respiratory chain complex I defect. *V. El Ghouzzi[1], Z. Csaba[2], P. Olivier[1], C. Verney[1], P. Rustin[1], P. Gressens[1]* 1) INSERM U676, Dept of Pediatric Neurology, Hosp. Robert Debre, Paris, France; 2) Neuroendocrine Research Laboratory, Hungarian Academy of Sciences and Semmelweis University, Dept of Human Morphology and Developmental Biology, Budapest, Hungary.

Apoptosis-inducing factor (AIF) is a mitochondrial protein which acts as a promoter of cell death after its release from mitochondria and translocation to the nucleus in response to apoptotic stimuli, but its mitochondrial function in non-apoptotic cells is unclear. The recent discovery that AIF deficiency compromises oxidative phosphorylation (OXPHOS) and that Harlequin (Hq) mice, where AIF is downregulated, develop a severe mitochondrial complex I (CI) deficiency has uncovered a mitochondrial function for AIF and pointed out the Hq mice as a natural model of the most frequent OXPHOS disorders. However, the brain phenotype reported to date specifically involves the cerebellum whereas human CI deficiencies often manifest as complex multifocal neuropathologies. To evaluate whether this model can be used as a valuable tool to study CI-deficient disorders, the whole brain of Harlequin mice was investigated during the course of the disease. Neurodegeneration was not restricted to the cerebellum but progressively affected thalamic, striatal and cortical regions as well. Strong astroglial and microglial activation with extensive vascular proliferation was observed by 4 months of age in thalamic, striatal and cerebellar nuclei associated with somatosensory-motor pathways. At 2 months of age, degenerating mitochondria were observed in most cells in these structures, even in non-degenerating neurons, a finding that indicates mitochondrial injury to be rather a cause than an effect of neuronal cell death. Thus, mitochondrial degeneration precedes neuropathological signs in Hq mice and leads to progressive multifocal neuropathology of the somatosensory-motor system, a phenotype much wider than previously described, resembling histopathological features of devastating human neurodegenerative mitochondriopathies associated with CI deficiency.

Loss of *Tsc2* in radial glia models the brain pathology of tuberous sclerosis complex in the mouse. *M.J. Gambello, J. McKenna III, S. Way* Dept Pediatrics, Univ Texas Medical Sch, Houston, TX.

Tuberous sclerosis complex (TSC) is an autosomal dominant disorder caused by mutations in either the *TSC1* or *TSC2* gene, which encode the proteins hamartin and tuberin. Substantial morbidity and mortality are caused by brain lesions such as tubers, subependymal nodules, and other neuronal heterotopias. These lesions are associated with seizures, autism, and other developmental disabilities. The histology of TSC brain lesions suggests that they are developmental lesions resulting from abnormalities in cell growth, migration and differentiation. Consequently a current hypothesis of TSC brain pathogenesis is that loss of function of either TSC1 or TSC2 in neural progenitor cells initiates developmental neuropathology. At the cellular level, loss of function of either gene causes activation of the insulin signaling/mTOR pathway, leading to increased translation, cell growth and proliferation.

In the developing cortex, radial glia were thought to function mainly as a scaffold for migrating neurons. Recent data suggest, however, that radial glia are neuroglial precursors, contributing to the majority of cells in the cerebral cortex. Given this progenitor function of radial glia, we hypothesized that loss of function of TSC1 or TSC2 in radial glial cells might be an initiating event in TSC brain pathogenesis. To test this hypothesis we used a conditional disruption of the *Tsc2* gene and an *hGFAP-Cre* mouse that expresses Cre in radial glial progenitors. Mice deleted for *Tsc2* in radial glia develop megalencepahly, hydrocephalus, and die between 3 and 4 weeks of age. Their brains demonstrate cortical lamination defects, hippocampal heterotopias, and giant, dysplastic neurons. These histologic abnormalities are accompanied by activation of the mTOR pathway and are similar to human lesions. These results establish the novel concept that loss of function of Tsc2 in radial glial progenitors is an initiating event in the development of TSC brain lesions. This model will be useful to study TSC brain pathophysiology, test potential therapies, and identify other genetic pathways that are altered in TSC.

Genetic prediction of asthma exacerbation in children. *B.E. Himes[1,2], A.L. Berninger[2,3], S.T. Weiss[2,4,5], M.F. Ramoni[1,2,3,5]* 1) Harvard-MIT Division of Health Sciences and Technology, Cambridge, MA; 2) Harvard Partners Center for Genetics and Genomics, Boston, MA; 3) Childrens Hospital Informatics Program, Boston, MA; 4) Channing Laboratory, Brigham and Womens Hospital, Boston, MA; 5) Harvard Medical School, Boston, MA.

Exacerbations are the major cause of morbidity and mortality in asthma, a complex lung disease that affects 6.2 million American children. In this work, we used Bayesian networks to create a multivariate predictive model of asthma exacerbations using genetic data. The Childhood Asthma Management Program (CAMP) was a clinical trial that followed asthmatic children for approximately four years. A subset of Caucasian CAMP participants not randomized to steroid treatment, who have been followed for an additional 6 years, were selected (n=290). An asthma exacerbation case (n=83) was defined as a subject with at least one reported hospitalization; a control (n=207) was defined as a subject with no hospitalizations or emergency room visits. To handle the large amount of genetic data available for these subjects, 2443 SNPs in 349 candidate genes, a specialized Bayesian network algorithm that focuses the search process around the phenotype of interest was developed. It found that 132 SNPs in 55 genes predict asthma exacerbation status. The models predictive accuracy was assessed using fitted values and a 20-fold cross-validation. Fitted values were obtained by predicting exacerbation status in each subject used in the model creation. A 20-fold cross-validation was performed by splitting all subjects into 20 groups, and using each group as an independent dataset to predict exacerbations while the remaining 19 groups were used to quantify model parameters. Predicted and observed exacerbation statuses were compared using areas under receiver operating characteristic curves (AUROCs). The AUROC for fitted values is 0.97 and for 20-fold cross-validation is 0.84. The models good predictive accuracy is shown to be superior to single gene analysis. The results of this work demonstrate the promise of using Bayesian networks to study the genetic architecture of complex traits.

Large scale replication of a genome-wide association study in celiac disease. *K.A. Hunt[1], L. Franke[2], R. Gwilliam[3], A. Zhernakova[2], M. Inouye[3], W. McLaren[3], R. McManus[4], R. McGinnis[3], L.R. Cardon[5], P. Deloukas[3], C. Wijmenga[6], D.A. van Heel[1]* 1) Queen Mary University of London, UK; 2) University Medical Center Utrecht, The Netherlands; 3) Wellcome Trust Sanger Institute, Cambridge; 4) Trinity College Dublin, Ireland; 5) Wellcome Trust Centre for Human Genetics, UK; 6) University Medical Center Groningen, The Netherlands.

INTRODUCTION: Celiac disease is a common (1% prevalence) chronic inflammatory small bowel disease with strong heritability. An immune response against dietary wheat, rye and barley occurs. We performed (Nature Genetics June 2007) a genome wide association (GWA) study using Illumina Hap300/550 BeadChips in 778 UK celiac individuals and 1422 population controls. AIMS: 1. to confirm GWA findings in further independent collections 2. test optimal strategies for SNP selection for replication studies METHODS: 1536 SNPs from the UK celiac GWA study were selected for genotyping in Dutch, further UK, and Irish celiac case-control collections (total ~8000 samples). SNP selection was based on the most significant findings from the following analyses: single SNP association (criteria P<0.0025); sliding window and CEU HapMap based two SNP haplotype association (criteria haplotype P<0.001 and no SNP showing single SNP association); nsSNP association (criteria P<0.01); SNPs over-represented in specific biological pathways (pathway P<0.01, selected from Reactome, KEGG, HPRD, BIND, IntAct and BioGrid). RESULTS: Outside the HLA, the most significant finding (UK GWA P=2.0 x 10-7) was in a linkage disequilibrium block containing the IL2/IL21 cytokine genes. Association was confirmed using further SNPs and using two further independent collections (meta-analysis of 4600 samples P=10-10 to 10-14, OR 0.6). Replication data of further regions will be presented. CONCLUSIONS: We have identified and confirmed, using a genome wide association study and replication approach, novel risk variants in the IL2/IL21 region predisposing to celiac disease. We are confirming further regions and finding optimal strategies for replication.

Development, Evaluation, and Use of a Genetic Literacy Concept Inventory for Undergraduates. *B.V. Bowling, E.E. Acra, C.A. Huether* Dept of Biological Sciences, Univ Cincinnati, Cincinnati, OH.

There is continued emphasis on increasing and improving genetics education for grades K-12, medical professionals, and the general public. An additional critical audience is the undergraduate student in introductory biology and genetics courses. There has been little effort to assess these students understanding of genetics concepts and their level of genetic literacy (i.e. genetics knowledge as it relates to and impacts their lives). We have developed, evaluated, and used a new survey instrument to assess the genetic literacy of undergraduate students taking introductory biology or genetics courses. The Genetic Literacy Concept Inventory (GLCI) is a 31-item multiple choice test that addresses 17 concepts identified as central to genetic literacy by a team of ASHG professional geneticists. The items were selected and modified based upon reviews by 25 genetic professionals and educators. The inventory underwent additional review in student focus groups and pilot testing. Analysis was carried out on content validity, discriminate validity, internal consistency, and stability of the inventory, with results indicating it is reasonably valid and reliable. The GLCI has been utilized pre-course and post-course in six introductory non-major biology and genetics courses, with over 350 students taking the inventory. Current data from students in introductory biology courses show a pre-course average of 41% correct. Post-course scores increased only modestly to an average of 48% in these courses which emphasized genetics to varying degrees. Even in an introductory genetics course the pre-course average of 54% increased to only 59%. These results are consistent with similar studies in physics and chemistry where concept inventories have been implemented in courses using more traditional teaching methods. This study directly enhances genetics education research by providing a valid and reliable instrument for assessing genetic literacy in undergraduate students. It also begins to look critically at current genetics education at the undergraduate level and suggests that to achieve genetic literacy, adjustments in the way we teach genetics may be necessary.

Endophenotype Analysis in Migraine. *N.J. Colson, R.A. Lea, L.R. Griffiths* Genomics Research Centre, Griffith University, Gold Coast, Qld, Australia.

Migraine is a common complex polygenic disorder demonstrating genetic and clinical heterogeneity. Numerous modest effect common genetic variants appear to be involved in migraine susceptibility. This study considered the hypothesis that the combined and interacting effect of these variants is a fundamental feature of migraine predisposition and its clinical heterogeneity. To test this, we analysed several previously identified migraine susceptibility variants in a large Australian migraine group to determine if specific genetic risk profiles associated with particular migraine sub-types, symptoms, and severity. The vascular genes under analysis were MTHFR, ACE, and MTRR. ESR1 and PGR were analysed as hormonal variants. Vascular risk subjects possessed at least 2 susceptibility genotypes in the vascular genes. Hormonal risk subjects possessed at least 2 susceptibility genotypes in the hormonal genes. No risk, subjects did not possess any risk genotypes. Of the 202 subjects, 26 had a complete hormonal risk profile, 38 had a complete vascular risk profile, 3 had both risk profiles and 4 were in the no risk group. The remaining subjects did not fall into any category and were grouped as unclassified. Examination of clinical data revealed that typical migraine symptoms were more likely in risk subjects than no risk subjects. Notably, subjects with both vascular risk and hormonal risk profiles all reported more severe migraine associated symptoms of nausea, phonophobia, photophobia, eye discomfort and pulsating head pain, and that their mother also suffered migraine. Severe migraine symptoms and a mother who suffered migraine were much less likely in the no risk group. Of the subjects who suffered both MA and MO, 25 percent had a complete hormonal genetic risk profile even though just 8 percent of the total profiling group had a complete hormonal risk profile. This suggests that hormonal influences may be higher in subjects who suffer from both MA and MO. The development of polygenic endophenotypic risk profiles for migraine sufferers may be the next step in the process of unravelling the genetic basis of the disorder.

Intrathecal enzyme therapy in mucopolysaccharidosis I cats reduces storage throughout the brain. *M. Haskins[1], S. Walkley[2], J. Rhodes[1], P. O'Donnell[1], C. Bryan[1], N.M. Ellinwood[3], R. Cahayag[4], A. Cheng[4], C. Henschel[4], C.A. O'Neill[4], J. White[4], C. Vite[1]* 1) Sch Vet Med, Univ Pennsylvania, Philadelphia, PA; 2) Albert Einstein, Col Med, Bronx, NY; 3) Dept An Sci, Iowa State Univ, Ames, IA; 4) BioMarin Pharmaceutical, Inc., Navato, CA.

Mucopolysaccharidosis (MPS) I is a lysosomal storage disease caused by deficient activity of alpha-L-iduronidase (IDUA). The most common subtype has severe mental retardation associated with storage of central nervous system (CNS) glycosaminoglycans (GAGs). An orthologous cat model of MPS I has widespread storage of CNS GAGs. Approved clinical therapy for MPS I is weekly intravenous enzyme replacement with recombinant human IDUA (Aldurazyme;ALD). To determine if intrathecal administration of ALD could alter CNS lesions, we injected 8 adult MPS I cats with ALD (0.1 mg/kg in Elliots B, 0.5 mL/kg) and 4 adult MPS I cats with vehicle (equivalent mL/kg), each treated 3 times, 4 days apart. Prior to each injection, cerebrospinal fluid (CSF) was collected from the cysterna magna, immediately followed by slow bolus injection of ALD or vehicle. Three cats given ALD and one given vehicle developed abnormal posture with lowered forelimbs, almost resting on their elbows. One set of cats (2 ALD and 1 vehicle) was terminated 2 days post last injection, a second set 28 days post last injection, and two remaining sets will be terminated at 2 and 4 months. MPS I cats, both untreated affected and those treated with vehicle, had 1% (1.0) of normal cat brain IDUA activity and a 72-fold (22) above normal GAG concentration across 4 brain regions. Two days post the last ALD treatment, MPS I cats had a 4-fold (0.6) increase in IDUA activity compared to normal and only a 4.1-fold (1.5) increase in GAG concentration compared to normal, along with reduced immunostaining for GM2 and GM3 ganglioside and unesterified cholesterol compared to control. After 28 days, treated MPS I cats had 22% (7.6) IDUA activity compared to normal and only 2.4-fold (2.4) the GAG concentration compared to normal cats. Histological evaluation and quantitation of brain gangliosides is ongoing. IDUA was not detected in CSF or blood from 2-28 days post-treatment.

Moebius syndrome: report of a new case. *G.Juarez Garcia[1], L.Hdez Gomez[2], D.Gomez Torres[3], F. castillo Lorca[4]* 1) Dept Genetics Neuropsicologia, Inst Nacional de Rehabilitacion, Mexico, D.F; 2) Dept Genetics, Audiologia, Inst Nacional de Rehabilitacion, Mexico, D.F; 3) Dept Genetics, Investigación, Inst Nacional de Rehabilitacion, Mexico, D.F; 4) Servicio de Audiologia de Gaes. México.

Moebius syndrome is an extremely rare disorder characterized by a lifetime facial paralysis, involving sixth and seventh cranial nerves with malformations of orofacial structures and the limbs. A number of mechanisms have been proposed to explain the pathogenesis, including prenatal ischemia. In some patients, the dysgenesis is genetically determined and can be isolated or form part of a more extensive polymalformation syndrome (mutations of organizing or regulatory genes). In most patients with brainstem dysgenesis, however, the disorder is caused by prenatal destructive or disruptive lesions of vascular origin. We present a new case: female mexican child 4-year 7 moths -old is the first child of young non consanguineous parentes, obteind pretermino. She presented paralysis facial left. That presents inconvenience of language, characterized by being found to level at level of sentences, well directed and structured with articulatory distortions. EEG normal. ABR responses in 30dB heard right, and 40dB heard left. transient evoked otoacoustic emissions 95% in both hearings. Normal intellectual capacity.

Influence of gender on phenotypic manifestations and their age of onset in 1013 probands with Marfan syndrome or related phenotypes with FBN1 mutations: an international study. *L. Faivre[1], G. Collod-Beroud[2], B. Loeys[3], A. Child[4], C. Binquet[5], E. Gautier[5], B. Callewaert[3], E. Arbustini[6], K. Mayer[7], M. Arslan-Kirchner[8], C. Beroud[2], C. Bonithon-Kopp[5], M. Claustres[2], L. Ades[9], J. De Backer[3], P. Coucke[3], U. Francke[10], A. De Paepe[3], C. Boileau[11], G. Jondeau[12]* 1) Centre de Génétique, CHU Dijon, France; 2) INSERM, U827, Montpellier, France; 3) Medical Genetics, Ghent University, Belgium; 4) Cardiological Sciences, St Georges Hospital, London, UK; 5) Centre dinvestigation clinique - épidémiologie clinique, CHU Dijon, France; 6) Molecular Diagnostic Unit, Policlinico San Matteo, Pavia, Italy; 7) Human Genetics, Martinsried, Germany; 8) Humangenetik, Hannover, Germany; 9) Marfan Research Group, Westmead Childrens Hospital, Sydney, Australia; 10) Genetics and Pediatrics, Stanford University, USA; 11) Génétique moléculaire, Hôpital Ambroise Paré, Boulogne, France; 12) Centre de Référence Marfan, Hôpital Bichat, Paris, France.

The cardinal features of Marfan syndrome (MFS) involve the ocular, cardiovascular and skeletal systems. Taking advantage of the data of a large international study including 1013 probands with a pathogenic FBN1 mutation, we analysed the influence of gender on the patients phenotypes. Using the Kaplan-Meier method for features for which the age at diagnosis was available and the Mantel-Haensel test for other features, we did not find any significant difference for age at diagnosis of MFS or related disorder, survival, skeletal, lung and dural involvements in males as compared to females. However, significant differences were found for the cumulative probability of aortic surgery in patients with aortic dilatation. Indeed, 46% of males had surgery for aortic dilatation before or at 40 years compared to 34% in females (p=0.0002). A marginally significant result was found for the cumulative probability of ascending aortic dilatation, with a probability of 80% (99.9%-CI=35%-57%) before or at 40 years in males compared to 70% in females (99.9%-CI=23%-48%)(p=0.0036). In conclusion, the gender of a patient might influence the risk of developing ascending aortic dilatation as well as its severity.

Association of a Common Haplotype in the Annexin A5 (ANXA5) Gene Promoter with Recurrent Pregnancy Loss. *J. Horst[1], N. Bogdanova[1], M. Chlystun[2], P.J.P. Croucher[3], A. Nebel[4], A. Bohring[1], A. Todorova[5], S. Schreiber[4], V. Gerke[2], M. Krawczak[3], A. Markoff[2]* 1) Institut für Humangenetik der WWU Münster, Münster, Germany; 2) Institut für Medizinische Biochemie, ZMBE, WWU Münster, Germany; 3) Institut für Medizinische Informatik und Statistik, Christian-Albrechts-University, Schleswig-Holstein, Kiel, Germany; 4) Institut für Klinische Molekulare Biologie, Christian-Albrechts-University, Schleswig-Holstein, Kiel, Germany; 5) Laboratory of Molecular Pathology, University Hospital of Obstetrics and Gynecology, Medical University of Sofia, Sofia, Bulgaria.

Annexin A5 is a typical member of the chordate annexin family and is one of the few annexins that can be found extracellularly (12). Annexin A5 is thought to function as an inhibitor of coagulation owing to its ability to bind to anionic phospholipids exposed on the surface of, for example, platelets, thereby inhibiting aggregation. In this work we sought to verify whether variation in the promoter of the placental anticoagulant protein annexin A5 (ANXA5) gene represents a risk factor for recurrent pregnancy loss (RPL). Sequence analysis of 70 German RPL patients revealed four consecutive nucleotide substitutions in the ANXA5 promoter that were transmitted as a joint haplotype (M2). Reporter gene assays revealed that M2 reduces the in vitro activity of the ANXA5 promoter to 37-42% of the normal level. Carriers of M2 were found to exhibit a more than two-fold higher RPL risk than non-carriers (odds ratio = 2.42, 95% confidence interval: 1.27 - 4.58) when using unselected controls (PopGen), and an almost four-fold higher risk when using the Münster super-controls, i.e. women with successful pregnancies and no previous history of pregnancy losses (odds ratio = 3.88, 95% confidence intervall: 1.98 - 7.54). This statistically significant association should facilitate the development of improved prognostic algorithms for RPL, involving a more precise assessment of individual disease risks, and provide a guide to offering adequate therapies where relevant.

Financial Incentives for the Procurement of Oocytes for Research: In Search of Ethical and Political Consistency. *R. Isasi* Ctr Recherche en Droit, Univ Montreal, Montreal, PQ, Canada.

The recent South Korean scandal involving fraud and gross ethical violations in stem cell research has re-opened the debate on both the appropriateness of allowing healthy women to provide oocytes for research use and on the use of financial incentives. As the South Korean case illustrates, the debate is increasingly reduced to a confrontation between ethics, science and the welfare of women. It is plausible that the expansion of international research efforts, paired with the growing trend towards liberalizing stem cell research policies, will have the inevitable effect of increasing the demand for the human reproductive materials needed to conduct such research. The scarcity of oocytes available for conducting research for the derivation of stem cell lines have caused concerns over: the possible emergence of a black market, the growing trend towards increasing financial incentives for donors, and, the appropriateness and sufficiency of current regulatory frameworks to safeguard donors. While consensus exists regarding the impermissibility of commercializing the donation of human reproductive materials, divergence exists regarding the amount of compensation that is reasonable to offer and the conditions under which compensation should be granted. Providing financial incentives for the procurement of oocytes for research is a controversial issue that can only be situated within the larger context of the donation of other human material (blood, organs). Likewise, it must be analyzed in the context of the overall acceptability of providing financial rewards to donors or providers of gametes and embryos for assisted reproductive technologies. In this presentation I will (1) explore the use and the implications of providing financial incentives for oocyte donation (with special emphasis on stem cell research) and (2) analyze the models (e.g. free market, pure gift, fixed compensation, minimum wage, and reimbursement of expenses) proposed in the literature and implemented in various jurisdictions. Examples will be drawn from the regulatory frameworks adopted by 17 countries that are members of the International Stem Cell Forum.

Elastin Gene Mutations: Genotype-Phenotype Correlations in Supravalvular Aortic Stenosis. *V. Hucthagowder[1], L. Jonggadipo[1], P. Kaplan[2], B.A. Kozel[1], D. Kathy Grange[1], M.C. Johnson[1], Z. Urban[1,3]* 1) Department Pediatrics, Washington University, St. Louis, MO, USA; 2) Division of Biochemical Genetics, Childrens Hospital, Philadelphia, PA, USA; 3) Department of Genetics, Washington University, St. Louis, MO, USA.

The goal of this study was to better define the genetic epidemiology of familial supravalvular aortic stenosis (SVAS). We recruited 50 probands with SVAS and screened the elastin gene (ELN) for mutations using genomic DNA by a combination of denaturing high performance liquid chromatography and direct DNA sequencing. Additional family members were genotyped for mutations discovered and clinical data was collected from 34 participants using questionnaire and a review of medical records. Skin fibroblasts were collected from 11 participants and ELN expression was analyzed by quantitative RT-PCR and sequencing. Selected mutations were evaluated using luciferase reporter assays. We identified 15 novel and 6 previously described ELN mutations. The majority (81%) of the mutations were predicted to cause premature termination codons. Four of these premature termination mutations were shown to activate a nonsense-mediated decay pathway resulting in null alleles. Two further mutations caused reduced transcription by disrupting the elastin promoter. In addition to obstructive vascular disease and structural heart defects, patients showed facial and connective tissue characteristics previously described only in Williams syndrome. Male patients had significantly ($p=0.026$) more severe SVAS requiring surgery than females. Asymptomatic mutation carriers showed significantly higher residual elastin expression than patients with SVAS. We conclude that despite significant allelic heterogeneity the functional haploinsufficiency of the elastin gene is a unifying disease mechanism for familial SVAS. Our clinical data showed significant connective tissue involvement in these patients in addition to cardiovascular disease. Finally, gender and residual elastin gene expression emerge as significant modifying factors of SVAS.

Genome-wide SNP Linkage Analysis of Korean Multiplex Schizophrenia Families. *K.S. Hong[1, 2], H-H. Won[2], E-Y. Cho[2], H.O. Jeun[2], S-S. Cho[2], Y-S. Lee[3], D.Y. Park[1], Y.L. Jang[1], K-S. Choi[5], D. Lee[1], M-J. Kim[2], S. Kim[2], J.W. Kim[2, 4]*
1) Dept Psychiatry, Samsung Med Ctr, Sungkyunkwan Univ Sch Med, Seoul, Korea; 2) Samsung Biomedical Research Institute, Seoul, Korea; 3) Yong-In Mental Hospital, Yong-In, Korea; 4) Dept Laboratory Medicine & Genetics, Samsung Med Ctr, Sungkyunkwan Univ Sch Med, Seoul, Korea; 5) Dept Psychiatry, Eulji University Sch Med, Taejeon,Korea.

The present study reports the results of a genome-wide SNP linkage scan for schizophrenia in the Korean population. Fifty-six multiplex schizophrenia families were analyzed. Clinical evaluations on all subjects were performed by raters of a single research team. Multipoint non-parametric linkage analysis was performed, and empirical simulations were generated to determine genome-wide significance. Eight chromosomal regions yielded NPL Z scores above 2.0 for broad and narrow phenotype classes. We found genome-widely significant evidence of linkage for schizophrenia to chromosome 2p24.3 (NPL Z=3.18), 6q27 (NPL Z=2.90), 3q24 (NPL Z=2.74), and 18q22.3 (NPL Z=2.59). Four other chromosomal regions, i.e., 13q12.3, 20p12.2, 4p14, and 1p36.12, were found to have NPL Z scores higher than 2.0. Although linkage to these loci has not received prominent attention in studies on Caucasian families, multiple overlaps were observed between our loci (on 2p, 3q, and 13q) and linkage peaks generated from extended families of various isolated populations. Fine mappings and the detection of candidate genes within these regions are warranted.

Daily physical activity modifies the association between endothelial nitric oxide synthase gene variant and blood pressure. *V. Karani Santhanakrishnan[1], P. W. Franks[2], I. Barroso[3], S. Brage[1], U. Ekelund[1], N. J. Wareham[1], R.J.F Loos[1]* 1) MRC Epidemiology unit, Cambridge, UK; 2) Genetic Epidemiology & Clinical Research Group, Department of Public Health & Clinical Medicine, Division of Medicine, Umeå University Hospital, Umeå, Sweden; 3) The Wellcome Trust Sanger Institute, Metabolic Disease Group, The Wellcome Trust Genome Campus, Hinxton, UK.

The endothelial nitric oxide synthase (NOS3) gene encodes the enzyme (eNOS) that synthesises the molecule nitric oxide which facilitates endothelium-dependent vasodilation in response to exercise. Thus, variation at NOS3 may modify the association between physical activity and blood pressure. To test this hypothesis, we genotyped 11 NOS3 polymorphisms, capturing all common variations, in 726 men and women from the MRC Ely Study (age (mean SD): 5510 years, BMI: 26.44.1 kg/m2). Free-living total energy expenditure (TEE) was assessed via individually calibrated heart rate monitoring over 4 days. The intronic variant, IVS25+15 GA, was significantly associated with blood pressure; GG homozygotes had significantly lower levels of diastolic blood pressure (DBP) (- 2.8 mmHg; p= 0.016) and systolic blood pressure (SBP) (- 1.9 mmHg; p= 0.018) than A-allele carriers. The interaction between TEE and IVS25+15 was also significant for both DBP (p= 0.006) and SBP (p= 0.026); i.e the association between the GG-genotype and blood pressure was only significant in the individuals with the highest energy expenditure (DBP: - 4.9 mmHg, p=0.02. SBP: -3.8 mmHg, p=0.03). Similar results were observed when the outcome was dichotomously defined as hypertension. In summary, the NOS3 IVS25+15 is directly associated with blood pressure and hypertension in UK Europids. However, the associations are most evident in physically active individuals. These results may be informative for targeted disease prevention, where the selection of individuals for lifestyle intervention programs could be guided by knowledge of their genotype.

Breast cancer risk and C677T thylenetetrahydrofolate reductase polymorphism in Mexican population. *M. Gallegos[1], D. Ontiveros[2], J. Alfaro[1,3], AM. Puebla[3]* 1) Dept Med Molec, Guadalajara, CIBO, IMSS, Jalisco, Mexico; 2) Unidad Médica de alta Especialidad, Hospital de Gineco-obstetricia, Fisiología Obstétrica CMNO, IMSS; 3) Laboratorio de Inmunofarmacología de productos Naturales, CIBO, IMSS, Universidad de Guadalajara.

Methylenetetrahydrofolate reductase (MTHFR), a polymorphic enzyme involved in folate metabolism, plays a role in DNA biosynthesis, methylation, and repair in actively dividing cells. The polymorphism C677T of MTHFR gene, lead to decreased enzyme activity and affect chemosensitivity of tumor cells. We investigated whether this MTHFR polymorphism could be a risk factor for breast cancer in Mexican patients. Methods: In this case - control study, we genotyped 280 patients with breast cancer and 170 women controls, was assessed for the presence of the C677T mutation by PCR amplification. The allele frequencies of the MTHFR 677T were 50% in the breast cancer cases and 42% in the controls. Frequencies of MTHFR 677TT, 677TC and 677CC were 31, 39 and 30% in the breast cancer patients and 19, 53 and 34% in the controls, respectively. The results of a 2 analysis indicated that the MTHFR 677T allele was significantly distributed (2 = 4.89; p = 0.027). Likewise, the MTHFR T677T genotype showed a 1.91 fold increased risk for breast cancer. In conclusion, our data suggest that the MTHFR 677TT genotype is genetic risk factors for women with sporadic breast cancer.

Frequency of C677T Polymorphism of MTHFR Gene in Mexican Adult with Acute Lymphoblastic Leukemia. *D. Carbajal[1], AM. Puebla[2], LE. Figuera[3], M. Gallegos[1]* 1) Medicina Molecular, CIBO, Instituto Mexicano del Seguro Social, Guadalajara, Guadalajara, Mexico; 2) Laboratorio de Inmunofarmacología Experimental, CUCEI, Universidad de Guadalajara; 3) Division de Genetica, CIBO, IMSS.

The factors governing susceptibility to acute lymphoblastic leukemia (ALL) have not yet been identified. The MTHFR enzyme is involved in carcinogen metabolism and have been shown to influence the risk a variety of solid tumors in adults. Folate availability is critical for DNA integrity, required for the transfer of methyl groups in the biosynthesis of thymidilate. Reduction of 5,10-methylenetetrahydrofolate, a donor for methylating dUMP to dTMP in DNA synthesis, to 5-methyltetrahydrofolate, the primary methyl donor for methionine synthesis, is catalyzed by 5,10-methylenetetrahydrofolate reductase (MTHFR). The MTHFR polymorphisms C677T have been shown in some studies to alter the risk of a range of different malignancies. We evaluated the role of the C677T polymorphism on acute lymphoblastic leukemia (ALL) risk by genotyping 107 patients and 170 healthy controls. The odds ratio of ALL associated with 677TT and 677CT genotypes were 0.49 (95% CI; 0.21-1.07) and 1.1 (95% CI; 0.66-1.84) respectively. This data indicate that the MTHFR polymorphism C677T do not significantly contribute to an inherited genetic susceptibility to ALL in adult Mexican population.

Association analyses of retinol binding protein 4 (*RBP4*) genetic variants on circulating RBP4 concentration and phenotypes related to glucose metabolism in Chinese subjects. *C. Hu, W. Jia, R. Zhang, C. Wang, X. Ma, Q. Fang, J. Lu, K. Xiang* Shanghai Diabetes Institute, Shanghai Jiao Tong University Affiliated Sixth People's Hospital, Shanghai, China.

Retinol binding protein 4 (RBP4) was a newly discovered adipokine that played a role in insulin resistance and obesity. Previous studies showed that its circulating concentration was significantly higher in subjects with obesity and diabetes. In this study, we investigated the relationship among genetic variants of *RBP4* gene, circulating RBP4 concentrations and phenotypes related to glucose and lipid metabolism in the Chinese population. We sequenced exons and the putative promoter region of *RBP4* gene, and identify six single nucleotide polymorphisms (SNPs) in 32 Chinese subjects. Additional, we selected four SNPs from public database to increase marker density in introns. Taking account of the pairwise linkage disequilibrium and minor allele frequencies, five SNPs were further genotyped in 627 well phenotyped individuals, including 255 type 2 diabetes patients and 372 normal controls. Phenotypes measured includes plasma glucose concentrations, serum insulin and C-peptide levels during an oral glucose tolerance test, lipid profiles, body fat distribution and circulating concentration of RBP4 and adiponectin. We found none of the individual SNPs were significantly associated with type 2 diabetes in this study. But a rare haplotype CAA formed by +5388 C>T, +8201 T>A and +8204 T>A was significantly more frequent in type 2 diabetes patients than that in the normal control subjects (P=0.0343). In both groups, several non-coding SNPs were associated with circulating RBP4 concentrations (P<0.05). In the normal glucose regulation subjects, the SNP +5388 C>T was associated with serum C-peptide levels in both fasting status and 2-hours after oral glucose tolerance tests (P=0.0162 and P=0.0075, respectively). Our findings suggest that the genetic variants in the *RBP4* gene may play a role in the susceptibility to type 2 diabetes in Chinese.

The development and evaluation of a genetics concept inventory. *A.M. Hott* Department of Biology, Southern Connecticut State University, New Haven, CT.

Modern science education reform includes the development of standards and recommendations for content as well as the development and evaluation of pedagogy, but demonstrates limited assessment of student knowledge. Student knowledge assessment is an important factor in measuring the scientific literacy of current students. Concept inventories have been developed and used for the past fourteen years to assess non-science major student conceptual understanding of a content area. Inventories have been developed in the fields of physics, astronomy, chemistry and biology. The development and evaluation of a Genetics Concept Inventory (GCI) based on the ASHG genetics content recommendations for non-science majors is presented here. A study of 130 tracked students of introductory biology for the non-science major resulted in a reliability estimate of 0.62 that is supported by a respected panel of genetics educators revisions, no significant gender bias, and the ability of junior and senior biology majors to outperform the non-science majors. Pretest/Posttest comparisons show a significant increase in five of six genetics content areas as well as a 9% increase on the overall percent score for the instrument.

SIX3 mutations in holoprosencephaly (HPE) are loss-of-function alleles. *S. Domene[1], K.B. El-Jaick[2], E. Roessler[1], F. Lacbawan[1], B. Feldman[1], M. Muenke[1]* 1) NHGRI/NIH, Bethesda, MD; 2) Laboratorio de Genetica Molecular, Brazil.

Holoprosencephaly (HPE) is the most common structural anomaly of human forebrain development, with a prevalence of ~1 in 250 conceptuses and ~1 in 16,000 at birth. Mutations in at least eight different genes have been identified in human HPE patients. We have previously shown that SIX3, a transcription factor known to be involved in midline forebrain and eye formation during early development in the mouse, is associated with HPE in humans. No functional studies have been performed to date. It consists of two highly conserved domains: a SIX domain needed for interaction with other proteins and a DNA-binding homeodomain. SIX3 interacts with groucho corepressor proteins through two eh1-like motifs located within the SIX domain. This interaction is required both for the autorepression of six3 itself and for the regulation of other early developmental genes.

In addition to 18 previously reported SIX3 mutations we describe here 29 novel mutations. The total of 47 mutations are located throughout the entire SIX3 gene and include 33 missense, 5 nonsense, 8 frameshift mutations and 1 in frame deletion. To demonstrate the function of these mutations we established several complementary approaches using the zebrafish as a model system: 1) overexpression of SIX3, 2) morpholino (MO) knockdown and rescue assay and 3) detection of marker changes using in situ hybridization. With these assays we have functionally characterized these SIX3 mutations for the first time as significant loss-of-function alleles. For example, single point mutations in the eh1-like motif result in loss of function suggesting that interaction with groucho is essential for SIX3 activity. In addition, several nonsense mutations located in the SIX domain and homeodomain which result in early termination of the protein result in loss of function. Our data elucidate how SIX3 functions during development and increase our understanding of its role in the pathogenesis of HPE. Furthermore, these results are crucial for genetic counselling of families with children with HPE.

in situ.

Glia specific changes associated with motor neuron vulnerability in ALS and FTD: DNA and tissue microarray study. *L.C. Kudo[1], J. Pomakian[2], L.V. Parfenova[1], H. Vinters[2], M. Wiedau-Pazos[1], S.L. Karsten[1,3]* 1) Dept Neurology; 2) Dept. of Pathology and Lab. Med., UCLA, Los Angeles, CA 90095; 3) Los Angeles Biomedical Institute, Harbor-UCLA Medical Center, Torrance 90509.

Amyotrophic lateral sclerosis (ALS) is a devastating neurodegenerative disease that selectively affects motor neurons in the central nervous system. Recently, it was shown that glia is one of the key factors contributing to specific motor neuron vulnerability. To complement our study performed on motor neurons (Kudo et al, ASHG 2006) and to identify specific glial factors that may contribute to motor neuron degeneration we examined glial expression profiles in two mouse models of motor neuron degeneration: familial ALS linked to SOD1-G93A and frontotemporal dementia with ALS linked to TAU-P301L. Dissected frozen lumbar spinal cords from 3 months old female transgenic mice and their non-transgenic littermates were axially cryosectioned. Glia surrounding motor neurons from the anterior horn of the spinal cord was laser-capture microdissected according to previously established protocol (Kudo et al, 2006). RNA extracted from these cells was used for microarray experiments using Aglilents Mouse Whole Genome Oligonucleotide Microarray. Identified gene expression changes indicated that SOD1-and TAU- induced neurodegeneration might have partially common mechanism. We further investigated the relevance of our findings in mouse models to human disease by performing protein expression analysis on post-mortem ALS samples using tissue microarray technology (TMA). We constructed ALS TMA with CNS tissues from ALS patients, ALS with frontotemoporal dementia (FTD) patients, and age and sex matched controls. Each TMA block includes ALS, ALS with FTD, and control samples of the most affected regions, such as the cervical and lumbar spinal cord, and less vulnerable regions, such as the cortical and subcortical areas of the brain. Of the 8 motor neuron specific genes altered in both SOD1 and TAU mouse models, 5 had commercially available antibodies and were tested on our TMA. MWP and SLK co-directed this project.

Van Den Ende-Gupta syndrome: Expansion of the phenotype and confirmation of autosomal recessive inheritance. *C.W. Carr[1], J. Zhang[2], J.D. Carron[3], R.S. Lachman[4], J.M. Graham[5], N.A. Kramer[5], O.A. Abdul-Rahman[1]*
1) Preventive Medicine, University of Mississippi Medical Center, Jackson, MS; 2) Department of Neurosurgery, University of Mississippi Medical Center, Jackson, MS; 3) Department of Otolaryngology and Communicative Sciences, University of Mississippi Medical Center, Jackson, MS; 4) International Skeletal Dysplasia Registry, Cedars-Sinai Medical Center, Los Angeles, CA; 5) Department of Medical Genetics, Cedars-Sinai Medical Center, University of California, Los Angeles, CA.

Van den Ende-Gupta syndrome (VDEGS) is a multiple congenital anomaly syndrome characterized by blepharophimosis, arachnodactyly, and congenital contractures in the absence of psychomotor retardation. We report two African-American sisters born to non-consanguineous parents who have been diagnosed with VDEGS based on the presence of blepharophimosis, crumpled ears, arachnodactyly, and congenital contractures. The older sibling had an unusual laryngeal malformation characterized by globular cuneiform cartilages, short aryepiglottic folds, a tightly coiled epiglottis, and laryngomalacia. The second child born to this couple was examined in the newborn period and represents the first neonatal diagnosis of VDEGS, suggesting that VDEGS is recognizable at birth. The younger sibling is also experiencing upper airway obstruction and an otolaryngological evaluation is underway. This family provides evidence for expanding the phenotype to include laryngeal anomalies and support the concept of autosomal recessive inheritance. We are currently working to identify the genetic basis for this disorder using RNA expression profiling of skin fibroblasts and linkage studies. We suspect that based on a phenotype overlapping that of Beals syndrome, the gene involved likely plays a role in the fibrillin pathway. Additionally, the recessive nature of VDEGS suggests that the gene may function as an enzyme involved in the modification of fibrillin or other connective tissue matrix proteins.

Maternal fever and congenital heart defects: findings from the National Birth Defects Prevention Study. *L.D. Botto[1], M. Bishop Stone[2], E. Lammer[3], M.L. Browne[4], M.L. Feldkamp[1], G.M. Shaw[5], and the National Birth Defects Prevention Study* 1) Pediatrics/Medical Genetics, University of Utah, Salt Lake City, UT; 2) Utah Birth Defect Network and University of Utah, Salt Lake City, UT; 3) Children's Hospital, Oakland, CA; 4) New York State Department of Health, Troy, NY; 5) California Birth Defects Monitoring Program, Berkeley, CA.

Maternal fever in early pregnancy has been associated with an increased risk for heart defects in some studies. However, it is unclear whether such risk varies by type of defect and febrile illness. To examine these aspects we used data from the National Birth Defects Prevention Study (NBDPS). NBDPS is an ongoing population-based study of birth defects in the United States. Cases are ascertained through population-based registries, and controls are selected randomly from births in the same areas and birth years. Detailed information on fever is obtained through structured maternal interviews. Pediatric cardiologists classified cardiac phenotypes. The study includes 5,446 case-infants with major heart defects and 5,008 unaffected controls with birth years from 1997 through 2003. To help disentangle fever from infection, we defined three main first-trimester exposure groups: mothers with a reported fever, mothers with a reported infection but no fever, and mothers with neither (reference group). We excluded mothers with diabetes, and we adjusted analyses for maternal demographics, lifestyle factors, vitamin use, and chronic illness. Febrile illness, rather than illness alone, was associated with a moderately increased risk for selected defects, with some variation by source of fever. With fever from respiratory illness, the estimated relative risk for heterotaxy was 1.9 (95% confidence interval 1.1 to 3.2) and for aortic stenosis was 1.8 (1.0 to 3.3); with fever due to urinary tract and pelvic infections, the risk for right-sided obstructive defects was 4.1 (1.8 to 9.5); with fever from other sources, the risk for hypoplastic left heart syndrome was 5.0 (1.4 to 18.0) and for conotruncal defects was 3.4 (1.4 to 8.1). If such associations are causal, febrile illness may be a cardiac teratogen with some specificity by underlying infection.

Protein profile analysis and associated genes in laryngeal cancer treated by hypomethylation agent 5aza2dc. *Y. Guo[1], J. Li[1], Z. M. Xu[2], K.L. Sun[1], W.N. Fu[1]* 1) Medical Genetics, China Medical University, Shenyang; 2) 463 Hospital of PLA, Shenyang, 110042, China.

The demethylating drug 5-aza-2'-deoxycytidine has been shown to affect many genes expression in several kinds of cancers. Proein profiles from Hep-2 cells treated with 2m 5aza2dc for three days were obtained by two dimensional gel elctrophoresis. Several Differentially expressed protein spots were cut off and analyzed by mass spectrometry. They were S100 calcium-binding protein A4, proteasome (prosome, macropain) subunit, alpha type 5, neuropolypeptide h3, phosphoglycerate mutase 1 (brain), Chain A, 14-3-3 Protein Epsilon Complexed to Peptide, stathmin 1 and enolase 1, respectively. In conclusion, we established the protein profiles related to 5aza2dc in Hep-2 cells. The seven differentially expressed proteins identified provide us novel targets for further studying the molecular mechanisms of laryngeal carcinoma.

Proteomic Analysis of Retinoic Acid-induced Clubfoot-like Deformity in Rat Fetuses. *Z.G. Li[1,2], W.N. Fu[1], H. Ji[1], K.L. Sun[1]* 1) Medical Genetics, China Medical Genetics, Shenyang, Liaoning, China; 2) National Research Center of the New Drug Evaluation, Shenyang, 110021, P. R. China.

he etiology of idiopathic talipes equinovarus (ITEV) (clubfoot) is considered to be complex. Here we explore the expressions of clubfoot-related proteins and the change of the apoptosis rate in the clubfoot-like deformity model in rat fetuses induced by all-trans retinoic acid (ATRA). Clubfoot-like deformity model in rat fetuses were induced with ATRA (135mg/kg) in E10 pregnant Wister rats. Two-dimensional gel electrophoresis (2-DE) was applied to separate the total proteins of spinal cord, tibia-fibulae musculature, ankle joint tissue and ankle joint bone of the animal models. The Coomassie Brilliant Blue staining gels were analyzed by 2-DE software PDQuest 7.1.0. Selected differential protein spots were identified with peptide mass fingerprinting based on matrix-assisted laser adsorption/ionization time-of-flight mass spectrometry and database searching. XIAP, TNNT1 and Col21, three of the differential proteins, were identified furthermore. Apoptosis study was performed in terminal deoxynucleotidyl transferase nick end labeling. 23 protein spots were identified to be differential expressed in the clubfoot-like deformity model. In addition, three genes of XIAP, TNNT1 and Col21 were confirmed to be significantly down-regulated by the RT-PCR, and XIAP was further confirmed to be significantly down-regulated with immunohistochemistry. In ATRA-induced clubfoot-like deformity in rat fetuses, the rates of the apoptosis in the spinal, vertebra and muscle of the clubfoot-like deformity fetuses was 5.4, 10 and 3.7 times of those in the normal fetuses. The result suggests that certain differentially expressed proteins, such as XIAP and TNNT1, and Col21 showed a significant correlation with ITEV. Apoptosis plays a key role in the development of ITEV. The identification of protein alterations specify to ITEV would clarify the pathogenetic mechanisms involved in the disease and might be of prognostic and therapeutic benefit.

Protein-protein interactions and subcellular localisation of spartin (SPG20) in primary neuronal tissues. *R.D. Cook, H. Patel, A.H. Crosby* Clinical Developmental Science, St George's University of London, Tooting, United Kingdom.

We have previously shown that mutation of spartin (SPG20) underlies an autosomal recessive complicated form of hereditary spastic paraplegia (HSP). Spartin is a protein of unknown function, but contains a MIT (contained within microtubule-interacting and trafficking molecules) domain found in proteins involved in membrane trafficking as well as in spastin, a gene commonly mutated in an autosomal dominant form of HSP. Our earlier work has shown that spartin has a ubiquitous and complex localisation in neuronal-like cells including dynamic nuclear and cytoplasmic localisations as well as a vesicular pattern along differentiated neurites. Here we define biochemical studies which indicate that synaptic associated proteins co-immunoprecipitate with spartin from synaptic enriched membrane fractions. Also, in developing primary neurons spartin, which contains a putative NLS sequence, has a dynamic nuclear localisation and is ubiquitously expressed in neuronal processes. Further work is underway to determine spartins role in the early stages of neuron development as well as the significance of its presence in the nucleus.

Notch 3 gene mutation associated with Sneddons syndrome- a complex disorder of unknown etiology with variable clinical features overlapping the phenotype of cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy [CADASIL]. *D. Kumar[1], J. Holroyd[1], I. Frayling[1], I. Ferguson[2]* 1) Clinical Geneticist,Institute of Medical Genetics,University Hospital of Wales,Cardiff,UK; 2) Dept of Neurology,Frenchay Hospital,Bristol,UK.

A 42 year old lady was referred with a clinical diagnosis of Sneddons syndrome who has a long medical history of multiple medical problems including Raynauds disease, one episode of major cerebrovascular accident, recurrent transient ischaemic attacks [TIAs], one emergency admission with chest pain due to pulmonary embolism, recurrent joint stiffness with non-specific musculoskeletal symptoms, recurrent migrainous headaches and skin rash in the form of livedo reticularis and erythema. The family history includes her two daughters with early onset migraine-like headaches and father who had recurrent TIAs, stroke and Alzheimers type senile dementia. Molecular testing for mutations in the Notch 3 gene confirmed a heterozygous C>T transition at nucleotide 3646 in exon 22 (Arg1190Cys). This is a known pathogenic mutation for cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy [CADASIL]. This is probably the first report describing the pathogenic association of Notch 3 gene mutation with Sneddons syndrome. Sneddon syndrome is a chronic complex connective and/or vascular tissue inflammatory disease of unknown etiology that usually presents with recurrent complicated migraine, skin rash (erythematous rash and livedo reticularis), non-specific musculoskeletal symptoms, TIAs, stroke and dementia. A small subset of families might have multiple affected members following autosomal dominant inheritance pattern. This is probably the first report describing Notch 3 gene mutations in Sneddon syndrome. Molecular testing should be considered in a patient/ family presenting with clinical features falling within the broad spectrum of CADASIL. More clinical and genetic data are required to establish genotype-phenotype correlations of Notch 3 gene mutations with CADASIL, Sneddons syndrome and other similar disorders with overlapping clinical features.

Tiling resolution array CGH, expression, and methylation analyses of dup(1q) in Burkitt lymphomas and pediatric high hyperdiploid acute lymphoblastic leukemias reveal clustered near-centromeric breakpoints and overexpression of genes in 1q22-32.3. *J. Davidsson[1], A. Andersson[1], K. Paulsson[1], M. Heidenblad[1], M. Isaksson[1], A. Borg[2], J. Heldrup[3], M. Behrendtz[4], I. Panagopoulos[1], T. Fioretos[1], B. Johansson[1]* 1) Department of Clinical Genetic, Lund University Hospital, Lund, Scania, Sweden; 2) Department of Oncology, Lund University Hospital, and Lund Strategic Research Center for Stem Cell Biology and Cell Therapy, Lund University, Lund, Sweden; 3) Department of Pediatrics, Lund University Hospital, Lund, Sweden; 4) Department of Pediatrics, Linköping University Hospital, Linköping, Sweden.

Although gain of 1q occurs in 25% of Burkitt lymphomas (BLs) and 10% of pediatric high hyperdiploid ALLs, little is known about its molecular genetic characteristics and functional outcome. Ten dup(1q)-positive BLs/ALLs were investigated by tiling resolution array CGH analysis, which revealed that proximal breakpoints in all cases were near-centromeric, in eight of them clustering within a 1.4 Mb segment in 1q12-21.1. The 1q distal breakpoints were heterogeneous, being more distal in the ALLs than in the BLs. The minimally gained segments in the ALLs and BLs were 57.4 Mb [dup(1)(q22q32.3)] and 35 Mb [dup(1)(q12q25.2)], respectively. Satellite II DNA on 1q was not hypomethylated, as ascertained by Southern blot analyses of 15 BLs/ALLs with and without gain of 1q, indicating that aberrant methylation was not involved in the dup(1q) origin, as previously suggested for other neoplasms with 1q rearrangements. Global gene expression analyses revealed that five genes in the minimally gained region - B4GALT3, DAP3, RGS16, TMEM183A, and UCK2 - were significantly overexpressed in dup(1q)-positive ALLs compared to ALLs without dup(1q). The DAP3 and UCK2 genes were among the most overexpressed genes in the BL case with gain of 1q investigated. The DAP3 protein has been reported to be highly expressed in invasive glioblastoma multiforme cells, whereas expression of the UCK2 protein has been correlated with sensitivity to anticancer drugs. However, involvement of these genes in dup(1q)-positive ALLs and BLs has previously not been reported.

Thumb abnormalities in the form of triphalangeal thumbs, hypoplastic thumbs, and polydactylous thumbs in 9 cases of velocardiofacial (VCF) syndrome. A vastly under appreciated feature of VCF syndrome. *B.D. Hall[1, 2], G.A. Stapleton[2], R.C. Rogers[2]* 1) Department of Pediatrics, University of KY, Lexington, KY; 2) Greenwood Genetic Center, Greenwood, SC.

Limb abnormalities of the upper extremities, except for the frequently recognized thin/long appearing fingers, are uncommonly reported in velocardiofacial (VCF) syndrome. Frequencies have varied between 1 and 6 percent of VCF cases. Preaxial involvement has been noted by Ming et al. (1997), Ryan et al. (1997), Kasaprzak et al. (1998), DeSilva et al. (1995), Shalev et al. (1996), Florez et al. (2004), and McDonald-McGinn et al (2005) totaling approximately 17 cases out of the thousands of reported VCF syndrome cases. This does not include 3 cases (mother and 2 children) reported by Hall (Proc Greenwood Genetic Center 24:145) in 2005 with hypoplastic or triphalangeal thumbs. Hall and colleagues are adding an additional 6 cases of VCF who have bilateral thumb abnormalities in the form of triphalangeal thumbs, hypoplastic thumbs, polydactylous thumbs, or broad thumbs. In some instances the diagnosis of VCF syndrome had not been considered because of the presence of preaxial defects and in others it had been relegated to "possible" or rule/out diagnosis. Even those VCF cases without overt preaxial deficiencies or defects often had flexion crease aberrations of the thumb with normal thenar muscle mass suggesting that the majority of VCF cases have some preaxial abnormality. This may be an important additional clue in raising the suspicion of the VCF diagnosis.

A Genome-wide linkage analysis for urinary albumin excretion In a cohort of West Africans with type 2 diabetes.
G. Chen, A. Adeyemo, J. Zhou, Y. Chen, C. Rotimi Natl Human Genome Ctr, Howard Univ, Washington, DC.

Diabetic nephropathy currently accounts for approximately 50% of all new cases of chronic renal failure in USA. Among persons with type2 diabetes (T2D), increased genetic susceptibility, high blood pressure, obesity, smoking, and increased glomerular filtration are important factors that contribute to the development and progression of end stage renal disease (ESRD). However, the specific underlying genetic determinants are still unknown. We performed a genome wide linkage scan in a genome panel of 372 autosomal short-tandem repeat markers at an average spacing of 9cM in 691 T2D patients (321 sib pairs and 36 half-sib pairs). enrolled from West Africa. To identify QTLs for log Urinary albumin to creatinine ratio (ACR), multipoint variance components linkage analysis was conducted adjusting for gender, age, pulse pressure, duration of T2D and hypertension. The strongest linkage evidence to urinary log ACR phenotype was observed in 19p13.2 region with a LOD score 2.14 (nominal p-value = 0.0008 and empirical p-value = 0.0017) at 21cM, near marker D19S1034 and in 16q23 region with a LOD score 1.50 (nominal p-value = 0.0043 and empirical p-value = 0.0093) at 111cM, near marker D16S3091. In conclusion, linkage regions in 19p13.2 and 16q23 may harbor genes influencing variation in urinary ACR phenotype in West Africans with T2D.

Haplotype-Sharing Test as a tool to map genes for familial cardiomyopathy. *F. Gerbens[1], J.P. van Tintelen[1], P.A. van der Zwaag[1], L.G. Boven[1], J.J. van der Smagt[2], R.N. Hauer[3], R.M.W. Hofstra[1], G.J. te Meerman[1]* 1) Department of Genetics, University Medical Center Groningen, Groningen; 2) Department of Clinical Genetics, University Medical Center Utrecht, Utrecht; 3) Department of Cardiology, University Medical Center Utrecht, Utrecht, The Netherlands.

In Mendelian diseases, such as arrhythmogenic right ventricular and dilated cardiomyopathies (ARVC and DCM), chromosomal regions identical-by-descent (IBD) from a common founder can be ascertained both by linkage analysis and by haplotype-sharing methods. Finding shared haplotypes is greatly facilitated with the currently available high-density SNP arrays. However, determining which of the shared haplotypes is IBD and contains the disease-associated mutation, and which are identical-by-state (IBS) and are shared by chance, is difficult. However the probability for shared haplotypes to be IBD rather than IBS increases with an increasing number of SNPs. We hypothesized that the largest shared haplotype is the most likely region to hold the causative disease mutation. We designed the Haplotype-Sharing Test (HST) using SNP genotyping data from isolated patients and parent-offspring pairs and trios to identify the largest possibly shared haplotypes between patients that are members of a (large but unobserved) pedigree. We applied HST to: (A) three distantly related families each with at least one ARVC patient using 10K SNP arrays, and (B) a large family with 5 DCM patients using 250K SNP arrays. In pedigree A a haplotype run of 118 SNPs spanning 32 MB on chromosome 12p12.3-q13.13 was identified. This haplotype is substantially larger than any other area that is shared due to random effects. Screening of the PKP2 gene, located in this region, revealed a pathogenic splice mutation. In family B (DCM) the largest shared haplotype was 178 SNPs, spanning 3.5 MB on chromosome 15. Sequencing of potential candidate genes (a.o. TPM1) is pending. Identification of the causative mutation in pedigree A in the largest shared region shows that our hypothesis, though heuristic in character, was correct. More importantly, besides linkage analysis, HST is a powerful tool for identifying disease-causing genes in single and extended families.

Homozygous mutation in desmocollin-2 in arrhythmogenic right ventricular cardiomyopathy. *D. Ahnood, M.A. Simpson, S. Mansour, E.R. Behr, A.H. Crosby* St George's University of London, London, United Kingdom.

Arrhythmogenic right ventricular cardiomyopathy (ARVC) is a myocardial disorder associated with ventricular arrhythmias, heart failure and sudden death. The disease is characterised by progressive loss of cardiomyocytes and fibrofatty replacement, primarily occurring in the right ventricle though left ventricular involvement may also arise. Autosomal recessive mutations causing ARVC have been described in plakoglobin (JUP) and desmoplakin (DSP) and are characterised by the triad of ARCV with palmoplantar keratoderma and woolly hair. We present the identification homozygous single base deletion in exon 16 of the desmocollin-2 (DSC2) gene in a 30 year old male with ARVC, woolly hair and mild palmar-plantar keratoderma. Whilst 3 autosomal dominant mutations have been identified in DSC2 in patients with ARVC, this is the first reported homozygous mutation. A panel of microsatellite markers located in and around the 5 desmosomal genes previously identified in the pathogenesis of ARVC were genotyped in this individual. Heterozygosity in the proband was revealed at 4 of the 5 loci investigated (JUP, DSP, PKP2, DSG2). However, a region of homozygosity was identified in the proband at the DSC gene cluster located on chromosome 18. Sequence analysis of the DSC2 gene, revealed a single basepair deletion in exon 12 (1841delG). This mutation is predicted to lead to a frameshift and a premature termination codon at position 625 (S614fsX625).

Association of the -308G>A polymorphism of TNF alfa gene in Mexicans patients with breast cancer. *A. Escoto*[1], *D. Ontiveros*[2], *A.M. Puebla*[1,3] 1) Medicina Molecular, CIBO, Instituto Mexicano del Seguro Social, Guadalajara, Guadalajara, Mexico; 2) Unidad Médica de alta Especialidad, Hospital de Gineco-obstetricia, Fisiología Obstétrica CMNO, IMSS; 3) Laboratorio de Inmunofarmacología Experimental, CUCEI, Universidad de Guadalajara. Guadalajara, Jal., México.

Purpose Genetic polymorphisms in the promoter region of the tumour necrosis factor (TNF) gene can regulate gene expression and have been associated with inflammatory and malignant conditions. We have investigated the polymorphism in the promoter of the TNF gene (-308 G>A) in breast cancer susceptibility in Mexican population. Methods Using a Unmatched case-control design, breast cancer patients (n = 188) and woman controls (n = 122) were genotyped for these TNF polymorphism. Results Allele frequencies for patients and controls were different ($p<0.05$) with OR 7.71(IC95% 4.39-14.28). Conclusions We demonstrated association between the -308G>A polymorphism in the promoter region of TNF and susceptibility to breast cancer, in a sample of Mexican population.

Germline SDHB and SDHD mutations in a hospital-based series of patients with hereditary pheochromocytoma and paraganglioma. *E. Edelman[1], K. Zbuk[1], A. Shealy[1], R.R. Lorenz[2], C. Eng[1]* 1) Genomic Medicine Institute, Cleveland Clinic Foundation, Cleveland, OH; 2) Head and Neck Institute, Cleveland Clinic Foundation, Cleveland, OH.

Homozygous or compound heterozygous germline mutations of autosomal genes affecting mitochondrial energy production are associated with progressive childhood or adult-onset disease, often with multisystemic involvement. More recently, heterozygous germline mutations in this pathway have been implicated in heritable neoplasia syndromes. Heterozygous germline mutations in complex II succinate dehydrogenase subunits B, C, and D (SDHB, SDHC, and SDHD) and fumarate hydratase (FH) are associated with the Hereditary Pheochromocytoma and Paraganglioma and Hereditary Leiomyomatosis and Renal Cell Cancer syndromes, respectively. Hereditary Pheochromocytoma and Paraganglioma is an autosomal dominant condition characterized by an inherited susceptibility to adrenal pheochromocytoma (PC) and extraadrenal paraganglioma (PGL). From 2006 to present, 16 patients with PC/PGL were referred for cancer genetics consultation. Of the 16, research and/or clinical SDHB, SDHC, and SDHD sequencing results are available on 9. SDHB or SDHD mutations were identified in 5/9 (56%) cases. Heterozygous SDHD mutations were identified in 3/3 familial cases (100%) and heterozygous SDHB mutations were identified in 2/6 (33%) sporadic cases. No SDHC mutations were found. The average age at presentation in mutation positive patients was 46 years (range 18 - 72 years) compared to 53 years (30 - 67 years) in mutation negative patients. A Pro81Leu SDHD mutation was identified in a patient with a personal history of multiple head and neck PGLs as well as hemangioma and chordoma, neither of which have been previously reported in SDHD carriers. These families illustrate the variability in disease presentation in individuals with SDHB and SDHD mutations. Genetic counseling issues specific to hereditary PC/PGL include highly variable age of onset, maternal imprinting in SDHD carriers, reduced penetrance with SDHB mutations, and the risks of renal cell carcinoma and papillary thyroid cancer, especially in SDHB carriers.

Ultraconserved Knockout Mice are Viable. *N. Ahituv[1,2,3], A. Visel[1], Y. Zhu[1], L.A. Pennacchio[1,4], E.M. Rubin[1,4]* 1) Genomics Division, Lawrence Berkeley National Laboratory, Berkeley, CA; 2) Department of Biopharmaceutical Sciences, University of California, San Francisco, CA; 3) Institute for Human Genetics, University of California, San Francisco, CA; 4) US DOE Joint Genome Institute, Walnut Creek, CA.

Ultraconserved elements, sequences exhibiting 100% identity over 200bp or greater between human-mouse-rat, have been suggested to retain extreme evolutionary conservation due to their essential functional properties. To investigate the necessities of these elements *in vivo*, we removed four non-coding ultraconserved elements (ranging in length from 222 to 731 base pairs) from the mouse genome. To maximize the likelihood of observing a phenotype, we chose to delete elements adjacent to genes that exhibit marked phenotypes both when completely inactivated in the mouse as well as when their expression is altered due to genomic modifications. Remarkably, all four resulting lines of mice lacking these ultraconserved elements were viable and fertile, and failed to reveal any critical abnormalities when assayed for a variety of phenotypes including growth, longevity, pathology, and metabolism. In addition, more targeted screens based on the knowledge of the adjacent genes biological characteristics did not show any notable abnormalities. These results, while clearly not inclusive of all the possible phenotypic impact of the deleted sequences, indicate that extreme sequence constraint does not necessarily reflect crucial functions required for viability.

Osteofibrous Dysplasia: Description of Mendelian Inheritance and Identification of Positional Candidates. *X. Gao[1], D. Zhang[2], L. A. Karol[1,2], E. Smith[1], C. A. Wise[1,2]* 1) Seay Center, and Orthopaedics, Texas Scottish Rite Hospital, Dallas, TX; 2) Department of Orthopaedic Surgery, and McDermott Center, University of Texas Southwestern Medical Center at Dallas.

Osteofibrous dysplasia (OD) (MIM #607278) is an early-onset condition marked by isolated, tumor-like lytic lesions bone in skeletally immature patients. The site of involvement is typically the cortex of the tibia, although other bony involvement is described. Symptomatic children usually present at less than five years of age with anterolateral bowing or subsequent pathologic fracture of the affected bone. The differential diagnosis of OD includes congenital pseudoarthrosis of the tibia (CPT), a condition usually associated with neurofibromatosis type 1, and the more common fibrous dysplasias. Resemblance to adamantinoma of long bones, a low-grade malignant neoplasm affecting mostly the tibia of young adults, has led to the suggestion that OD may be related to this condition. Interestingly, cytogenetic studies of OD and adamantinoma bone specimens have revealed apparently overlapping results, with trisomies 7, 8, and 12 observed in each disease. Despite these observations, the pathogenesis of OD is unknown, and until recently was not generally considered heritable. We ascertained a three-generation family in which eight individuals were considered affected with OD and performed a genome-wide scan of polymorphic loci spaced at 10-15 cM density. LOD scores were calculated from the resulting genotypes under a model of dominant inheritance and varying penetrances. Importantly, evidence of linkage was not detected for loci in the region of the NF1 or TNFRSF11A genes responsible for neurofibromatosis type 1 and familial expansile osteolysis, respectively. We obtained strongest results for regions of chromosomes 3q13-21 and 8q23-24, where subsequent fine-mapping produced maximum multipoint LOD ~ 2.0 for the chromosome 8 linkage peak. This is of particular interest given the previous cytogenetic observations in OD. Genes encoded in linked regions, particularly those that function in pathways of early osteogenesis, are candidates for further investigation in both familial and sporadic cases of OD.

Evolution of Metabolic Networks. *H. Dong[1], YH. Xiao[2], L. Jin[1], M. Xiong[1,3]* 1) Dept Genetics, Fudan Univ, Shanghai, China; 2) Dept of Computer Science, Fudan University, Shanghai, China; 3) Human Genetics Center, University of Texas, School of Public Health.

Recently, there has been increasing interests in application of general theory of complex network to evolution study of metabolic networks. Although general theory of complex networks can explain many features of topology of metabolic networks, this approach rarely compare the structure patterns of networks and investigate their different forms within and between species. Therefore, the structure variations of networks within and between species will be difficult to discover by pure application of general theory of complex networks to metabolic networks. To overcome these limitations, we first develop new methods for network alignment. Then, we explore basic idea of DNA sequence evolution theory for developing a novel paradigm for evolution of metabolic networks. We propose a novel concept of distance between the metabolic networks to measure difference in the structure of the networks. We use algebra topology to identify the symmetry structure and find the equilibrium of evolution of the metabolic networks for each specifies. Based on the distance between the metabolic networks and the equilibrium of the evolution of the metabolic networks, we construct the evolutionary tree of the metabolic networks. Finally, the proposed algorithms and methods were applied to evolution of more than one hundred of metabolic networks. We compare the evolutionary trees of the species based on evolution of metabolic networks with that based on DNA sequences.

Familial supernumerary teeth - clinical variability and genetic heterogeneity. *C. Albu, R. Purcarea, D.F. Albu, E. Severin* Dept of Human Genetics, Carol Davila Univ Med Pharm, Bucharest, Romania.

Background: Supernumerary teeth are a developmental anomaly characterized by teeth in excess of the normal number. Extra teeth are relatively common in the permanent dentition. Heredity is often involved, but specific genes are not yet known. Clinical variation included the number, location, direction of eruption and morphologically type of the supernumerary teeth. Objectives: To analyze the inheritance pattern of familial supernumerary teeth; to describe the clinical phenotype and supernumerary teeth pattern in families; to identify the genetic cause of clinical variability of anterior maxillary supernumerary teeth as observed in our cases. Patients and Methods: A group of 26 Caucasian patients (15 males and 11 females) with isolated supernumerary teeth located in premaxilla were investigated; the diagnosis of supernumerary teeth has been made by oral and radiographic examinations; information about families medical history of supernumerary teeth was collected. Results: The upper incisor region was the common site for supernumerary teeth. The most frequent permanent extra tooth was mesiodens followed by the supplemental upper lateral incisor. Familial inheritance occurred and involved two or three generations. The inheritance pattern of supernumerary teeth was different and no simple mode of transmission was found.The affected members within the same family often exhibited variability in clinical presentation. Familial predisposition to increase the number of teeth in the relatives of those affected was noted. Conclusions: Supernumerary teeth are an inherited developmental anomaly in families. Various clinical phenotypes of an isolated extra tooth are determined by mutations in different genes. Early diagnosis of supernumerary teeth prevents the clinical complications.

Digenic Inheritance of Apparent Autosomal Dominant Keratoconus in a Large Australian Pedigree. *K.P. Burdon[1], D.J. Coster[1], J.C. Charlesworth[2], J.E. Craig[1]* 1) Dept Ophthalmology, Flinders University, Bedford Park, SA, Australia; 2) Southwest Foundation for Biomedical Research, San Antonio, Texas, USA.

Keratoconus is a debilitating, blinding disease characterized by progressive asymmetrical thinning of the cornea. The onset is typically in early adulthood and over 30% of corneal grafts are attributable to keratoconus. It is a complex disease and multiple linked loci have been described, although only one gene has been reported (VSX1). A large four generation pedigree with autosomal dominant keratoconus was identified by the treating physician undertaking corneal grafting in multiple family members. Additional affected and unaffected family members were recruited and underwent a full ophthalmic examination and medical history. A genome wide linkage scan was conducted using the Affymetrix 10K SNP array, with multipoint parametric linkage analysis conducted in MERLIN. Analysis under a fully penetrant dominant model did not reveal any linkage. With the penetrance in heterozygotes reduced to 70%, two peaks were identified on 1p36.23-36.21 and 8q13.1-q21.11, with LOD scores of 1.9 and 2.0 respectively. Haplotype analysis revealed that all affected individuals carried identical haplotypes at both loci, while unaffecteds carried only one or neither of the haploytpes. Digenic linkage analysis was undertaken in GENEHUNTER-TWO LOCUS. The maximum LOD score of 3.4 was observed at 19.1cM on chromosome 1 and from 84.4 to 93.5cM on chromosome 8. Non-parametric analysis revealed a maximum NPL score of 7.8 with a p-value of 0.00024 at the same location as the parametric analysis. Thus, although the pedigree appears to demonstrate simple autosomal dominant inheritance, the disorder is likely digenic. Ingenuity Pathways Analysis was used to help prioritise candidate genes by looking for reported interactions between transcripts or proteins located under the two peaks. An interaction between SPSB1 (reportedly expressed in cornea) and TCEB1 (expressed in fetal eye and anterior segment) was identified, making these genes a high priority for follow-up. Given the digenic inheritance observed, this pedigree may provide a link between simple inherited forms of keratoconus and complex sporadic cases.

Mitochondrial DNA mutations and polymorphism in idiopathic asthenozoospermic men of Indian origin. *R. Kumar[1], A. Bhat[2], R.K. Sharma[3], R.N.K. Bamezai[2], R. Dada[1]* 1) Anatomy, AIIMS, NEW DELHI, DELHI, India; 2) SCHOOL OF LIFE SCIENCES, JNU, New Delhi India; 3) army R and R hospital, delhi cantt.India.

Rakesh Kumar1, Audesh Bhat2, Sharma R K3, R N K Bamezai2,Dada R1 Department of Anatomy, AIIMS1, School of life sciences, JNU2, Army R & R Hospital New Delhi. India Background: Studies on sperm function especially motility turned attention to the possible role of sperm mitochondria in male infertility. There are no introns between genes but all exons, so every change in mitochondrial DNA (mt DNA) is potentially lethal to cellular respiration. During spermatogenesis sperms require energy for biosynthetic processes and motility. Inhibition of sperm OXPHOS and rearrangements to the mt. DNA genome can affect sperm function. As copy number of mitochondrial genome in sperm is far less than somatic cells, therefore slight damage to the mitochondrial genome results in impaired sperm function and infertility with less severe effect on other tissues and systems. Aims: The aim of this study was to identify point mutations which may be associated with human male infertility. Methods: The whole mitochondrial genome was isolated form sperm and blood and mutations were screened with the help of DNA sequencing. The semen and blood samples analyzed were obtained from 25 oligoasthenospermic idiopathic infertile men and 20 controls. Results: G to A transition was detected in ND4 gene at nucleotide position 11719 in sperm DNA of 19 cases and only 14 from blood DNA. Though this is a non-synonymous change, the aminoacid remaining the same. The polymorphism A750G, A4769G and A8860G has been found in all the semen as well blood DNA of the cases but only in 12 controls. A750G, A4769G are non-synonymous changes but A8860G polymorphism in ATPase 6 gene changes aminoacid threonine to alanine. Though A8860G is a known polymorphism in the Indian Subcontinent but it needs a relook as its frequency seems to be more in infertile men than in controls. Conclusion: Further studies are in progress to see the effect of these mutations on the ATP depletion and Reactive oxygen species (ROS) production.

A genome-wide association scan identifies the hepatic cholesterol transporter ABCG5/ABCG8 as a susceptibility factor for human gallstone disease. *S. Buch[1,2,3], C. Schafmayer[3,4], H. Völzke[6], A. Franke[2], C. Becker, C. Kluck, I. Bämann[7,9], H. von Eller-Eberstein, B. Timm, C. Höll[3], M. Brosch[1], F. Lammert, J.F. Miquel[10], F. Nervi[11], M. Wittig, A. ElSharawy[2], J. Seeger[1], T. Lu[5], D. Rosskopf[12], J. Egberts, F. Fändrich[4], U.R. Fölsch[1], M. Krawczak[5], S. Schreiber[2,3], P. Nürnberg[7,8], J. Tepel[4], J. Hampe[1]* 1) Department of Medicine; 2) Institute for Clinical Molecular Biology; 3) POPGEN Biobank; 4) Department of General and Thoracic Surgery; 5) Institute of Medical Statistics and Informatics, 1-5 all at Univ. Hospital Schleswig-Holstein, Kiel / Germany; 6) Institute of Community Medicine, Univ. Hospital Greifswald / GER; 7) Cologne Center for Genomics, Univ. of Cologne / GER; 8) Center for Molecular Medicine Cologne (CMMC), Univ. of Cologne / GER; 9) RZPD,German Resource Center for Genome Research / GER; 10) Department of Internal Medicine I, Univ. Hospital Bonn / GER; 11) Depart. de Gastroenterologia, Facultad de Medicina Univ. Catolica, Santiago / Chile; 12) Institute of Pharmacology, Univ. Hospital of the Ernst Moritz Arndt Univ. Greifswald / Germany.

Cholelithiasis represents one of the most frequent health problems of industrialized countries. A 500K-association scan was performed in 280 gallstone cases and 360 controls. In a follow-up of 235 SNPs in 1105 cases and 873 controls, the disease association of SNP A-1791411 in the *ABCG8* gene was replicated (allelic $p=4.110^{-9}$). Fine-mapping of the ABCG5/ABCG8 locus, using both haplotype and logistic regression analysis, revealed that non-synonymous SNP rs11887534 in the *ABCG8* gene (D19H) was found to represent the major source of gallstone risk. Further replication was performed in 728 patients from Germany ($p=2.810^{-7}$) and in 167 patients from Chile ($p=0.02$). The odds ratio (OR) for D19H carriership in German Caucasians was 2.2 (95% CI 1.8-2.6). In a post-hoc logistic regression analysis, the genotypic effect was found to be independent of BMI, age and sex. Association with D19H carriership was stronger (OR=3.3) in patients with cholesterol gallstones, suggesting that 19H might be associated with a more efficient transport of cholesterol into the bile.

Molecular characterization of tuberous sclerosis patients in Taiwan. *D. Chu[1], M. Huang[1], J. Lin[2], C. Wang[2], C. Hou[2]* 1) Graduate Inst Medical Biotech, Chang Gung Univ, Sch Med Tech, Tao-Yuan, Taiwan; 2) Department of Pediatrics, Chang Gung Memorial Hospital, Taiwan.

Background: Tuberous sclerosis (TS, MIM#191100) is an autosomal dominant disorder characterized by hamartomatous lesion in multiple organs, especially in the skin and brain. Other common clinical features include epilepsy, learning difficulties, and behavioral problems. TS patients display genetic heterogeneity, with the existence of two different causative genes on chromosomes 9q34.3 (TSC1) and 16p13.3 (TSC2), respectively. Mutations in either of these two genes lead to loss of tumor suppressor function. Materials and Methods: one hundred and thirteen peripheral blood samples were obtained from TS cases (37 families) or their family members. Genomic DNA was extracted. Denaturing high performance liquid chromatography (dHPLC) was conducted to screen possible genetic lesions in TSC1 and TSC2 genes. Direct DNA sequencing was then performed to confirm dHPLC findings. Results: data showed that genetic lesions were found in 22 patients, including 2 missense, 1 nonsense, 1 insertion, and 1 deletion mutations in the TSC1 gene, while 4 missense, 1 nonsence, 7 deletions and 2 insertions in TSC2 gene. In addition, we performed real-time quantitative PCR to determine the quantities of hamartin and tuberin mRNA in patients with mutations. Data showed that there was no significant difference between the hamartin or tuberin mRNA levels. Clinically, 95% of the study cases presented epilepsy, 62% of them showed kidney symptom, 48% of them had heart striated muscle tumor. Benign angiomyolipomas, the most common TS lesion, were found in 62% of these TS cases. Cardiac rhobdomyoma was observed in 48% of TS cases. All cases with TSC2 gene mutations were mentally retarded. No evidences of correlation between TSC1 and TSC2 mutations and other spectacular clinical phenotypes in these patients studied were observed. Conclusions: The genetic lesions leading to TS and clinical features are highly heterogeneous. It is practical to screen TSC1and TSC2 genes with dHPLC followed by DNA sequencing to aid accurate diagnosis of TS.

DJ-1 gene confers susceptibility to Parkinsons disease. *G. Annesi, P. Tarantino, I.C. Cirò Candiano, E.V. De Marco, F. Condino, F.E. Rocca, G. Provenzano, S. Carrideo, G. Nicoletti, F. Annesi* Inst Neurological Sci, National Research Council, Cosenza, Italy.

DJ-1 mutations cause autosomal recessive early-onset parkinsonism, dystonia in rare families (PARK7). In the present study we investigated whether an 18 bp insertion/deletion variant and single nucleotide polimorphisms (SNP) within the DJ-1 gene are associated with Parkinsons disease. We analyzed 297 patients with sporadic Parkinson and 290 unrelated healthy subjects from the same geographical area. Genomic DNA was extracted by standard method. The study of DJ-1 variants involved two phases. In the first phase, we identified a subsample of 30 unrelated control subjects with an age, gender, and ethnicity distribution similar to the cases. We determined the DJ-1 gene sequence in this subsample and identified 20 polymorphisms across a full length of the gene. Five SNP and an 18 bp insertion/deletion provided informative (minor allele frequencies >25%) , were easy to assay using multiplex SNaPShot, and had genotype frequencies consistent with Hardy-Weinberg equilibrium expectation. In the second phase, we genotyped the full sample of PD patients and unrelated control subjects of these polymorphisms.We constructed all possible locus haplotypes as defined by the five SNP and 18 bp I/D variant and studied their association with PD for the analyses. We performed score tests and determined pvalues. Haplotype analysis was performed using Haplowiev 3.2 and UNPHASED. We observed associations overall the six polymorphisms. There were significant differences in the genotypes or allele frequencies between the two groups PD and control subjects. Each marker, taken individually, did show association to PD. In our haplotypes we observed significant differences in the inferred haplotype frequencies of PD and control subjects ($p<0.001$). Our data show that in the southern Italy population, genetic variability within the DJ-1 is highly associated with susceptibility to idiopathic PD. This is in contrast with three previous findings, that did not show an association between DJ-1 polymorphisms and PD.

Molecular Study of Five Ethnic Groups of Rajasthan. *M. Ghaznavi Idris[1], M. Rupak[3], K. Harpreet[3], K.N. Saraswati[3], S.S. Kamboj[1], S. Bhardwaj[4], K. Kucheria[2], R. Dada[1]* 1) Department of Anatomy,All India institue of Medical Sciences, New Delhi, India; 2) Department of Endocrinology,All India institue of Medical Sciences, New Delhi, India; 3) Department of Anthropology,Delhi University,Delhi,India; 4) Department of Zoology,Government College,Banswara, Rajasthan,India.

INTRODUCTION: Rajasthan is a state in north-western India with several ethnic and tribal groups such as the Rajputs, Minas, Bhils, Sahariyas, Damaria and Garasiya. These groups still maintain their ethnic identity which makes a very useful cohort in studying their genetic imprinting. In the present study seven human-specific Alu insertion / deletion and five Restriction Fragment Length Polymorphisms (RFLPs) have been analyzed. MATERIAL AND METHODS: Intra venous blood samples were taken after written consent from 26 Damaria, 34 Rajput, 30 Saharia, 34 Mina, 53 Garasiya, and 47 Bhil individuals and DNA was isolated according to the standard protocol of phenol chloroform given by Maniatis. PCR amplification was done for Alu insertion / deletion polymorphism and RFLP. Five different restriction enzymes were used to digest the PCR products for RFLP markers. The results were visualized in UV light after running them in agarose gel. RESULTS AND DISCUSSION: Gene counting method was used for estimating allele frequencies. Ht, Hs and Gst values were computed using the programme DISPAN. A phylogenetic tree was constructed on the basis of genetic distance using the programme DISPAN. The Gst value which is the genetic differentiation between the 6 populations groups is found to be 4.9%. The Ht and Hs values are 0.457 and 0.435 respectively. The marker wise Ht values are found to be very high, all of them approaching the theoretical maximum i.e. 0.5, except for CD4 (0.36). These high heterozygosity values indicate the fixation of these alleles in the population groups under study.

The Statistical Equivalent Of The Binary TDT For Quantitative Traits. *S. Ghosh* Human Genetics Unit, Indian Statistical Institute, Kolkata, India.

The classical Transmission Disequilibrium Test (TDT) for binary traits proposed by Spielman et al. is a family-based alternative to population-based case-control studies and circumvents the problem of population stratification as it tests for allelic association in the presence of linkage. However, since the clinical end-point traits are often defined by quantitative precursors, it has been argued that it may be a more prudent strategy to analyze the quantitative phenotypes without dichotomizing them into binary traits. The paradigm of linkage disequilibrium in the context of quantitative traits is not straight forward and methods have generally considered the intuitive concept of differences in allelic frequencies between individuals having high values of the quantitative trait and those with low values of the trait as evidence of linkage disequilibrium between the marker locus and the QTL. Although some methods have been developed for testing transmission disequilibrium in the context of quantitative traits, these are not direct extensions of the classical TDT. We propose a simple logistic regression based test which can be analytically shown to be statistically equivalent to the TDT for binary traits, and hence is not susceptible to the presence of population stratification in the data. We perform Monte-Carlo simulations under a wide spectrum of disease models and varying parameter values of linkage disequilibrium to evaluate the power of the proposed procedure. We find that similar to the binary TDT, the power decreases with increase of dominance and decrease of heterozygosity at the QTL. We apply our method to analyze an alcoholism related phenotype from the Collaborative Study on the Genetics Of Alcohism (COGA) project. The endophenotype defined as the number of externalizing symptoms associated with anti-social behavior has exhibited significant evidence of linkage on Chromosome 4 in the alcohol dehydrogenase (*ADH*) gene cluster. We find significant association between the quantitative phenotype and a biallelic marker in the *ADH1C* gene.

Generalized epilepsy with febrile seizures plus: linkage analysis in three families from Southern Italy. *S. Carrideo[1], G. Incorpora[2], F. Annesi[1], E.V. De Marco[1], G. Provenzano[1], F.E. Rocca[1], L. Pavone[2], A. Labate[1,3], A. Gambardella[1,3], G. Annesi[1]* 1) Inst Neurological Sci, CNR, Mangone, Italy; 2) Department of Paediatrics, University of Catania, Italy; 3) 3Institute of Neurology, University Magna Graecia, Catanzaro, Italy.

Generalized Epilepsy with Febrile Seizures Plus (GEFS+) is a genetic disorder transmitted as an autosomal dominant trait with incomplete penetrance. GEFS+ is characterized by febrile seizures, that persist beyond the age of six, and by heterogeneous afebrile seizures that may include tonic-clonic, myoclonic, atonic seizures and absence. So far GEFS+ has been associated with mutations in SCN1A, SCN2A, SCN1B genes (encoding respectively the alpha 1, alpha 2 and beta 1 voltage-gated sodium channel subunits) and GABRG2 gene (encoding the GABAA receptor gamma subunit). The aim of this study is to better define the genetics of GEFS+ by analyzing 3 large families from Southern Italy. We enrolled 3 unrelated families with GEFS+. The diagnosis was made in accordance with the International League Against Epilepsy criteria. DNA was extracted from peripheral blood samples after informed consent. To investigate the role of the known genes we performed a linkage study on 22 affected and 17 non affected subjects belonging to these three families. We used microsatellite markers selected from those available in the NCBI data base. The following chromosome regions were examined: 2q24-33 (SCN1A-SCN2A), 19q13 (SCN1B), 5q31-33 (GABRG2). Two point linkage analysis was performed by LINKAGE. Linkage analysis allowed us to exclude the involvement of SCN1A and SCN2A genes in all these families. As regarding the remaining genes negative LOD score values (less than -2) were obtained for all informative markers in two families, while the study is still in progress in the third family. In two of our families the results showed no association between GEFS+ and the genes already described for this disease while more studies are needed in the third family. Our results provide further evidence for the high level of genetic heterogeneity associated with GEFS+ suggesting the involvement of at least one more gene in this syndrome.

Genome wide linkage of a large serbian family with GEFS+. *F. Annesi[1], G. Provenzano[1], S. Carrideo[1], A.J. Ristic[3], S. Jankovic[3], G. Maksimovic[3], B. Gnjatovic[3], I. Petrovic[3], N. Vojvodic[3], D. Sokic[3], A. Gambardella[2], G. Annesi[1]* 1) Inst Neurological Sci, National Research Council, Mangone, Cosenza, Italy; 2) Institute of Neurology, University Magna Graecia, Catanzaro, Italy; 3) Institute of Neurology, Clinical Centre of Serbia, Belgrade.

Generalized epilepsy with febrile seizures plus (GEFS+) is an autosomal dominant epilepsy syndrome with incomplete penetrance characterized by heterogeneous phenotypes within the same family. The most common phenotypes include febrile seizures (FS) and febrile seizures plus, in which FSs persist beyond 6 years of age or associated with afebrile, mostly generalized or more rarely partial, seizures. Four genes associated with GEFS+ have been identified: SCN1A, SCN2A, SCN1B and GABRG2. In addition some GEFS+ loci have been reported but the causative genes have not yet been identified. We conducted a genome-wide linkage study in a large multigenerational Serbian family showing a clear dominant Mendelian inheritance pattern of GEFS+. The GEFS+ Serbian family shows 20 affected individuals over four generations. Patients with GEFS+ express a variable phenotype combining febrile seizures, afebrile generalized seizures and partial seizures. Genomic DNA was obtained on 22 living members (11 affected, 11 unaffected). Initially we excluded SCN1A, SCN2A, SCN1B, GABRG2 genes and known loci with linkage analysis. Subsequently, a genome wide scan was conducted genotyping 382 microsatellite markers. Two point parametric linkage analysis was performed by MLINK (LINKAGE 5.1), LOD score values were calculated by assuming a disease-allele frequency of 0.001, equal allele frequencies and autosomal dominant inheritance with 0.90 penetrance. Some regions with LOD scores above 1 were found in parametric two-point linkage analysis. Loci suggestive of linkage were genotyped with additional markers and haplotype analysis of implicated regions is in progress. Our linkage data clearly exclude all known loci and genes for GEFS+ demonstrating genetic heterogeneity of this syndrome. Genome scan revealed linkage at some chromosomal loci and analysis of candidate regions is underway.

genetic analysis in patients with a clinical picture of Myotonic Dystrophy. *I.C. Ciro Candiano[1], P. Tarantino[1], S. Carrideo[1], E.V. De Marco[1], D. Civitelli[1], F. Annesi[1], F.E. Rocca[1], V. Greco[1], M. Caracciolo[1], C. Rodolico[2], A. Toscano[2], G. Vita[2], G.* 1) 1Intitute of Neurological Sciences, National Research Council, Mangone (Cosenza), Italy; 2) 2Institute of Neurology, University of Messina.

Myotonic dystrophy (DM) is a dominantly inherited disorder; the classic form (DM1) is caused by an expanded CTG repeat in the 3-UTR of the dystrophia myotonica-protein kinase gene (DMPK) on 19q13. Disease severity varies with the number of repeats: normal subjects have 5 to 37 repeats; individuals with premutation (38÷49 repeats) are asymptomatic but premutation alleles are unstable; mildly affected persons have 50 to 80 repeats (protomutation); severely affected patients have 2,000 or more repeats. DM can also be caused by a CCTG expansion (mean ~5,000 repeats) in intron 1 of the zinc finger protein 9 (ZNF9) gene on 3q21 (DM2). We performed a molecular study of DMPK gene in patients with clinical features of DM. We analyzed the probands of 10 families and 71 unrelated patients. All patients samples were initially screened by PCR identify unaffected individuals, demonstrating two alleles in the normal range and small expansions often observed in minimally affected cases. The patients showing only one PCR allele within the normal range require a Southern confirmation that has two possible outcomes: A) the patient is ruled homozygous for the normal allele, B) an expanded allele is detected, thus confirming the diagnosis of DM. Thirty-three subjects are wild-type; among them one presents a premutation. Fourty-seven patients are genetically confirmed DM1. Molecular analysis of DMPK gene in 81 subjects revealed the expanded CTG repeat in 47 patients with varying clinical severity and various sizes of repeat amplification; one patient from a consanguineous family DM1-linked had an expansion of CTG repeat on both alleles (65 and 933 repeats) but in DM homozygotes do not differ phenotipically from heterozygotes. Two individuals carried a protomutation (50÷80 CTG repeats). For the 33 unaffected patients other neuromuscular diseases should be considered; alternatively, many milder phenotypes may be caused by DM2 mutations.

A novel locus for an autosomal recessive form of hereditary spastic paraplegia (SPG35) maps to chromosome 16q21-q23. *K.J. Dick[1], R. Al-Mjeni[2], W. Baskir[2], R. Koul[2], M.A. Simpson[1], M.A. Patton[1], S. Raeburn[2], A.H. Crosby[1]* 1) Medical Genetics, St. Georges, University of London, London, United Kingdom; 2) Sultan Qaboos University Hospital, Muscat, Oman.

The hereditary spastic paraplegias (HSPs) are a group of clinically and genetically heterogeneous neurodegenerative disorders in which the cardinal pathological feature is upper motor neuron degeneration leading to progressive spasticity and weakness of the lower limbs. To date, 14 autosomal recessive HSP loci have been mapped. We have identified a large consanguineous Omani family in which an autosomal recessive form of HSP is segregating. The age of onset of the condition varies from 6-11yrs and is associated with seizures in two individuals. Following exclusion of known ARHSP loci, we performed 250K gene chip SNP analysis of all affected individuals. All affected individuals shared a 20.4Mb (3.25cM) region of homozygosity located on chromosome 16q21-q23.1, defined by SNP markers rs149428 and rs9929635 (peak multipoint LOD score of 4.86) designated SPG35. Two candidate genes, dynein, cytoplasmic 1, light intermediate chain 2 (DYNC1LI2) and vacuolar protein sorting 4 homolog A (VPS4A) were sequenced but no disease causing mutations were identified.

INCREASED SENSITIVITY TO IONISING RADIATION IN MADA LAMINOPATHY. *A. di Masi[1], R. Ricordy[2], M.R. DApice[3], F. Lombardi[3], F. Gullotta[3], C. Tanzarella[1], G. Novelli[3,4]* 1) Department of Biology, University Roma Tre, Rome, Italy; 2) Centro Genetica Evoluzionistica, CNR, Rome (Italy); 3) Department of Biopathology and Diagnostic Imaging, Tor Vergata University of Rome, Italy; 4) Arkansas Medical School, Little Rock, USA.

Mandibuloacral dysplasia type A (MADA; OMIM # 248370) is a premature ageing disease caused by the homozygous R527H mutation in the LMNA gene. At cellular level, MADA is characterized by unprocessed prelamin A accumulation, nuclear architecture alterations, chromatin defects and increased incidence of apoptosis. These biochemical and morphological alterations involve genomic instability as demonstrated in other progeroid laminopathies (e.g. HGPS). We investigated the sensitivity of MADA cells to the ionising radiation-DNA-induced damage. MADA and age-matched normal fibroblasts were exposed to X-rays, with doses comprises between 1 and 4 Gy. We observed that the ability of MADA cells to repair the damage was significantly reduced compared to control fibroblasts, as demonstrated by the increased percentage of chromosome aberrations and the higher percentage of residual -H2AX foci, corresponding to unrepaired DNA-damage sites. MADA cells showed a markedly reduced phosphorylation of p53 at Ser15 and a lower induction of p53 and CDKN1A proteins after irradiation, compared to the control cell line. We also detected expression differences of some p53 downstream target genes in their response to DNA damage. In addition, MADA cells showed defects in checkpoint response, particularly in G1/S activation. Our results indicate that accumulation of the lamin A precursor protein determines a defect in DNA damage response after X-ray exposure, supporting a crucial role of lamin A in regulating DNA repair process and cell cycle control.

Heterozygous mutations in the carnitine transporter gene SLC22A5 are not associated with cardiomyopathy. *C. Amat di San Filippo[1], M.R.G. Taylor[2], L. Mestroni[2], L.D. Botto[1], N. Longo[1,3]* 1) Medical Genetics/Pediatrics, Univ Utah, Salt Lake City, UT; 2) Dept Medicine, Univ Colorado, Denver CO; 3) Dept Pathology and ARUP Laboratories, Univ Utah, Salt Lake City, UT.

Carnitine is essential for the transfer of long-chain fatty acids across the mitochondrial membrane for subsequent beta-oxidation. Primary carnitine deficiency, a recessive disorder caused by defective OCTN2 carnitine transporters, can present with hypoketotic hypoglycemia and/or cardiomyopathy. Heterozygotes for this disease can have low plasma carnitine levels and can develop benign cardiac hypertrophy as adults. This study tested whether heterozygosity for primary carnitine deficiency was associated with cardiomyopathy. The frequency of mutations in the SLC22A5 gene encoding the OCTN2 carnitine transporter was determined in 324 patients with cardiomyopathy and compared to that described in the normal population. Missense variations identified in normal controls and patients with cardiomyopathy were expressed in Chinese Hamster Ovary cells to confirm a functional effect. Exons 2-10 of the SLC22A5 gene were amplified by PCR in the presence of LCGreen I^{TM} and analyzed by dye-binding/high-resolution thermal denaturation followed by sequencing if needed. Exon 1 of the gene was sequenced in all patients. Heterozygosity for L144F, T264M, I312V, E317K and R488H was found in 6/324 patients with cardiomyopathy. Expression studies indicated that T264M decreased, E317K increased, while L144F, I312V, and R488H did not significantly affect carnitine transport. Expression studies of variants identified in normal controls indicated that L17F and Y449D had a functional effect, while F144L, V481I, V481F, M530V, and P549S did not change significantly carnitine transport. The frequency of variants affecting carnitine transport was 2/324 in patients with cardiomyopathy (0.61%) as compared to a reported frequency of 3/270 (1.11%) in the general population (odds ratio 0.6, 95% Confidence interval 0.1 to 3.3). Heterozygosity for primary carnitine deficiency is not more frequent in patients with unselected types of cardiomyopathy and is unlikely to be an important cause of cardiomyopathy in humans.

Aging in Neurofibromatotis 1 (NF1): Survival and Comorbidity According to US Death Certificates. *B.A. Carnes, J.J. Mulvihill, T.A. Teasdale, M.A. Grim, J.L. Mester* Geriatric Medicine, Oklahoma University Helath Sciences Center, Oklahoma City, OK.

To gain insight into issues of aging in neurofibromatosis 1 (NF1), US multiple cause of death files for 1988-1998 (24.2 million death certificates) were examined in order to compare survival and morbidity characteristics between young and old NF1 decedents and between these groups and their age-matched non-NF1 counterparts. Median age at death for NF1 decedents was 54 for males and 60 for females. Although males with NF1 as a concomitant disorder died 7 years earlier than their female counterparts, the gender gap was eliminated for those dying from NF1 as the cause of death. Recursive partitioning revealed that decedents dying with NF1 at older ages had less cancer (connective tissue tumor and brain neoplasm) and congestive heart failure than those dying at younger ages; whereas those dying because of NF1 at older ages had less cardiovascular (cerebrovascular, chronic ischemic and congestive heart) disease and pulmonary disease (COPD). Logistic regression analyses, stratified by sex, confirmed that young and old NF1 decedents can be distinguished (area under the ROC = 0.77) purely on the basis of their comorbidity profiles (array of ICD codes). Conditional logistic regression and standardized death rate ratios revealed that younger NF1 decedents have a greater risk of intrinsic (non-accidental) death than older NF1 decedents, relative to their age- and sex-matched non-NF1 counterparts. These findings suggest that younger NF1 decedents may have a more severe form of the comorbidities associated with this single gene disorder. Parallel analyses are underway for Canadian and Danish death certificates, as part of a large project to identify geriatric issues in this common Mendelian disorder. (Funded in part with DOD-US Army Neurofibromatosis Program grant W81XWH-06-1-0465).

The Phenotypic Association of Transverse and Central Ray Limb Deficiencies. *A.M. Elliott, J.A. Evans* Dept Biochem & Medical Gen, Univ Manitoba, Winnipeg, MB, Canada.

Central ray deficiency (Split Hand Foot Malformation, SHFM) can occur as an isolated anomaly or in association with other malformations. Classifications of SHFM include typical (central V-shaped cleft, often multimelic with positive family history) or atypical (central deficiency, sporadic, one affected limb). Typical SHFM is considered more genetic in nature and atypical more vascular. The most severe expression of typical SHFM is considered to be fifth finger monodactyly. However, Maisels proposed the Centripetal Suppression Theory that explains split hand as a progressive insult to the developing hand plate ranging from a simple cleft with no tissue deficiency to the most severe formaphalangiaa terminal transverse defect (TTD) (Hand, 1970). Geneticists generally associate TTD with vascular insult. We performed a detailed clinical epidemiologic study to investigate the association of central ray deficiency and TTD. Isolated and syndromic patients were evaluated from the literature and the local (Manitoba) population. Inclusion criteria consisted of central ray deficiency and TTD in the same patient. This phenotypic combination was seen in both syndromic and isolated SHFM patients. Syndromic cases included those with long bone deficiency (e.g. tibial aplasia/ectrodactyly, femur-fibula-ulna complex). It was also associated with ulnar deficiency, hypoglossia-hypodactyly, chromosome anomalies and mutations in TP63. The underlying genetic defect, if any, has not been elucidated for many of these disorders. The finding of this phenotypic combination in the same patient suggests TTD are not exclusively vascular in nature and likely represent the most severe expression of SHFM, thus supporting Maisels' theory.

A high-density SNP genome-wide linkage search of 206 families identifies susceptibility loci for chronic lymphocytic leukemia. *L.R. Goldin[1], G.S. Sellick[2], R.W. Wild[2], S.L. Slager[3], D. Catovsky[4], N. Caporaso[1], R.S. Houlston[2]* 1) Genetic Epidemiology Branch, Divsion of Cancer Epidemiology and Genetics, National Cancer Institute, Bethesda, MD; 2) Section of Cancer Genetics, Institute of Cancer Research, Sutton, Surrey, UK; 3) Division of Biostatistics, Dept. of Health Sciences Research, Mayo Clinic College of Medicine, Rochester, MN; 4) Section of Haemato-oncology, Institute of Cancer Research, Sutton, Surrey, UK.

Chronic lymphocytic leukemia (CLL) and other B-cell lymphoproliferative disorders display familial aggregation. To identify a susceptibility gene for CLL we assembled families from the major European (ICLLC) and American (GEC) consortia to conduct a genome-wide linkage analysis of 101 new CLL pedigrees using a high-density single nucleotide polymorphism (SNP) array and combined the results with data from our previously reported analysis of 105 families. Here we report on the combined analysis of the 206 families. Multipoint linkage analyses were undertaken using both non-parametric (model-free) and parametric (model-based) methods. After the removal of high linkage disequilibrium SNPs we obtained a maximum NPL of 3.02 (P= 1.3 x 10-3) on chromosome 2q21.2. The same genomic position also yielded the highest multipoint heterogeneity LOD (HLOD) score under a common recessive model of disease susceptibility (HLOD = 3.11; P= 7.7 x 10-5) which was significant at the genome-wide level. In addition, 2 other chromosomal positions 6p22.1 (corresponding to the major histocompatibility locus) and 18q21.1 displayed HLOD scores >2.1 (P < 0.002). None of the regions coincided with areas of common chromosomal abnormalities frequently observed in CLL. These findings provide direct evidence for Mendelian predisposition to CLL and evidence for the location of disease loci.

Implications of a Novel *SOX9* Mutation on the Sexual Phenotype of a Fœtus with True Hermaphroditism and Acampomelic Campomelic Dysplasia. *M. Beaulieu Bergeron[1,2,4], G. Scherer[5], J.-C. Fournet[1,2,4], E. Lemyre[3,4], N. Lemieux[1,2,4]* 1) Département de Pathologie et biologie cellulaire, Université de Montréal, Canada; 2) Département de Pathologie; 3) Département de Pédiatrie and; 4) Centre de Recherche, CHU Sainte-Justine, Canada; 5) Institute of Human Genetics and Anthropology, University of Freiburg, Germany.

Campomelic dysplasia (CD) is a rare disease caused by a mutation in *SOX9*, a gene involved in both chondrogenesis and sexual development. Along with severe skeletal malformations, CD causes sex reversal in 75% of 46,XY patients. We report here on a fœtus presenting with the acampomelic form of CD and true hermaphroditism. The 22 weeks-old fœtus, who has a homogenous 46,XY constitution in both fibroblasts and amniocytes, was found to have a left testis, a right ovary and normal male external genitalia. Analyses revealed a novel mutation of *SOX9*, caused by a *de novo* cytosine insertion in codon 381. Since a case of true hermaphroditism in CD was previously published, we compared the two mutations. Although both mutations were caused by a cytosine insertion inducing a frameshift, the published mutation generates a truncated protein missing almost entirely its third exon while our novel mutation is translated in a protein that has its transactivation domain replaced by an aberrant amino acids sequence. We also examined if the abnormal sexual development of the fœtus was caused by hidden 45,X/46,XY mosaicism in the gonads. FISH experiments performed on formalin-fixed and paraffin embedded gonadal tissues revealed no significant mosaicism in the testis or the ovary. So far, no genotype-phenotype correlation has been found for any of the *SOX9* mutations, and some individuals bearing identical mutations are known to have a variable sexual development. Recent evidence suggests that the sexual phenotype of patients with CD could be influenced by polymorphisms in the *SOX8* gene. Indeed, experiments in knock-out mice showed that *Sox8* could partially substitute for *Sox9*. Further experiments will be needed to explain the effects of this *SOX9* mutation on sexual development.

Investigation of tRNA $^{Leu/lys}$ and ATPase 6,8 genes mutation in Huntington's Disease. *S. Kasraie[1], S. EtemadAhari[1], M. Houshmand[1], M. Moin[2], M.A. Bahar[3], M. Shafa Shariat Panahi[1]* 1) Department of Medical genetics, National Research Center of Genetic Engineering and Biotechnology (NIGEB), Tehran, Iran; 2) Immunology, Asthma & Allergy Research Institute, Tehran, Iran; 3) Shahid Motahari Burn & Reconstruction Research Center, Iran University of Medical Sciences & Health Services, Tehran, Iran.

Huntington disease (HD) is a genetically dominant condition caused by expanded CAG repeats coding for glutamine in the HD gene product huntingtin. Huntingtin is expressed in almost all tissues, so abnormalities outside the brain might be expected. Mitochondria dysfunction is reported in HD brains. Mitochondria are organelles that among other functions regulate apoptotic cell death. Involvement of nuclei and mitochondria in HD pathophysiology has been suggested. The tRNA gene mutations are one of hot spots that cause mitochondrial disorders. We performed mutation screenings of tRNA $^{leu/lys}$genes and also ATPase 6,8 genes in 20 patients with HD and 100 aged-matched controls. Mitochondrial tRNA $^{leu/lys}$ genes and ATPase 6,8 genes were studied by PCR method and automated DNA sequencing to evaluate any possible mtDNA damage. We found novel mutations in HD patients including G8950A, T8395C, A8656G, A8460G, and C8300T. We propose that A8656G could be considered as a modifier factor in HD severity. Understanding the role of mitochondria in the pathogenesis of neurodegenerative diseases could potentially be important for the development of therapeutic strategies in HD.

Molecular screening of FMR1 mutation among autism and mental retardation patients in China. *W. Ju[1], X-Z. Wang[2], N. Zhong[1,2]* 1) Dept Human Genetics, New York State Inst Basic Res, Staten Island, NY; 2) Peking University Center of Medical Genetics, Beijing, China.

Fragile X syndrome (FXS) is the most common inherited form of mental retardation. It is resulted from an unstable expansion of which consequently silences FMR1 gene expression. Our earlier study has determined that FXS accounts for 3.2% of the Chinese mental retarded population. Recently, FMR1 mutation has been found in clinically diagnosed autistic patients. In this report, we present a pilot study of molecular screening of FMR1 mutation in a subset of Chinese autistic MR patients. A total number of 323 DNA samples, including 195 samples from autism patients (183 males and 12 females) and 128 samples from mental retardation (MR) patients (114 males and 14 females), were studied for FMR1 mutations. Among the samples screened, 311 (124 MR and 187 autism) were shown to be normal and 12 (4 MR and 8 autism) were found to carry expanded mutant CGG repeats at FMR1 gene. Our pilot study provided us a feasibility to conduct a larger size of autism samples.

Identification of novel interactive partner proteins for PCBP1. *B. He[1,2], L-R. Huo[1,2], N. Zhong[1,2,3]* 1) Peking University Center of Medical Genetics, Beijing, China; 2) Peking University Health Science Center, Beijing, China; 3) New York State Institute for Basic Research in Developmental Disabilities, Staten Island, NY.

PCBP1 is a family member of heterogeneous nuclear ribonucleoproteins (hnRNPs), which belong to RNA-binding proteins and bear three KH domains. The protein plays a pivotal role in post-transcriptional regulation for RNA metabolism and RNA function in gene expression. We hypothesized that the regulating function of PCBP1 is performed along with other proteins, with which a protein complex may be formed. To test our hypothesis, an approach of protein walking with the yeast two-hybrid system is employed for this study. The PCBP1 is used as the initial walker to search for its interactive partner proteins, which were identified with a yeast two-hybrid (Y2H) system and validated by pulling down, co-immunoprecipitation, and co-localization. Eight partners have been identified, which include a previously identified actin and seven novel proteins of MYL6, RECAM1, CSH1, Rab7, p57KIP2, PSG4, and RBMS1. It is likely that these novel interactive partners have mediated PCBP1 functions involved in apoptosis through regulating cell cycle, in cell autophagy through molecular migration and controlling translation.

BLOC-2 and BLOC-3 deficient melanocytes demonstrate distinct defects in TYRP1 trafficking. *A. Helip Wooley, H. Dorward, W. Westbroek, R. Hess, B. Pederson, M. Huizing, W.A. Gahl* Medical Genetics Branch, NHGRI NIH, Bethesda, MD.

Hermansky-Pudlak syndrome is an autosomal recessive disorder characterized by oculocutaneous albinism and bleeding resulting from defects in any of eight distinct genes (HPS-1 through HPS-8). With the exception of HPS-2, the human HPS genes encode proteins of unknown function. Several of these proteins interact with each other in Biogenesis of Lysosome-related Organelles Complexes or BLOCs. Specifically, HPS1 and HPS4 form BLOC-3 and HPS3, HPS5 and HPS6 comprise BLOC-2. To characterize and distinguish these BLOCs at the cellular level, we examined cultured melanocytes from individuals with HPS-1 and -4 (BLOC-3) and HPS-3, -5 and -6 (BLOC-2). BLOC-3 deficient melanocytes contained fewer dark melanosomes than BLOC-2 deficient melanocytes. Localization of melanosomal proteins by confocal immunofluorescence microscopy revealed TYRP1 staining in BLOC-3 melanocytes concentrated in the perinuclear region, with a large degree of overlap with the TGN. In BLOC-2 melanocytes, TYRP1 staining extended into the dendrites but failed to appropriately collect in the tips. Antibody uptake experiments demonstrated increased trafficking of TYRP1 via the cell membrane in BLOC-2 but not in BLOC-3 deficient melanocytes. BLOC-2 appears to sort TYRP1 from an early endosomal compartment to developing melanosomes. In the absence of BLOC-2, TYRP1 is mis-sorted to the plasma membrane. BLOC-3 likely functions earlier in the pathway such that TYRP1 does not reach the BLOC-2 endosomal compartment in BLOC-3 deficient melanocytes. BLOC-2 and BLOC-3 deficient melanocytes demonstrate distinct defects in TYRP1 trafficking, reflecting their actions in disparate steps of the pathway.

Behavioral features in patients with FG (Opizt-Kaveggia) syndrome and a recurrent mutation, p.R961W, in the MED12 gene. *J. Graham[1], J. Visootsak[2], E. Dykens[3], R. Clark[4], K. Jones[5], J. Moeschler[6], R. Rogers[7], C. Schwartz[7], M. Friez[7], R. Stevenson[7]* 1) Cedars-Sinai Medical Center, Los Angeles, CA; 2) Emory University Medical Center, Atlanta, GA; 3) Vanderbilt University Medical Center, Nashville, TN; 4) Loma Linda University Children's Hospital, Loma Linda, CA; 5) Department of Pediatrics, UCSD School of Medicine, San Diego, CA; 6) Dartmouth-Hitchcock Medical Center, Lebanon, NH; 7) Greenwood Genetic Center, Greenwood, SC.

Opitz and Kaveggia (1974) reported a family of males with X-linked mental retardation, macrocephaly, imperforate anus and hypotonia. Risheg et al. (2007) identified an identical nucleotide substitution in exon 21 of MED12 causing tryptophan to replace arginine at amino acid 961 (p.R961W) in 6 families with FG (Opitz-Kaveggia) syndrome, including a surviving affected male from the original family. The previously defined behavioral phenotype consists of hyperactivity, affability, and socially-oriented attention-seeking behaviors. We conducted behavioral assessments on 10 patients with FG syndrome caused by this recurrent mutation, and compared their characteristics with data from individuals with Down syndrome (DS), Prader-Willi syndrome (PWS), non-specific mental retardation (NSMR), and Williams syndrome (WS), using the Vineland Adaptive Behavior Scales, the Reiss Profile of Fundamental Goals and Motivation Sensitivities, and the Achenbach Child Behavior Checklist. In our previous studies using clinically diagnosed patients with FG Syndrome, FG boys were significantly less anxious and withdrawn, but had similar socially-oriented, attention-seeking behaviors, when compared with WS. FG boys were physically more energetic and more curious than WS boys, with more need for order, while FG boys appeared less sensitive to pain, somatic complaints, rejection, and slights from others than WS boys. FG boys demonstrated significant relative strengths in their socialization skills, consistent with their personality.

Heritability and prevalence of migraine in the Norfolk Island population isolate. *H. Cox[1], C. Bellis[1], S. Quinlan[1], T. Dyer[2], J. Blangero[2], L. Griffiths[1]* 1) Genomics Research Centre, Griffith University, Gold Coast, Australia; 2) Southwest Foundation for Biomedical Research, San Antonio, TX, United States.

Studies have shown that the onset of migraine with and without aura is influenced by both genetic and environmental variables. Presently the type and number of susceptibility genes involved in both of these common forms of migraine are unknown. The objective of this study was to assess the prevalence and heritability of migraine in the population of Norfolk Island, a genetic isolate located several thousand kilometers off the eastern coast of Australia. Migraine was assessed by questionnaires and diagnosed using International Headache Society criterion. A total of 372 individuals with phenotypic data were assessed for migraine prevalence. These individuals comprise a complete pedigree of 6537 individuals dating back 11 generations to 12 maternal Tahitian and 6 paternal European founders. A total migraine prevalence of 23% was observed. Migraine with and without aura were reported to affect 13% and 10% of individuals, respectively. Interestingly 5% of males compared to 18% of females were affected. These results are comparable to estimates in out-bred populations, which have been reported to vary from 4-9% in males to 11-25% in females. Heritability estimates were generated using the statistical program SOLAR (v4.0.7). The heritability of migraine was significant ($P<0.05$) and calculated as 0.42. Heritability estimates for migraine have been reported to range from 34-57% in worldwide populations. This data supports the use of the Norfolk Island population as a potentially useful genetic isolate for gene mapping studies aimed at identifying migraine susceptibility genes.

Phase 3 extension 96-week study data for Naglazyme (galsulfase) enzyme replacement therapy in MPS VI patients. *P. Harmatz[1], R. Giugliani[2], I. Schwartz[2], N. Guffon[3], C.Sa. Miranda[4], E. Teles[4], J.E. Wraith[5], M. Beck[6], M. Scarpa[7], Z.F. Yu[8], J. Rhorer[8], S. Swiedler[9], S. Turbeville[9], H. Nicely[9], J. White[9], C. Decker[9]* 1) Childrens Hospital, Oakland, USA; 2) Med Genet Serv HCPA, Brazil; 3) Hosp Edouardo Herriot Pavillon, France; 4) Hosp de Sao Joao and IBMC, Portugal; 5) RMCH, Manchester, UK; 6) Children's Hosp, U of Mainz, Germany; 7) Pediatrics, U of Padova, Italy; 8) Statistics Collaborative, Inc, USA; 9) BioMarin Pharmaceutical Inc, USA.

Background: MPS VI is a rare, fatal lysosomal storage disease. ERT with rhASB (galsulfase) has shown positive results in clinical studies. This study reports the findings of the phase 3 open-label extension study. Methods: Efficacy and safety are reported through 96 weeks for the phase 3, open-label extension study. Endpoints included 12-minute-walk test (12MWT), 3-minute-stair-climb (3MSC), level of urinary glycosaminoglycans (GAGs) and pulmonary function. Results: Patients receiving rhASB (n=19) improved by a mean of 183 meters from baseline to week 96 in the 12MWT ($p < 0.001$). The placebo group (n=18), which was switched to active drug at week 24, improved by a mean of 117 meters from week 24 to week 96 ($p < 0 .001$). Similar improvements in the rate of stairs climbed (3MSC) were also observed ($p < 0.001$). Both groups demonstrated a sustained reduction in urinary GAGs. Forced vital capacity improved in the rhASB-treated group by 0.11 L/min from baseline to week 96 ($p = 0.039$), and in the placebo group by 0.07 L/min from week 24 to week 96 ($p < 0.001$). All but one patient developed anti-rhASB antibodies, with 90% developing a persistent antibody response, 26% developing an enzyme-neutralizing antibody response, 39% developing a receptor-binding neutralizing antibody response, and 55% developing a persistent IgE response. These antibodies were not associated with IARs or lack of clinical benefit. Pharmacokinetic parameters did vary between week 1 and week 24, but difference was not associated with IARs, antibodies, or a PK/PD correlation. Conclusions: These data support continued improvement in endurance, pulmonary function, and urinary GAGs with an acceptable safety profile.

Assay system for evaluation of allele-specific gene silencing by RNA interference (RNAi). *H. Hohjoh[1,4], Y. Ohnishi[1,2,3,4], Y. Tamura[1], M. Yoshida[1], K. Tokunaga[2]* 1) National Institute of Neurosci, NCNP, Tokyo, Japan; 2) Dept Hum Genet, Univ Tokyo, Tokyo, Japan; 3) JSPS Research Fellow; 4) equally contributed to this work.

Allele-specific gene silencing by RNA interference (ASP-RNAi) is an advanced application of RNAi technique and is therapeutically useful for specifically inhibiting the expression of alleles associated with diseases without suppressing the expression of their corresponding wild-type alleles. To realize such allele-specific gene silencing by RNAi, the design and assessment of small interfering RNA (siRNA) duplexes conferring allele-specific gene silencing is vital, but is also difficult. We developed an assay system with mutant and wild-type reporter alleles encoding the Photinus and Renilla luciferase genes for assessment of allele-specific gene silencing by RNAi, and selected competent siRNA duplexes conferring ASP-RNAi against mutant allele carrying double nucleotide substitutions related to familial Alzheimers disease. In this study, we focused on the human Prion Protein (PRNP) mutant alleles carrying various single nucleotide substitutions, and attempted to improve ASP-RNAi against the single nucleotide mutations by using the system described above. From the data, it was suggested that introduction of one base mismatch into siRNAs and shRNAs could yield enhancement of discrimination between the mutant and wild-type alleles in allele-specific gene silencing, and more interestingly that the introduced mismatches that conferred marked improvement of ASP-RNAi, were intensively present in a portion of the guide siRNA element, corresponding to the 'seed region' in microRNAs. Therefore, it is possible that disturbance of base pairing in the corresponding 'seed region' as well as the central position (participating in determination of cleavage site in target mRNAs) of guide siRNA element could greatly influence discrimination of target mutant alleles from wild-type alleles.

MICA and MICB polymorphism and linkage disequilibrium with HLA-B and -DRB1 in Koreans. *M.H. Kim, H.J. Chung, S.E. Choi, C.H. Cha, O.J. Kwon, H.B. Oh* Department of Laboratory Medicine, University of Ulsan College of Medicine and Asan Medical Center, Seoul, Korea.

Allele and haplotype frequencies of MICA and MICB genes whose loci are located within the major histocompatibility complex are different according to ethnic groups. In this study, MICA and MICB polymorphism was assessed in 139 unrelated healthy Koreans by means of sequence-based typing (SBT) of exons 2, 3, 4, and 5. Seventeen different MICA alleles of extracellular domains (1 -3) were identified; MICA*010 was noted as the highest frequency (20.9%), followed by MICA*00201 and *00801. Eight different MICB alleles were identified; MICB*00502 was noted as the highest frequency (57.2%), followed by MICB*002 and *004. Five different MICA alleles of transmembrane domains (exon 5) were identified and allele A5 was the most common (29.5%), followed by allele A6. MICA*010 showed strong linkage disequilibrium with MICB*00502 (19.8% of HF). The frequencies of three loci haplotype extending from HLA to MIC gene were also analyzed; the most common haplotypes were B*1501-MICA*010-DRB1*0406 (5.8%), B*1501-MICA*010-MICB*00502 (10.4%), MICA*010-MICB*00502-DRB1*0406 (5.8%). Among B-MICA-MICB-DRB1 haplotypes, the most common haplotype was B*1501-MICA*010-MICB*00502-DRB1*0406 (5.8%), followed by B*4403-MICA*004-MICB*00502-DRB1*1302 (4.6%). This is the first report on the frequencies of MICB alleles and of haplotypes extending from HLA-B and -DRB1 in high-resolution to MICA and MICB genes in Koreans. These results will be of great use in elucidating association between HLA or MIC genes and autoimmune or infectious diseases in Koreans.

Steroid 21-hydroxylase gene analysis in a cohort of Indian patients with classical Congenital Adrenal Hyperplasia. *S. Dubey[1], S. Rao[2], C. Saravanan[1], A. Maitra[1]* 1) National Institute for Research in Reproductive Health, JM Street, Parel Mumbai, India; 2) Bai Jerbai Wadia Children's Hodpital, Parel, Mumbai, India.

Steroid 21-hydroxylase enzyme deficiency is the most common cause of congenital adrenal hyperplasia. It is an autosomal recessive disorder with a wide range of clinical manifestations ranging from severe to mild form. The disease is attributed to mutations in the 21-hydroxylase gene (CYP21), encoding 21-hydroxylase enzyme. A total of 14 common mutations and 29 polymorphisms have been identified in CAH patients, apart from about 100 rare mutations specific to different populations. Data in Indian population is however sparse. Present study has been undertaken with the specific objective to identify mutations in the 21-hydroxylase gene in Indian cases with classical CAH. The approach involves the selective amplification of active CYP21 gene followed by multi-step sequencing and identification of the variant by automated analysis against the reference sequence. Forty-five index cases along with their family members were enrolled with the aim of determining frequency of different mutations in a cohort of Indian patients. Seven kinds of mutations were found in the 45 index cases analyzed. These were; intron-2 splice (28.8%), Q318X (20%), gene deletion (17.7%), I172N (11%), R356W (4.4%), cluster of mutations (N235E, I236N, V237E, M239) in exon 6 (4.4%) and 306insT (4.4%). More than 15% of patients were compound heterozygous. Two novel mutations, F305V (GeneBank Accession No. EF563986) and an insertion of 9 bases in exon 2 (codon 70) were found in two of these cases. Good genotype phenotype correlation was also observed in our study. This is the first report of screening of CYP21 gene by sequencing in the Indian population. Intron-2 Splice and Q318X are the most frequent mutations found in our CAH patients.

Identification of the *DLX3* mutation (c.561-562delCT) in a new family and its phenotypic variation. *J-W. Kim*[1,2], *S-K. Lee*[2] 1) Department of Pediatric Dentistry & Dental Research Institute, Seoul National University, Seoul, Korea; 2) Department of Cell and Developmental Biology & Dental Research Institute, Seoul National University, Seoul, Korea.

The tricho-dento-osseous (TDO) syndrome is an autosomal dominant disease characterized by curly hair at birth, enamel hypoplasia, taurodontism, and thick cortical bone. Common 4 bp deletion (c.571-574delGGGG) in *DLX3* gene has been identified in multiple families with variable clinical phenotype. Recently another mutation (c.561-562delCT) in *DLX3* gene has been reported to cause autosomal dominant amelogenesis imperfecta with taurodontism. Here we report identification of c.561-562delCT mutation in *DLX3* gene in a new family and its clinical phenotype. The family was 3 generation Korean kindred. Enamel was hypomatured and slightly hypoplastic. Several teeth were suffered from excessive wear resulting spontaneous pulp exposures. The characteristic taurodontic feature was not identified in 3 affected individuals. Increased bone density or thickness could not be revealed by cephalometric and panoramic radiographs. Affected individuals reported that their fingernails and toenails were brittle. And also they had curly hair at birth. This study clearly showed that c.561-562delCT mutation had not only enamel defects, but also the other clinical phenotypes resembling TDO syndrome. This work was supported by a grant from the Korea Health 21 R&D Project, Ministry of Health & Welfare, Republic of Korea (A060010) and the Korea Science and Engineering Foundation (KOSEF) through the Biotechnology R&D program (#2006-05229).

GENETIC ANALYSIS IN RECURRENT IVF FAILURE. *M. Bilal Shamsi[1], R. Dada[1], R. Kumar[1], N.P. Gupta[2], R.K. Sharma[3], R. Kumar[2]* 1) Department of Anatomy, All India Institute of Medical Sciences, New Delhi, India; 2) Department of Urology, All India Institute of Medical Sciences, New Delhi, India; 3) Research and Referral Hospital, Delhi Cantt.

Infertility is the lack of pregnancy after one year of regular unprotected sexual intercourse. About 15-20% couples harbour genetic abnormalities. These Chromosomal abnormalities in infertile couples results in spermatogenic arrest, premature ovarian failure, implantation failure and consequently failure of InVitro fertilization (IVF). The aim of the study was to determine genetic basis for recurrent ART/IVF failure. Fiftyfour infertile couples with IVF failure having poor blastocyst development and implantation were analyzed cytogenetically and for molecular analysis of AZF loci in the men. Two females with recurrent IVF failure showed partial deletion of Xq, three had deletion in the Xp22.3-24, and the other female had 10% cell line showing deletion of pericenteromeric region of long arm of chromosome number 1. Four men had chromosomal abnormality. Out of this two had a translocation in the D-D group chromosomes and two had balanced reciprocal translocations on autosomes. Of these couples microdeletion analysis of 50 cytogenetically normal infertile men, only two cases showed deletion; one with AZFc loci and the other case had deletion of AZFb loci. The couples where female partner had deletion of long arm of X chromosome (Xq-) resulted in repeated failure of blastocyt development, in 4 IVF cycles. The case with AZFb microdeletion had maturation arrest and case with AZFc deletion had hypospermatogenesis. In these cases sperms could be retrieved from the testis and to be used for IVF or Intracytoplasmic sperm injection. (ICSI). In cases with sex chromosomal and autosomal aberrations there is probability of poor embryo development and consequently poor implantation, which may be a result of high segregation abnormalities and may negatively affect the outcome of assisted reproductive techniques. ART is a very expensive technique and recurrent ART/IVF failure results in severe financial stress coupled with emotional stress, thus all couples opting for ART must undergo genetic analysis.

FCGR3A genotypes influence response to tumor necrosis factor alpha inhibitors in patients with rheumatoid arthritis. *K. Ikari, S. Tsukahara, E. Sato, M. Shinozaki, T. Tomatsu, M. Hara, H. Yamanaka, S. Momohara, N. Kamatani* Inst Rheumatology, Tokyo Women's Med Univ, Tokyo, Japan.

Tumor necrosis factor (TNF)-alpha inhibitors improve symptoms and physical function in patients with rheumatoid arthritis (RA). They have emerged as standard therapy for those whom traditional disease-modifying anti-rheumatic drugs have failed to control disease activity. However, a lower response to TNF-alpha inhibitor was observed in some patients in the clinical trials. Prediction of treatment outcome of patients with RA may allow better targeting of aggressive treatment. Recently, a polymorphism in the FCGR3A gene (encoding the Fc gamma IIIa receptor, which influences the binding of the Fc portion of the immunoglobulin) that results in an amino acid-changing polymorphism (phenylalanine /valine, rs396991) has been shown to be associated with increased likelihood of response to TNF-alpha inhibitors in the treatment of RA. The aim of the present study was to determine whether this FCGR3A polymorphism is associated with clinical response to TNF-alpha inhibitors in Japanese RA patients.

Today, 2 structurally different TNF-alpha inhibitor are commercially available in Japan: infliximab and etanercept. DNA samples were obtained from 33 patients treated with infliximab and 4 patients with etanercept. Genotyping of rs396991 was performed using TaqMan SNP genotyping assay. Responses to the treatment were assessed using the DAS28 and the EULAR response criteria. Each patient was categorized as being a good or moderate responder (responder), or a nonresponder according to the therapeutic response at 22 weeks. Genotype comparisons were performed with 2X3 tables and calculation of Chi-square test.

Thirty-one of the patients were considered to be responders and 2 were nonresponders. Four patients dropped out due to side effects. The distribution of genotypes was found to be significantly different between the patients with a differential response to TNF-alpha inhibitors ($P = 0.00017$). We conclude that the FCGR3A polymorphism is associated with clinical response to TNF-alpha inhibitors in Japanese RA patients.

Altered expression of *FGF8* in myxoinflammatory fibroblastic sarcoma characterized by a recurrent t(1;10)(p22;q24-25). *K. H. Hallor[1], R. Sciot[2], H.C.F Bauer[3], I. Panagopoulos[1], N. Mandahl[1], F. Mertens[1]* 1) Dept. of Clinical Genetics, University Hospital, Lund, Sweden; 2) Dept. of Pathology, Catholic University of Leuven, Leuven, Belgium; 3) Department of Orthopedics, Karolinska Hospital, Stockholm, Sweden.

Recurrent structural chromosomal changes are relatively frequent findings in sarcomas and are thought to play an important role in their development. Myxoinflammatory fibroblastic sarcoma (MIFS) is a low-grade malignant lesion believed to be of fibroblastic origin and is predominantly found distally in the extremities. Its genetic background is largely unknown; one MIFS has previously been reported presenting a complex karyotype with a t(1;10)(p22;q22-24). In the present study, six tumors initially diagnosed as myxofibrosarcoma and dermatofibrosarcoma protuberans were genetically investigated. The tumors were selected on the basis of a recurrent translocation between chromosomes 1 and 10. Histopathologic re-examination showed that the morphology in all cases was compatible with MIFS or hemosiderotic fibrolipomatous tumor. Fluorescence in situ hybridization analysis of the chromosomal breakpoints showed that the *TGFBR3* gene was affected in 1p22, and that the break in 10q24 was located in or near the *MGEA5* gene. Microarray expression analysis and real-time quantitative PCR did not show altered expression levels of *TGFBR3* and *MGEA5*, and no *TGFBR3-MGEA5* fusion transcript could be detected. In contrast, increased expression levels were observed for *NPM3* and in particular *FGF8*, two consecutive genes located adjacent to, and transcribed in the same direction as, *MGEA5*. Thus, our results show that there is a nonrandom clustering of breakpoints in sarcomas with t(1;10), and that deregulation of *FGF8* expression by juxtapositioning to remote regulatory elements might explain the oncogenic consequences of the translocation. In accordance with this, previous studies have shown that increased expression of *FGF8* can stimulate the growth of fibroblasts and altered expression of this growth factor has been implicated in tumor development.

Alert to asymtpmatic arterial hypertension in Williams-Beuren syndrome in childhood. *R. Honjo, E.A. Furusawa, D.R. Bertola, L.M.J. Albano, L. Suzuki, V.H.K. Koch, C.A. Kim* Instituto da Criança, São Paulo, SP, Brazil.

Williams-Beuren Syndrome (WBS) is caused by a microdeletion at 7q11.23 and is characterized by a distinctive facial appearance and overfriendliness behavior. Among the most important genes deleted in WBS, the ELN gene, encoding elastin, is thought to be responsible for the vascular abnormalities. Supravalvar aortic stenosis is the most common cardiovascular malformation in WBS. However, other peripheral systemic vascular stenosis can represent an important complication, leading to arterial hypertension and stroke. The hypertension found in ~40% of WBS patients is not often associated with visible vascular stenosis on duplex US and appears to fall in the category of essential hypertension with no well-defined structural cause, since anatomic renovascular hypertension is an infrequent finding. Here we describe a patient with WBS who developed hypertension due to a vascular stenosis in a very precocious age, reinforcing the need to supervise the blood pressure in WBS soon in childhood. CASE REPORT: female, 10yo, referred to the Genetics Unit due to myocardial hypertrophy and dysmorphism at age 6. The facial appearance, mild motor and speech delay, and overfriendliness behavior suggested a diagnosis of WBS. At age 8, in a follow-up consultation, it was detected a high blood pressure, although the patient was asymptomatic. The duplex US showed an increase acceleration velocity in the renal arteries, suggesting stenosis. The angiotomography revealed a narrowed aorta, from the descending segment to the emergency of the superior mesenteric, renal arteries, and celiac trunk. The patient underwent an aortorenal and ileorenal bypass procedure. Two years later, she experienced arterial hypertension once again. The angiotomography did not show abnormalities concerning the grafts but there was a significant worsening of the aortic stenosis and its branches. DISCUSSION: The current case shows us the importance of blood pressure supervision since childhood in all WBS patients, even in asymptomatic ones, and the need to check over vascular stenosis if arterial hypertension is detected, once a surgical procedure may be indicated and prevent other renal complications.

***PDE8B*, encoding a high affinity cAMP phosphodiesterase, is mutant in Micronodular Adrenocortical Hyperplasia.** *A. Horvath, C. Giatzakis, E. Levine, P. Osorio, A. Robinson-White, K. Tzang, S. Boikos, M. Nesterova, C.A. Stratakis* NIH, NICHD, SEGEN, CBethesda, MD.

Adrenocortical micronodular hyperplasia (MAH) represents a distinct type of cortisol-producing neoplasm. Genetic aberrations in cAMP signaling pathway have been found to play role in many types of adrenal tumors (ADTs); we recently identified mutations of a phoshodiesterase (PDE) gene (*PDE11A*) on 2q31-33 in 7 out of 17 MAH patients. Genome-wide allelotyping in that study (Nat Genet 2006,38:794-800) indicated that another locus on 5q14, harboring another PDE, *PDE8B*, was likely to contain a disease-related gene. In this present study, 20 patients with MAH were tested for sequence alterations of the *PDE8B* gene. We identified a single base substitution that resulted in a proline-to-histidine change in an evolutionarily-conserved residue of the protein (c.914A>T/p.H305P) in a female patient with Cushing syndrome due to MAH. The substitution was not present among 1030 unrelated control individuals. To estimate the effect on the protein function, we performed in vitro studies on HEK293 cells. We introduced the c.914A>T substitution in pCMV6-XL6 constructs containing the *PDE8B* open reading frame and measured significantly higher cellular cAMP after transfection with mutant *PDE8B* construct (15.92.6 pmol/ml/ug of protein for the mutant vs 5.030.06 for the wild type, P=0.002). *PDE8B* was found to be expressed highly in the adrenal cortex in both human and mouse tissues. A novel *PDE8B* isoform that includes one additional exon of 53 bp at the 5 end and skips the currently recognized first exon *PDE8B* was identified. This isoform showed high expression in the adrenal gland and other endocrine tissues. Mouse tissues show early expression of the *PDE8B* gene in the developing adrenal and other endocrine tissues. In conclusion, we describe here that, in addition to *PDE11A*, another PDE - *PDE8B* - is mutated in a patient with MAH. The identification of mutations of one more PDE in patients with MAH underscores the role of cAMP signaling in ADT formation and points to the possible involvement of other molecules of this pathway in ADT genetics.

A Cross Talk between SMRT and Jag2 in Multiple Myeloma. *p. ghoshal[1], c. houde[1], a. Szafranek[1], a. Nganga[1], t. Johnson[1], a. Bigelow[1], j. Moran-Guiati[1], j. Dolce[1], d. Smiraglia[1], a. Chanan-Khan[2], l. Coignet.[1]* 1) cancer genetics, Roswell park cancer institute, Buffalo, NY; 2) Department of Medicine,Roswell park cancer institute, Buffalo, NY.

Multiple myeloma (MM), affects terminally differentiated B cells. In the bone marrow, the myeloma cells and stromal cells secrete cytokines, which support the growth and survival of the myeloma cells and lead to osteolytic complications associated with MM. It is now well recognized that interleukin-6 (IL-6) is a major cytokine, regulated by the NOTCH gene, promotes the proliferation of malignant plasma cells in MM. Previously published work suggested that JAG2 localized in 14q32.3 might be the ligand of interest for NOTCH in the MM context.JAG2 is also down-regulated during normal bone marrow differentiation. We hypothesized that over-expression of JAG2 in myeloma cells induce production of IL-6 in stromal cells, and subsequent binding with NOTCH receptor which enhances the proliferation of myeloma cells. JAG2 has been shown to be over-expressed in all cell lines and patient samples studied (n=5), both at the RNA and protein levels. To explore the reason for JAG2 overexpression, we assessed the modification of the JAG2 promoter region in both MM cell lines and patient samples by studying both methylation and histone acetylation levels. It appears that difference in H4 acetylation level might play a critical role in MM. Acetylation state of histones can be regulated by the recruitment of histone deacetylases (HDAC). HDACs are typically recruited to promoter regions through interaction with nuclear co-repressors such as SMRT. The cell lines and patient samples studied presented significantly reduced levels of SMRT. So based on these observations we can propose a model that partial down regulation of SMRT recruits less active HDAC3 (confirmed by immunoprecipitation), as a result the deactylation process of histones in promoter region has been impaired and the cells lost their control on transcriptional regulation of Jag2. This is the first report of SMRT alteration and its direct involvement in MM pathogenesis and might open a new area for potential therapeutic approaches in the treatment of MM.

Pleiotropy and principal components of heritability combine to increase power for association analysis. *L. Klei*[1], *B. Devlin*[2], *K. Roeder*[3] 1) Computational Genetics, Western Psychiatric Institute & Clinic, Pittsburgh, PA; 2) Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, PA; 3) Department of Statistics, Carnegie Mellon University, Pittsburgh, PA.

When many correlated traits are measured the potential exists to discover the coordinated control of these traits via genotyped polymorphisms. A common statistical approach to this problem involves assessing the relationship between each phenotype and each single nucleotide polymorphism (SNP) individually (PHN); and taking a Bonferroni correction for the effective number of independent tests conducted. Alternatively, one can apply a dimension reduction technique, such as estimation of principal components, and test for an association with the principal components of the phenotypes (PCP) rather than the individual phenotypes. Building on the work of Lange and colleagues we develop an alternative method based the principal component of heritability (PCH). For each SNP the PCH approach reduces the phenotypes to a single trait that has a higher heritability than any other linear combination of the phenotypes. As a result, the association between a SNP and derived trait is often easier to detect than an association with any of the individual phenotypes or the PCP. When applied to unrelated subjects, PCH has a drawback. For each SNP it is necessary to estimate the vector of loadings that maximize the heritability over all phenotypes. We develop a method of iterated sample-splitting that uses one portion of the data for training and the remainder for testing. This cross-validation approach maintains the Type I error control and yet utilizes the data efficiently, resulting in a powerful test for association. Results will also be presented on an extension of the method to a multi SNP/gene level analysis.

Genetic association between interferon regulatory factor 5 (IRF5) and systemic lupus erythematosus in minority populations. *J.A. Kelly[1], J.C. Edberg[2], K.M. Kaufman[1,3,4], J. Kilpatrick[1], G.R. Bruner[1], J.T. Merrill[1,4], J.A. James[1,4], M.C. Marion[5], C.D. Langefeld[5], M.A. Petri[6], J.D. Reveille[7], R. Ramsey-Goldman[8], L.M. Vilá[9], G.S. Alarcón[2], R.P. Kimberly[2], J.B. Harley[1,3,4]* 1) Oklahoma Medical Research Foundation, OKC, OK; 2) Univ of Alabama at Birmingham, Birmingham, AL; 3) US Dept of Veterans Affairs Medical Center; 4) Univ of Oklahoma Health Sciences Center, OKC, OK; 5) Wake Forest Univ, Winston-Salem, NC; 6) Johns Hopkins Univ School of Medicine, Baltimore, MD; 7) Univ of Texas Health Science Center, Houston, TX; 8) Northwestern Univ School of Medicine, Chicago, IL; 9) Univ of Puerto Rico Medical Sciences Campus, San Juan, Puerto Rico.

Reports demonstrate genetic association between systemic lupus erythematosus (SLE) and the interferon regulatory factor 5 (IRF5) gene in European-Americans (EA). We evaluated up to seven polymorphic loci within or near IRF5 in a large collection of SLE cases and controls from minority (African-Americans (AA), Hispanics (HI), and Hispanics from Puerto Rico (HI-PR)) and EA samples. A total of 6020 samples from two independent collections (2683 cases and 3337 controls) were evaluated. Case-control association tests were evaluated using Pearson chi-square statistics and conditional haplotype analyses were conducted using WHAP. Genetic associations (p0.0002) were observed with SLE and rs2004640 and rs3807306 in the AA and HI collections. Both loci also demonstrated strong association with SLE in the EA collection ($p5.7x10^{-13}$). Suggestive association between rs3807306 and SLE in the HI-PR collection was also observed. We identified a 5-marker risk haplotype in the AA and HI collections, with rs3807306 accounting for the majority of the observed statistical effect. The risk haplotype was again observed in the EA collection, and though its effect was not significantly different than a 3-marker haplotype previously reported, haplotypes containing the common A risk allele at rs3807306 were predictive of SLE risk (LR ^{2}=38.55, $p=5.4x10^{-10}$). In summary, we establish association with SLE and IRF5 in AA and HI, providing evidence that IRF5 is likely to be a crucial component in lupus pathogenesis in multiple ethnic groups.

Identification of a novel gene responsible for Charcot-Marie-Tooth disease (CMT4J). *C.Y. Chow[1], Y. Zhang[2], J.J. Dowling[3], N. Jin[2], M. Adamska[1], K. Shiga[4], K. Szigeti[4,6], M.E. Shy[8], J. Li[8,9], X. Zhang[8], J.R. Lupski[4,5,7], L.S. Weisman[2], M.H. Meisler[1]* 1) Human Genetics; 2) Life Sciences Institute; 3) Department of Neurology, University of Michigan, Ann Arbor MI; 4) Departments of Molecular and Human Genetics; 5) Pediatrics; 6) Neurology, Baylor College of Medicine, Houston TX; 7) Texas Children's Hospital, Houston TX; 8) Department of Neurology, Wayne State University School of Medicine, Detroit MI; 9) John D. Dingle VA Medical Center, Detroit MI.

The spontaneous mouse mutant *pale tremor* displays a severe movement disorder with extensive loss of neurons from sensory and autonomic ganglia during the neonatal period. There is also neuron loss from specific brain regions by 3 weeks of age. Sciatic nerves exhibit reduction in the number of large myelinated axons and reduced nerve conduction velocity and amplitude of the compound action potential. LAMP2-positive vacuoles accumulate in mutant cells demonstrating involvement of the late endo-lysosomal pathway. We generated a large F2 cross with CAST/Ei and mapped the *pale tremor* gene to a 2 Mb nonrecombinant region of mouse Chr10. Analysis of genes in this region identified insertion of an Etn2 transposon in the intron of a novel gene, resulting in loss of the normal transcript. The disrupted gene is homologous to a yeast gene that regulates the levels of $PI(3,5)P_2$. To evaluate the role of the *pale tremor* gene in human peripheral neuropathy, we screened DNA from 95 patients with CMT disorder who were negative for mutations in known CMT genes. Mutations were identified in four unrelated Caucasian patients with severe disease. All four individuals were compound heterozygotes carrying a distinct protein truncation mutation on one chromosome. All four also carried the same missense mutation, I41T, on a common 15 kb haplotype. This variant was not present in 300 neurological normal controls. Pedigree analysis shows autosomal recessive transmission from heterozygous, unaffected parents. The corresponding mutation in the yeast homolog resulted in partial loss of function. The sensitivity of neurons to $PI(3,5)P_2$ levels reveals an unappreciated role of this low-abundance signalling lipid.

Molecular events underlying the genesis of Cerebral Cavernous Malformations. *A.L. Akers[1], R. Shenkar[2], E.W. Johnson[3], I.A. Awad[2], D.A. Marchuk[1]* 1) Mol Genet & Microbio, Duke University, Durham, NC; 2) Div of Neurosurgery, Northwestern University, Chicago, IL; 3) PreventionGenetics, Marshfield, WI.

Cerebral cavernous malformations (CCM) are vascular lesions of the brain consisting of closely-packed, grossly-dilated vessels within a matrix of connective tissue. Radiological analysis has shown the lesions develop from small dilated vessels into complex, multicavernous lesions with a propensity for bleeding often leading to seizures and/or hemorrhagic stroke. CCM may occur sporadically or may be inherited as an autosomal dominant disorder due to mutation in one of three genes, *CCM1*, *CCM2*, or *CCM3*. While the causative genes have been identified, the molecular events initiating lesion formation have yet to be elucidated. We and others have hypothesized that CCM lesion genesis occurs due to second-site somatic mutations following a Knudsonian two-hit model. Support for this hypothesis comes from epidemiological evidence; sporadic patients typically develop single CCM lesions, while multiple lesions are observed in patients with familial CCM. The neural predilection for CCM limits accessibility of human tissue to surgically resected specimens which are typically very late stage, bleeding lesions; thus, severely limiting molecular analyses at the earliest stages of lesion development. We have created mouse models for *Ccm1* and *Ccm2* that in conjunction with MRI technology, allow us to identify and dissect CCM lesions at the earliest stages of genesis. Using laser capture microscopy, we have micro-dissected the vascular components from these lesions and have amplified DNA for both loss-of-heterozygosity and somatic mutation analyses. From MRI-identified, bulk lesion tissue both DNA and RNA have been isolated and are being examined. The nature of the knockout mutation and assay design allows for specific amplification of the wildtype allele at the cDNA level. While in the first lesion examined no consistent sequence changes have been identified, additional lesions are being analyzed. We are similarly examining a series of late-stage human lesions resected from *CCM1* patients. Both of these studies are ongoing and we will report the results of our investigation.

A flexible, high-density array platform for genome-wide characterization of epigenetic mechanisms. *L. Dannenberg, H. Liu, H. Holster, J. Kitzman, L. Iniguez, R. Green, X. Zhang* NimbleGen Systems Inc., Madison, WI.

Epigenetic mechanisms, such as DNA methylation and histone modification, play important roles in the control of eukaryotic cellular functions. High-density DNA microarrays, derived from a digital design process, have allowed researchers to examine epigenetic events at an unprecedented scale and resolution. Several methods for measuring the status of genome-wide cytosine methylation have been developed on this platform, and side-to-side comparison demonstrated how these methods can complement each other. Besides DNA methylation, the state of histones provides key information regarding chromatin structure. Multiple array based technologies are available to study different aspects of chromatin structure, including histone modification, histone replacement, and nucleosome positioning. New development on the platform, specifically the 2.16 million feature long-oligo arrays, has expanded the horizon of studies on chromatin structure. The latest progress on epigenetic applications of this unique array platform will be discussed.

Reimbursement for genetic counseling and related services. *J. Dungan, C. Yates, A. Trivedi, T. Bamlett Sherman, L. Shulman* Dept OB/GYN, Northwestern Univ Sch of Med, Chicago, IL.

Introduction: The AMA CPT Editorial Board and CMS recently introduced a new CPT code (96040) to cover genetic counseling (GC) visits provided by counselors only. Previously, GC-related consultations were billed as Evaluation & Management (E&M) visits that necessitated presence of a physician to qualify for payment from most third-party payors. We sought to determine to what extent counselor-only visits at our center billed with this new CPT code have been reimbursed.

Methods: We reviewed the billing statements and account information from patients who presented to our center seeking GC or related consultations during the months of January-March 2007. Services were provided by counselors and/or physicians in the Division of Reproductive Genetics, and include prenatal diagnosis and screening, as well as consultations for hereditary gynecologic cancer families. We categorized visits by CPT code and calculated the mean reimbursement for each code. Only CPT codes used on more than 5 occasions were evaluated.

Results: During the interval reviewed, we billed for 372 visits using CPT code 96040. From this group, excluding those visits still awaiting payment, third-party insurers did not cover any portion of the charges for 3.2% (12/372). Average reimbursement for 96040 was $53.87. In the small number of instances where multiple submissions of 96040 were made because of a prolonged GC visit, payment for each submission was the same. Mean reimbursement for other E&M services were: 99211-$17.25, 99212-$31.57, 99213-$61.00, 99214-$101.65, 99202-$59.96, 99241-$67.79, 99242-$113.17, 99243-$146.25, $99244-$243.68, 99245-$249.38.

Conclusions: Most private insurance carriers are paying for GC-only visits at our center. Although these visits do not require physician presence, reimbursement for physician-attended E&M consultations is much higher for a comparable period of time. Individual centers will need to determine what approach to provision of GC services will best suit their own circumstances, and what personnel are needed to deliver those services.

Growth retardation, hyperactivity, abnormal anxiety-related responses, and impaired neuromuscular and sensorineural coordination in a mouse model overexpressing *Rai1*. *S. Girirajan[1], N. Patel[2,3], R.E. Slager[4], M.E. Tokarz[5], M. Bucan[6], J.L. Wiley[5], S.H. Elsea[1,2]* 1) Department of Human Genetics, Virginia Commonwealth University, Richmond, VA; 2) Department of Pediatrics, Virginia Commonwealth University, Richmond, VA; 3) Department of Chemistry, University of the West of England, Bristol, U.K; 4) Department of Pediatrics, University of Nebraska Medical Center, Omaha, NE; 5) Department of Pharmacology and Toxicology, Virginia Commonwealth University, Richmond, VA; 6) Department of Genetics, University of Pennsylvania School of Medicine, Philadelphia, PA.

Gene dosage or copy number studies has taken a pivotal role in the discovery of complex morphogenetic and behavioral pathways in humans. Retinoic acid induced 1 (*RAI1*) when deleted or mutated results in Smith-Magenis syndrome (SMS), and duplication of 17p11.2, including *RAI1*, results in the dup(17)p11.2 syndrome. In order to assess the dosage sensitivity of *Rai1*, a BAC transgenic mouse overexpressing *Rai1* was created. Transgenesis was confirmed by copy number assessment and expression analyses for *Rai1*. Phenotypic consequences of *Rai1* overexpression were evaluated using both qualitative (modified SHIRPA) and quantitative (functional observational battery) methodologies for physical, neurological, and behavioral paradigms in transgenic and non-transgenic mice. Our analyses show that the *Rai1* transgenic mice have postnatal growth retardation which normalizes by adulthood. Further, the transgenic mice have increased exploratory motor activity, hyperactivity, and decreased anxiety-related rearing behavior. *Rai1* transgenic mice also have an altered gait with short strides and long sways, impaired ability on cage-top hang test, decreased forelimb grip strength, and a dominant social behavior. Analyses of homozygous transgenic mice with increased *Rai1* copy number and expression showed a dosage-dependent progression of severity of the phenotypes, including extreme growth retardation, severe neurological deficits, and increased hyperactivity. These studies indicate a definitive role for *Rai1*, in a dosage-dependent manner, in development, behavioral-modification, and neuromuscular and sensorineural coordination.

Moore, Greenberg, and and Catalona: Should patients retain any property rights in donated tissue samples? *S.M. Carter[1,2], S.J. Gross[1]* 1) Reproductive Genetics, Montefiore Medical Ctr, Bronx, NY; 2) Rutgers University-School of Law, Newark, NJ.

In **Moore v. Regents of Univ. of California, 793 P.2d 479 (Cal. 1990)**, the plaintiff underwent treatment for hairy cell leukemia. The defendants obtained numerous tissue samples from him over 7 years under the guise of patient care because of their great commercial and scientific value. After concealing their research activities, they established a cell line from Moore's T-lymphocytes that they patented for commercial development. Moore alleged breach of fiduciary duty, lack of informed consent, intentional infliction of emotional distress, and conversion. A majority of the California Supreme Court concluded that Moore did not have a cause of action for conversion but did have a claim for breach of fiduciary duty and lack of informed consent. In **Greenberg v. Miamis Childrens Hosp., 264 F. Supp 2d 1064 (S.D. Fla. 2003)**, the plaintiffs with a family history of Canavan disease provided blood and tissue samples to develop genetic testing. After the research team isolated and patented the gene, they restricted any activity related to the Canavan disease gene. The parties finally agreed to allow the Hospital to collect royalties for clinical testing but to permit license free use for research. In **Wash. Univ. v. Catalona, 437 F. Supp. 2d 985 (E.D. Mo. 2006)**, research participants (RPs) donated tissue samples for cancer research and signed an informed consent relinquishing ownership rights to any medical products derived from research with their sample. They could also withdraw from the research at any time but did not retain the right to have their samples transferred to another institution. The PI moved to another university and requested the RPs to release their samples to him continue his research. The court ruled that the University was the sole owner of the research samples.
We discuss why researchers cannot take patients altruism for granted, must seek partnerships that will facilitate research, and whether patients should retain any rights in donated tissue

.

A de novo case of the 17q11.2 microdeletion syndrome presenting with multiple congenital anomalies and brain abnormalities to a consanguinous family: A challenging example in genetic counseling. *R.E. Falk, R. Conway*
Medical Genetics Institute, Cedars-Sinai Medical Ctr., Los Angeles, CA.

We present a 3 year old girl, born to consanguineous Sephardic Jewish parents, who are known carriers of Sandhoff disease, for which prenatal diagnosis was performed with normal results. The child presented initially in the newborn period with dysmorphic facies and multiple congenital anomalies, including complex congenital heart disease, imperforate anus, and unilateral dysplastic kidney likely secondary to vesiculoureteral reflux. Her brain MRI was abnormal with frontal lobe hypoplasia and decreased sulcation and the neurologic picture was significant for microcephaly, hypotonia, and seizures. The newborn exam was also significant for three cafe-au-lait macules. The diagnosis of the 17q11.2 deletion syndrome encompassing the NF1 locus was confirmed by comparative genomic hybdridization after routine chromosome analysis was found to be unremarkable. The child remains severely globally developmentally delayed, without any regression. With time additional cafe-au-lait macules and early intertriginous freckling have developed, providing a clinical diagnosis of neurofibromatosis, type 1. Neither parent showed the deletion by confirmatory FISH of the 17q11.2 locus. This case was also significant for a sister of the proband who died in the newborn period of fetal hydrops and congenital heart disease. FISH on liver tissue obtained from autopsy of the sister did not show the 17q11.2 deletion, excluding the possibility of gonadal mosaicism as an explanation for her findings. Our patient has a more severe neurodevelopmental phenotype than is typical for the 17q11.2 deletion syndrome. Moreover, while congenital heart disease is reported as a common feature in other patients with this microdeletion, imperforate anus and urinary tract anomalies are not reported frequently and we believe they may represent new features of the 17q11.2 deletion syndrome. While this case may expand the phenotype of this particular microdeletion, the consanguinity in this case and the family history raises the possibility of a secondary recessive diagnosis and complicates genetic counseling for the family.

KRAS gene mutation analysis in a cohort of 50 Brazilian patients with Noonan and Noonan-like syndromes. *D.R. Bertola[1], A.S. Brasil[1], A.C. Pereira[2], L.M.J. Albano[1], R.S. Honjo[1], C.A. Kim[1], J.E. Krieger[2]* 1) Pediatrics, Instituto da Criança, São Paulo, SP, Brazil; 2) Heart Institute (InCor), Cardiology, São Paulo, SP, Brazil.

Noonan and Noonan-like syndromes comprise a group of disorders caused by deregulated RAS-MAPK signaling. In Noonan syndrome, three genes (PTPN11, KRAS and SOS1) in this pathway were described as responsible for its phenotype. In the case of cardiofaciocutaneous (CFC) syndrome, the main genes are: BRAF, MEK1 and MEK2 and in Costello syndrome, the HRAS gene is responsible for more than 80% of the cases. Mutations in KRAS gene have been described in a small proportion of Noonan syndrome patients (3%), as well as in CFC and some Costello syndrome individuals. We performed KRAS gene sequencing in 38 Noonan syndrome individuals, negative for PTPN11 mutations (2 with Noonan-like/multiple giant cell lesion syndrome), and 12 patients with Noonan-like syndromes (10 patients with CFC syndrome and 2 with Costello syndrome). None gene alterations were found in 38 Noonan syndrome and 10 CFC syndrome patients. A K5E substitution was found in exon 2 of the KRAS gene in one of the Costello syndrome individual. This patient showed some atypical findings, such as lymphedema and prominent corneal nerves, characteristics of Noonan syndrome. The involvement of several genes in Noonan and Noonan-like syndromes pose a complex task in the delineation of the molecular defect of these disorders. KRAS gene mutations were reported in some cases with a clear phenotypic overlapping of Noonan syndrome, CFC and Costello syndromes. Further descriptions of atypical cases and their molecular basis could improve the establishment of a more precise genotype-phenotype correlation and give a better direction of which gene should be screened first in each case.

Refining the molecular and clinical definitions for JP-HHT syndrome. *C.J. Gallione[1], C.L. Clericuzio[2], T.P. Leedom[1], J.C. Fahl[2], J.M. Drautz[2], J.D. Waldman[2], K. Henderson[3], M.J. Beis[4], M. Ludman[5], T. Berk[6], M.K. Maisenbacher[7], C.A. Williams[7], Z. Fan[8], A.S. Aylsworth[8], J. Garvie[9], M.E. Faughnan[10], R.I. White[3], D.A. Marchuk[1]* 1) Duke Univ Medical Center, Durham, NC; 2) Univ of New Mexico School of Medicine, Albuquerque, NM; 3) Yale Univ School of Medicine, New Haven, CT; 4) IWK Health Centre, Halifax, Canada; 5) Dalhousie Univ Faculty of Medicine, Halifax, Canada; 6) Mount Sinai Hospital, Toronto, Canada; 7) Univ of Florida College of Medicine, Gainesville, FL; 8) Univ of North Carolina at Chapel Hill, Chapel Hill, NC; 9) St. Joseph Hospital Medical Center, Phoenix, AZ; 10) St. Michael's Hospital, Univ of Toronto, Toronto, Canada.

Mutations in *SMAD4* are known to be a cause of the gastrointestinal cancer disorder Juvenile Polyposis (JP). We recently described individuals and families where *SMAD4* mutations co-segregate with a combined phenotype of JP and the inherited vascular disorder, Hereditary Hemorrhagic Telangiectasia (JP-HHT syndrome). The initial series of patients all met clinical criteria for both JP and HHT and showed a pattern of *SMAD4* mutations that clustered in the exons encoding the MH2 domain of the protein. Presented here are molecular and clinical findings from additional individuals that challenge both the apparent genotype:phenotype correlation and the clinical spectrum of the syndrome. We show that mutations in the MH1 domain of SMAD4 can lead to the vascular phenotype associated with JP-HHT, arguing that any mutation in *SMAD4* places the carrier at risk for JP-HHT syndrome. There is a high rate of *de novo* JP-HHT cases, and in a number of patients, the epistaxis and muco-cutaneous telangiectases are less pronounced than in typical HHT, suggesting that the Curaçao criteria for HHT diagnosis should be relaxed or modified for JP-HHT patients. The emerging clinical picture of JP-HHT is that of a young individual with JP who presents with visceral arteriovenous malformations, particularly in the lung, with no family history of either JP or HHT. Molecular diagnosis and careful monitoring for the full spectrum of JP-HHT symptoms in all *SMAD4* mutation carriers is critical to the clinical care of these patients.

Genetic contribution to vitamin D status in Hispanic and African Americans: the IRAS Family Study. *C.D. Engelman[1], T.E. Fingerlin[2], C.D. Langefeld[3], D.W. Bowden[3], P.J. Hicks[3], L.E. Wagenknecht[3], J.M. Norris[2]* 1) University of Wisconsin School of Medicine and Public Health; 2) University of Colorado at Denver and Health Sciences Center School of Medicine; 3) Wake Forest University School of Medicine.

The role of vitamin D sufficiency in optimal health is increasingly evident, making the high prevalence of vitamin D deficiency of public health concern. Vitamin D deficiency is associated with bone disease, cancer, multiple sclerosis and diabetes. Although much is known about non-genetic factors of vitamin D status, little has been reported on genetic factors. Two forms of vitamin D, 25-hydroxyvitamin D (25[OH]D), the precursor and predominant circulating form, and 1,25-dihydroxyvitamin D (1,25$[OH]_2$D), the more biologically active form, were measured in the plasma of 507 Hispanic Americans from San Antonio, Texas (SA), 505 Hispanic Americans from the San Luis Valley, Colorado (SLV) and 515 African Americans from Los Angeles, California (LA) from 60, 30 and 42 families, respectively, recruited in the Insulin Resistance Atherosclerosis (IRAS) Family Study. In addition, 30 SNPs (average spacing of 4.5 kb) in the vitamin D receptor (VDR), vitamin D 1-hydroxylase (CYP27B1), and vitamin D-binding protein (GC) genes were genotyped. Variance components analysis was conducted using SOLAR software. The heritability of 25[OH]D adjusting for gender, age, clinic site, season, and body mass index was 0.330.06 ($P < 0.0001$) and of 1,25$[OH]_2$D adjusting for gender, age, clinic site and 25[OH]D was 0.310.06 ($P < 0.0001$). Adjusting for gender and age, two non-synonymous SNPs in high LD within the GC gene were associated with 25[OH]D ($P = 0.005$, 0.0003, 0.016 for rs4588 [Thr420Lys] in SA, SLV and LA, respectively and 0.008, 0.001 and 0.054 for rs7041 [Asp416Glu] in SA, SLV and LA, respectively). Rs4588, was also associated with 1,25$[OH]_2$D ($P = 0.007$, 0.025, 0.122 in SA, SLV and LA, respectively). We posit that these variants may decrease the affinity of circulating vitamin D binding protein in blood for 25[OH]D and 1,25$[OH]_2$D, resulting in lower levels of these forms of vitamin D being transported in blood and vitamin D deficiency.

Prevalence of autism spectrum disorders in patients with Möbius sequence. *E. Kluczink[1], C.A. Kim[3], C.H. Gonzalez[2], J.A. Paz[2], M.J. Marques-Dias[2]* 1) Psychiatry, Hospital das Clínicas da FMUSP, São Paulo, SP, Brazil; 2) Neurology, Instituto da Criança, São Paulo, SP, Brazil; 3) Genetics Unit, Instituto da Criança, São Paulo, SP, Brazil.

Introduction: Autism spectrum disorders (ASD) are neurodevelopment disorders without an established single etiology but with important contributions from genetics, neuropsychiatry, functional and neuroimage investigations. Möbius sequence (MS) is a rare congenital disorder characterized by complete or partial facial and abducens nerve palsy (hypomimia and strabismus). Other cranial nerves involvement, orofacial malformations and limb defects are frequently associated. MS may have a genetic or environmental origin and, in Brazil, it has been related to misoprostol use in abortion attempts. Even if the exact time of developmental insult for each of these conditions cannot be identified, there are evidences suggesting that it may occur as early as 4 to 6 weeks of embryogenesis. Many studies suggest that association of cranial nerve palsies, a variety of limb and systemic malformations, both with genetic and environmental origin, may be associated with autism spectrum disorders, statistically more frequent than in normal population. Here we studied a cohort of MS patients to detect ASD. Methods: 36 patients (19 girls and 17 boys), 52.7% with misoprostol exposition in uterus, preliminarily diagnosed with MS in a multidisciplinary basis have been prospectively submitted to a psychiatric evaluation utilizing CARS and Vineland adaptative behavior scale. Results: eleven patients (30.5%) have been diagnosed as having ASD, five of them with a history of misoprostol exposition. Conclusions: The high prevalence of ASD in this series is similar to that detected in a Swedish study of thalidomide exposed patients and in another Brazilian study of the effects of the use of misoprostol in pregnancy. These findings suggest that early insults in embryogenesis could be associated with ASD.

Novel familial duplication 10q23.2-q23.32: clinical manifestations and further delineation of chromosome 10q22-24 atrial fibrillation locus. *J. Buchholz, H. Ardinger, R. Ardinger* Sections of Medical Genetics and Molecular Medicine and Cardiology, Children's Mercy Hospitals and Clinics, Kansas City, MO.

We report a non-dysmorphic 2 year-old female with a history of a secundum atrial septal defect and branch pulmonary artery stenosis requiring surgery, mild speech delay, intrauterine growth restriction, and postnatal growth delay. High resolution chromosome analysis revealed a 10q23 duplication. Subsequent 1MB microarray analysis was positive for a 4.5-7.7 Mb duplication of 9 clones at 10q23.3-q23.32. Family studies revealed the same duplication in the proband's father and sister. The probands 5 year-old sister has a similar history of intrauterine growth restriction, postnatal growth delay, speech delay, a functional heart murmur with normal echocardiogram and electrocardiogram, and is otherwise non-dysmorphic. The fathers history is remarkable for problems gaining weight, learning difficulties, and atrial fibrillation which was symptomatic at age 23 and diagnosed at age 30. His echocardiogram revealed a structurally normal heart.

While the distal trisomy 10q syndrome is well described in the literature to involve varying degrees of ocular, limb, renal, cardiac, hearing, and speech abnormalities along with mental retardation and facial dysmorphism depending on the chromosomal segment involved, most of these described chromosomal aberrations begin at or distal to the 10q24 region. There are no patients reported to have the same duplication as seen in the present family which appears to be associated with a remarkably mild phenotype.

Of considerable significance is the presence of the fathers early onset atrial fibrillation and the fact that the 10q23.3-q23.32 region overlaps the 10q22-24 familial atrial fibrillation locus discovered in linkage studies in 3 Spanish families by Brugada et al (1997). The causative gene for this type of familial atrial fibrillation has not yet been identified. We believe that the chromosome findings in our report could be of critical importance in narrowing the chromosomal region of interest in screening for candidate genes related to atrial fibrillation on 10q.

Angiokeratoma: an important clue for the diagnosis of Fabry disease. *L.M.J. Albano[1], C. Rivitti[2], R. Giugliani[3], L.C.F. Sá[1], D.R. Bertola[1], R.S. Honjo[1], C.A. Kim[1]* 1) Pediatrics, Instituto da Criança, São Paulo, SP, Brazil; 2) Dermatology, HC-FMUSP, São Paulo, SP, Brazil; 3) Genetics, HCPA, Porto Alegre, RS, Brazil.

Fabry disease (FD) - an X-linked inborn error of glycosphingolipid catabolism - is the second most frequent glycosphingolipid lysosomal storage disease, after Gaucher disease. Unfortunately, the diagnosis is usually late, at third or fourth decades of life. As it is important to recognize this group of patients, especially now, with the proven efficacy of the enzymatic replacement therapy, we studied 16 men with angiokeratoma confirmed by biopsy. The relatives of these cases were also included, totalizing 29 individuals. After a clinical and laboratorial evaluation, we performed the enzymatic assay in 10 patients that showed strong evidence of FD. Among them, we detected three cases. Case 1: a 29 year-old man with penoscrotal and umbilical angiokeratoma since age 12. In childhood, due to severe attacks of pain and burning sensation on extremities, a rheumatic disorder was suspected. The values of -Gal A enzyme were reduced in both the patient and his mother. They have never realized that they could be affected by FD or other kind of medical problem until our screening. The mothers investigation showed bilateral renal cysts, left ventricular hypertrophy and uterine myoma. Cornea verticilata was present in both mother and son. Case 2: a man already deceased due to renal disease with a clinical diagnosis of FD. Asking the family, we found out that her sister, a 54 year-old woman, had been investigated some years ago due to the positive familial history of FD The activity of the -Gal A was normal in this woman, but molecular study showed a mutation (Y86H) in the -Gal A gene. Case 3: a kidney transplanted 41 year-old man with clinical findings suggestive of FD. His enzymatic assay disclosed an -Gal A activity in the inferior limit. This type of screening, looking for FD in patients with angiokeratoma, could be a good strategy for its diagnosis, since we detected 3 cases among 10, whose clinical and laboratory findings favored this hypothesis.

Clinical Characteristics of MPS I Patients in the MPS I Registry. *O. Bodamer, for the MPS I. Registry European Board of Advisors* General Pediatrics, University Children's Hospital, Vienna, Austria.

Background and Methods: Mucopolysaccharidosis I (MPS I) is a progressive and often life-threatening autosomal recessive disease caused by deficiency of the lysosomal enzyme -L-iduronidase and resultant multisystemic accumulation of glycosaminoglycans. Data collected by the MPS I Registry (established by BioMarin/Genzyme LLC) provide insights on the natural history and broad phenotypic spectrum of MPS I. Demographics and frequency and age of onset of signs and symptoms were evaluated for all patients and different phenotypic presentations in the Registry.
Results: As of January 2007, the MPS I Registry contained data from 585 patients (292 males, 293 females) in 29 countries. Median current age was 9.4 y. Most patients (59%) were classified as Hurler (H), followed by Hurler-Scheie (H-S) (26%) and Scheie (S) (12%). Median age at diagnosis was 0.8 y for H patients, 3.7 y for H-S patients and 9.0 y for S patients. The five most common signs and symptoms varied according to phenotype. In H patients they were: coarse facial features (94%), corneal clouding (88%), hepatomegaly (83%), kyphosis (81%) and hernia (75%); in H-S patients: corneal clouding (84%), coarse facial features (83%), hepatomegaly (81%), hernia (73%) and joint contractures (72%); and in S patients: valve abnormalities (87%), corneal clouding (86%), joint contractures (81%), hernia (65%) and carpal tunnel (62%). These signs and symptoms were first reported at median ages of 1.1 y for H patients, 3.3-4.2 y for H-S patients and 2.5-12.5 y for S patients. In all phenotypes, median age at onset of corneal clouding was similar to age at diagnosis and median age at onset of hernia was 3.3 y.
Conclusions: Corneal clouding and early hernia are prominent in all MPS I patients. Coarse facial features and hepatomegaly are more prominent on the severe end of the MPS I spectrum (H and H-S) whereas joint contractures and carpal tunnel are more prominent on the attenuated end (S).

Regulatory polymorphisms in IL18 are associated with hepatitis C virus clearance. *P. An[1], C.L. Thio[2], G.D. Kirk[3], S. Donfield[4], J.J. Goedert[5], S.J. O'Brien[6], C.A. Winkler[1]* 1) Laboratory of Genomic Diversity, SAIC-Frederick Inc, Frederick, MD; 2) Department of Medicine, Johns Hopkins Medical Institutions, Baltimore, MD; 3) Department of Epidemiology, Johns Hopkins School of Public Health, Baltimore, MD; 4) Rho, Inc., Chapel Hill, NC; 5) Epidemiology Branch, National Cancer Institute, Bethesda, MD; 6) Laboratory of Genomic Diversity, National Cancer Institute, Frederick, MD.

Hepatitis C virus (HCV) infection is a major cause of chronic liver disease. People with chronic HCV infection are at risk of developing liver cirrhosis and cancer. After acute HCV infection, the majority of individuals become persistently infected and only about 20% achieve clearance. The precise host and viral factors responsible for differential outcomes of HCV infection have not yet been defined. The recover from acute HCV infection was generally associated with vigorous HCV-specific T-cell responses. Thus, genetic variation in host factors involved in immune response may influence HCV outcome. Interleukin (IL)-18 is a pivotal mediator of Th1-driven immune response, and a high level of expression of IL18 has been reported to correlate with HCV persistence and hepatic injury. We hypothesized that IL-18 polymorphisms may play a role in HCV clearance. Two functional promoter SNPs was genotyped in a matched case-control sample consisting of 91 African Americans who were infected with HCV parenterally but subsequently cleared the virus and 182 matched controls with persistent infection. The case and controls were matched on ethnicity, gender and HIV-1 status. The SNP and haplotype associations were analyzed using a conditional logistic regression. Both SNPs were associated with viral clearance (OR=2.21 to 2.90; $p<0.01$). Among three haplotypes formed by these two SNPs, two haplotypes were also significantly associated with viral clearance compared to the most common haplotype, which has been associated with high gene express level. These results suggest a plausible role of IL18 in resolving HCV infection. [Funded by NCI contract NO1-CO-12400].

Shorter telomere length in women who experienced multiple trisomic pregnancies. *C.W. Hanna[1], K.L. Bretherick[1], J.L. Gair[2], M.D. Stephenson[3], W.P. Robinson[1]* 1) Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 2) Island Medical Program, University of Victoria, Victoria, BC, Canada; 3) Recurrent Pregnancy Loss Program, University of Chicago, Chicago, IL, USA.

As women approach menopause they experience a decrease in oocyte quality leading to an increased rate of miscarriage due to aneuploidy. We previously found an increase in skewed X-chromosome inactivation (XCI) in women who have recurrent miscarriage with at least one trisomic pregnancy, which was greatest among women who had experienced multiple trisomic pregnancies. Skewed XCI may be a consequence of accelerated stem cell depletion, possibly reflecting a biological (and reproductive) age that is older than chronological age. Thus, we hypothesized that these women will also tend to have shorter mean telomere lengths, as this also reflects age-related stem cell turnover. DNA was extracted from peripheral blood from mothers of a single trisomy (ST) (N=68), mothers with multiple trisomies (MT) (N=22), control women between ages 20-55 with no history of miscarriage (C1) (N=86), and women who had a healthy pregnancy after age 37 with no miscarriages (C2) (N=41). Quantitative PCR was used to measure average telomere length. The age adjusted mean relative telomere length for ST, MT, C1, and C2 were 0.89, 0.82, 0.89, and 0.93 respectively (p=0.03, ANCOVA). The ST were not significantly different from either control group; however, the MT had smaller telomeres than C1 (p=0.05) and C2 (p=0.01). Because most of the MT women were ascertained through recurrent miscarriage, shorter telomere length may alternatively reflect an association with recurrent miscarriage. There was no association between telomere length and XCI skewing within all the samples or in the MT specifically. This suggests that reduced telomere length occurs independently of the mechanism for increased skewed XCI. Telomere lengths may be shorter due to a variety of mechanisms including: 1) a direct effect, such that women with multiple trisomic pregnancy losses have shorter telomere lengths from conception; 2) increased exposure to oxidative stress; 3) stem cell turnover independent of the mechanism for skewed XCI.

Changes in histone modifications reactivate the expression of epigenetically silenced tumor suppressor genes in cancer cells. *S. Fukushige, E. Kondo, A. Horii* Department of Molecular Pathology, Tohoku University School of Medicine, Sendai, Miyagi, Japan.

Epigenetic modifications such as DNA methylation and histone modification play crucial roles in the pathogeneses of cancer by transcriptional silencing of tumor suppressor genes. Although the use of DNA hypomethylating agent such as 5-azacytidine effectively reactivates the expression of methylated tumor suppressor genes, the inhibitors of histone deacetylase alone normally do not have much effect on it. Here we report that the combination of demethylation at histone H3 lysine 9 and histone acetylation, which changes major histone modifications of most epigenetically silenced genes in cancer cells, reactivates the expression of densely methylated genes. To accomplish these changes in histone modifications, we used the JMJD2D which is a histone demethylase specific for dimethylated and trimethylated histone H3 lysine 9 and the NFB transcriptional activation domain which recruits p300 histone acetyltransferase. These two components were linked to the methyl-CpG binding domain (MBD) to be recruited at the methylated promoter. As the *MLH1* gene is epigenetically silenced in HEK293T and AN3CA cells, we performed transfection experiments of this DNA construct and found the reactivation of the *MLH1* gene. Because MBD is used to recruit this construct at the *MLH1* methylated promoter, it is thought that this reactivation occurred without DNA demethylation of promoter region. Furthermore, the *CDKN2A* gene in DLD1 cell and the *GSTP1* gene in LNCaP cell were also reactivated by the use of above mentioned construct. These results suggest that changes in histone modifications are sufficient for reactivation of these methylated tumor suppressor genes without the use of DNA hypomethylating agent such as 5-azacytidine.

Analysis of sperm and Blood mitochondrial DNA in pathogenesis of oligoasthenoteratozoospermia. *R. Dada[1], R. Kumar[1], R. Kumar[2], N.P. Gupta[2], R.K. Sharma[3]* 1) Anatomy, AIIMS, New Delhi, Delhi, India; 2) urology, AIIMS, New Delhi, Delhi, India; 3) Army R and R Hospital Delhi Cantt.India.

The mitochondria is the sperm midpiece are the energy generator for mammalian sperm. Sperm require a sufficient supply of adenosine triphosphate (ATP) from mitochondrial oxidative phosphorylation for normal function (delamirande E et al., 1992, Manfredi et al., 1997). In somatic cells, mitochondrial respiratory chain function depends on the coordinated gene expression of both the mitochondrial and nuclear genomes. Sperm count is decreasing at an alarming rate of 2% per annum for last 20 years. This relates to the remarkable decrease of semen quality among healthy young men. Male fertility largely depends on the quality of sperm production. Studies on sperm function especially motility turned attention to the possible role of sperm mitochondria, which produce large quantities of energy for biosynthesis and motility in sperm and are found in high concentration in sperm midpiece. Mitochondria have their own genome, which codes for proteins involved in the respiratory chain and oxidative phosphorylation. Mutation in mitochondrial DNA has been known to cause several neuromuscular diseases, cardiomyopathies but little is known of their role in pathogenesis of spermatogenetic arrest and impaired sperm motility is not known. In the present study we analysed mitochondrial mutation in blood and sperm mitochondrial DNA. The mitochondrial DNA mutation in sperm DNA was higher (32 substitutions) as compared to blood (20 substitutions). A comparison of the sequences of the above genes with a reference sequence revealed a total of 32 nucleotide substitutions in the sperm mtDNA but not in the DNA from the blood cells. Of the 32 substitutions in sperm DNA, 7 were in COI, 12 were in COII, 4 were in ATPase8, and 9 were in ATPase6. This may be due to free radical (ROS) mediated damage. As sperm has just 10-100 copies of mitochondrial genome, mutations in these result in early phenotype manifestation. In such case infertile men with OAT had high mtDNA mutation. The mean sperm count in cases with mtDNA mutation was 2.23 millions /ml. The effects of these mutations to correlate the mitochondrial DNA mutation with phenotype are required. This will aid in providing comprehensive counseling and most adapted therapeutics to the couple.

Variation in Global Cancer Incidence Rates is Associated with Population-Level Genetic Background. *N.V. Campbell[1], C.M. Nievergelt[1], E.O. Lillie[1], N.J. Schork[1,2,3]* 1) Center for Human Genetics and Genomics, University of California San Diego, La Jolla, CA; 2) Scripps Genomic Medicine, The Scripps Research Institute, La Jolla, CA; 3) Department of Molecular and Experimental Medicine, The Scripps Research Institute, La Jolla, CA.

Cancer incidence rates vary widely across different human populations. The reasons for this are complex and reflect the interplay between variation in genetic susceptibility, environmental exposures, medical and public health practices, and social factors. Although the influence of genetic background on cancer incidence has been probed by many model organism and anecdotal or small-scale studies on humans, few, if any, studies have actually tested the hypothesis that genetic background is associated with human cancer incidence rates on a global scale using relevant incidence and population genetic data. We have examined the relationship between variation in global human cancer incidence rates and genetic background using a wide variety of resources, including statistics collected by the WHO and other international organizations as well as data available on the Human Genetic Diversity Panel (HGDP). We attempted to control for environmental and social factors using available population data and social indicators. We ultimately find very strong associations between genetic background and global human cancer incidence rates. We do, however, acknowledge the limitations of our studies as well as areas for further research.

Novel PANK2 gene mutations in three Pakistani patients with pantothenate kinase-associated neuro-degeneration (PKAN). *P.M. Frossard[1], Z. Aly[2], T. Ali[2], M.H. Arshad[2], B. Khealani[3], D. Saleheen[1,4]* 1) Dept. Biological & Biomedical Sciences; 2) Medical College; 3) Neurology Section, Dept. Medicine; Aga Khan University Medical College, Karachi, Pakistan; 4) Dept. Public Health and Community Medicine, Cambridge University, UK.

Pantothenate kinase-associated neuro-degeneration (PKAN) is an autosomal recessive disorder associated with iron accumulation in basal ganglia. The disease can present either as a rapidly progressive disorder with early childhood onset, or as a slowly progressive disorder with late onset and decreased severity. Signs include dystonia, rigidity and gait impairment leading to restriction of activities and loss of ambulation. T2-weighted MRIs show a characteristic eye of the tiger sign in the patients. The disease is caused by defective iron metabolism due to pantothenate kinase defects, which is encoded by PANK2 gene. We report here a mutation screen conducted on three patients who had clinical symptoms suggestive of PKAN.

The three patients belonged to two unrelated, Pakistani families. MRI findings revealed a marked ring of hypodensity circumscribing a hyperdense area in the basal ganglia (eye of the tiger sign), particularly the globus pallidus and the substantia nigra, in all three patients.

DNA was extracted by a phenol-chloroform reference protocol and *PANK2* was amplified by multiplex PCRs on the patients and all available family members. Mutation screen was carried out by direct DNA sequencing using an MJ Research PTC-225 Peltier Thermal Cycler. Two novel mutations (H173Y and Y176C in *PANK2* exon 2) were identified in the patients; neither of the two mutations was found in 200 control alleles. The two *PANK2* mutations found in these Pakistani patients form the basis for the development of a pre-symptomatic genetic test for PKAN. The molecular diagnosis also confirms the specificity of the clinical finding of the eye of the tiger sign on T2-weighted MRI in the diagnosis of PKAN.

COMPLEX CHROMOSOMAL ABNORMALITIES IN AN ADOLESCENT WITH ALVEOLAR RHABDOMYOSARCOMA. *N. Chen[1], Q. Tao[1], H. Liu[1], W. Nugent[1], H.O. Shah[1,2], J. Lin[1,2]* 1) Department of Pathology, Nassau University Medical Center, East Meadow, NY; 2) Health Science Center, State University of New York, Stony Brook, NY.

Rhabdomyosarcoma (RMS), the most common pediatric soft tissue sarcoma, likely results from dysregulation of the precursor cells during skeletal myogenesis. RMS can be classified into three subtypes histologically: the most common embryonal rhabdomyosarcoma (ERMS), the less common but more aggressive alveolar rhabdomyosarcoma (ARMS), and the rare adult variant pleomorphic rhabdomyosarcoma (PRMS). Cytogenetically, ARMS is characterized by a t(2;13)(q35;q14) (PAX3/FKHR fusion protein) or a t(1;13)(p36;q14) (PAX7/FKHR fusion protein), whereas ERMS by gaining chromosomes 2, 8, 11, 12 and 13. In addition, loss of heterozygosity (LOH) at 6p, 11p, 16q and 18p has been frequently observed in both types. We present here an 18 year-old male with negative family history who presented initially with generalized lymphadenopathy, bilateral pleural effusion and hydronephrosis. FNAs on neck and left inguinal masses showed highly atypical cells, suspicious for lymphoma and recommend for tissue diagnosis. A 3.5 cm neck mass was removed and histologically showed small blue cell tumor which is positively stained for Desmin, Vimentin, Actin, MyoD1 and Myogenin. Final diagnosis is ARMS, stage IV. Patient underwent chemotherapy and radiation therapy for 6 months and resulted in a complete remission. One year later patient developed 2 subcutaneous nodules in the right thigh and back, which were proved to be recurrence of ARMS. Cytogenetic study showed a hypertetraploid composite karyotype with multiple structural and numerical aberrations: 99~100,XXYY,+X,+Y,+1,add(1)(p13)x2,add(2)(q35)x2 or der(2)t(2;13)(q35;q14),-4,+5,+6,-7,-8,+11,+11,+12,-13,-16,-16,-17,-18,+20,+20,+5~6mar[cp2]/46,XY[4]. Chromosomal abnormalities in this case include an add or der(2) probably resulting from a translocation between chromosomes 2q35 and 13q14, which is observed in approximately 80% ARMS. However, the traslocation complexed with many other chromosomal changes is rare in ARMS. Further studies may help to unveil more details of pathogenesis in RMS and provide useful information for predicting tumor biological behavior.

A Proteomic Analysis of In vivo Circulating Monocytes in Chinese Pre-menopausal Females with Discordant Bone Mineral Density. *F.Y. Deng[1,3], Y.Z. Liu[3], C. Jiang[1], L.M. Li[1], S. Wu[1], Y. Chen[1], H. Jiang[1], F. Yang[1], P. Xiao[4], S.M. Xiao[1], L.J. Tan[1], X. Sun[1], J.X. Xiong[1], M.Y. Liu[1], S.F. Lei[1], X.D. Chen[1], J.Y. Xie[1], G. Xiao[1,2,5], S.P. Liang[1], H.W. Deng[1,3]* 1) Laboratory of Molecular and Statistical Genetics, College of Life Sciences, Hunan Normal University, Changsha, Hunan, P. R. China; 2) Key Laboratory of Protein Chemistry, College of Life Sciences, Hunan Normal University, P. R. China; 3) Departments of Orthopedics Surgery and Basic Medical Sciences, University of Missouri - Kansas City, Kansas City, Missouri, USA; 4) Osteoporosis Research Center and Department of Biomedical Sciences, Creighton University Medical Center, Omaha, NE, USA; 5) Department of Pediatrics, Harbor-University of California, Los Angeles, CA, USA.

Osteoporosis (OP) is a major public health problem and bone mineral density (BMD) is an important determinant of OP. Circulating monocytes (CMCs) may serve as progenitors of osteoclasts and produce a wide variety of factors important to bone metabolism. However, little is known about the specific roles of CMCs in the pathogenesis of OP. Our study sample was composed of a total of 42 otherwise healthy Chinese pre-menopausal females, with 21 having high BMD and 21 having low BMD (average Z score [SD]: +1.63[0.16] vs. -1.67[0.15]). CMC samples were extracted using a monocyte negative isolation kit, with purity high up to 90%. Proteomics techniques of 2-dimensional electrophoresis coupled with matrix assisted laser desorption and ionization - time of flight/time of flight mass spectrometry were used for comparative protein expression profiling of the CMCs between the two BMD subgroups. We screened out, identified, and verified with western blotting five proteins which were differentially expressed in the two subgroups of samples: RSU1, GSN, SOD2 (up-regulated in low BMD subgroup), and GPX1 and P4HB (down-regulated low BMD subgroup). These proteins might affect monocyte trans-endothelium, osteoclast differentiation, and/or osteoclast functions. Therefore, they probably contribute to differential osteoclastogenesis and BMD variation, thus be invovled in pathogenesis of human osteoporosis.

Neuroimaging findings in macrocephaly-cutis marmorata telangiectatica congenita. *R.L. Conway[1], B.D. Pressman[1], W.B. Dobyns[2], M.G. Butler[3], E. Zackai[4], S.C. Saitta[4], L. Campbell[4], C.L. Clericuzio[5], J.M. Milunsky[6], H.E. Hoyme[7], J. Shieh[7], J.B. Moeschler[8], B. Crandall[9], J.L. Lauzon[10], D. Viskochil[11], B. Harding[12], J.M. Graham[1]* 1) Cedars Sinai Medical Ctr., Los Angeles, CA; 2) Univ. of Chicago, IL; 3) Childrens Mercy Hospital, Kansas City, MO; 4) Children's Hospital of Philadelphia, PA; 5) Univ. of New Mexico School of Medicine, Albuquerque, NM; 6) Boston Univ. School of Medicine, Boston, MA; 7) Stanford Univ. Medical Ctr., Stanford, CA; 8) Dartmouth Medical School, Lebanon, NH; 9) UCLA School of Medicine, Los Angeles, CA; 10) Alberta Children's Hospital, Canada; 11) Univ. of Utah School of Medicine, Salt Lake City, UT; 12) Great Ormond St. Hospital for Children, London, UK.

To investigate neuroimaging abnormalities found in the overgrowth syndrome Macrocephaly-Cutis Marmorata Telangiectatica Congenita (M-CMTC) we analyzed available brain MRI or CT scans from 17 unpublished patients and compared their findings with features identified through a review of published cases. Common findings included white matter irregularities, ventriculomegaly and brain asymmetry. A distinctive feature in more than half was cerebellar tonsillar herniation (CTH), usually associated with rapid brain growth and progressive posterior fossa crowding during infancy; in 4 such cases this was an acquired event. Concurrent with the development of CTH, ventriculomegaly and dilated dural venous sinuses were seen along with prominent Virchow-Robin spaces in many patients. We postulate the constellation of these features suggests a dynamic process of mechanical compromise in the posterior fossa, perhaps initiated by a rapidly growing hindbrain which causes congestion of venous drainage and compromised cerebrospinal fluid reabsorption. We also found numerous examples of focal cortical dysplasia and polymicrogyria, a high frequency of cavum septum pellucidum or vergae, thickened corpus callosum, wide optic nerve sheaths, and one case of venous sinus thrombosis. One case had a perifalcine mass resembling a meningioma at age 5 years. This is the second apparent occurrence of this tumor in M-CMTC, adding to the unique CNS abnormalities in this syndrome.

Williams syndrome-like phenotype in a mother and daughter with normal FISH results for Williams syndrome.

M.J. Hajianpour[1], Y. Bruno[2] 1) Gene Trek Genetics, Burbank, CA; 2) White Memorial Medical Center, Los Angeles, CA.

We present a 31-month-old female, born at 30 weeks of gestation to a 27-year-old G1, P0 mother. Her birth weight was three pounds. She had congenital heart defect probably an aortic valve stenosis or coarctation of the aorta (?) which required surgery after birth. She also has congenital scoliosis with mild kyphosis and developmental delay. A recent chromosome analysis and fluorescence in situ hybridization for Williams syndrome and velocardiofacial syndrome were normal. Her weight and height are over 90th percentile and her head size is at 85th percentile for age. Other facial features include epicanthic folds, right eye esotropia, hypertelorism, Broad nasal bridge, anteverted nares, thick prominent lips, wide internipple distance, dorso-lumbar scoliosis to the right, lower dorsal kyphosis, mild hypermobility of fingers, and hypoplastic distal interphalangeal crease of the fifth fingers with restricted movement of distal IP joint. Her mother is similarly affected with congenital valvular heart defects, scoliosis, mental deficiency and thick prominent lips, all of which have been reported in WS. Several of clinical features may be seen in fifth digit syndrome, but the patients do not show overall facial gestalt and other related features.

The Homozygosity Haplotype allows a genome-wide search for the autosomal segments shared among patients.

K. Hagiwara[1], H. Miyazawa[1], M. Kato[2], T. Awata[3,4], H. Iwasa[5,6], N. Koyama[1], T. Tanaka[1], X. Huqun[1], S. Kyo[2], Y. Okazaki[5,6] 1) Respiratory Medicine, Saitama Medical University, Moroyama, Saitama, Japan; 2) Cardiovascular Surgery, Saitama Medical University, Moroyama, Saitama, Japan; 3) Endocrinology and Diabetics, Saitama Medical University, Moroyama, Saitama, Japan; 4) RI laboratory, Saitama Medical University, Moroyama, Saitama, Japan; 5) Functional Genomics and Systems Medicine, Saitama Medical University, Moroyama, Saitama, Japan; 6) Translational Research, Saitama Medical University, Moroyama, Saitama, Japan.

When identifying disease susceptibility genes for both single and multiple gene diseases, a promising strategy is to search patients autosomes for shared chromosomal segments derived from a common ancestor. Such segments are characterized by the distinct identity of their haplotype. The methods and algorithms currently available have only a limited capability for determining a high-resolution haplotype genome wide. We herein introduce the homozygosity haplotype (HH), a haplotype described by the homozygous SNPs that are easily obtained from a high density SNP genotyping data. The HH represents haplotypes of both copies of homologous autosomes, allowing for direct comparisons of the autosomes among multiple patients, and enabling the identification of the shared segments. The HH successfully detected the shared segments from members of a large family with Marfan syndrome that is an autosomal dominant single gene disease. It also detected the shared segments from patients with model multigene diseases originating from common ancestors who lived 10-25 generations ago. HH is therefore considered to be useful for the identification of disease susceptibility genes in both single gene diseases and multigene diseases.

Redefining candidate region of, and identification of specific genetic changes for the chromosome 16q22.1-linked autosomal dominant cerebellar ataxia. *K. Ishikawa[1], T. Amino[1], N. Sato[1], K. Kobayashi[2], S. Asakawa[3], T. Toda[2], H. Mizusawa[1]* 1) Dept Neurology and Neurological Sciences, Graduate School, Tokyo Medical & Dental Univ, Tokyo, Japan; 2) Dept Human Genetics, Graduate School, Osaka University, Osaka, Japan; 3) Dept Molecular Biology, Keio University, Tokyo, Japan.

The chromosome 16q22.1-linked autosomal dominant cerebellar ataxia (16q22.1-ADCA; OMIM #117210) is the third frequent ADCA in Japan, and also shares responsible chromosome region with SCA4 found in Utah and Northern Germany. Clinically, 16q22.1-ADCA is characterized by late age-of-onset (average: 55.5 years) and purely cerebellar ataxia. Corresponding to the clinical features, the Purkinje cell in the cerebellum undergoes predominant degenerations in 16q22.1-ADCA. While the cause(s) of 16q22.1-ADCA and SCA4 had been elusive, a single-nucleotide -16C>T substitution in the *puratrophin-1* gene was identified specific for the 16q22.1-linked ADCA (Ishikawa et al. *Am J Hum Genet* 2005). However, one affected individual without the *puratrophin-1* genetic change was found subsequently in a new family, in which all other affected members harbored the -16C>T *puratrophin-1* genetic change. This would suggest the presence of causative gene instead of the *puratrophin-1* gene. To identify the real cause of 16q22.1-linked ADCA, we collected 65 families from diverse regions of Japan, and typed with densely mapped microsatellite and SNP markers in and around chromosome 16q22.1. We identified a new critical region where groups of markers showed identical alleles in all families including the aforementioned exceptional family. We also found a family in which 4 members had homozygous, two identical disease haplotypes, while two others harbored heterozygous, disease and normal haplotypes. These homozygotes had earlier age of onset than the heterozygotes. We have also found several genetic changes specific for all patients, since such changes were not seen in 600 control Japanese chromosomes. We are focusing some of these changes which may explain the cause of the 16q22.1-linked ADCA.

Neocentromere marker chromosome of distal 3q mimicking dup(3q) syndrome phenotype. *K. Kosaki[1], K. Izumi[1], M. Aramaki[1], R. Kosaki[2]* 1) Department of Pediatrics, Division of Medical Genetics, Keio University Tokyo, Japan; 2) Department of Clinical Genetics and Molecular Medicine, National Ctr for Child Health and Development, Tokyo, Japan.

Supernumerary marker chromosomes lacking alpha-satellite sequences and possessing a newly derived functional centromere are referred to as neocentromere marker chromosomes. Although the delineation of the chromosome content of these neocentromere marker chromosomes would be helpful for genetic counseling, such fine mapping has been difficult because of the limited sizes of the involved segments. We report a female patient with mosaic neocentromere marker chromosome involving 3q26.3-3qter, the content of which was determined using an array CGH analysis. Our results support the validity of an array CGH-based approach to investigating the origins of SMCs. Further FISH analyses revealed that the neocentromere marker chromosomes represented de novo inverted duplications of the distal segments of chromosome 3, 3q26.3-3qter. The present case had many manifestations of dup(3q) syndrome, the critical interval of which is considered to be 3q26.3-q27. Common features included mental and growth retardation, hirsutism, synophrys, a broad nasal root, anteverted nares, downturned corners of the mouth, and malformed ears. The observation gives further credence to the concept that the critical region responsible for the dup(3q) phenotype to 3q26.3-q27.

Germline BRCA2 mutations and the risk of esophageal squamous cell carcinoma. *M.R. Akbari[1,2,3], R. Malekzadeh[3], D. Nasrollahzadeh[3], D. Amanian[3], F. Islami[3], I. Zandvakili[2], R. Shakeri[3], M. Sotoudeh[3], P. Boffette[4], S.M. Dawsey[5], P. Ghadirian[6], S.A. Narod[2]* 1) Institute of Medical Science, Faculty of Medicine, University of Toronto, Toronto, Canada; 2) Womens College Research Institute, University of Toronto, Toronto, Canada; 3) Digestive Disease Research Center, Tehran University of Medical Sciences, Tehran, Iran; 4) International Agency for Research on Cancer, Lyon, France; 5) Division of Cancer Epidemiology and Genetics, National Cancer Institute, Bethesda, Maryland, USA; 6) Epidemiology Research Unit Research Centre, CHUM- Hôtel-Dieu, University of Montreal, Montreal, Canada.

The incidence of esophageal squamous cell carcinoma (ESCC) among the Turkmen population of the southeastern Caspian littoral is very high. Family studies suggest that there is a genetic component to the disease. Because Turkmen are ethnically homogenous, they are well-suited for studies of ESCC genetics. A previous study from China suggested that BRCA2 might play a role in the etiology of ESCC in regions of high incidence. We screened for mutations in the coding region of the BRCA2 gene in the germline DNA of 197 Turkmen patients with ESCC in northern Iran. A nonsense variant, K3326X, was identified in 9 of 197 cases (4.6%) versus 2 of 254 controls (0.8%)(OR = 6.0, 95%CI = 1.3 - 28; P = 0.01). This mutation leads to the loss of the C-terminal domain of the BRCA2 protein, a part of the region of interaction with the FANCD2 protein. We observed nine other BRCA2 variants in single cases only, including two deletions (501-513del-CCAATCTCCTGTA and 3734del-A), and seven missense mutations (Y42C, C315S, L1019V, I2490T, T2542M, K2729N and Q3227E). None of these variants detected in controls. Six of these (Y42C, C315S, I2490T, K2729N and two deletions) were judged to be pathogenic. In total, a suspicious deleterious BRCA2 variant was identified in 15 of 197 ESCC cases (7.6%). Eleven patients had mutations (K3326X, I2490T and K2729N) which have been seen in patients with Fanconi anemia. Therefore it is tempting to speculate that BRCA2 mutations increase the risk of ESCC by a mechanism related to the Fanconi anemia pathway.

Increased Elastolysis Contributes to the Phenotype of Cutis Marmorata Telangiectasia Congenita. *S. Jain[1,5,6], A. Hinek[2,6], M. Baghetti[3,6], H. Tresurer[2,6], G. Taylor[4,6], M. Silver[4,6], D. Nykanen[3,6], D. Chitayat[1,6]* 1) Clinical Genetics & Metabolics; 2) Cardiovascular Research; 3) Cardiology; 4) Pathology; 5) Hospital for Sick Children; 6) University of Toronto, Toronto, Canada.

Cutis Marmorata Telangiectasia Congenita (CMTC) is a cutaneous vascular anomaly presenting at birth with levido reticularis, phlebectasia, and telangectasia. Multiple anomalies and involvement of other systems is noted in 30-80% of cases. Macrocephaly-CMTC has been described as a new syndrome and findings include macrocephaly, hypotonia, developmental delay, hemihypertrophy, connective tissue defect and toe syndactyly. We report a child with CMTC, born with extensive generalized phlebectasia, nevus vascularis reticularis, skin ulcers and developed intracerebral hemorrhage, retinal detachments, hypothyroidism and pulmonary hypertension. Initially serum copper levels of 29.8 umol/L(normal=10.5-23umol/L) and serum ceroloplasmin of 522 mg/L(normal=269-473 mg/L) were noted. The patient died at the age of 20 months. Autopsy confirmed multiorgan telangiectasia, ectatic capillary and venous proliferation and severe medial thickening of the small pulmonary arteries. Fibroblast studies revealed poor deposition of well assembled elastic fibers despite initially synthesizing normal amounts of tropoelastin, microfibrillar scaffolds, collagen type I and fibronectin. Additional assays indicated a heightened elastolytic activity of serine elastase(s) in patients fibroblasts. Moreover, while incubation of CMTC fibroblasts with copper sulfate increased their elastolytic activity, addition of calcium chloride or 1-antitrypsin, but not phenantrolin and C-64 (inhibitors of metalo- and serine- proteases, respectively) reduced their elastolytic activity to normal levels. We also found that treatment with copper sulfate eliminated beneficial effect of 1-antitrypsin in cultures of CMTC and normal fibroblasts. We postulate that an increased concentration of copper can inactivate 1-antitrypsin, thereby creating deficiency of this natural inhibitor of serine elastases. This, in turn may facilitate elastolysis, leading to the connective tissue and vascular disorders observed in our patient with CMTC.

Solute Carrier Family 11 member 1 linking: Infections, Autoimmunity and Cancer? *A. Awomoyi* Microbiology & Immunology, Univeristy of Maryland Baltimore, Baltimore, MD.

Slc11a1 encodes an integral membrane protein, expressed on endosomal/lysosomal compartment of MØs and PMNs. Slc11a1 exacts pleiotropic effects on MØ function; enhanced KC, TNF- , IL -1 , iNOS & MHC class II expression; important in induction and maintenance of autoimmunity and cancer but essential for resistance to pathogens. Slc11a1 delivers bivalent metal cations from cytosol into acidic late endosomal/lysosomal compartment by generating toxic antimicrobial radicals for direct antimicrobial activity against phagocytosed organisms. Prolonged accumulation of toxic radicals can have detrimental effects causing damage and contribute to numerous diseases. SLC11A1 associations with infections, autoimmunity and cancer are with a 5 Z- DNA repeat polymorphism. 5UTR SLC11A1 genomic region analysis in mice and humans reveal differences between species in TF binding sites. An ATF-3 binding site, adjacent to this Z-DNA repeat, present in humans is absent in mouse. Genetic differences exist at SLC11A1 locus. SLC11A1 ATF-3 putative motif and Z-DNA promoter repeat are interrupted by mutations. My hypothesis is that homodimer ATF-3 upon binding to this motif in SLC11A1, should repress transcriptional activation of SLC11A1. I will test whether epigenetic & genetic differences at SLC11A1 locus result in altered susceptibility to diseases, disorders and therapy. Carriage of major slc11a1 allele promotes Th1-type response to vaccination whereas minor allele promotes Th2-type response. Effect of SLC11A1 alleles on immune responses could impact on vaccine delivery and efficacy. This study should provide an understanding of the mechanisms by which SLC11A1 might affect the outcome of infections, disorders, therapy and aging.

Demonstration of PCBP1 in regulation of fundamental cellular metabolism. *L. Huo*[1,2], *N. Zhong*[1,2,3] 1) Peking University Center of Medical Genetics, Beijing, China; 2) Peking University Health Science Center, Beijing; 3) New York State Institute for basic Research in Developmental Disabilities.

PCBP1 is known to participate in biological regulation of RNAs transcription, pre-mRNAs processing and maturating, and mRNAs export through its RNA binding functions. To further investigate the transcript targets of PCBP1, we have studied gene expression profiles by knocking down endogenous PCBP1 transcript and by over expression of exogenous PCBP1 in neuroblastoma SH-SY5Y cell lines. Either an shRNA specifically targets endogenous PCBP1 was constructed into a lentiviral plasmid, packaged, and transducted, or a full length of PCBP1 cDNA was expressed with a plasmid of pcDNA6. Gene expression profiles of global RNAs were analyzed using Agilent oligochip. Our results showed that the expression level of a total number of 1,606 transcripts has been significantly altered when endogenous PCBP1 were knocked down. This alteration includes 974 down-regulated and 732 up-regulated transcripts. Compared to this alteration, there were 679 transcripts up-regulated and 58 down-regulated after exogenous PCBP1 was over-expressed in SY5Y cells. Functional analyses showed that the PCBP1 targeted transcripts are involved in a certain number of cellular pathways, which include in TGH beta signaling pathway, hypertrophy model pathway, cell cycle related pathway, integrin-mediated cell adhesion pathway, translational factors related pathway, apoptosis related pathway, GI3 signaling pathway, etc. Our study provided evidence for the first time of identifying PCBP1 targeted global cellular transcripts in different metabolic pathways.

Iron-related Gene Variants Increase Childhood Leukemia Risk and Birth Weight. *M.T. Dorak[1], R. MacKay[1], C.L. Relton[1], M. Worwood[2], L. Parker[3], A.G. Hall[1]* 1) School of Clinical Medical Sciences, Newcastle University, UK; 2) Dept of Haematology, Cardiff University School of Medicine, UK; 3) Dept of Pediatrics, Dalhousie University IWK Health Centre, Halifax, Canada.

To test our hypotheses that variation in the hemochromatosis gene (HFE) and other iron-related genes modify genetic risk for childhood acute lymphoblastic leukemia (ALL) and birth weight, a population-based study of 172 incident cases and 1005 newborn controls (533 with their mothers) from the North of England was undertaken. Fifteen HFE variants, the transferrin receptor gene (TFRC) S142G variant and several other variants were examined. Using genomic control loci, cryptic population substructure was ruled out. Frequency distribution of HFE haplotypes constructed on PHASE was different between cases and controls (P = 0.01) but in males only (P = 0.02). HFE H63D (OR = 1.6) and an intervening sequence 1 (IVS1) variant (OR = 2.1) showed independent (dominant model) associations but C282Y did not. Homozygosity for TFRC S142G (recessive model) individually increased risk (OR = 1.4) and interacted with the HFE IVS1 (OR = 3.4; 95% CI = 1.5 to 7.6, P = 0.004). H63D, IVS1 and C282Y also increased birth weight statistically significantly in healthy newborns with sex effect: 79g by C282Y (240g in boys); 87g by H63D (138g in boys); 177g (188g in boys) by IVS1. These effects were greater in interaction with TFRC or when the mother was also positive for the HFE variants. IVS1 variant in combination with S142G homozygosity increased birth weight (188g) with greater effect in boys (450g). Compound heterozygosity (C282Y/H63D) increased birth weight but in boys only (434g, P < 0.01). Cord blood iron indices showed non-significant changes in 214 newborns examined. Thus, we showed that an HFE x TFRC interaction modified childhood ALL susceptibility and the same genotypes increased birth weight with maternal and sex effects. Our findings complement the previously established links between high body iron levels and increased cancer risk presumably due to iron's genotoxic effects. The influence of iron on dividing cells may, on the other hand, explain the well-known association between birth weight and childhood ALL.

"Circumpapillary dysgenesis of the pigment epithelium" is in fact NOT a Pigment Epithelial Disease. *K.M. Janisch, J. Tosi, C.L.C. Chou, J.M. Kasanuki, J.F. Flynn, S.H. Tsang* Bernard & Shirlee Brown Glaucoma Laboratory, Edward S. Harkness Eye Institute and Dept. of Pathology, Columbia Univ. College of Physicans & Surgeon, New York, NY.

PURPOSE: Circumpapillary dysgenesis of the pigment epithelium is an autosomal dominant condition (OMIM108985). Lesions begin in the peripapillary area but the macula will be the eventual site of involvement causing blindness and loss of activities of daily living. This disease is also characterized by bilateral geographic, helicoid destruction of the choroid, retinal pigment epithelium (RPE), and photoreceptors. The cellular origin of the disease is unknown, but may arise from abnormal RPE and/or choroidal function. A 1261T-C transition mutation in TEAD1 has been identified in affected families but the location of TEAD1 expression in the eye is unknown. METHODS: To determine the anatomical basis of disease, members of a three-generation New Jersey family were ascertained. Electroretinography (ERG) and genetic screening were performed. Fundus photographs, fundus RPE autofluorescence and optical coherence tomography were reviewed. Autofluorescence images were obtained by illuminating the fundus with argon laser light (488 nm) and viewing the resultant fluorescence through a band pass filter with a short wavelength cut off at 495 nm. To detemine the location of TEAD1 expression, we analyzed dissected mouse RPE and choroid by immunoblotting with an anti-TEAD1 antibody. RESULTS: ERG findings rule out neurosensory retinal involvement even at late stages of the disease. The presence of relatively intact RPE and diseased choroid in a three-year old proband indicates that the RPE is not involved in early stages of circumpapillary dysgenesis. Furthermore, Tead1 expression was observed in the choroid and not the RPE layer of cells. CONCLUSIONS: The primary cellular cause of circumpapillary dysgenesis of the pigment epithelium may be the choroid and not the RPE. Studies of the downstream targets of TEAD1 will open new avenues of research in the development of treatments for choroidal diseases.

Genome-wide association study identifies new HSCR loci. *M. Garcia-Barcelo[1], C. Tang[2], S. Cherny[2,3], P. Sham[2,3], P. Tam[1]* 1) Dept Surgery, Univ Hong Kong, Hong Kong; 2) Dept Psychiatry, Univ Hong Kong, Hong Kong, Hong Kong; 3) Genome Research Centre, Univ Hong Kong, Hong Kong.

Hirschsprungs disease (HSCR, aganglionic megacolon) is a developmental disorder characterised by the absence of the enteric ganglia along a variable length of the intestine. HSCR exhibits significant clinical and genetic heterogeneity and has greater prevalence in males. Its incidence varies among populations, being more frequent in Asians (2.8 per 10,000 life births). HSCR mostly presents sporadically, although it can be familial (20%). The gene encoding a receptor tyrosine-kinase (*RET*) is the major HSCR gene, although coding sequence mutations (CDS) only account for 7%-35% of the sporadic and up to 50% of the familial HSCR cases. Reduced penetrance of *RET* CDS mutations, lack of genotype-phenotype correlation, and a highly frequent low penetrance locus in *RET* intron 1 indicates that the disease likely results from the interaction of several yet unknown susceptibility loci. A major feature of phenotypes with a complex pattern of inheritance is the segregation of multiple predisposing loci with cumulative effects. HSCR is as an oligogenic entity being genetically dissected and used as a paradigm for the study of polygenic/complex diseases. To find additional HSCR loci, two independent genome-wide screenings on Caucasian and Chinese populations are being carried out on the International HSCR Consortium set of patients. Initial data obtained from genotyping 72 Chinese HSCR trios using the GeneChip Mapping 500K Set (Affymetrix) revealed suggestive susceptibility loci on 7q31.2, 5q34, 18q12.2, and Xq27.3 chromosomal regions, in addition to 10q11.2 (*RET*). Our data provide support for *RET* to be the most important locus for HSCR, with several SNPs reaching significant p-values. Analyses of interactions among these loci and a follow up on the most significant SNPs on 192 HSCR cases and 192 controls will be presented.

Genotyping for Graves' Ophthalmopathy. *S.W.Y. Chiang, K.K.L. Chong, P.O.S. Tam, C.P. Pang* Department of Ophthalmology and Visual Sciences, The Chinese University of Hong Kong, Hong Kong.

Purpose: A high incidence of childhood Graves disease (GD) has been documented in the Hong Kong Chinese population and the patients are commonly presented with ocular manifestations. Several genes, such as CTLA-4 and IL-13, have been identified to be associated with GD. However their effects on Graves ophthalmopathy (GO) remain controversial. The aim of this study is to investigate the possible association of genetic polymorphisms in CTLA-4 and IL-13 with GD and its ocular manifestations in pediatric GD patients. Methods: 177 childhood GD patients (age range 5-23) and 151 healthy control subjects (age range 4-18) were recruited. Blood samples were collected for DNA extraction. We genotyped 2 SNPs in IL-13 (-1112C>T and 2044G>A), 2 SNPS in CTLA-4 (49A>G and 8358A>G) and the variant fragment length of the dinucleotide (AT)n repeats in the 3UTR of CTLA-. The genotype results were then correlated with clinical phenotypes, biochemical parameters and ocular manifestations. Results: The 2 SNPs in CTLA-4 (49A>G and 8358A>G) are in the same haplotype block with the GG haplotype significantly associated with increase GD risk (p=0.0072). The variant length of dinucleotide (AT)n repeats in CTLA-4 also associated with GD with the shortest allele (192 bp) conferred a protective effect (p=0.000047). On the other hand, IL-13 did not confer association to GD risk. IL-13 -1112C>T may associated with IgE elevation (p=0.044) and 2044G>A may be associated with increased risk of proptosis (p=0.02). However, the difference is insignificant after bonferroni correction (pc=0.22 and 0.1 respectively). Association of these polymorphisms with GO cannot be established. Conclusions: Our study shows that CTLA-4 confers susceptibility to our childhood GD patients in Hong Kong Chinese while IL-13 confers no association to GD risk but may affects the biochemical and ocular features of the patients. No association between these 2 genes and clinically evident GO can be found.

Cerebral infarction in a 3-year-old patient with progeria. *R. Kosaki[1], M. Uno[2], K. Mizuguchi[3], Y. Abe[3], T. Nagasawa[3], O. Migita[1], T. Tanaka[1], T. Okuyama[1], K. Kosaki[4], A. Oka[3]* 1) Dept Strategic Medicine, Natl Ctr Child Health & Dev, Tokyo, Japan; 2) Dept Interdisciplinary Medicine,Natl Ctr Child Health & Dev, Tokyo, Japan; 3) Dept of Neurology ,Natl Ctr Child Health & Dev, Tokyo, Japan; 4) Dept of Pediatrics,Keio Univ.School of Medicine,Tokyo Japan.

Hutchinson-Gilford progeria syndrome (HGPS) is an autosomal dominant disorder caused by mutations in LMNA and is characterized by prematurely accelerated aging that manifests at age one or two years. The life expectancy was 6-20 years, with the average of 12.6 years. Significant morbidity and mortality is associated with various cardiovascular complications, most notably coronary insufficiencies, due to premature atherosclerosis. Here we report a HGPS patient who developed cerebral infarction at unusually early age of 3 years and 5 months. The Japanese girl was born at 38 weeks gestation with birth weight of 2022g. Clinical diagnosis of HGPS was made at 18 months of age on the basis of the characteristic features including growth failure, loss of subcutaneous fat and sparse hair. At the age of 3 year 2 months, she complained of a mild headache. Three months later, she developed left-sided clonic convulsion and left arm paresis. Magnetic resonance imaging on the brain showed acute infarctions at the right frontal cortex. Magnetic resonance angiography disclosed decreased perfusion in the right middle cerebral artery and in the anterior cerebral artery. On ultrasound examination of the carotid arteries, right carotid artery was poorly visualized. She was diagnosed as having anterior cortical watershed infarction of the right hemisphere due to occlusion of the right internal carotid artery. The left arm paresis improved and she has been medicated with aspirin and dipyridamole. Review of the literature revealed 9 HGPS cases who had cerebrovascular accident. The onset of the patient herein reported is earlier than that of any of the 9 previously reported cases. We would recommend monitoring carotid patency of HGPS patient as early as three years of age so that preventive prescription could be initiated in a timely manner.

Prevention of Homozygous b-thalassemia by Carrier Screening and Prenatal Diagnosis in India. *Sarita. Agarwal, M. Pradhan* Genetics, SGPGIMS, Lucknow, UP, India.

We report here results of a 3-year pilot voluntary screening program coupled with prenatal diagnosis directed to the prospective prevention of homozygous b-thalassemia in India. The screening program took two approaches: testing of the extended family members of the high risk couples and secondly screening of all referral anemia cases to rule out thalassemia carrier status for premarital genetic counseling in unmarried carriers while married were educated for prenatal diagnosis. The screening of extended family members of high risk couple was very effective as, out of 200 couples, in 113 cases the procedures were performed as both the partners were carrier and women were pregnant at the time of screening. The DNA diagnosis revealed 28% affected fetuses, 61% carriers and 24% fetuses as normal. On screening of 2287 cases, 291 cases were identified as b-thalassemia, 56 as b-thalassemia with structural hemoglobin variants [Eb, Sb & Db]. Genotype-phenotype correlation confirmed 243 cases as thalassemia heterozygous & 48 cases as thalassemia homozygous. In 50 cases where both the partners were carrier of b-thalassemia of which only 20 couples could opt for prenatal diagnosis after counseling since pregnancy was positive. 20 CVs samples of this screening group revealed, 5 affected fetuses. In total 33 affected fetuses were terminated from high-risk couples [133]. Prenatal detection was achieved by DNA analysis on chorionic villus samples obtained by ultrasound guided trans abdominal or trans vaginal procedures. The ARMS-PCR and sequencing methods were used for the identification of mutations. The PND program through carrier screening and extended family screening program has prevented the birth of thalassemia homozygous by 1.33% [33/2487] in India. By introducing PND program in the country it is possible to prevent the disease in large to avoid mental & physical trauma to the family and financial burden on medical & health services in the country. For PND program the idea of molecular spectrum of the disease in different parts of the India needed where endogamy and consanguinity in various ethnic groups is quiet common.

CGH array analysis of a cohort of patients with mental retardation reveals imbalances in at least 20% of the cases and suggests new candidate genes. *S. Jaillard[1,2], C. Dubourg[1,3], L. Pasquier[4], C. Bendavid[1], C. de La Rochebrochard[4], D. Bonneau[5], A. Guichet[6], H. Journel[7], B. Gilbert-Dussardier[8], A. Toutain[9], A. David[10], D. Martin[11], P. Parent[12], J. Mosser[1], V. David[1,3], S. Odent[1,4]* 1) UMR 6061, IFR 140 GFAS, Faculty of Medicine, Rennes, France; 2) Cytogenetics, CHU, Rennes, France; 3) Molecular Genetics, CHU, Rennes, France; 4) Medical Genetics, CHU, Rennes, France; 5) Medical Genetics, CHU, Angers, France; 6) Cytogenetics, CHU, Angers, France; 7) Medical Genetics, CHBA, Vannes, France; 8) Medical Genetics, CHU, Poitiers, France; 9) Medical Genetics, CHU, Tours, France; 10) Medical Genetics, CHU, Nantes, France; 11) Medical Genetics, CH, Le Mans, France; 12) Medical Genetics, CHU, Brest, France.

Mental retardation (MR) affects 1 to 3% of the general population. It is described by impaired intelligence and function in adaptative skills, before age 18. Its etiology is very heterogeneous: numerous genetic and environmental causes have been reported, but the molecular bases remain undetermined in half of MR patients. We initiated an array CGH study using high performance Agilent arrays 4x44K, to detect microrearrangements that could not be observed by standard karyotyping and subtelomeric FISH. Clinically relevant copy number abnormalities (from 210 kb to 12.5 Mb) were identified in at least 20% of the 65 studied patients: 11 deletions and 6 duplications. Novel microdeletions in 2q and in 17q were detected, and fit with new microdeletional syndromes characterized by dysmorphic features, developmental delay, hypotonia. These regions include candidate genes for RM. In the same way, a microdeletion in 17p11 was observed in a RM patient with a muscular hypertrophy. This CGH array technology also allowed us to detect a rearrangement of the chromosome 18 and to suspect a mosaicism, which was then confirmed by FISH showing an isodicentric chromosome 18 in 5% of the cells. Our results indicate that the diagnostic yield of CGH array approach in the general population of patients with MR is at least twice higher than standard karyotyping. Therefore this powerful molecular tool allowed us to give accurate genetic counselling in mental retardation.

A genome wide scan for linkage in families with early onset Maturity onset diabetes of the young suggest a potential role for genes on chromosomes 2p 3q, 4q and 10q in glucose homeostasis. *A.L. Gloyn[1], B. Barrow[1], M. van de Bunt[1], D. Hammersley[1], M. Shepherd[2], K. Elliot[3], N.W. Rayner[3], S. Ellard[2], C.M. Lindgren[1,3]* 1) Oxford Centre for Diabetes, Endocrinology & Metabolism, University of Oxford, Oxford, UK; 2) Peninsula Medical School, UK; 3) Wellcome Trust Centre for Human Genetics, University of Oxford, UK.

Maturity-onset diabetes of the young (MODY) is an autosomal dominantly inherited early onset subtype of non-insulin dependent diabetes. MODY causing mutations in 6 genes have been described but only explain around 87% of cases. We hypothesised that patients with a very young age of diagnosis (<15 yrs) may represent a genetically homogenous group and could facilitate identification of novel MODY genes. The aim of this study was to identify potential novel loci for further gene candidacy testing for MODY. We performed an autosomal genome wide linkage scan in 40 individuals (20 affected) from 5 families with 6 members with onset of diabetes 15 years. Samples were genotyped using the Illumina IV linkage panel. Extensive quality checks were performed including HapMap concordance (0.2%) within genotyping concordance (0.4%) and checking of Mendelian inconsistencies. 5,131 markers were used for linkage analysis using both non-parametric linkage analysis and a parametric autosomal dominant model taking linkage disequilibrium into account (r^2 >0.1). The highest NPL score 3.75 (pnominal <0.0001, HLOD 1.5), was observed on chromosome 10q. Three additional regions showed a NPL score >3.00 on chromosomes 2p (NPL 3.38 pnominal<0.0005, HLOD 0.83), 3q (NPL 3.10 pnominal=0.0010, HLOD 1.81) and 4q (NPL 3.00 pnominal<0.0015, HLOD 1.43). About 145 genes map to the 1 NPL drop off region of these 4 loci of interest, including strong biological candidates, potassium channels, transcription factors and cell signalling components. In conclusion, we have identified 4 novel loci which potentially harbour novel genes involved in the pathogenesis of MODY. Utilizing families with an early age of diagnosis in combination with advanced bioinformatics to prioritise candidacy, is a strategy to facilitate identification of novel disease loci by linkage mapping.

Novel EXT1 and EXT2 Gene Mutations in Hereditary Multiple Exostoses Families of Indian Origin. *Vanita. Kumar[1], K. Sperling[2], H.S. Sandhu[3], P.S. Sandhu[3], J.R. Singh[1]* 1) Centre for Genetic Disorders, Guru Nanak Dev University, Punjab, India; 2) Institute of Human Genetics, Charitè Humboldt-University, Berlin, Germany; 3) Dr. Hardas Singh Orthopaedic Hospital and Super Speciality Research Centre, Amritsar.

Background: Hereditary multiple exostoses (HME) is an autosomal dominant bone disorder, characterized by short stature and the presence of multiple benign tumors mainly at the ends of long bones. HME is genetically heterogeneous with two known genes on 8q24 (EXT1) and 11p11 (EXT2), and a third minor locus mapped to 19p (EXT3). The majority of EXT1 and EXT2 gene mutations result in premature protein truncation and loss of function. Materials and Methods: We analyzed two autosomal dominant HME families of Indian origin. Linkage analyses using fluorescently labeled microsatellite markers at the candidate gene regions was performed. Mutation analyses was carried out by bi-directional sequencing of purified PCR products. Results: We found linkage in one family to EXT1 gene and in the other family to EXT2 gene. Mutation screening in the EXT1 gene revealed a novel frame-shift mutation, in exon 1. This mutation segregated in all affected members and was absent in the unaffected family members and 60 unrelated controls. In the second family a previously unreported stop mutation, was observed in the EXT2 gene in all affected members and in none of the unaffected family members nor in 90 unrelated controls. Conclusions: Our findings expand the mutation spectrum of EXT1 & EXT2 and highlight the genetic and phenotypic heterogeneity of HME.

Alpha synuclein in familial Parkinsons disease and Lewy body dementia. *V. Greco, E.V. De Marco, F.E. Rocca, P. Tarantino, F. Annesi, D. Civitelli, G. Provenzano, V. Scornaienchi, I.C. Cirò Candiano, S. Carrideo, G. Nicoletti, G. Annesi* Inst of Neurol Sciences, National Research Council, Mangone, Cosenza, Italy.

Alpha-synuclein has been implicated in the pathology of certain neurodegenerative diseases, including Parkinsons disease (PD) and dementia with Lewy bodies (DLB). Alpha-synuclein is the major component of the filamentous Lewy bodies and Lewy neurites that define these diseases at a neuropathological level. Missense mutations (A30P and A53T) in alpha-synuclein gene cause familial forms of PD and DLB. Recently, a third missense mutation (E46K) in alpha-synuclein gene was described in an inherited form of DLB. The aim of this study was to evaluate the role of E46K mutation as a risk factor in DLB and in familial PD. We analysed the E46K mutation in seventeen sporadic DLB patients and thirty-seven familial PD patients. The clinical diagnosis of DLB was based on the criteria proposed by an international consortium on DLB that include the presence of cognitive decline plus at least two of the following: spontaneous parkinsonian symptoms and signs, visual hallucinations and fluctuations in consciousness. PD patients were diagnosed according to UK Brain Bank criteria. We conducted a genetic analysis by standard PCR and restriction digestion method. None of the subjects examined had the E46K mutation of the alpha-synuclein gene. The E46K mutation was identified in affected members of a Spanish family with autosomal dominant DLB and parkinsonism. This mutation substitutes the glutamic acid with the lysine in a much conserved area of the protein, causing likely severe disturbance of protein function. Moreover the A53K alpha-synuclein mutation was found in an elder case with DLB from Greece. These cases suggest that E46K and A53T mutations should be considered in the differential diagnosis of DLB. We did not found the E46K mutation in patients with DLB or in familial PD. These results do not support a role for this mutation in our patients with DLB or familial PD, in agreement with the emerging consensus that mutations in the alpha-synuclein gene are associated with PD in few families worldwide.

PITX2 gain-of-function induced defects in mouse forelimb development. *J. Holmberg[1], G. Gustavsson[2], C. Johansson[2], P. Leander[2], T.A. Hjalt[1]* 1) Experimental Medical Science, Lund University, LUND, Sweden; 2) Radiation Physics, Lund University, MALMOE, Sweden.

Limb development and patterning originates from a complex interplay between the skeletal elements and muscles of the limb. One of the genes involved in patterning of limb muscles is the transcription factor Pitx2 but its role in forelimb development is uncharacterized. Pitx2 is expressed in the majority of premature presumptive forelimb musculature at embryonic day 12.5 and then maintained throughout embryogenesis to adult skeletal muscle. In vitro studies have shown that over-expression of Pitx2 in myoblasts arrests differentiation. To further study the role of Pitx2 in forelimb development we have generated transgenic mice that exhibit a pulse of Pitx2 over-expression at embryonic day 13.5 in the developing forelimb. These mice exhibit a distal misplacement of the biceps brachii insertion during embryogenesis, which twists the forelimb musculature resulting in severe skeletal malformations. These skeletal malformations have some similarities to the pathogenesis of Leri-Weill dyschondrosteosis, which is characterized by disproportionate short stature and a characteristic curving of the radius, known as the Madelung deformity. Taken together, the tendon, muscle, and bone anomalies further support a role of Pitx2 in forelimb development and may also shed light on the interaction between the skeletal elements and muscles of the limb during embryogenesis.

Exploration of genes related to X-linked mental retardation (XLMR) by MCG X-tiling array. *S. Honda[1,2,3], S. Hayashi[1,2], I. Imoto[1,2], E. Nakagawa[4,5], Y. Goto[4,5], J. Inazawa[1,2,3]* 1) Dept. of Mol. Cytogenet., Med. Res. Inst., Tokyo Med. and Dent. Univ; 2) Core Res. for Evolutional Science and Technology, Japan Science and Technology Agency; 3) 21st Century Center of Excellence Program for the Frontier Res. on Mol. Destruction and Reconstruction of Tooth and Bone; 4) Div. of Child Neurol., Musashi Hosp., Natl. Center of Neurol. and Psychiat; 5) Dept. of Mental Retardation and Birth Defect Res., Natl. Inst. of Neurosci., Natl. Center of Neurol. and Psychiat.

An estimated 13-15% of mental retardation (MR) is caused by mutation on the chromosome X. Although 59 XLMR genes have been identified to date, many genes involved in XLMR remain to be identified. Known XLMR genes have been identified by conventional positional-cloning strategies, but cryptic copy number aberrations (CNA) cannot be detected by routine karyotyping due to its limited resolutions. Since array-based comparative genomic hybridization (array-CGH) can detect such cryptic CNAs, we constructed a high-density and high-resolution chromosome X array (MCG X-tiling array) for array-CGH, which contains a total of 1001 bacterial artificial chromosome (BACs) throughout chromosome X except pseudoautosomal regions. To identify novel XLMR-associated genes, we have screened 73 families with XLMR or probable XLMR by MCG X-tiling array and detected CNAs related to MR in 5 families (7%). Among these 5 CNAs, 2 had duplication of known XLMR-associated genes which have already been reported, whereas, in other 3 families, the genomic materials involved in CNAs have never been reported so far: (1) duplication containing 2 genes completely, (2) duplication harboring 2 genes partially, and (3) deletion involving no known protein-coding gene. Since all CNAs detected were not de novo and also observed in females in some families, the pattern of X-chromosome inactivation in a female was evaluated by FISH with metaphase chromosome using BrdU-labeling technique in late S-phase. MR phenotype in female was correlated with preferential activation of chromosome X with each of those CNAs. Our results demonstrate that array-CGH using X-tiling array is the powerful tool to explore novel CNAs related to XLMR.

Recessive non-syndromic prelingual hearing impairment, GJB2 mutation scope in cochlea implant patients. *R. Birkenhäger, R. Laszig, A. Aschendorff* Department of Otorhinolaryngology , University Hospital Freiburg, Germany.

Congenital sensorineural hearing impairment affects approximately 1-2/1000 newborn. Especially mutations in the GJB2 gene connexin-26 are the reason for non-syndromic hearing impairment. In the present study 289 patients with severe to profound hearing impairment and no evidence of any additional syndrome and abnormality in CT images of the temporal bones and inner ear, were analyzed for genetic alterations in the GJB2 and GJB6 genes. Mutations in the GJB2 gene were found in 133/289 (46,02 %) patients. 24/289 patients were heterozygous for GJB2 alterations, no other mutations were detectable (8,31 %). In three cases the mutation delGJB6-D13S1830 was found in combination with the c.35delG mutation in the GJB2 gene. In 129/289 patients with severe to profound hearing impairment, no mutations or gene alterations were detectable in the GJB2 gene (44,63 %). Twenty-eight different mutations were detected, ten of these gene alterations are novel (Met1Ile, Trp24Leu, c.146delC. Trp134 Stop, Val167Met, Cys169Tyr, Ser183Phe, Ile196Val, Leu213Met, Lys221Asn). These mutations were found partially in combination with the most common c.35delG mutation. These results demonstrate that individuals with severe to profound hearing impairment or deafness should be investigated for GJB2 (connexin-26) mutations. In the case of identification of GJB2 mutations genetic consulting can be offered. Additional screening of newborns with suspected hearing impairment can provide early identification of patients who require intensive speech therapy, need hearing aid and might be candidates for cochlear implantation.

Hypomethylation of the *H19* imprinting control region in Silver-Russell syndrome. *S. Bruce[1,2], K. Hannula-Jouppi[2], C.M. Lindgren[3,4], M. Lipsanen-Nyman[5], J. Kere[1,2]* 1) Karolinska Institutet, Department of Biosciences and Nutrition, Huddinge, Sweden; 2) University of Helsinki, Department of Medical Genetics, Helsinki, Finland; 3) University of Oxford, Wellcome Trust Centre for Human Genetics, Oxford, UK; 4) University of Oxford, Oxford Centre for Diabetes, Endocrinology and Medicine, Oxford, UK; 5) University of Helsinki, Hospital for Children and Adolescents, Helsinki, Finland.

Silver-Russell syndrome (SRS) is a congenital growth retardation syndrome that has recently been found associated to hypomethylation of an imprinting control region (ICR) on chromosome 11p15.5 (*H19* ICR). In this study we investigated the methylation status of the *H19* and *KCNQ1OT1* ICRs in 39 SRS patients and the *H19* ICR in 84 children born small for gestational age (SGA). The methylation status was investigated using methylation-sensitive restriction enzyme digestion of genomic DNA from whole blood, followed by quantitative real-time PCR. We further genotyped 4 microsatellites in the SRS patients and their parents to search for maternal duplications of the 11p15 region. The normal range of methylation was 46% (standard deviation (SD) 6%) at both the *H19* and *KCNQ1OT1* ICR as established by screening 40 normal length individuals. This corresponds well to the expected 50% methylation at an imprinted locus. Twenty-five of the SRS patients (65%) were found to have methylation percentages below 35% (-2SD) at the *H19* ICR, while only one of the SGA children (1%) had an abnormal methylation profile. This patient had many dysmorphic features compatible with SRS. Methylation at the *KCNQ1OT1* ICR was within the normal range for all investigated patients. Among the hypomethylated SRS patients, a strong negative correlation between the degree of hypomethylation and minus SD in length at birth and at 2 years was found (P=0.001, P=0.002, respectively). This suggests that among the hypomethylated SRS patients, the hypomethylation seem to explain a large part of the variation in length up till the age of 2 years. No maternal duplications for the region were found, and therefore the mechanism of hypomethylation remains unexplained.

Genetic Mapping and Characterisation of Non-Syndromic X-Linked Mental Retardation in a Saudi Family. *H. Abalkhail[1], Z. Al-Hassnan[2], M. Faiyaz Ul-Haque[1], N. Sakati[2], M. Al-Owain[2], A. Tbakhi[1], M. Al-Dosari[3], F. AL-Sharief[1], E. Faqieh[2]* 1) Department of Pathology & Lab Medicine, King Faisal Special Hospital and Research center, Riyadh, Saudi Arabia; 2) Department of Medical Genetics, King Faisal Special Hospital and Research center, Riyadh, Saudi Arabia; 3) Department of Neuroscience, King Faisal Special Hospital and Research center, Riyadh, Saudi Arabia.

Abstract: X-linked mental retardation (XLMR) is a genetically and clinically heterogeneous disorder affecting approximately 1 in 1000 males. Clinically, XLMR exists in syndromic and non-syndromic forms. In syndromic forms, mental retardation is associated with other neurological, behavioral, and/or metabolic abnormalities, while in the non-syndromic forms, the only consistent phenotypic manifestation is mental retardation. We examined a large Saudi family with non-syndromic X linked mental retardation recruited for this study. We carried-out a preliminary X chromosome screening using DNA from a large Saudi family with 4 affected males in two different sib ships, connected through healthy females. All affected family members were examined by a clinical geneticist; families with a known diagnosis for mental retardation, male-to-male transmission, fragile-X syndrome or an abnormal G-banded karyotype were excluded from study. Following an X chromosome scan with the use of 48 microsatellite markers (ABI PRISM linkage mapping set v2.5) distributed along the X chromosome, we successfully identified a recombination in the four affected family members flanked at 7.22 cM between the proximal DXS8043 (Xq27.3) and the distal DXS8087 (Xq28) that corresponded to a physical distance of 8.7 Mb. Haplotype analysis was performed manually and a shared haplotype was identified in all affected individuals. To further refine the initial region (~7.22 cM), additional markers were investigated at a higher resolution in order to perform multipoint / two point linkage analysis and to identify a potential disease locus. To our knowledge, this is the first clinical study of its kind carried-out on Saudi population.

Moral distress and burnout among clinical genetics service providers (GSPs). *B.A. Bernhardt[1], K. Kolodner[2], G. Geller[2]* 1) Medicine, University of Pennsylvania, Philadelphia, PA; 2) Johns Hopkins School of Medicine, Baltimore, MD.

In providing patient care, GSPs may experience moral distress through threats to integrity and personal identity. To investigate the nature and consequences of moral distress, we surveyed 386 GSPs. The survey included the Maslach Burnout Inventory (MBI) and 38 items associated with moral distress identified through focus groups of genetic counselors (GCs), MD clinical geneticists (MD) and nurses in genetics. Of the 173 responses to date, the majority of GSPs reported experiencing a moderate or high degree of distress associated with 3 of the moral distress items: experiencing sadness or grief, and feeling inadequate about how to help a patient. Over one-third experienced similar distress by feeling frustrated by unreasonable patient expectations, worrying that a patients decision will come back to haunt them, feeling unsupported by colleagues, and disrespecting a colleagues approach to patient care. Other common sources of distress differed by provider type. MDs were more likely to report distress from feeling angry at (41%) or disliking a patient (26%). GCs reported more distress from feeling disrespected by MDs (39%), feeling that they were overly optimistic (42%) or pessimistic (37%) in the information given patients, and difficulty reconciling their faith with being a GSP (24%). Nurses reported more distress from feeling disrespected by GCs (33%), and from not being able to make a recommendation because of emphasis on patient autonomy (28%). GCs had the highest mean MBI scores, followed by MDs and then nurses. The majority of GCs and MDs scored high on the depersonalization subscale. Many items on the moral distress inventory were correlated with burnout. 21% of MDs, 22% of GCs and 6% of nurses reported thinking about leaving patient care. Some sources of distress experienced by GSPs, especially those related to disrespect, reconciling faith, and inadequacy with regard to assisting patients with decision-making may be unique to genetics. Interventions are needed to assist GSP to minimize the consequences of moral distress so as to decrease burnout and increase the satisfaction derived from providing patient care.

The unfolding clinical spectrum of POLG mutations. *M.J. Blok[1,2], B. van den Bosch[2], E. Jongen[1], C. van de Burg[2], A. Hendrickx[1], M. Pieters[1], J. Bierau[1], I. de Coo[3], H. Smeets[1,2]* 1) Clinical Genetics, academic hospital Maastricht, Maastricht, Netherlands; 2) Department of Genetics and Cell Biology, Maastricht University, Maastricht, Netherlands; 3) Department of Neurology, Erasmus Medical Center Rotterdam, Rotterdam, Netherlands.

Mutations in the nuclear encoded polymerase-gamma (POLG) gene turn out to be a major cause of a broad spectrum of mitochondrial diseases and of secondary mtDNA defects, like mtDNA depletion and multiple mtDNA deletions. We have screened 114 patients, based on clinical criteria and/or the presence of multiple deletions and mtDNA depletions in muscle, for POLG mutations. We have identified 39 mutations in 22 patients, the majority of which cause recessive disease and only a few display a dominant segregation pattern. The group of 39 consisted of 16 different mutations, in which the substitution p.A467T was most frequently observed (n=13). Four new mutations, p.A804T, p.S1095R, p.L966X and p.R275X were found, of which the mutations p.S1095R and p.L966X mutation were detected in severe childhood cases, together with the known mutations p.D1184N and p.A467T, respectively. We also detected for the first time the presence of the known mutation p.R943H in a family with dominant chronic progressive opthalmoplegia and premature ovarian failure. Furthermore, we question the pathogenicity and dominant nature of the previously reported p.G517V mutation, based on the detection of this mutation in multiple unaffected individuals from different families. The clinical presentation of POLG defects is extremely variable, but, in contrast to other reports, we do not observe a gender bias for the childhood cases with this mutation. In addition, the p.A467T mutation did not appear to be more frequent in childhood cases than in adult cases, since we found equal frequencies. Patients with POLG mutations are at risk of death from status epilepticus and liver failure, if exposed to sodium valproate. This requires that the result of genetic testing is available within a day and prior to treatment.

Alpha cardiac actin mutations cause atrial septal defects. *J.S. Eason[1], H. Matsson[2], C.S. Bookwalter[3], J. Klar[2], P. Gustavsson[2], J. Sunnegårdh[4], H. Enell[5], A. Jonzon[6], M. Vikkula[7], I. Gutierrez[7], J.T. Granados Riveron[1], M. Pope[1], F. Bu'lock[8], J. Cox[8], T.E. Robinson[1], F. Song[1], J.D. Brook[1], S. Marston[9], K.M. Trybus[3], N. Dahl[2]* 1) Institute of Genetics, University of Nottingham, Nottingham, United Kingdom; 2) Department of Genetics and Pathology, The Rudbeck Laboratory, Uppsala University and University Hospital, Uppsala, Sweden; 3) Department of Molecular Physiology and Biophysics, University of Vermont, Burlington, USA; 4) The Queen Silvia Children's Hospital, Göteborg, Sweden; 5) Department of Paedriatics, County Hospital of Halmstad, Sweden; 6) Childrens Hospital, Uppsala University, Uppsala, Sweden; 7) Human Molecular Genetics (GEHU), Christian de Duve Institute & Université catholique de Louvain, Brussels, Belgium; 8) Department of Paediatric Cardiology, Glenfield Hospital, Leicester, UK; 9) National Heart and Lung Institute, Imperial College, London, UK.

Congenital heart defects are common developmental defects and a leading cause of morbidity and mortality in early life. Alpha cardiac actin (ACTC1) is essential for cardiac function and mutations in *ACTC1* have been associated with dilated and hypertrophic cardiomyopathy. We identified a missense mutation in exon 2 of *ACTC1* associated with isolated atrial septal defect (ASD) in affected members from two families. This is predicted to lead to an M123V substitution. Functional analysis of ACTC1 with a M123V substitution shows a reduced affinity for myosin with retained actomyosin motor properties. We screened a cohort of apparently sporadic CHD patients for *ACTC1* mutations and identified a patient with ASD and a 17bp deletion. We hypothesised that the mutant transcript would be non-functional due to nonsense mediated decay resulting in haploinsufficiency of ACTC1. We used a morpholino to knock down ACTC1 in early chick embryos to assess the effect on the developing heart. The treated embryos showed delayed looping and reduced atrial septal size compared to wild type. Thus, we show for the first time that ACTC1 has a crucial role in the formation of atrial septa. In conclusion ACTC1 appears to have a role in both embryogenesis and in the contractile function of the adult heart.

Identification and characterization of cell type-specific and ubiquitous chromatin regulatory elements. *G.E. Crawford[1], H. Xi[2], H.P. Shulha[2], J.M. Lin[2], T.R. Vales[1], Y. Fu[2], D.M. Bodine[3], R.D.G. McKay[4], J.G. Chenoweth[4], P.J. Tesar[4], T.S. Furey[1], B. Ren[5], Z. Weng[2]* 1) Institute for Genome Sciences & Policy, Duke University, Durham, NC; 2) Boston University, Boston, MA; 3) National Human Genome Research Institute, Bethesda, MD; 4) National Institute of Neurological Disorders and Stroke, Bethesda, MD; 5) Ludwig Institute for Cancer Research, University of California San Diego, La Jolla, CA.

The identification of regulatory elements from different cell types is necessary for understanding the mechanisms controlling cell type-specific and housekeeping gene expression. Mapping DNaseI hypersensitive (HS) sites is an accurate method for identifying the location of functional regulatory elements. We have used a high throughput method, called DNase-chip, to identify 3904 DNaseI HS sites from six cell types across 1% of the human genome. A significant number (22%) of DNaseI HS sites from each cell type are ubiquitously present among all cell types studied. Surprisingly, nearly all of these ubiquitous DNaseI HS sites correspond to either promoters or insulator elements: 86% of them are located near annotated transcription start sites (TSS) and 10% are bound by CTCF, a protein with known enhancer blocking insulator activity. We also identified a large number of DNaseI HS sites that are cell type-specific (only present in one cell type); many of these regions do not map to promoters, are enriched for enhancer elements and correlate with cell type-specific gene expression as well as cell type-specific histone modifications. Finally, we find that approximately 8% of the genome overlaps a DNaseI HS site in at least one the six cell lines studied, indicating that a large percentage of the genome is potentially functional. Collectively, these results show that ubiquitous chromatin structures are predominantly associated with promoters and insulators while enhancers tend to associate with cell type-specific chromatin structures.

A powerful and flexible multi-locus association test for quantitative traits. *L.C. Kwee[1], D. Liu[2], D. Ghosh[3], X. Lin[4], M.P. Epstein[5]* 1) Dept Biostatistics, Emory Univ, Atlanta, GA; 2) Center for Statistical Sciences, Brown Univ, Providence RI; 3) Dept Biostatistics, Univ Mich, Ann Arbor, MI; 4) Dept Biostatistics, Harvard Univ, Cambridge, MA; 5) Dept Hum Genetics, Emory Univ, Atlanta, GA.

For association mapping of quantitative traits, debate exists regarding the most efficient approach for analyzing tag SNP genotype data within a candidate gene of interest. A popular approach tests each tag SNP individually, but such tests could lose power due to incomplete linkage disequilibrium (LD) between the genotyped tag SNP and the trait-influencing variant. Alternatively, one can jointly test all tag SNPs simultaneously within the gene (using genotypes or haplotypes), but such tests have large degrees of freedom that can also compromise power. Here, we consider a semiparametric model that uses LD information from multiple tag SNPs simultaneously in analysis but still produces test statistics with small degrees of freedom. We fit this model using least-squares kernel machines, which we show is identical to analysis using a linear-mixed model (which we can fit using standard software packages like SAS and R). Using simulated tag SNP data from the International HapMap Project, we demonstrate our approach has superior performance relative to existing approaches for association mapping of quantitative traits for common causal variation. Our approach is also flexible, as it allows easy modeling of covariates and, if interest exists, high-dimensional interactions among genetic and environmental predictors.

Human miR-155 on chromosome 21 differentially interacts with its polymorphic target in the AGTR1 3UTR - a mechanism for functional SNPs related to phenotypes. *C. Borel[1], P. Sethupathy[2], M. Gagnebin[1], C. Gehrig[1], G.R. Grant[2], S. Deutsch[1], T.S. Elton[3], A.G. Hatzigeorgiou[2], S.E. Antonarakis[1]* 1) Dept Genetic Medicine, Univ Geneva Medical Sch, Geneva, Switzerland; 2) Penn Center for Bioinformatics, School of Medicine, University of Pennsylvania, Philadelphia; 3) Davis Heart and Lung Research Institute, The Ohio State University, Columbus.

Animal microRNAs (miRNAs) regulate gene expression through base pairing to their targets within the 3 UTR of protein coding genes. Single Nucleotide Polymorphisms (SNPs) located within such target sites can affect miRNA regulation. We mapped annotated SNPs onto a collection of experimentally supported human miRNA targets. Out of the 143 experimentally supported human target sites, nine contain twelve SNPs. We further experimentally investigated one of these target sites for hsa-miR-155, within the 3 UTR of the human AGTR1 gene that contains SNP rs5186. Using reporter silencing assays, we show that hsa-miR-155 downregulates the expression of only the 1166A, and not the 1166C allele, of rs5186. Remarkably, the 1166C allele has been associated with hypertension in many studies. Thus the 1166C allele may be functionally associated with hypertension by abrogating regulation by hsa-miR-155, thereby elevating AGTR1 levels. Since hsa-miR-155 is on chromosome 21, we hypothesize that the observed lower blood pressure in trisomy 21 is partially caused by the over-expression of hsa-miR-155 leading to allele-specific under-expression of AGTR1. Indeed we have shown in fibroblasts from monozygotic twins discordant for Trisomy 21 that AGTR1 protein is lower in trisomy 21.

Ichthyosis, follicular atrophoderma, and hypotrichosis is associated with mutations in matriptase. *T. Alef[1], S. Kolberg[1], S. Torres[1], I. Hauer[2], D. Metze[3], U. Türsen[4], G.G. Lestringant[5], H.C. Hennies[1]* 1) Univ. of Cologne, Cologne Center for Genomics, Div. of Dermatogenetics, Germany; 2) Univ. of Heidelberg, Dermatology, Germany; 3) Univ. of Münster, Dermatology, Germany; 4) Univ. of Mersin, Dermatology, Turkey; 5) Tawam Hospital, Al Ain, United Arab Emirates.

Autosomal recessive congenital ichthyosis encompasses a large, heterogeneous group of disorders of cornification. Isolated forms and ichthyosis associated with other signs of disease can be differentiated. We have recruited two consanguineous families with similar phenotypes from the United Arab Emirates and Turkey. Five sibs of the Emirati family, three girls and two boys, showed normal stature, diffuse congenital ichthyosis, patchy follicular atrophoderma, generalized and diffuse non-scarring hypotrichosis, and marked hypohidrosis. The affected girl of the Turkish family showed dispersed congenital ichthyosis, follicular atrophoderma, hypotrichosis, and woolly hair. Histopathologically, epidermis was of regular thickness, stratum granulosum thinned and stratum corneum orthohyperkeratotic. Hair follicle epithelium was thinned, hair infundibulum showed hyperkeratosis and a very thin stratum granulosum. EM analysis showed deposits of lamellar bodies in the lower parts of the stratum corneum. By genome wide linkage analysis we identified regions with LOD scores 3 on chromosomes 2 and 11. The interval on 11q24-q25 contained the suppression of tumorigenicity 14 gene (*ST14*), which has 19 exons and spans 50 kb of genomic DNA. Its gene product, matriptase, is a type II transmembrane serine protease expressed in most epithelia. We found a homozygous splice site mutation (c.2269+1GA) in the Emirati patients and a 1-base deletion (c.2034delG) leading to a premature stop codon in the Turkish patient. The mutations confirm the role of matriptase as an essential enzyme in the process of epidermal differentiation. Western blot analysis showed reduced proteolytic activation of prostasin and processing of filaggrin. Since filaggrin monomers play a pivotal role in epidermal barrier formation, we suggest that matriptase acts upstream of prostasin in a zymogen activation cascade that regulates terminal epidermal differentiation.

Occurrence of Bone Crises in Adolescents on Enzyme Replacement Therapy for Gaucher Disease. *P.S. Kishnani, J. Mackey, B.G. Crissman* Department of Pediatrics, Division of Medical Genetics, Duke University Medical Center, Durham, NC.

Introduction: Children with Gaucher disease (GD) are at risk for developing irreversible bone complications during a critical period of growth. The standard of care for type 1 GD is enzyme replacement therapy (ERT) with imiglucerase, which has been shown to reduce the frequency of bone crises (BC) in patients with type 1 GD[1] and improve other manifestations of bone disease. However, due to the rapid growth and increased metabolic needs that occur during puberty, a static dose of ERT may leave adolescents susceptible to complications due to an inadequate dose. We report the effects of dose of ERT with imiglucerase on the occurrence of BC in otherwise stable adolescents with type 1 GD. Methods: Medical records of 5 adolescents with type 1 GD managed at our center were reviewed. Results: All cases (3M, 2F) began ERT prior to puberty (median age 16.6y, range: 13-20y) at an initial dose of 60U/kg/2wks with good response to ERT. The total ERT dose of 2 male patients remained static over time due to effectiveness noted in hematological, visceral, and growth parameters. However, following the onset of puberty both patients developed BC requiring hospitalization, by which time ERT doses had decreased to 27 and 49U/kg/2wks. Both patients dosages were reinstated at 60U/kg/2wks and no further BC occurred. Based on this experience, ERT doses in 3 subsequent adolescents have been adjusted to maintain adequate levels (45-60U/kg/2wks) throughout onset of puberty. All cases have passed onset of puberty without occurrence of BC; doses have since been reduced. Conclusions: In this case series adolescents who experienced a reduction in ERT dose during puberty were susceptible to BC, while those whose dose per body weight was maintained based upon these observations have not suffered from BC. These data suggest that during adolescence, a period of high physiological stress, rapid growth and increased metabolic demands, GD patients require close, regular monitoring and individualization of ERT dose based upon all clinical manifestations of GD in order to prevent skeletal complications such as BC. Larger studies are needed. [1]Charrow J, et al. Clin.Genet. 71:205-211, 2007.

Higher order interaction integration: how do you minimize multiple comparisons? *C.C. Aragaki, K.E. Klos, E. Boerwinkle* Epidemiology and Biostatistics, UT School of Public Health: Human Genetics Center, Houston, TX.

In order to elucidate the pathways involved in complex disease, new analytic strategies need to be developed to integrate the human genome and environmental factors. In particular, the sheer number of potential combinations and integration of the multiple biologic pathways are two problems which need to be solved by new methods. One analytic strategy is to combine current differing analytic techniques to minimize each problem. In the following approach, we use Moores multifactor dimensionality reduction (MDR) within a biological pathway on an intermediate endpoint to determine combinations that impact disease and then integrate multiple pathways in a Hierarchical Bayes approach. METHODS: Using candidate nonsynonymous SNPs in the lipid metabolism and renin-angiotensin pathways and cardiovascular risk factors measured in the Atherosclerosis Risk in Communities cohort study, we determined SNP-environmental factor pathway combinations that impact risk for hypertension and hyperlipidemia. We then regressed these results on cardiovascular events in a hierarchical Bayes Cox regression. RESULTS: We found that genes and environmental factors explained risk variation better than either alone.

Familial Chronic Intestinal Pseudo-Obstruction and Recurrent Pancreatitis in Patients Harboring the Mitochondrial DNA A3243G Mutation. *D. Bonneau[1], C. Verny[2], P. Bonneau-Amati[1], F. Letournel[3], N. Dib[4], C. Le Maréchal[5], C. Férec[5], P. Reynier[1]* 1) Department of Genetics and Biochemistry, INSERM U694 and CHU, Angers, France; 2) Department of Neurology, CHU, Angers, France; 3) UPRES EA 3859, IFR 132, CHU, Angers, France; 4) Department of Gastroenterolgy CHU, Angers, France; 5) Department of Genetics, INSERM U613 and CHU, Brest, France.

The A3243G point mutation in the MTTL1 gene is associated with a broad spectrum of clinical manifestations including mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS) and maternally inherited diabetes mellitus with deafness (MIDD). Although gastrointestinal symptoms are often reported in MELAS as well as in MIDD, they are not usually prominent features of these diseases. Patients and methods: We report a family in which five members carried the mitochondrial DNA (mtDNA) A3243G mutation and presented with chronic intestinal pseudo-obstruction (CIPO); three of these patients also suffered from recurrent pancreatitis. The mutation was quantified in several tissue samples from affected patients. Respiratory chain activity was studied on muscle biopsies and fibroblast cultures. In addition, the thymidine phosphorylase gene involved in MNGIE, and three genes involved in chronic pancreatitis (PRSS1, SPINK1 and CFTR) were sequenced in affected patients. Finally, MTTL1 was tested in 36 unrelated patients suffering from recurrent pancreatitis; the sequencing of the PRSS1 and the SPINK1 genes in these patients had shown no mutations. Results: Heteroplasmy for the mtDNA A3243G mutation was found in all tissue samples obtained from affected patients. No mutations were found in the genes coding for thymidine phosphorylase, PRSS1, SPINK1 and CFTR in the affected patients. None of the 36 unrelated patients with recurrent pancreatitis carried any MTTL1 mutations. Conclusion: The mtDNA A3243G mutation is responsible for the gastrointestinal manifestations observed in this family and must therefore be regarded as a cause of the CIPO and the unexplained recurrent pancreatitis. However, this mutation is weakly involved in cases of recurrent pancreatitis without associated signs of mitochondriopathy.

Evaluation of ODC1 genotype as a modifier of adenoma number in attenuated FAP. *M.W. Condie[1], K.M. Boucher[1, 2], R.W. Burt[1, 3], D.W. Neklason[1, 2]* 1) Huntsman Cancer Institute, University of Utah, Salt Lake City, UT; 2) Department of Oncological Sciences University of Utah, Salt Lake City, UT; 3) Depatment of Medicine University of Utah, Salt Lake City, UT.

Mutations in the APC gene result in increased expression of c-Myc which activates genes involved in proliferation including Ornithine Decarboxylase (ODC1). ODC has been implicated in epithelial cancers including colon. The SNP rs2302615 (G/A) in intron 1 of ODC1 resides between two Myc/Max binding sites (E-box). c-Myc results in increased transription of the A allele ODC1 compared with the G allele. Furthermore, the competitor of c-Myc, Mad1, represses the A allele more than the G allele. Recent reports describe that individuals homozygous for the A allele have reduced prevalence of precancerous colonic adenomas and their polyps are further reduced by NSAID usage. We tested the hypothesis that this ODC polymorphism could be a genetic modifier, influencing the number of adenomatous polyps in individuals with a germline mutation in APC. Penetrance of the adenomatous polyps is highly variable in attenuated familial adenomatous polyposis (AFAP) even with the identical underlying genetic mutation. Associations between adenoma number (set as tertiles of <7, 7-43, and >43 adenomas) and age, gender or ODC genotype were evaluated using ordered multinomial regression analysis under a multivariate model in 161 individuals with the AFAP founder mutation APC c.426_427delAT. Advancing age and male gender correlated statistically with more adenomas. However, there was no statistical difference between ODC genotypes and number of adenomas. NSAID usage was also evaluated in 79 individuals, and there was no interaction between NSAID usage and ODC genotype. ODC genotype has been reported to also have a more significant effect on advanced adenomas. Based on our data, it is likely that polyp initiation is influenced by factors other than ODC in AFAP. The possibility that the ODC genotype may influence development of advanced adenomas or cancer in both AFAP and FAP remains to be evaluated.

Angiogenin gene mutations in a large cohort of Italian ALS patients. *C. Gellera[1], C. Colombrita[2], N. Ticozzi[2], B. Castellotti[1], A. Ratti[2], C. Bragato[1], F. Taroni[1], V. Silani[2]* 1) Department of Biochemistry and Genetics, Fondazione IRCCS - Istituto Neurologico Besta, Milano, Italy; 2) Department of Neuroscience, University of Milan - IRCCS Istituto Auxologico Italiano, Milano, Italy.

Amyotrophic Lateral Sclerosis (ALS) is a rapidly progressive and ultimately fatal neurodegenerative disorder. Most ALS are sporadic (SALS), and 10% of them are familial (FALS). Mutations in SOD1 gene account for about 20% of familial ALS cases. Mutations in alsin, VAPB, SETX, and dynactin genes are rare. Angiogenin (ANG) is a novel candidate gene for the pathogenesis of ALS. It is an angiogenic factor up-regulated by hypoxia highly expressed in motor neurons. Missense mutations in ANG gene have been identified in Northern Europe patients both in SALS and FALS patients. A significant allelic association with the rs11701 SNP has also been described in the Irish and Scottish ALS cases. We screened 738 Italian ALS patients (605 sporadic and 132 familial) and 517 controls for ANG gene coding region, 5UTR and 3UTR sequences. We used both DHPLC and direct sequencing procedures. We found no association with the previously reported rs11701 SNP in our ALS population. We identified seven different mutations in 14 patients (8 SALS and 6 FALS). We found six novel heterozygous mutations, three of which (M-24I, F-13S, P-4S) were located in the ANG signal peptide region, two (V113I, H114R) in the mature protein and one (+5C>T) in the 3UTR region. These mutations were not present in the control population. The previously described I46V mutation was detected in six patients (0.8%) and in one healthy control (0.2%). We also found a new synonymous substitution (G20G) in two ALS patients, but not in controls. We found a statistically significant difference in the mutational frequency between ALS patients and controls (1.9% vs 0.2%; p=0.014). The frequency of mutations was 4.5% in FALS and 1.3% in SALS. Our results provide evidence that variations in ANG gene also occur in the Italian ALS patients. ANG may have an important role as a risk factor for ALS although functional evidences of ANG mutations are still missing. These data further support a possible link between ALS disease and angiogenic factors.

Complement C3 polymorphisms associated with Dense Deposit Disease. *M.A. Abrera-Abeleda[1,2], C. Nishimura[1], S. Sethi[3], P. Zipfel[4], S. Ramaswamy[5], G. Silvestri[6], G. Hageman[7], R.J.H. Smith[1,2,8]* 1) Dept Otolaryngology, Univ of Iowa, Iowa City, IA; 2) Genetics PhD Program, Univ of Iowa, Iowa City, IA; 3) Dept Lab Med and Pathology, The Mayo Clinic, Rochester MN; 4) Leibniz-Institute for Natural Products Research and Infection Biology,Jena, Germany; 5) Dept of Biochemistry, Univ of Iowa, Iowa City, IA; 6) Department of Ophthalmology, Queens University, Belfast, UK; 7) Dept of Ophthalmology , Univ of Iowa, Iowa City IA; 8) Dept of Internal Medicine, Univ of Iowa, Iowa City IA.

Dense Deposit Disease (or Membranoprofilerative Glomerulonephritis type II, DDD/MPGNII) is a rare cause of chronic renal dysfunction. Deficiency of Factor H (FH) in pigs and mice is associated with the development of DDD/MPGNII, suggesting that dysregulation of the alternative pathway of the complement cascade is important in its pathophysiology. Consistent with this hypothesis, we have shown that DDD/MPGNII is associated with specific polymorphisms of FH and Factor H-related 5. Because alternative pathway control is dependent on the interaction of complement proteins, we screened the coding regions and splice sites of C3, Factor B (FB), Factor I (FI) and Factor D (FD) for allele variants in 38 DDD/MPGNII patients and 103 controls. Our results showed a significant association of the R102G ($p<0.0007$) and L314P ($p<0.05$) polymorphisms of C3 with DDD/MPGNII. Both of these SNPs are located in the beta-chain of C3 and may affect the conformational structure of C3, which could change binding affinities for FH and FB, and expose novel epitopes of C3b, which may potentiate the formation of the DDD/MPGNII-specific autoantibody, C3NeF. In addition we identified an unreported missense mutation in one MPGNII/DDD patient. This K1203R change is located in the alpha-chain of C3 near to a FH and complement receptor 2 binding site, suggesting that it may affect the binding of the two proteins to C3. Several SNPs were identified in FB, FI and FD, but none was associated with the DDD/MPGNII. Our results suggest that DDD/MPGNII is a complex genetic disease and provide further evidence to implicate the alternative complement pathway in its pathogenesis. (Supported in part by NIH grant R01DK074409).

Homozygous CHRNG mutation in multiple pterygium syndrome, Escobar variant with CNS malformations. *A.I. Dagli[1], A. Michalk[2], K. Hoffmann[2], R.T. Zori[1]* 1) Division of Genetics,Department of Pediatrics, University of Florida, Gainesville; 2) Institute of Medical Genetics, Charité Berlin, Humboldt University 13353 Berlin, Germany.

Multiple pterygium syndrome, Escobar variant is a non lethal form characterized by webbing of the neck and joints and arthrogryposis multiplex. This syndrome is an autosomal recessive disorder caused by mutations in the CHRNG gene that codes for the subunit of the acetylcholine receptor. The subunit is present before the 33rd week of life and is important for neuromuscular development (Hoffman et al., Am J Hum Genet, 2006).

We report dizygotic twin boys with clinical features of Escobar syndrome. They were born to healthy, non-consanguineous parents. Multiple pterygia, webbing of the neck, hip dislocation, scoliosis, rocker bottom feet and camptodactyly were present. They had an expressionless face with ptosis, micrognathia, cleft palate and prominent nasolabial folds. Both had undescended testicles. In addition, MRI of the head in one twin showed type 1 schizencephaly on the right, open Sylvian fissure on the left and cortical abnormalities. The other twin had a unilateral open Sylvian fissure.

The twins were found to have a homozygous mutation, c.752delCT, in exon 7 of the CHRNG gene. Though other clinical features are consistent with described cases, central nervous system malformations have not been reported. These CNS malformations may represent an independent phenomenon or an added rare feature of CHRNG related Escobar syndrome.

Hypomethylation at the *H19/IGF2* ICR1 in the human placenta is associated with fetal intrauterine growth restriction. *D.K. Bourque[1], L. Avila[1], M.S. Peñaherrera[1], P. von Dadelszen[2], W.P. Robinson[1]* 1) Medical Genetics; 2) Obstetrics and Gynaecology, Univ of British Columbia, Canada.

Placental insufficiency can lead to pre-eclampsia (PET) and/or intrauterine growth restriction (IUGR), each affecting 5% of pregnancies. Methylation at the *H19/IGF2* imprinting control region 1 (ICR1) is thought to play an important role in fetal and placental development. As methylation at this site is inversely correlated with expression of the important growth promoting gene *IGF2*, abnormalities may affect fetal and placental growth. To evaluate the hypothesis that abnormal levels of methylation at the *H19/IGF2* ICR1 significantly contribute to pre-eclampsia and IUGR, we collected two chorionic villous samples each from control (N=20), PET (N=11), IUGR (N=8), and combined PET+IUGR placentas (N=13). We assessed methylation status at two CpG sites (C10 and C12) within the ICR using a SNuPE assay. There was low correlation in level of methylation between samples from the same placenta (R^2=0.34, p<0.001), but high correlation between C10 and C12 CpG sites from one sample (R^2=0.81, p<0.001). There was a reduced mean percent methylation in the IUGR group (29.7%) as compared to the control (36.5%, p<0.01), PET (37.1%, p<0.01) and PET+IUGR (37.1%, p<0.01) groups. These results suggest that IUGR with and without PET may be different in etiology and that decreased expression of *IGF2* in the placenta may be involved in isolated IUGR. As a marker of fetal methylation status, we assessed methylation in amnion samples (N=5 from each group). Mean methylation was 35.8% for control placentas, 36.5% for IUGR, 34.5% for PET and 37.2% for IUGR/PET. Methylation level in amnion was not correlated with clinical group or with corresponding villi samples. This indicates that changes in methylation may be confined to the placenta. We also assessed *H19/IGF2* ICR1 methylation in whole villi from 16 placentas with confined trisomy 16, a situation often associated with fetal IUGR. The mean methylation in these placentas was 30.8% (p=0.009, vs. controls, one-way ANOVA). Decreased methylation at the *H19/IGF2* ICR1 may occur as a response to poor placental implantation rather than being a spontaneous error.

Linkage disequilibrium mapping for schizophrenia susceptibility genes on 8p23.3-p12 in a large European ancestry sample. *J.B. Duan[1], A.R. Sanders[1], M. Martinez[2], D. He[1], J. Li[3], G. Burrell[1], N.G. Buccola[4], B.J. Mowry[5], R. Freedman[6], F. Amin[7], D.W. Black[8], J.M. Silverman[9], W.F. Byerley[10], R.R. Crowe[8], C.R. Cloninger[11], D.F. Levinson[3], P.V. Gejman[1]* 1) ENH/Northwestern Univ, Evanston, IL; 2) INSERM, Toulouse, France; 3) Stanford Univ, Palo Alto, CA; 4) LSU Health Sciences Center (HSC), New Orleans, LA; 5) QCSR and Univ Queensland, Brisbane, Australia; 6) Univ Colorado HSC, Denver,CO; 7) Atlanta VA Med Ctr & Emory Univ, Atlanta, GA; 8) Univ Iowa, Iowa City, IA; 9) Mt. Sinai School of Med, New York, NY; 10) UCSF, San Francisco, CA; 11) Washington Univ, St. Louis, MO.

In our previous linkage genome scan of 409 schizophrenia (SZ) ASPs, the largest signals were observed across a ~60 cM region of 8p23.3-p12. We report here a dense LD mapping association study of this region in a large EA sample that includes 1765 cases (SZ or schizoaffective disorder) and 1956 controls screened for psychosis. Ancestral similarity of cases and controls was established with 194 ancestry informative SNPs. The 2,757 SNPs achieved an average 4 kb/tag SNP density for 236 RefSeq genes, capturing >80% of HapMap CEU common SNPs (r^2>0.8), and included tags within all conserved intergenic sequences plus all non-synonymous SNPs. A q-q plot of observed vs. expected p-values showed a small departure from (elevation above) the null line, consistent with association with variant(s) with small effects. Five single SNPs in or near CSMD1, MFHAS1, PSD3 or EBF2 produced nominal p<0.001, with the lowest value (p=0.0002, OR=1.21) for rs2059527, 48kb telomeric to EBF2. Genotyping 334 additional SNPs in these genes plus MCPH1 improved HapMap coverage (~90%) but not significance. Global haplotypic p-values were not more statistically significant. Empirical significance analyses are in progress. We also analyzed copy number variants, and found a rare 72 kb deletion (rs9650391 to rs418920) in MSR1 overrepresented in cases (p=0.029). We did not detect region- or genome-wide evidence for association. One or more of the nominally associated genes could be involved in SZ susceptibility. Replication in other independent samples is essential.

Towards recommendations for genetic counselling. *H. Kaariainen[1,2], E. Rantanen[2], M. Hietala[2], U. Kristoffersson[3], I. Nippert[4], J. Schmidtke[5], J. Sequeiros[6]* 1) Dept of Molec Med, National Public Health Institute, Helsinki, Finland; 2) Dept Med Genet, University of Turku, Finland; 3) Dept Clin Genet, University Hospital of Lund, Sweden; 4) Dept Hum Genet, Westfaelische Wilhelms-University Muenster, Germany; 5) Inst Hum Genet, Hannover Medical School, Germany; 6) ICBAS and IBMC, University of Porto, Portugal.

As genetic tests are increasingly offered across the borders, EuroGentest, a NoE aiming at improving the quality of testing, also aims at harmonizing the quality of genetic counselling. To achieve this, we analyzed European and global guidelines and policies related to genetic counselling, as well as some relevant American and other documents. The most prominent topics (mentioned in 30/56 of the documents) were considered to form the ideal of genetic counselling. This consisted of (1) appropriately trained professionals, who understand well genetics and its ethical implications; (2) relevant and objective information; (3) assurance of counselees understanding; (4) psychological support; (5) informed consent; (6) confidentiality; (7) considering familial implications; (8) dealing properly with potential discrimination; and (9) assuring autonomous decision-making. We also investigated regulations and practices related to genetic counselling in European countries by an electronic survey among the National Societies of Human Genetics in 29 countries and contact persons in the 9 countries where a Society could not be traced. There is legislation related to counselling in 13 and guidelines in 21 countries, 70% of respondents hoped for more regulation. The topics most often covered in the regulations were counselling in the context of prenatal testing, informed consent, confidentiality, training of the counsellors, and non-directiveness. The seldom-covered topics were counselling in the context of predisposition testing for multifactorial diseases, duty to recontact the patient afterwards, and counselling persons from ethnic minorities. Based on this data, as well as two expert workshops and consultation rounds among human genetic societies, we are finalizing European recommendations for genetic counselling related to genetic testing.

Cell biology, genetics and genomics; a powerful liaison to match genetic to phenotypic variation: the example of Reactive Oxygen Species. *H. Attar[1], K. Bedard[2], H. Prokisch[3], T. Meitinger[3], D. Mehta[3], E. Wichmann[3], ET. Dermitzakis[4], KH. Krause[2], SE. Antonarakis[1]* 1) Genetic Medicine, Geneva University, Geneva, Switzerland; 2) Rehabilitation and Geriatrics, Geneva University Hospital, Switzerland; 3) GSF Research Center, Human Genetics and Epidemiology, Neuherberg, Germany; 4) The Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK.

Natural variation in DNA sequence contributes to individual differences in complex quantitative traits. To date, few cellular traits have been studied that are more closely related to clinical manifestations. Here, we investigate the production of reactive oxygen species (ROS), a complex cellular phenotype involved in a number of human disorders including trisomy 21. We assessed individual variation for ROS production in EBV-transformed B-lymphoblastoid cell lines (LCL) with a fluorescent AmplexRed assay to identify the genetic architecture and potential regulatory loci. We found substantial individual variation in ROS production and a heritability of 45% (10 CEPH families). We identified 2 genome-wide significant linkage signals on loci of Hsa12 and Hsa15. To further refine our search for contributing variation, we performed a genome-wide association analysis for HapMap individuals (N=60). Results confirmed previously detected linkage signals; in addition 8 new significantly associated loci were detected (2.2 million SNP markers, P 1.00 e^{-8}). Given the limited size of the HapMap population, we repeated a genome-wide association in an independent sample of LCLs of healthy German individuals (KORA project). Analysis of 200 LCLs confirmed the locus on Hsa15 and replicated two previously associated loci on Hsa4 and Hsa6 (550K Affymetrix SNP markers, P 1.00 e^{-8}). Furthermore, genome-wide gene expression variation of 47000 transcripts from the HapMap population was correlated to ROS variation. Several genes close to linked and associated loci were among the highest correlations, providing additional biological evidence for the involvement of detected loci in regulation of ROS production. Cellular phenotypes could be used as proxies for complex disorders, and the approach described here may contribute to genetic dissection of these traits.

Carrier Frequency of Recurring Mutation Causing Severe/Lethal Recessive Type VIII Osteogenesis Imperfecta in African-Americans. *W.A. Cabral[1], A.M. Barnes[1], F.D. Porter[2], J.C. Marini[1]* 1) Bone and Extracellular Matrix Branch, NICHD/NIH, Bethesda, MD; 2) Heritable Disorders Branch, NICHD/NIH, Bethesda, MD.

The majority of cases of Osteogenesis imperfecta (OI) are caused by dominant mutations in either of the two genes encoding type I collagen, *COL1A1* and *COL1A2*, with an incidence of 1/20,000 births. Two recessive forms of OI have recently been shown to be caused by defects in the genes encoding cartilage-associated protein (*CRTAP*) or prolyl 3-hydroxylase 1 (*LEPRE1*). Although recessive OI accounts for approximately 5% of OI cases overall, we have identified a recurring mutation in the *LEPRE1* gene, IVS5+1G>T (Cabral and Chang et al, Nat Genet (2007) 39:359-365). The common mutation occurs in a compound heterozygous or homozygous state in 6 of 8 probands (9 of 16 alleles) with severe/lethal recessive type VIII OI (OMIM #610915). All six probands with the IVS5+1G>T mutation were born to carrier parents of West-African (Nigerian or Ghanaian) or African-American descent, suggesting the existence of a stable mutant allele in this population. In order to determine the carrier frequency of the IVS5+1G>T mutation in African-Americans, we screened genomic DNA extracted from 1429 random African-American newborn metabolic screening cards from Pennsylvania. Five carriers were identified, predicting a carrier frequency of 1 in 286 African-Americans newborns (0.35%) in Pennsylvania. Our results predict a 1 in 330,000 rate of occurrence of lethal type VIII OI in African-Americans due to homozygosity for the LEPRE1 IVS5+1G>T mutation. The proportion of African-Americans currently in Pennsylvania who trace their ancestry to contemporary Nigeria or Ghana is unknown. This mutation may have a higher frequency in states (i.e. Maryland or Virginia) whose pre-Civil War slave populations include a higher proportion of individuals originating in this area of West Africa. In addition, screening of this population has identified a previously reported SNP, g.IVS5+115A>G occurring with an allele frequency of 2.1%. This polymorphism is not linked to the mutant allele, but may be useful for haplotype analysis of the African-American population.

Loci associated with successful aging in the Amish. *P.J. Gallins[1], J.L. McCauley[2], L. Jiang[2], A.E. Crunk[2], M. Creason[1], L. Caywood[1], D. Fuzzell[2], C. Knebusch[2], C.E. Jackson[3], J.R. Gilbert[1], M.A. Pericak-Vance[1], J.L. Haines[2], W.K. Scott[1]* 1) University of Miami, Miami, FL; 2) Vanderbilt University, Nashville, TN; 3) Scott & White, Temple, TX.

Successful aging (SA) involves maintaining cognitive and physical function, being socially engaged throughout the lifespan, and avoiding disease and disability. Several components of SA have demonstrated heritability in different samples: longevity, upper extremity strength, lower extremity function, and retention of cognitive ability. The oldest Amish communities of Indiana and Ohio were founded in the mid-1800s by few individuals and remain socially and genetically isolated. Isolation and a relatively homogeneous environment make the Amish a suitable population for identifying complex trait loci. We surveyed cognitively intact Amish age 80 and over, collecting DNA and subjective and objective measures of function, cognition, life satisfaction, and social support. Over 300 individuals have been enrolled in the study and 217 were included in a whole-genome SNP linkage screen (Illumina Linkage Panel IVb). All individuals can be linked back to common ancestors through 11 generations. 68 individuals met criteria for SA (cognitively intact, not depressed, satisfied with life, little self-reported limitation in activities of daily living or musculoskeletal function, in the top 1/3 of the sample on a lower-extremity physical function battery, and having adequate social support). 5,645 SNPs were analyzed for association with SA using the CC-QLS method (Bourgain et al., AJHG 2003; 73:612-26), which performs an adjusted chi-square test of association in related cases and controls, adjusting for correlated data using pairwise kinship coefficients. SNPs on 5 chromosomes were associated with SA (when using a fairly liberal screen threshold of $p<0.001$, chosen to correspond to a lod score of 2 in a whole genome screen): 1p, 3p, 6q, 15q, 16q. The region on 15q is notable because it confirms our preliminary analysis on a subset of 107 individuals. These results suggest that several regions of the genome might harbor loci that influence successful aging in the Amish, particularly the region on chromosome 15q.

Recovering Unused Information in Genomewide Association Studies: A Revision of Quality Control Convention.

D. Fardo[1], *C. Lange*[1,2] 1) Dept Biostatistics, Harvard School of Public Health, Boston, MA; 2) Channing Laboratory, Brigham & Women's Hospital, Boston, MA.

Although the rapid advancements in high-throughput genotyping technology have made genomewide association studies possible, these studies still remain an expensive undertaking, especially when considering the large sample sizes necessary to find the small-to-moderate effect sizes that define complex disease. It is therefore prudent to utilize all possible information contained in a genomewide scan. We propose a straightforward analytical approach to recover often unused information without sacrificing statistical validity.

Screening SNPs for Hardy-Weinberg Equilibrium (HWE) is a common quality control measure when performing genetic association studies (Gomes et al, 1999). There are at least two issues with testing for HWE in the context of genomewide association studies: the large number of tests being conducted increases the chance of observing large deviations from HWE and high-throughout genotype calling algorithms, oftentimes unsupervised, can be susceptible to miscalls, especially from true heterozygotes (Rabbee and Speed, 2006). Genomewide studies using HWE as a screening tool can effectively remove tens of thousands of SNPs from an analysis (Yeager et al, 2007).

We simulate heterozygote miscalls under a variety of models consistent with observed miscall rates and then conduct the standard Pearson chi-square test for departures from HWE. We find that true disease susceptibility loci subject to various levels of heterozygote miscalls can be largely out of HWE and, thus, be candidates for removal prior to association testing. We additionally show that miscalled null SNPs do not induce bias under certain ascertainment schema and suggest that HWE testing not be employed as a quality control measure when conducting genomewide association studies in these scenarios.

NEUROFIBROMATOSIS TYPE 1: NOVEL PHENOTYPES INVOLVING MINERALIZED CRANIOFACIAL TISSUES. *D.L. Domingo[1], J.L. Sloan[2], S.C. Mitchell[1], T.X. Wu[1], T.C. Hart[1], D.R. Stewart[2]* 1) NIDCR/NIH, Bethesda, MD; 2) NHGRI/NIH, Bethesda, MD.

OBJECTIVE: Neurofibromatosis type 1 (NF1) is an autosomal dominant disorder (50% de novo mutations) involving the NF1 gene, characterized by cafe-au-lait spots and neurofibromas. Osseous features (i.e., macrocephaly) have been described. Oral features are poorly defined. Our prospective study identified abnormalities of oral & craniofacial mineralized tissues. METHODS: 50 postpubertal NF1 patients (range:16-73yrs, mean:34.1yrs; 20males,30females) received clinical, radiographic & cone-beam CT evaluations of the oral & craniofacial structures. Centile charts were constructed for occipitofrontal head circumferences (OFC) in relation to height. RESULTS: Using visual inspection & palpation, intraoral bony protruberances were found in 70%(n=35). To eliminate the ethnic divergences in previous reports, calculated prevalences in our study were limited to Caucasians (n=46;94%). Buccal exostoses - uni-/bilateral rows of asymptomatic bony nodules on the facial alveolar ridges - were observed in significantly higher numbers compared to historical norms: 26 Cauc NF1 patients (56%) manifested maxillary buccal exostoses (normal freq:17.3%;p=2.02x10-12) and 9(19.6%) manifested mandibular buccal exostoses (norm:5%;p=1x10-5). Mandibular tori - bony protuberances on the lingual mandible above the mylohyoid line - also occurred in significantly higher frequencies (n=6;14%;norm:5.9%;p=0.0398). Assessing all NF1 patients, occipital osteophytes were observed radiographically in 28(56%) and were significantly more common in males (n=17;60.7%) than females (n=11;39.3%) (p=0.0012). Age distribution were as follows: teens:33%; 20s:44%; 30s:33%; 40s:82%; >50yrs:100%. Among those with OFC <90th percentile, 68%(n=17) manifested occipital osteophytes. CONC: Tissue growth excess is common in NF1. Significant overgrowth of craniofacial mineralized tissues were demonstrated, suggesting that these new findings are part of the NF1 clinical spectrum. The age-related increased occurrences of occipital osteophytes suggest a possible secondary etiology; these also were more common in patients without macrocephaly. Our observations may shed additional insight on this highly variable disease.

Association of *BDNF* haploinsufficiency with childhood overweight in WAGR Syndrome. *J.C. Han[1], C.M. Menzie[1], E.L. Sanford[1], D.C. Adler-Wailes[1], M.J. Raygada[1], M. Jones[2], F.L. Lacbawan[2], O.M. Rennert[1], J.A. Yanovski[1]*
1) National Institute of Child Health and Human Development, Bethesda MD; 2) National Human Genome Research Institute, Bethesda, MD.

Background: WAGR Syndrome (Wilms tumor, aniridia, genitourinary anomalies, mental retardation) is caused by contiguous gene deletions at 11p13. Haploinsufficiency of *WT1* and *PAX6* accounts for the main features, but deletion of other genes may cause additional features, such as hyperphagia and obesity, which are observed in a subset of patients. Brain-derived neurotrophic factor (*BDNF*), located 4 Mb telomeric to *PAX6*, has been shown in animals to be important in energy homeostasis. We hypothesized that the obesity sub-phenotype in WAGR is attributable to *BDNF* haploinsufficiency. **Methods**: 28 patients with WAGR (age 11.87.4y) had deletion mapping by microarray oligonucleotide CGH, with 57k probes spanning 11p (average resolution 400 bp) and 43k probes genome-wide. Confirmatory genotyping used 30 microsatellite markers spanning 11p12-14. Fasting serum BDNF concentration was measured by ELISA. **Results**: 11p deletions were 1.0 to 26.5 Mb in size, and 61% had a deletion involving *BDNF* (*BDNF+/-*). *BDNF+/-* had significantly higher BMI Z-scores at age 5y (1.971.10 vs. 0.111.82, p=0.008) and 10y (2.180.33 vs. 0.871.20, p=0.043) compared to those without *BDNF* deletion (*BDNF+/+*). These differences remained significant after adjusting for parental BMI (5y: p=0.002, 10y: p=0.007). Childhood overweight (BMI>95th%ile by 10y) occurred in all *BDNF+/-* subjects, but in only 1 *BDNF+/+* subject (p<0.0001). Consistent with haploinsufficiency, *BDNF+/-* had approximately 50% lower serum BDNF concentration compared to *BDNF+/+* (13.95.4 vs. 29.314.5 ng/mL, p=0.006). **Conclusions:** *BDNF* haploinsufficiency was associated with lower serum BDNF and higher BMI Z-score in WAGR patients, suggesting that BDNF is important in human energy homeostasis and that WAGR patients with deletions involving *BDNF* will develop the obesity sub-phenotype. Further studies are needed to establish other genotype-phenotype correlations in WAGR Syndrome, and high-resolution CGH may be beneficial in defining molecular breakpoints to guide clinical care.

Finding Mouse Models of Human Disease In MGI. *S.M. Bello, D.L. Burkart, M.A. Updegraff, L.L. Washburn, B. Richards-Smith, A. Anagnostopoulos, M.N. Knowlton, R. Babiuk, H. Onda, M. Tomzuk, I. Lu, H. Dene, C. Smith, J.T. Eppig* The Jackson Laboratory, Bar Harbor, ME.

Mammalian models of human disease are critical to increasing our understanding of disease mechanisms and discovering potential new therapies. The use of the mouse to create such models is facilitated by the wealth of genetic tools available, including high-resolution genetic maps, a multitude of inbred strains, a sequenced genome, and well-developed transgenic techniques, as well as the accessibility of all life stages of the mouse to investigation. The Mouse Genome Informatics Database (MGI, http://www.informatics.jax.org/) provides integrated access to genetic and phenotypic data for mouse models of human disease.

There are multiple ways to find disease models in MGI. Users can search or browse Online Mendelian Inheritance in Man (OMIM) disease terms to find published models for a specific disease. In addition, the integration of phenotypic and genetic data allows users to search for potential disease models using key characteristics of the disease alone or in combination with other criteria, such as chromosomal location or gene function. For example one can ask "What mutation or combination of mutations result in coloboma along with heart and ear abnormalities?". Finally, if a user is interested in a model involving a specific gene, they may search by gene name or synonym to find all known mutant alleles for that gene, as well gene trapped ES cell lines. These searches return information about the allele(s) including, details of the molecular mutation, descriptions of genotype specific phenotypic characteristics, any known human disease model associations, and a bibliography of relevant papers.

MGI currently includes almost 2000 genotypes associated with OMIM disease terms and over 10% of OMIM terms have one or more associated mouse models.

Supported by NIH grant HG000330.

Health educators likelihood of practicing public health genomics. *L.S. Chen, P. Goodson* Department of Health & Kinesiology, Texas A&M University , College Station, TX.

Introduction: With the completion of the Human Genome Project, a new field, Public Health Genomics, which addresses the application of genomic discoveries into population health, emerges. While health educators are responsible for conducting genomic education and increasing genetic literacy for lay communities, it is unknown whether they are ready to be involved in this new field. Therefore, the purpose of this study is to examine health educators likelihood to incorporate genomic information and technologies into their practice. Methods: We surveyed a nationwide sample of health educators regarding their likelihood of practicing public health genomics. A theoretical model, developed to predict their likelihood, was tested with the survey data utilizing Structural Equation Modeling analytical techniques. Results: From 1,607 surveys included in the final analysis, our sample is not very likely to practice public health genomics. The proposed model fit the survey data well (CFI = 0.961, RMSEA = 0.066), and suggested participants genomic knowledge, attitudes, and self-efficacy were significantly and positively correlated to their likelihood of adopting genomic competencies. Conclusion: Although professional groups have advocated for the practice of public health genomics in recent years, health educators in our sample still exhibited little likelihood of incorporating this innovation. As genomic knowledge, attitudes, and self-efficacy were associated with intention to practice public health genomics, education efforts may successfully increase health educators involvement in public health genomics.

On Summarizing and Modeling Higher Order Linkage Disequilibrium Patterns. *S. Feng[1], Z-B. Zeng[2], B. Weir[3]* 1) Biostatistics & Bioinformatics, Duke University, Durham, NC; 2) Bioinformatics, North Carolina State University, Raleigh, NC; 3) Biostatistics, University of Washington, Seattle, WA.

Studies on multi-loci linkage disequilibrium (LD) patterns are important for population genetic research and gene-disease association mapping. A novel statistical method is developed to measure the complexity of higher order LD structures among multiple single nucleotide polymorphism (SNP) markers on a dense map. Derived from a multi-order Markov Chain model, this method uses the order of Markov Chain as a quantity to estimate the order of LD and summarize general LD structures along chromosomes. Based on the new method, complicated LD structures can be decomposed into multiple constraints, with each interpreted exactly as functions of conventional LD parameters. As a by-product of the novel approach, a new three-locus LD measure emerges naturally. It is defined similarly to the widely used three-locus LD measure, but sensitive to the order of the three loci on the chromosome. Some statistical properties are investigated by simulation studies. To illustrate the power and effectiveness, the proposed method is applied to re-analyze two published data sets.

Mapping the susceptibility genes for Carney Triad: Application of original tools for SNP chip analysis of component neoplasias. *G. Assie[1], M. Muchow[2], J. Bertherat[3], J.A. Carney[4], C. Stratakis[2], C. Eng[1]* 1) Genomic Medicine Institute, Cleveland Clinic Foundation, Cleveland, OH; 2) Sect of Endocrinology & Genetics, NICHD, NIH, Bethesda, MD; 3) Dept of Endocrinology, Institut Cochin, Paris; 4) Dept of Pathology, Mayo Clinic, Rochester.

The Carney Triad (CT) denotes the presence of paragangliomas, gastroinstestinal stromal tumors and chondromas in a single individual. The relatively rare CT occurs sporadically. To map the causal gene(s), we developed a novel program designed for SNP chip analysis of tumor tissues. Original features of the program include automated detection and report of deletions, amplifications and copy-neutral allelic imbalances; and determination of the percentage of cells affected by these alterations, enabling discrimination of germline versus somatic events and therefore reliable inference of germline genotypes from tumor samples. The algorithm relies on the SNP minor allele frequencies and intensities provided by Illumina BeadStudio 2.0. We ran Illumina Humanhap300 chips on 54 samples (42 tumors and 12 normal tissues) from 26 patients. The smallest detected deletion was 10 kb, and the smallest amplification was 7 kb. The boundaries were validated visually with BeadStudio. No obvious alterations were missed. Several of these alterations were experimentally confirmed by semi-quantitative PCR or array CGH. Agreement between germline genotype inferred from the tumors and normal tissue was > 99% of SNPs. Utilizing this approach, we mapped relevant CT loci, defined as loci of common germline chromosomal alterations across at least 3 patients and with significant association with CT cases compared to 331 population-matched controls (Haploview v3, Fisher test with Bonferroni correction). Six common loci of germline deletions and 1 common amplification were identified. We also identified previously known as well as novel somatic alteration-hotspots, some being common with germline alterations. Of note, one locus showed common germline and somatic deletions, and significant association in cases over controls, suggesting that this is a major/the susceptibility locus for CT.

A Genome-wide Scan for Estimated Glomerular Filtration Rate (eGFR): The Family Investigation of Nephropathy and Diabetes (FIND). *R.P. Igo, The FIND Consortium* Epidemiology & Biostatistics, Case Western Reserve Univ, Cleveland, OH.

Diabetic nephropathy (DN) is a leading cause of mortality and morbidity in patients with type 1 and type 2 diabetes, accounting for almost half of all cases of end-stage renal disease in the Western world. The multi-center FIND Consortium aims to identify genes for DN by studying quantitative traits of kidney function, including the eGFR, in diabetic individuals from four populations: African American (AA), American Indian (AI), European American (EA) and Mexican American (MA). A genome-wide scan containing more than 5500 autosomal single-nucleotide polymorphism markers (average spacing of 0.6 Kosambi cM) was carried out on 1235 pedigrees (3972 diabetic participants, including 6.7% with type 1, 55.5% type 2, and 37.8% unknown) ascertained for DN. eGFR was calculated using the four-variable Modification of Diet in Renal Disease (MDRD) equation. We report here the results of genome-wide linkage analysis for eGFR.

The strongest peaks from an initial linkage scan, performed without covariates using Haseman-Elston regression, were on chromosome 10p in EA families (27 cM, $p = 1.9 \times 10^{-4}$) and on 20q in MA families (57 cM, $p = 3.5 \times 10^{-5}$). Additional linkage peaks were observed on chromosome 1q (259 cM, $p = 4.7 \times 10^{-4}$) and 7p in MA pedigrees (78 cM, $p = 1.0 \times 10^{-3}$) and on chromosome 15q in EA pedigrees (11 cM, $p = 1.2 \times 10^{-3}$). The latter overlaps a previously reported locus for eGFR in an independent EA sample (Leon et al. (2002) *Nephrol. Dial. Transplant.* **22,** 763). Suggestive evidence for linkage on chromosome 2q in both AA (188 cM, $p = 1.1 \times 10^{-3}$) and EA (184 cM, $p = 6.0 \times 10^{-3}$) samples contributed to the strongest overall genetic signal (188 cM, $p = 2.6 \times 10^{-3}$). After adjusting for body-mass index and duration of diabetes at enrollment, an additional peak on chromosome 3p was found in EA families (108 cM, $p = 7.5 \times 10^{-4}$), near a locus reported for DN in an AA sample (Bowden et al. (2004) *Kidney Int.* **66,** 1517). These findings both identify novel genetic factors for eGFR in diabetes and replicate previously identified loci for DN phenotypes.

Analytical Validation of TaqMan Allelic Discrimination and Multiplex MALDI-TOF Assays for CYP2C9, CYP2D6 and CYP3A5 Genotyping. *J.A. Isler[1], A.M. Slager[1], W. Zhong[2], O.E. Vesterqvist[1], M.E. Burczynski[1]* 1) Biomarker Laboratory, Clinical Translational Medicine, Wyeth, Collegeville, PA; 2) Biological Technologies, Wyeth, Collegeville, PA.

Genotyping assays for the detection of a core set of functionally relevant polymorphisms in three major ethnic populations (Caucasian, African-American, and Asian) in the CYP2C9, CYP2D6 and CYP3A5 genes were analytically validated using the TaqMan allelic discrimination and MALDI-TOF platforms. For CYP2D6, to avoid false genotyping results by non-specific co-amplification of the highly homologous pseudogenes CYP2D7P and CYP2D8P, a two round PCR strategy was designed to amplify a 6.4 kb region of the CYP2D6 gene prior to amplification of smaller regions containing the targeted polymorphism, and the strategy was coupled with multiplex primer extension MALDI-TOF assays. MALDI-TOF assays were also designed and validated for several CYP2C9 alleles, and TaqMan allelic discrimination assays were validated for detection of additional CYP2C9 and CYP3A5 alleles. Analytical validation of all assays demonstrated that the various methods were of suitable specificity, efficiency, reproducibility and accuracy for conducting genotyping assessments in clinical trials. Storage stability experiments demonstrated that the assays were efficacious when performed on genomic DNA isolated from whole blood stored frozen for up to at least 6 months. The assays were applied to commercially available DNA samples of various ethnicities to establish a sample database of known CYP2C9, CYP2D6 and CYP3A5 genotypes. Finally, to demonstrate the clinical utility of the validated assays, CYP2C9 and CYP2D6 assays were applied in an early phase clinical studies to classify the metabolizer status of subjects to illustrate the dependence of pharmacokinetic characteristics of administered CYP2C9-metabolized drug substrates on CYP2C9, but not CYP2D6, genotypes.

A High-Density SNP Genome-wide Linkage Scan in a Large Autism Extended Pedigree. *K. Allen-Brady[1], J. Miller[2], N. Matsunami[3], J. Stevens[3], H. Block[2], M. Farley[2], L. Krasny[2], C. Pingree[2], J. Lainhart[2], M. Leppert[3], W.M. McMahon[2], H. Coon[2]* 1) Dept of Biomedical Informatics, Univ of Utah, Salt Lake City, UT; 2) Dept of Psychiatry, Univ of Utah, Salt Lake City, UT; 3) Dept of Human Genetics, Univ of Utah, Salt Lake City, UT.

We performed a high-density, single nucleotide polymorphism (SNP), genome-wide scan on a six-generation pedigree from Utah with seven affected males, diagnosed with autism spectrum disorder. Using a two-stage linkage design, we first performed a non-parametric analysis on the entire genome using a 10K SNP chip to identify potential regions of interest. To confirm potentially interesting regions, we eliminated SNPs in high linkage disequilibrium (LD) using a principal components analysis method and repeated the linkage results. Three regions met genome-wide significance criteria after controlling for LD: 3q13.2-q13.31 (NPL=5.58), 3q26.31-q27.3 (NPL=4.85) and 20q11.21-q13.12 (NPL=5.56). Two regions met suggestive criteria for significance 7p14.1-p11.22 (NPL=3.18) and 9p24.3 (NPL=3.44). All five chromosomal regions are consistent with other published findings. Haplotype sharing results showed that five of the affected subjects shared more than a single chromosomal region of interest with other affected subjects. Although no common autism susceptibility genes were found for all seven autism cases, these results suggest that multiple genetic loci within these regions may contribute to the autism phenotype in this family, and further follow-up of these chromosomal regions is warranted.

Metabolically Biotinylated Helper Dependent Adenovirus: a new and rapid approach for targeting of High-Capacity Adenoviral Vector. *A. Erez, V. Cerullo, M. Seiler, C. Clarke, M.A. Barry, B. Lee* Dept Human Molecular Genetics, Baylor Col Medicine, Houston, TX.

Developing cell-targeting vectors is an important goal in gene therapy. Metabolic biotinylation of first-generation adenoviral vectors for cell targeting has already been shown. However, there are several advantages in using helper-dependent adenoviral vectors; HD-Ad contain only the noncoding termini of the viral genome, can deliver large DNA fragments of up to 36 Kb into target cells, elicit reduced toxicity and generate prolonged transgene expression in vivo. We constructed a novel metablically biotinylated Helper Virus (Fib2102) to package HD-Ad vectors. Co-infection of a helper-dependent packaging cell line with the fiber-modified helper virus and various HD-Ad constructs would allow the production of fiber-modified HD-Ad expressing different transgenes, obviating the requirement to fiber-modify each individual transgene-expressing HD-Ad. We modified the c-terminus of the Ad5 fiber by addition of a 70 amino acid biotin acceptor peptide (BAP) in our helper virus backbone by homologous recombination. Adenovirus particles bearing the BAP were metabolically biotinylated during vector production by the endogenous biotin ligase to produce covalently biotinylated virions. The resulting biotinylated vectors can be used to transduce different cell type receptors by conjugation to specific biotinylated antibodies. In particular, we tested whether a biotinylated HD-Ad generated with this system expressing the LacZ transgene could transduce chondrocytes in vitro and in vivo. We found that a fiber-modified HD-Ad coupled to the chondrocyte specific -10 integrin antibody was more efficient at transducing chondrocytes than vectors bearing wild type fiber . We show here the novel construction of a fiber-modified helper adenovirus which can be used to propagate high titers of fiber-modified HD-Ad. When coupled to cell-specific antibodies, it improves transgene expression both in vitro and in-vivo. This study demonstrates progress in retargeting strategies for helper-dependent vectors more specifically for low transducing cell types.

A Gene Dosage Map of the Human Genome: A Map with Clinical Utility. *J.D. Cody, P.L. Heard, A.C. Crandall, E.M. Carter, D.E. Hale* Dept Pediatrics, Univ Texas Health Sci Ctr, San Antonio, TX.

We have developed an annotated dosage map of chromosome 18 that depicts the regions with known clinical consequence as well as regions identified as dosage insensitive. Data from a variety of sources has shown that there are thousands of regions in the genome that are dosage insensitive i.e. copy number variations (CNV). In the clinical realm, array comparative genomic hybridization (aCGH) detects changes in copy number in patients. Whether or not those changes are CNVs or have clinical relevance is not easily determined. We saw the need for clinical aCGH results to be compared to genome and gene function data in order to make predictions about potential phenotypic consequences. Predictions about possible phenotypic consequences would be valuable in planning and implementing therapeutic options for patients. We have combined data from the UCSC Genome Browser, with data on individual genes from the literature and our own data on critical regions linked to particular phenotypes in people with chromosome 18 deletions and duplications. These data were compiled to create a dosage map of chromosome 18 in which we assigned regions and/or genes to one of 4 general dosage categories: Haplolethal (dosage critical - prenatal lethal) Haploinsufficient (dosage sensitive) Conditional Haploinsuifficient (dosage sensitive dependent on other genetic or environmental factors) Haplosufficient (dosage insensitive) This information, displayed as a Custom Track on the UCSC Genome Browser, is now predominantly small genomic regions. It will evolve from genomic regions to specific genes as more is learned about gene function. This map allows us to align patient aCHG deletion/duplication data alongside the critical region and CNV data to determine what phenotypes the individual patient is at risk of developing. As more interventions are developed for the phenotypic manifestations of chromosome abnormalities, such a map will be the link between diagnosis and treatment.

Shorter Telomeres in Older Male Individuals with the Fragile X Premutation, FXTAS, and FXTAS with Dementia. *E.C. Jenkins[1], F. Tassone[2,3], L. Ye[1], H. Gu[1], W.T. Brown[1], R.J. Hagerman[2,4], P.J. Hagerman[2,3]* 1) Dept Hum Genetics, NYS Inst Basic Res Dev Disab, Staten Island, NY; 2) MIND Institute, UC Davis Health System, Sacramento, CA; 3) Dept Biochem Mol Med, UC Davis School of Medicine, Sacramento, CA; 4) Dept Ped, UC Davis Health System, Sacramento, CA.

We have recently reported shorter telomeres, chromosomal termini with highly conserved TTAGGG repeats, in T lymphocytes of people with trisomy 21 Down syndrome (DS) and dementia compared to people with DS only. We have since hypothesized that similar shortening may occur in people with fragile X-associated tremor/ataxia syndrome (FXTAS) and dementia. Shorter telomeres also have been associated with cell senescence, Alzheimer Disease, neoplastic transformation, and increased psychological stress. To address the question of telomere shortening in FXTAS, approximately 300,000 mononuclear cells/ml were PHA-cultured from 10% dimethylsulfoxide(DMSO)-cryoprotected buffy coats that had been obtained from male individuals who carried the premutation with or without FXTAS and/or dementia. Telomeres were detected with an FITC-labeled peptide nucleic acid (PNA) probe [(CCCTAA)3-Cy3]. Telomere fluorescent light intensity measurements were obtained as previously described (Jenkins et al., 2006). Twenty metaphases were analyzed for each individual specimen type and compared to an age-matched control. Five control specimens were studied pairwise with age-matched premutation specimens. Shorter telomeres were observed in 4/4 individuals with FXTAS and dementia, in 4/4 individuals with FXTAS, and in 2/2 individuals with the fragile X premutation only (p values ranged from <.000001 to <.05). We were surprised to observe shorter telomeres in people with the premutation only. Additional studies to test younger individuals with the premutation are being carried out to see at what age significant telomere shortening begins compared to controls. It is possible that increased telomere shortening may serve as a biomarker before the emergence of both tremor/ataxia and dementia thus facilitating future prevention, intervention or treatment strategies. This work was supported in part by the NYS Office of Mental Retard. and Develop. Disabil.[553x105].

Genotype and phenotype correlation of *CRTAP* or *P3H1* mutations with recessive osteogenesis imperfecta. *D. Baldridge[1], R. Morello[1], J. Lennington[1], T.K. Bertin[1], M. Weis[2], D.R. Eyre[2], A. Green[3], J. Walsh[3], D. Lambert[3], D. Krakow[4], D.L. Rimoin[4], D.H. Cohn[4], U. Schwarze[5], P.H. Byers[5], B. Lee[1,6]* 1) Dept Mol & Human Gen, Baylor Col Med, Houston, TX; 2) Orthopaedics and Sports Med, U of Washington, Seattle, WA; 3) Natl Centre for Med Gen, Our Ladys Hosp, Dublin, Ireland; 4) Med Gen Inst, Cedars-Sinai Med Center, Los Angeles, CA; 5) Dept Pathology, U of Washington, Seattle, WA; 6) Howard Hughes Med Inst, Houston, TX.

Autosomal dominant osteogenesis imperfecta (OI) or brittle bone disease is a heritable disorder caused by mutations in the two genes encoding type I collagen (*COL1A2* or *COL1A2*). Recently, dysregulation of hydroxylation of a single proline residue in the -helical domain of fibrillar collagens has been implicated in the pathogenesis of recessive forms of OI. Cartilage-associated protein (CRTAP) interacts with prolyl-3-hydroxylase-1 (P3H1), and Crtap null mice lack fibrillar collagen prolyl 3-hydroxylation and display an OI-like phenotype. In our study of 72 OI subjects we report on a spectrum of recessively-inherited phenotypes, including OI types II and III, resulting from mutations in either *CRTAP* (3 patients) or *P3H1* (15 patients). The latter group includes a recurring mutation in patients from the Irish Traveller population, a community with a high degree of consanguinity and an increased incidence of OI. We report on nonsense, frameshift, and splice site alterations that lead to loss of mRNA and loss of function. In addition, the first case of homozygosity for a missense mutation in *CRTAP* was identified and associated with a milder phenotype. At the protein level, patient fibroblasts showed decreased collagen prolyl 3-hydroxylation. Patients with *CRTAP* or *P3H1* loss of function mutations were indistinguishable clinically, as both groups presented with multiple fractures at birth, decreased bone modeling (especially of the femur), extreme low bone mineral density and poor prognosis. Treatment with bisphosphonates appeared to be beneficial in at least one child with a *P3H1* null mutation. These results expand the genotype-phenotype correlations for the recently described recessive OI and support a DNA based approach to the diagnosis of OI.

PRESTO: Rapid calculation of order statistic distributions and multiple-testing adjusted p-values via permutation for one- and two-stage genetic association studies. *B.L. Browning* Nutrigenomics New Zealand and Department of Statistics, The University of Auckland, Auckland, New Zealand.

Genome-wide association studies are now being performed with hundreds of thousands of markers genotyped on thousands of individuals, yet disease-associated variants with sufficiently low frequency and/or modest effects may still remain undetected by these large-scale studies. When there are multiple independent weakly-associated variants there may be significantly more markers with p-values below some threshold than expected by chance, even when no single p-value is significant after adjusting for multiple testing.

The k-th order statistic is the k-th largest test statistic, and the distributions of order statistics can be used to test whether the top ranked markers have lower p-values than expected by chance. PRESTO uses permutation of the trait status to calculate the empirical distribution of order statistics for one- or two-stage genotyping designs under the null hypothesis of no disease-associated markers. These distributions can be used to calculate the statistical significance of any statistic that is a function of order statistics (e.g. rank-truncated products [1]), and can be used to determine the number of top-ranked markers to test in a second-stage experiment.

PRESTO can analyze a large whole-genome association study in a few hours of computing time, can perform any combination of allelic tests and genotypic tests (recessive, dominant, or overdominant), and can test both single markers and haplotype clusters identified by BEAGLE [2]. PRESTO is well-documented, easy-to-use, and freely available at http://stat.auckland.ac.nz/~browning/presto/presto.html.

Fetal parietal foramina: ultrasound and MRI findings. *T. Friedberg[1,3], S. Pentazi[2], S. Blaser[4], K. Murphy[3], D. Chitayat[1,3,5]* 1) The Prenatal Diagnosis and Medical Genetics Program; 2) Department of Diagnostic Imaging; 3) Obstetrics and Gynecology, Mount Sinai Hospital, Toronto, ON; 4) Department of Diagnostic Imaging; Divisions of Diagnostic Imaging and Neuroradiology; 5) Division of Clinical and Metabolic Genetics, The Hospital for Sick Children, Toronto, ON.

Enlarged parietal foramina are caused by poor or delayed ossification around the parietal notch causing bilateral openings in the parietal bones on the sides of the posterior sagittal suture. They are generally benign but can be associated with abnormal venous anatomy and seizures. Mutations in the *MSX2* and *ALX4* genes have been reported to cause these defects and can be inherited as an autosomal dominant condition. We present a family with parietal foramina detected through fetal ultrasound findings suggestive of parietal encephalocele. Case report: The couple was healthy, non-consanguinous and of European descent. The pregnancy history was unremarkable. The couple presented at 21 weeks gestation with fetal ultrasound findings of bilateral large choroid plexus cysts extending to the anterior horns and a focal midline deformity raising the possibility of encephalocele. After the ultrasound, the patient reported a family history of a posterior calvarial defect in herself, her daughter, mother, grandfather, and great-grandfather. Physical examination of the mother and daughter showed bilateral calvarial defects measuring 3x3cm at the posterior part of the parietal bones. Fetal MRI verified the finding of bilateral parietal foramina measuring 1.9x2.0cm with protrusion of 6.7mm of CSF filled spaces with no brain substance protruding. The isolated defects were confirmed in the newborn. DNA analysis of the *MSX2* and *ALX4* genes done on the mother identified a novel, but disease-causing mutation in the *ALX4* gene thought to be the cause of the autosomal dominant parietal foramina. To the best of our knowledge, there have been four case reports of parietal foramina detected in the second trimester by fetal ultrasound and one case detected by fetal MRI. Recognition of this condition is important as it can alleviate anxiety associated with suspected findings of encephalocele and to prevent head trauma at the time of delivery.

Mutations in the gene encoding the basal body protein RPGRIP1L, a novel nephrocystin-4 interactor, cause Joubert syndrome. *D. Doherty[1], H. Arts[2], S.E.C. van Beersum[2], M.A. Parisi[1], S.J.F. Letteboer[2], N.T. Gorden[2], T.A. Peters[3], T. Märker[4], K. Voesenek[2], A. Kartono[2], H. Ozyurek[5], F.M. Farin[6], H.Y. Kroes[7], U. Wolfrum[4], H.G. Brunner[2], F.P.M. Cremers[2], I.A. Glass[1], N.V.A.M. Knoers[2], R. Roepman[2]* 1) Dept Pediatrics, Univ Washington, Seattle, WA; 2) Department of Human Genetics, Radboud University Nijmegen Medical Centre and Nijmegen Centre for Molecular Life Sciences, Nijmegen, The Netherlands; 3) Department of Otorhinolaryngology, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands; 4) Institut für Zoologie, Johannes Gutenberg University, Mainz, Germany; 5) Department of Pediatrics, Ondokuz Mayis University, Samsun, Turkey; 6) Department of Environmental and Occupational Health Sciences, School of Public Health, University of Washington, Seattle, WA; 7) Division of Biomedical Genetics, University Medical Center Utrecht, Utrecht, The Netherlands.

Protein-protein interaction analyses have uncovered a ciliary and basal body protein network that, when disrupted, can result in a variety of disorders including nephronophthisis (NPHP), Leber congenital amaurosis, Senior-Løken syndrome (SLSN) and Joubert syndrome (JBTS). However, details of the molecular mechanisms underlying these disorders remain poorly understood. We have identified the RPGRIP1-like protein (RPGRIP1L), a homolog of RPGRIP1 (RPGR interacting protein 1), a ciliary protein previously shown to be defective in a subset of Leber congenital amaurosis. RPGRIP1L is ubiquitously expressed, and its protein product localizes to basal bodies. RPGRIP1L interacts with nephrocystin-4, and disease-causing mutations in each of these genes disrupts the RPGRIP1L-nephrocystin-4 interaction. We analyzed RPGRIP1L as a candidate gene for JBTS and found nonsense, missense and splice site mutations in families with the characteristic mid-hindbrain malformation (the molar tooth sign). This work identifies RPGRIP1L as a gene responsible for JBTS and establishes a central role for cilia and basal bodies in the pathophysiology of this disorder.

Irf6 allelic series in mouse shows differential defects in oral adhesions without cleft palate. *A. Kinoshita[1, 4, 5], M. Dunnwald[1], K.J. Trout[1], R. Richardson[2], M. Dixon[2], B. Yang[3], B.C. Schutte[1]* 1) Pediatrics, University of Iowa, Iowa City, IA; 2) Life Sciences and School of Dentistry, University of Manchester, Manchester, United Kingdom; 3) Obstetrics and Gynecology, University of Iowa. Iowa City, IA; 4) Human Genetics, Nagasaki University, Nagasaki, Japan; 5) Solution Oriented Research for Science and Technology (SORST), Japan Science and Technology, Kawaguchi, Japan.

IRF6 (interferon regulatory factor 6) is a member of the IRF family of transcription factors. We reported that mutations in *IRF6* cause Van der Woude (VWS) and popliteal pterygium syndromes (PPS) (Kondo *et al*., 2002). These autosomal dominant syndromes are characterized by cleft lip/palate and lip pits, and PPS also has pterygium (skin webbing). To establish a murine model for these orofacial clefting syndromes, we generated *Irf6* mutant mice with a gene trap allele ($Irf6^{gt}$). This allele does not produce detectable levels of *Irf6* in skin and palate. Heterozygous mice do not exhibit a cleft palate, but have intraoral adhesions in 10% of embryos. Homozygous mice exhibit craniofacial, skin and limb abnormalities, including cleft palate (Ingraham *et al*., 2006). To generate a murine model that better represents VWS, we made an *Irf6* allele with *Pgk-neo* cassette ($Irf6^{neo}$) inserted in intron 4. All embryos (6/6) that are compound heterozygotes for the gene trap and *Pgk-neo* alleles ($Irf6^{gt/neo}$) showed intraoral adhesions, along with hind paw syndactyly and kinked tail. Immunoblotting confirmed a gradient of Irf6 expression $Irf6^{+/+} > Irf6^{+/gt} > Irf6^{gt/neo} > Irf6^{gt/gt}$, demonstrating that $Irf6^{neo}$ is a hypomorphic allele. The phenotype of mice heterozygous for the most common PPS-associated allele R84C (Richardson *et al*., 2006) appears to be between $Irf6^{+/gt}$ and $Irf6^{gt/neo}$ and is consistent with a dominant-negative effect for this mutation. Finally, we generated a floxed *Irf6* allele without *Pgk-neo* ($Irf6^{fl}$) and a null allele that deleted exons 3 and 4 ($Irf6^{-}$) by cre-loxP recombination. To establish better models for VWS and PPS, we are crossing the *Irf6* conditional allele with transgenic mice that express Cre in craniofacial tissues.

Genetic Variants in the Lipoprotein Lipase Gene Are Associated with Both Liver Enzyme Levels and Insulin Resistance. *X. Guo[1], J. Cui[1], M.O. Goodarzi[1], K.D. Taylor[1], F-C. Hsu[2], S. Haffner[3], J.M. Norris[4], L. Wagenknecht[2], Y-D.I. Chen[1], J.I. Rotter[1]* 1) Cedars-Sinai Medical Ctr, Los Angeles, CA; 2) Wake Forest University, Winston-Salem, NC; 3) University of Texas Health Science Center, San Antonio, TX; 4) University of Colorado Health Sciences Center, Denver, CO.

Elevated liver enzyme (LE) levels have been related to insulin resistance (IR) and the metabolic syndrome. Heritability and co-heritability analyses indicate significant evidence for a genetic contribution to LE levels. We have previously reported that LE levels share common genetic determinants with IR. The lipoprotein lipase (LPL) gene is a potential candidate for LE levels as it has been shown to be associated with IR in two different cohorts of Hispanic Americans (HA). We evaluate here the role of genetic variants in the LPL gene on LE levels. 1017 non-diabetic individuals from 88 large HA families were recruited through the Insulin Resistance Atherosclerosis Study Family Study at two clinical sites (San Antonio, TX and San Luis Valley, CO). Three liver enzymes: aspartate aminotransferase (AST), alanine aminotransferase (ALT), and gamma-glutamyl transferase (GGT) were measured. None of the subjects self-reported a high alcohol consumption. Twelve single nucleotide polymorphisms (SNPs) in the LPL gene (all in the same block) were genotyped on these samples. The generalized estimating equation methods were used in the association analysis. After adjusting for age, sex, and body mass index, the second most common haplotype, which accounts for 18.8% of the sample and is identified by the minor alleles in SNP rs8292 and rs3200218, was significantly associated with increased GGT (40.82.1 vs 35.81.3, p=0.009), ALT (11.90.5 vs 10.40.3, p=0.010), and AST/ALT ratio (p=0.007). This is the same haplotype that we had previously reported being significantly associated with increased fasting insulin and triglycerides in this HA sample (Goodarzi MO, et al. J Clin Endocrinol Metab 92: 293-296, 2007). These results suggest that the LPL gene is a common genetic determinant for LEs and IR in the Hispanic American population, and that variation in LEs is a genetically determined component of the metabolic syndrome.

Whole genome array strategy for detection of tandem repeat length polymorphisms. *H.A. Bruce[1], A.J. Sharp[2], T.A. Richmond[4], S.G. Lin[1], C.A. Ross[1], E.E. Eichler[2], L.E. DeLisi[3], R.L. Margolis[1]* 1) Department of Psychiatry, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Department of Genome Sciences, University of Washington, Seattle, WA; 3) Department of Psychiatry, New York University, New York, NY; 4) NimbleGen Systems Inc, Madison, WI.

Recent findings using advances in array technology have shown that up to 12% of the human genome may be subject to variations in copy number. It is now possible to detect copy number variations on whole genome SNP arrays. However probes for these arrays have generally been selected to avoid repetitive regions, even though copy number variation is likely to occur in precisely these regions. We hypothesize that polymorphisms of longer tandem repeats (unit length of 50 bp to >150,000 bp), relatively unexplored features of the human genome, may also contribute to normal human variation and to disease. We developed an oligonucleotide array, using the NimbleGen Systems Inc. platform, specifically designed to detect changes in the number of repeating units in tandem repeats. The array contains 380,000 probes and targets 3430 tandem repeats with an average repeat length of 3877 bp. We tested the DNA from a series of test cases and a well characterized reference sample. We detected between 100 and 200 polymorphic tandem repeats per hybridization, using a log 2 signal ratio cut off of >0.5 or <-0.5. Selected polymorphic repeats were confirmed by PCR. This pilot experiment demonstrates that it is possible to detect polymorphic tandem repeats using a whole genome array technology. This strategy may prove of value in further understanding variation within the human genome and identifying risk factors for disease.

PUBLIC EDUCATION FOR LOW-INCOME PREGNANT WOMEN ON PRIMARY PREVENTION OF BIRTH DEFECTS IN RIBEIRãO PRETO-SãO PAULO-BRAZIL. *I. Gomy[1], M.L.O.C. Mesquita[2]* 1) Medical Genetics, Ribeirão Preto School of Medicine, University of São Paulo, Brazil; 2) Pastoral da Criança, Ribeirão Preto, São Paulo, Brazil.

Approximately eight million children with serious birth defects are born each year - 6% of all births worldwide. At least 3.3 million children under age five die yearly due to congenital anomalies and about three million of those who survive are handicapped. Birth defects are a global problem, but their impact is greater in middle- and low-income countries where there have been as much as 95% of deaths of children with congenital anomalies. In Brazil, infant mortality rate is 22.5/1000 live births (2004). In South and Southeast areas where infectious diseases are controlled, birth defects are the second cause of early infant deaths. Brazil's prevalence rate of congenital anomalies is 57.2/1000 live births whereas global prevalence ranges from 82/1000 (Sudan) to 39.7/1000 (France). These huge disparities are due to several risk factors, such as maternal exposure to teratogens and lack of public maternal health and preventive measures. High-income countries have some experience on preventing birth defects by up to 70% with actions such as food fortification with folic acid on prevention of neural tube defects. There are non-profitable and non-governmental organizations programs in Brazil that effectively plays a role on prevention of infant mortality, such as those of Pastoral da Criança. **Objective**: to provide low-income pregnant and childbearing age women with educational and healthy actions about primary prevention of birth defects. **Methods**: educative talks and explanatory leaflets were given monthly from January to December 2006 during Pastoral da Criança's programs in Ribeirão Preto, southeastern Brazil. **Results**: awareness and comprehension improved on how simple and feasible those preventive actions are. **Conclusion**: effective public education initiatives are urged to be taken by public health policy of developing countries on primary prevention of birth defects, in order to minimize morbidity and to decrease infant mortality rates.

Confirmation that a three base pair deletion in the MITF gene results in Tietz Syndrome. *R.K. Basran[1], T. Maher[1], M. Ito[1,2], J.M. Milunsky[1,2,3]* 1) Center for Human Genetics; 2) Department of Pediatrics; 3) Department of Genetics and Genomics, Boston University School of Medicine, Boston, MA.

Waardenburg syndrome (WS) is an autosomal dominant hearing-pigmentary disorder accounting for approximately 3% of congenitally deaf children. WS can be divided into four subtypes (I-IV) based on genetic and clinical criteria. The most common form, WS I, is characterized by the presence of congenital hearing loss, dystopia canthorum and pigmentary disturbances of the eyes, hair and skin. WS II can be distinguished from WS I by the absence of dystopia canthorum. A related hearing-pigmentary disorder with a similar clinical phenotype to WS II is Tietz syndrome (TS, MIM103500). TS is a rare autosomal dominant disorder characterized by congenital profound and completely penetrant hearing loss and pigmentary changes. Within WS II, the degree of depigmentation and hearing loss is more variable when compared to TS. Mutations within the MITF gene have been shown to cause both WS II and TS depending on their location. Mutations occurring in the basic region of the protein lead to TS whereas mutations interfering with the dimerization of the protein lead to WS II. A 1.5 year old boy with a clinical history of ocular albinism and hearing loss was referred to our laboratory for evaluation. Using automated DNA sequence analysis he was found to have a previously reported in-frame deletion of an arginine residue in exon 8. There have been a limited number of reports describing mutations within the MITF gene producing TS. The three base pair deletion of the arginine residue we describe here has been previously reported in one family with an albinism-deafness phenotype resembling the clinical picture of TS. Hence our case provides confirmation of this single amino acid deletion generating a phenotype of TS. Further clinical and genetic analysis of the probands family will provide insight into the classification of the syndrome generating hearing loss in this pedigree. Identification of this mutation within the MITF gene in the proband will now allow tracking through the family, more accurate genetic counseling, and the opportunity for prenatal diagnosis, if desired.

Evidence for natural selection at HLA class I-recognizing leukocyte immunoglobulin-like receptor (*LILR*) in Northeast Asians. *K. Hirayasu[1], J. Ohashi[1], H. Tanaka[2], K. Kashiwase[2], M. Takanashi[2], M. Satake[2], K. Tokunaga[1], T. Yabe[2]* 1) Human Genetics, University of Tokyo, Tokyo, Japan; 2) Tokyo Metropolitan Red Cross Blood Center, Tokyo, Japan.

[Purpose] On the basis of the structural feature, the LILR family is divided into activating, inhibitory, and soluble forms. Both LILRB1 and LILRB2 bind to a broad range of classical and non-classical HLA class I molecules. Last year at this meeting, we reported that high allele frequencies of the *LILRA3* deletion were observed in Northeast Asians, and novel alleles with a premature termination codon in exon 3 were detected only in Northeast Asians. In this study, we examined the linkage disequilibrium (LD) around the *LILRA3* gene.

[Methods] The PCR-SSP and sequencing-based typing method were performed in HapMap population samples (JPT, CHB, CEU, and YRI). LD analysis was performed using the Haploview program. F_{ST} statistic was calculated to measure the genetic differentiation between populations.

[Results] Strong LD was observed between *LILRA3* and *LILRB2*. Furthermore, East Asian and non-East Asian were significantly differentiated for the SNPs both in *LILRA3* and *LILRB2*.

[Conclusion] Our results suggest that natural selection has acted on *LILRA3*, or *LILRB2*, or both of them in East Asians, and lead us to speculate that the *LILR* genes may be involved in pathogen-host interaction.

Usage of a novel algorithm to rank candidate regions and genes after a high-density SNP genotyping study of families with a hypertrichosis insulin resistance disorder (Rosai-Dorfman-like).. *S.T. Cliffe[1,2], T. Roscioli[1,2,3], M. Wong[4], A. Darmanian[5], G. Peters[5], M.F. Buckley[1,2], R. Lindeman[1,2,6]* 1) Molecular and Cytogenetics Unit, Department of Haematology and Genetics, Prince of Wales Hospital, Sydney, Australia; 2) Centre for Vascular Research, University of New South Wales, Sydney, Australia; 3) Sydney South West Integrated Genetics Service, Royal Prince Alfred hospital, University of Sydney, Australia; 4) Department of Allergy, Immunology and Infectious Diseases, The Childrens Hospital Westmead, Sydney, Australia; 5) Department of Cytogenetics, The Childrens Hospital Westmead, Sydney, Australia; 6) School of Medical Sciences, University of New South Wales, Sydney, Australia.

We report the analytical procedure used to examine 55, 721 SNP genotypes in two consanguineous Lebanese-Australian families with an autosomal-recessive Rosai-Dorfman-like disorder. Traditionally STR markers have been used to detect regions of homozygosity, however high-density SNP genotyping is becoming more prevalent due to advantages in both cost and resolution. The binary nature of SNP alleles however accords low marker informativeness, which can be mitigated by using a much greater density of markers than a typical STR marker study. This can potentially result in a greater resolution, but requires more sophisticated analysis to detect significant regions of identity by descent.
Markers were scored based on a range of criteria, which included marker heterozygosity in the probands parents and siblings. A sliding window scoring homozygous segments in the probands was then employed to identify 40 candidate regions spanning 36 Mb in total. These regions contained 237 known genes that were ranked for significance using expression patterns, functional analysis and genome data-mining. The most significant candidate genes have been selected for further molecular testing.

Psychotherapeutic mechanisms of change: the role of genes in depression treatment outcome. *A. Kotte[1, 2, 3], J.R. McQuaid[1,3], J.R. Kelsoe[1,3]* 1) Psychiatry, University of California, San Diego, San Diego, CA; 2) Psychology, San Diego State University, San Diego, CA; 3) Veterans' Affairs Healthcare System, La Jolla, CA.

Introduction. Recent evidence suggests that genetic variation in the coding of BDNF (NTRK2) receptors and serotonin receptors (HTR2A) is associated with antidepressant (AD) response for major depression treatment. While no studies have examined whether these polymorphisms and their interactions predict response to psychotherapy, research using fMRI techniques has provided a model for the neurological basis of psychotherapy. Specifically, fMRI studies present evidence for neurobiological changes after treatment with cognitive behavioral therapy (CBT) similar to neurological changes after treatment with SSRIs suggesting commonalities in the biological mechanisms of psych- and pharmacotherapy. The current study investigated associations of the NTRK2 and HTR2A genotype with cognitive behavioral therapy (CBT) response.Methods. One hundred fifty one male veterans who completed a 16-week group CBT for unipolar depression in the past five years were initially contacted for this study. Sixty-five agreed to participate providing permission for review of their charts to assess treatment response. In addition, a 60 cc sample of blood was drawn for genotyping. Results. A repeated-measures ANOVA found a significant linear main effect for NTRK2, $F(1,65)=4$, $p=.05$ and a significant linear interaction for NTRK2 and HTR2A, $F(2,59)=3.8$, $p=.03$. For the main effect, AA NTRK2 homozygosity did better than the GG and AG genotype (BDI change: 26.7 to 18.8). For the interaction effect, those with a NTRK2 GG and HTR2A GG genotype did significantly better (BDI change: 21 to 15.2) than those with a combination of the HTR2A AA and AG and NTRK2 GG genotype (BDI change: 25 to 22.4). Discussion. Findings are the first to suggest that NTRK2-HTR2A genotype interactions predict response to CBT in the unipolar depression population. These results support a model where psycho- and pharmacotherapy share similar neurobiological mechanisms of action. However, our current results are preliminary and need to be interpreted cautiously.

Lethal neonatal presentation of Medium-Chain Acyl-CoA Dehydrogenase Deficiency. *J.M. Brumblay[1], T.M. Cowan[2], A. Manoukian[3,4], C. Matsumoto[5], L.H. Seaver[1,6]* 1) Kapi'olani Medical Specialists, Honolulu, HI; 2) Stanford University Dept. of Pathology, Palo Alto, CA; 3) John A. Burns School of Medicine Dept. of Pathology, Honolulu, HI; 4) Clinical Laboratories of Hawaii, Maui, HI; 5) Hawaii Dept. of Health, Newborn Metabolic Screening Program, Honolulu, HI; 6) John A. Burns School of Medicine Dept. of Pediatrics, Honolulu, HI.

Medium-Chain Acyl-Coa Dehydrogenase Deficiency (MCADD) is the most common inborn error of fatty acid oxidation. Clinical presentation varies greatly and is unpredictable. Infants born in the state of Hawaii are tested for MCADD on the newborn screening panel through measurement of acylcarnitines by tandem mass spectrometry (MS/MS). We report an infant who died at home on day 3 of life prior to the newborn screning result.

The infant was the first child of unrelated parents. The mother was of Korean ancestry and the father was of Swedish/Irish/French ancestry. The full term infant male was born via emergent cesarean section due to failure to progress and fetal heart rate decelerations. He briefly required oxygen after delivery. He was breastfed and discharged from the hospital at 35 hours of age. He was subsequently found unresponsive in his crib at 61 hours of age. The newborn screening result was reported 3 days later and reveal elevation of (C6) hexanoyl, (C8) octanoyl, (C10) decanoyl carnitines and elevated C8/C10, suggestive of MCADD. Postmortem acylcarnitine profile confirmed the newborn screen result. Autopsy revealed a nondysmorphic, slightly jaundiced, well developed infant with extensive microvesicular fatty metamorphosis of the liver by microscropy. Further laboratory testing revealed that the father had a normal acylcarnitine profile and the common K329E mutation in ACADM, the MCADD gene. His mother had normal plasma acylcarnitine and urine acylglycine profiles, and was found to have a rare mutation, 449_452delCTGA. This mutation has previously been reported in persons of Asian descent, and has also been associated with symptoms in the first week of life. This case illustrates the extreme variability in presentation of MCADD and the importance of rapid newborn screen results.

A scan for genetic determinants of human hair morphology: EDAR is associated with Asian hair thickness. *A. Fujimoto[1], R. Kimura[1], J. Ohashi[1], U. Samakkarn[2], W. Settheetham-Ishida[3], T. Ishida[4], Y. Morishita[5], T. Furusawa[6], M. Nakazawa[7], R. Ohtsuka[8], R. Yuliwulandari[1], L. Batubara[9], M.S. Mustofa[10], K. Tokunaga[1]* 1) Department of Human Genetics, Graduate School of Medicine, The University of Tokyo; 2) Rawai Health Centre; 3) Department of Physiology, Faculty of Medicine, Khon Kaen University; 4) Department of Biological Sciences, Graduate School of Science, The University of Tokyo; 5) Department of Molecular Pathology, Graduate School of Medicine, The University of Tokyo; 6) Division for International Relations, The University of Tokyo; 7) Socio-Environmental Health Sciences, Graduate School of Medicine, Gunma University; 8) National Institute for Environmental Studies; 9) Pharmacology Department, Yarsi University; 10) Biology Department, Yarsi University.

Hair morphology is one of the most differentiated traits among human populations. To identify hair morphology-determining genes, the levels of local genetic differentiation in 170 genes that are related to hair morphogenesis were evaluated by using data from the International HapMap project. Among highly differentiated genes, EDAR harboring an Asian-specific non-synonymous SNP (1540T/C, 370Val/Ala) was identified as a strong candidate. Association studies between genotypes and hair morphology suggested that the EDAR-1540T/C polymorphism is associated with hair thickness. The mean area of hair section in each genotype and in each population indicated that 1540T/C explains a major part of the difference in hair thickness between populations. The geographic distribution of 1540T/C and the long-range haplotype test suggest that 1540C arose after the divergence of Asians from Europeans and has been subject to positive selection in East Asian populations.

Vascular endothelial growth factor gene polymorphisms in Taiwanese women with cervical squamous cell carcinoma. *T.Y. Chang[1], Y.C. Yang[1, 2, 4], Y.J. Lee[1, 3, 5], T.H. Su[2, 4], W.F. Chen[1], H.W. Chan[1], H.F. Liu[1], C.C. Chu[1], M. Lin[1]* 1) Medical Research Department, Mackay Memorial Hospital, Taipei, Taiwan; 2) Department of Gynecology and Obstetrics, Mackay Memorial Hospital, Taipei, Taiwan; 3) Department of Pediatrics, Mackay Memorial Hospital, Taipei, Taiwan; 4) Mackay Medicine, Nursing and Management College, Taipei, Taiwan; 5) College of Medicine, Taipei Medical University, Taipei, Taiwan.

Human papillomavirus (HPV) is considered to be a necessary but not sufficient cause for cervical cancer. Genetic background might partake in the risk and development of cervical cancer. Vascular endothelial growth factor (VEGF) is an important regulator of angiogenesis that has been associated with many human malignancies including carcinoma of uterine cervix. The aim of this study is to evaluate the role of the functional polymorphisms of this gene as genetic markers for cervical squamous cell carcinoma (CSCC) susceptibility. The -2578 A/C, -634 G/C, and +936 C/T polymorphisms were genotyped in 141 CSCC patients and 378 age-matched healthy controls by TaqMan allelic discrimination assay. The presence and genotypes of HPV in CSCC patients were determined by PCR. We found no significant association between the polymorphisms or haplotypes and CSCC. Stratified by the positivity of HPV-16 infection also did not find marked association. Our findings provide no support for the hypothesis that VEGF polymorphisms are associated with increased risk for CSCC in the Taiwanese population.

Correlation of genotype/phenotype in different ethnic groups with primary Congenital Glaucoma. *D. Bercovich[1,2], C. Shochat[1], O. Geyer[3]* 1) The Human Molecular Genetics , Migal - Galilee Bio-Technology Center, Kiryat-Shmona, Israel; 2) Tel Hai Academic College; 3) Department of Ophthalmology, Carmel Medical Center, Haifa, Israel.

Mutations in the CYP1B1 gene are responsible for more than 50% of primary congenital glaucoma (PCG) and mutations in the myocilin gene (MYOC) have also been associated with this disease. The optineurin gene (OPTN), is known to be associated with primary open-angle glaucoma and low-tension glaucoma. We noticed a different clinical presentation of PCG in our patients according to ethnicity. Our goal was to find a correlation between genotype and phenotype in people with congenital glaucoma according to their ethnic origin. The medical history of patients with PCG including the numbers of affected and normal sibs available for each family were obtained by means of a questionnaire and details of the pedigree going back at least 4 generations. In the preliminary screen we screened the entire coding regions of the CYP1B1 gene in 25 individuals from five families of Israeli Moslem Arabs and one Druze family. First line screening was done by the DHPLC apparatus followed by sequencing the DNA. The screening revealed the cause for congenital glaucoma in three of these six families. The mutations includes a homozygous missense mutation R469W in exon 3 of the CYP1B1 gene. In the second family, the affected boy had the typical severe type of PCG and was compound heterozygous for two missense mutations (E229K (paternal) and R368H (maternal)). At another family the patient was also compound heterozygous, but from his mother he got two missense mutations (M1T & L432V) and from his father he got a frame-shift (Pro289 ins C). Screening the MYOC & OPTN genes in the rest of the families with no mutations in the CYP1B1 did not revile any DNA mutations. We are acquiring DNA samples from 15-20 more families from each selected ethnic groups. Establishing the genotype-phenotype correlations of PCG in our various ethnic backgrounds may add valuable knowledge for predicting the prognosis of the disease, for guiding therapeutic decision making and for genetic counseling of carriers of this cause of blindness in children.

Occurrence of germline *PALB2* mutations in ovarian cancer. *H. Erkko[1], J. Nikkilä[1], R. Bützow[2], K. Pylkäs[1], S.M. Karppinen[1], M. Reiman[1], B. Xia[3], D.M. Livingston[3], R. Winqvist[1]* 1) Dep.of Clinical Genetics, University of Oulu and Oulu University Hospital, Oulu, Finland; 2) Division of Pathology, Helsinki University Hospital, Helsinki, Finland; 3) Dana-Farber Cancer Institute and Harvard Medical School, Boston, MA, USA.

BRCA1 and *BRCA2* are the two major genes involved in hereditary predisposition to breast and ovarian cancer. Recently a novel BRCA2 interacting protein PALB2 (partner and localizer of BRCA2) was discovered and found crucial for the DNA damage response functions of BRCA2 (Xia et al. 2006). We have identified a relatively common heterozygous germline mutation c.1592delT in the *PALB2* gene conferring an approximately fourfold increase in the risk of developing breast cancer (Erkko et al. 2007). In the current study we wanted to investigate whether this protein truncating founder mutation is also associated with an increased risk of developing ovarian cancer, the other major phenotype of *BRCA2* mutation carriers besides breast cancer. Consequently, DNA samples of 593 unselected ovarian cancer cases were screened by conformation sensitive gel electrophoresis (CSGE) and direct sequencing for the presence of *PALB2* c.1592delT, and the results were compared to that of 2501 cancer-free controls (used previously in Erkko et al. 2007). Three mutation-positive ovarian cancer patients were identified. The frequency of carriers among ovarian cancer patients was approximately twofold higher than in the controls, but the difference was not statistically significant (p=0.4). Based on these results, and in contrast to the situation with *BRCA2* the relative contribution of *PALB2* mutations in ovarian cancer appears to be very limited.

Inflammatory genes confer risks of subclinical carotid atherosclerosis. *Y.C. Guo[1], H.F. Lin[1], E. Hsi[2], T. Rundek[3], R.L. Sacco[4], S.H.H. Juo[2,3]* 1) Hsiao-Kang Hospital, Kaohsiung City , Taiwan; 2) Graduate Institute of Medical Genetics, Kaohsiung Medical University, Kaohsiung, Taiwan; 3) Department of Neurology, College of Physicians and Surgeons, Columbia University, New York, USA; 4) School of Medicine, University of Miami, FL, USA.

Background and Purpose Carotid intima-media thickness (IMT) is a reliable surrogate marker for subclinical atherosclerosis and cardiovascular risks. Family studies have provided significant evidence for the heritability of IMT, but its genetic determinants remained unsolved.
Methods A total of 96 single nucleotide polymorphisms (SNPs) at 25 inflammatory genes were genotyped in 414 Caribbean Hispanics from the Northern Manhattan Study(NOMAS). Genotyping was performed by the Illumina technology and carotid IMT was assessed by high-resolution B mode ultrasound. The relationships between SNPs and the maximal difference between intima and media (max-IMT) at common carotid artery (CCA) and carotid bifurcation (BIF) were evaluated by multivariate regression analyses. Haplotype analyses were performed by Hap-Clustering program.
Results In the Hispanic population, the CCA max-IMT was significantly associated with age and hypertension (Pearson correlation $p < 0.01$) and the BIF max-IMT was associated with sex and diabetes ($p < 0.05$). Although the two phenotypes were highly correlated ($r^2 = 0.46$, $p < 0.001$), we found different genes in relation to the max-IMT values at these two segments ($p < 0.005$). The interleukin 6 receptor (IL6R) and the transforming growth factor beta 2 (TGFB2) genes were related to BIF max-IMT; while CXC motif chemokine ligand 12 gene (CXCL12) and the interleukin 6 (IL6) genes were related to CCA max-IMT. Haplotype analysis yielded similar results as single SNP analysis. Since the hemodynamic factors have different influences on CCA and BIF, the genetic determinants of the max-IMT values at different segments of carotid artery may vary substantially.
Conclusion The present study identified four inflammatory genes that confer risks to the subclinical carotid atherosclerosis.

A dinucleotide polymorphism in promoter of ankyrin repeat domain 9 gene associated with susceptibility to intestinal-type gastric cancer. *H. Ju, C. Kang* Dept Biological Sci, Rm 1217, KAIST, Daejeon, Korea.

Polymorphisms in promoters can increase or decrease target gene expression, and the altered expression levels may confer susceptibility to complex diseases. We sequenced 3-kb promoter region of the ankyrin repeat domain 9 gene whose expression is down-regulated in gastric cancer tissues and found 6 single-nucleotide polymorphisms (SNPs). The SNPs were genotyped for unrelated 178 intestinal-type gastric cancer patients and 406 non-patient controls. Five successfully genotyped SNPs were significantly associated with intestinal-type gastric cancer ($P < 0.033$). Among them, two adjacent SNPs located at -112 and -111 from the transcription initiation site were in complete linkage disequilibrium ($r^2 = 1$) of each other and had the strongest association (OR = 1.6, $P = 0.00076$). Two variant sequences carrying the dinucleotide polymorphism were inserted in three tandem copies to the pGL3 luciferase vector for promoter activity assay. The risk variant had 1.8-fold reduced promoter activity versus the non-risk variant ($P = 0.0034$) in MKN45 gastric cancer cells. Although functional implications of ankyrin repeat domain 9 in gastric tumorigenesis is not elucidated yet, these results suggest that the risk variant may be functionally associated with increased susceptibility to intestinal-type gastric cancer by reducing the gene transcription level.

Demographic history and natural selection in Oceanic populations inferred from a genome-wide SNP analysis. *R. Kimura[1, 2], J. Ohashi[2], Y. Matsumura[3], M. Nakazawa[4], T. Inaoka[5], R. Ohtsuka[6], K. Tokunaga[2]* 1) Forensic Medicine, Tokai University School of Medicine, Kanagawa, Japan; 2) Human Genetics, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan; 3) Health Informatics and Education, National Institute of Health and Nutrition, Tokyo, Japan; 4) Socio-Environmental Health Sciences, Graduate School of Medicine, Gunma University, Gumna, Japan; 5) Environmental Sociology, Faculty of Agriculture, Saga University, Saga, Japan; 6) National Institute for Environmental Studies, Ibaraki, Japan.

It is thought that major prehistoric human migrations to Oceania occurred twice: 50K and 4K years ago. Indigenous people in Australia and New Guinea, who are anthropologically classified to Australoid, are considered as descendants of the former. Descendants of the latter are thought to be Austronesian-speaking people, who have characteristics of Mongoloid. In this study, we carried out a genome-wide SNP typing on an indigenous New Guinean population, Gidra, and a Polynesian population, Tongans, by using Affymetrix 500K Assay. The SNP data were analyzed together with the data of HapMap samples (YRI, CEU, CHB, JPT) provided by Affymetrix. In agreement with previous studies, our phylogenetic analysis suggested that indigenous New Guineans are closer to Asian populations than to African and European populations. A population structure analysis revealed that genetic contribution to the Tongan population is 70% Mongoloid and 30% Australoid. A high degree of linkage disequilibrium observed in the Gidra and Tongans implies that these populations have experienced population bottlenecks. We performed a scan for natural selection by examining haplotypic variation and identified candidates of locally selected loci, which may include "thrifty genes" in Oceania. Such an approach based on evolutionary medicine, providing a clue to understand how human beings have been adapted to our environments and lifestyles, must also be contribute to revealing gene functions if it is employed together with association analyses and following functional analyses.

Polymorphic marker analysis is more informative in polar body vs. blastomere based PGD. *P. Renbaum[1], T. Eldar-Geva[2], B. Brooks[2], E.J. Margalioth[2], E. Levy-Lahad[1], G. Altarescu[1]* 1) Medical Genetics Unit,Zohar PGD Lab Shaare Zedek Medical Center, Jerusalem, Israel; 2) IVF Unit, Shaare Zedek Medical Center, Jerusalem, Israel.

We performed a retrospective analysis of the level of informativity of our complete marker set for 28 diseases for polar body (PB) and Blastomere analysis. Of 319 polymorphic markers flanking 28 disease genes, 90% provided an informative PB assay in all families undergoing PGD, while only 33% of these markers were informative for blastomere analysis. We also analyzed families carrying five different disorders to assess their eligibility for PB vs. Blastomere PGD. Usage of three or more linked markers in conjunction with the gene mutation nearly eliminates misdiagnosis due to ADO, therefore minimal requirements for PGD were set at 4 informative assays flanking the disease gene. Data was divided into families with four or more informative assays (eligible) and families with less than 3 informative assays (ineligible). In 100% of families recruited for PB-PGD at least 4 assays were always informative. Of 12 families with Myotonic Dystrophy, only 5 families (41%) had four informative markers (11 tested) for blastomere PGD. Ten of 16 carriers of FRAXA premutations (62%) were eligible for blastomere PGD (14 markers tested), while only 3 out of 7 CFTR carrier families (42%) were eligible for blastomere PGD (15 markers tested). For Tay Sachs and Non Syndromic Deafness, of 15 and 14 polymorphic markers analyzed (respectively), no family had four fully informative assays (including mutation) for use in blastomere analysis, and a majority of these families had two or less informative assays, making them ineligible for blastomere PGD. Conclusions: PB-PGD enables diagnosis using multiple polymorphic markers for a significantly higher number of families compared to blastomere PGD. In X-linked diseases where only 3 alleles are analyzed, more families have enough informative markers for blastomere PGD analysis. In diseases with founder mutations and couples from isolated ethnic groups it may be more difficult to perform blastomere PGD due to high frequency of identical haplotypes in the couple.

Mutational Analysis of 58 patients with oculocutaneous albinism in Denmark. *J. Ek, K. Grønskov, A. Sand, T. Rosenberg, K. Brondum-Nielsen* Kennedy Institute - National Eye Clinic, Glostrup, Denmark.

Oculocutaneous albinism (OCA) is a genetic heterogeneous disorder caused by hypopigmentation of the eyes, hair and skin. The hypopigmentation results from defects in melanin production. Lack of melanin in the eyes causes misrouting of the optic nerve fibers, resulting in nystagmus, foveal hypoplasia, strabismus, photophobia and greatly decreased visual acuity. Hypopigmentation of the skin results in enhanced disposition to skin cancers. Clinical diagnosis of subtypes of OCA is difficult due to phenotypic variation and overlap between the different types of OCA, and genetic analysis is often helpful in establishing the diagnosis, and essential for genetic counselling in relation to prenatal diagnosis. We investigated 58 patients with OCA for mutations in four genes known to cause OCA, namely TYR causing OCA1 (OCA1A and OCA1B), OCA2 causing OCA2, TYRP1 causing OCA3 and MATP causing OCA4. Overall, we found at least two mutations capable of explaining the OCA in 44 % of the patients (26 patients of 58), 29 % (17 of 58) had one mutation, and in the remaining 26 % (15 of 58) we did not find mutations in any of the four genes. Of the 26 patients with two mutations, 62 % (16 of 26) had two mutations in TYR, 31 % (8 of 26) had two mutations in OCA2 and 7 % (2 of 26) had two mutations in MATP. No mutations were found in TYRP1.

Glycine N-methyltransferase-/- mice develop chronic hepatitis and glycogen storage disease in liver. *Y.M. Chen[1], S.P. Liu[1], Y.S. Li[1], Y.J. Chen[2], E.P. Chiang[3], A. Li[4], Y.H. Lee[5], T.F. Tsai[2], M. Hsiao[6]* 1) Division of Preventive Medicine, Institute of Public Health, School of Medicine, National Yang-Ming University, Taipei 112, Taiwan; 2) Faculty of Life Sciences and Institute of Genome Sciences, National Yang-Ming University, Taipei 112, Taiwan; 3) Department of Food Science and Biotechnology, National Chung Hsing University, Taichung 402, Taiwan; 4) Department of Pathology, Veterans General Hospital, Taipei 112, Taiwan; 5) Institute of Molecular Biology, Academia Sinica, Taipei 115, Taiwan; 6) Genetics Research Center, Academia Sinica, Taipei 115, Taiwan.

Glycine N-methyltransferase (GNMT) affects genetic stability by regulating DNA methylation and interacting with environmental carcinogens. To establish a Gnmt knockout mouse model, two lambda phage clones containing a mouse Gnmt genome were isolated. At 11 weeks of age, Gnmt-/- mice had hepatomegaly, hypermethioninaemia, and significantly higher levels of both serum alanine aminotransferase and hepatic S-adenosylmethionine. Such phenotypes mimic patients with congenital GNMT deficiency. Real-time PCR analysis of 10 genes in the one carbon metabolism pathway revealed that 5,10-methylenetetrahydrofolate reductase, S-adenosylhomocysteine hydrolase (Ahcy), and formiminotransferase cyclodeaminase (Ftcd) were significantly down-regulated in Gnmt-/- mice. Results from pathological examinations indicate that 57.1% (8/14) of the Gnmt-/- mice had glycogen storage disease (GSD) in their livers. Focal necrosis was observed in male Gnmt-/- livers, while degenerative changes were found in the intermediate zones of female Gnmt-/- livers. In addition, hypoglycemia, increased serum cholesterol, and significantly lower numbers of white blood cells, neutrophils, and monocytes were observed in the Gnmt-/- mice. Real-time PCR analysis of genes involved in the gluconeogenesis pathways revealed that the following genes were significantly down-regulated in Gnmt-/- mice: fructose 1,6-bisphosphatase, phosphoenolpyruvate carboxykinase, and glucose-6-phosphate transporter (G6PT). The Gnmt KO mice model is useful for studies of the pathogenesis of congenital GNMT deficiency, the role of GNMT in GSD as well as in liver tumorigenesis.

Clinical usefulness of array CGH in screening test or diagnosis of male infertility. *D. Cha[1], J. Kang[2], J. Park[3], K. Lee[1], S. Lee[1]* 1) Dept OB/GYN, Kangnam CHA Hosp, Seoul, Korea; 2) Macrogen, Seoul, Korea; 3) Dept OB/GYN, Bundang CHA Hosp, Korea.

Objective: The main purpose of this study is to examine the usefulness of array CGH to detect the genetic abnormality in patients with severe male factor infertility. Methods: 13 infertile men were diagnosed with cytogenetic assay and Y chromosome deletions. 10 sequence-tagged sites (STS) markers were used. These markers were amplified by performing 5 separate multiplex PCR reactions. Genomic DNAs were extracted for MacArray Karyo4000 array. Probe labeling, hybridization, and analysis CGH were performed according to the manufacturer's instructions. The relative copy number of chromosomal segments was analyzed with real-time quantitative polymerase chain reaction. Results: Eleven out of 13 patients had various abnormal karyotyping and seven patients had Y chromosome microdeletions. All the results of BAC-chip were identical to the conventional cytogenetic results in the numerical aberration such as Klinefelter syndrome. Also, it could identify the Y microdeletion (sY117, sY127, 143, sY134, sY138, sY152, sY147, sY149, sY269, sY157, and sY158). and was confirmed by the real-time quantitative polymerase chain reaction. Conclusion: Chromosomal abnormalities and deletions of Y chromosome can result in chromosomally derived infertility. These findings strongly recommend the necessity of genetic screening using array CGH in unknown origin of infertile patients.

Genotype-phenotype correlation of the Phenylalanine Hydroxylase (PAH) Gene in a Multi-Origin Population. *A. Elimelech[1], Y. Anikster[4], G. Schwartz[4], S. Korem[1], T. Yardeni[1], J. Zlotogora[3], N. Gal[4], N. Goldstein[4], B. Vilensky[4], R. Segev[4], S. Avraham[4], R. Loewenthal[5], D. Bercovich[1,2]* 1) Dept Human Genetics, Kiryat-Shmona, Israel; 2) Tel Hai Academic College; 3) Hebrew University of Jerusalem; 4) Metabolic Disease Unit, Tel Hashomer; 5) 5Tissue Typing Unit, Tel Hashomer, Israel.

This study was aimed to characterize the molecular, clinical and epidemiological aspects of the Phenylketonuria (PKU), in Israel. The phenylalanine hydroxylase (PAH) gene that causes PKU, was scanned in order to define mutations, in different ethnic groups, among the Israeli populations (Jewish: Ashkenazi (AZ(/Sephardi (SF); Arabs: Muslim(MU) /Christians(CR); and Caucasian Christians). The research group consists of 180 unrelated PKU patients. The 13 fragments of the PAH gene scanned by DHPLC technology and DNA sequencing.49 different mutations were defined, which were mostly missense point mutations (61.2%). Mutations in the PAH gene were detected in 173 out of the 180 patients, which comprise 324/360 mutant alleles (90%). Nine novel mutations were identified in this study. The mutation L197F, demonstrated high significant association with the Arabs ethnic group. Six common mutations were: IVS10-11G/A, A403V, L48S, A300S, IVS4+5G/T and R408W (5-13.3%). Two mutations, A300S&L48S, demonstrated a significant correlation with ethnic groups, and were found more common in Jewish patients (20%). The IVS2+1G/A, IVS4+5G/T and F55fsX6 mutations, were mostly found in Arabs patients (33%). 17 mutations were defined as null mutations, demonstrating correlation among the in vitro and the metabolic in vivo phenotypes. Phenotype-genotype analysis revealed the effect of 14 missense mutations on the metabolic phenotype: 10 mutations, were consistency associated with the Classic PKU phenotype and 4 mutations, predict the Mild PKU phenotype. In 63.2% of the patients genotypes, the metabolic phenotype could predict the biochemical and clinical state of the patients. The mutation profile definition of PKU, enable us to construct a national database in Israel, and will be valuable for genetic consultation and prognostic evaluation of future cases of PKU.

Atypical Manifestation of Macrothrombocytopenia with Leukocyte Inclusions. *J.R. Choi, J. Song, J.W. Choi* Dept Laboratory Medicine, Yonsei Univ Col Medicine, Seoul, Korea.

Macrothrombocytopenia with Leukocyte Inclusions is a group of rare disorders including May-Hegglin anomaly, Sebastian syndrome, Fechtner syndrome and Epstein syndrome which share common features of giant platelets, thrombocytopenia and Döhle body-like cytoplasmic inclusions on neutrophils. They are all thought to be caused by mutations of MYH9 gene and categorized together as MYH9 disorders. We have experienced two cases with not all of aforementioned cardinal features together with some atypical features not described in literature. First patient was a female aged 30 who was referred to our institution for the evaluation of thrombocytopenia revealed by health screening program. Platelet count was 25,000 /L but actual count estimated by peripheral blood smear was 60,000 - 80,000 /L and giant platelets were frequently seen. Cytoplasmic inclusion was not observed in neutrophils. Besides these findings, moderate to severe elliptocytosis was also present. Bone marrow finding was not remarkable other than abundant megakaryocytes and frequently seen sea-blue histiocytes. Macrothrombocytopenia and elliptocytosis were also found in peripheral blood of her father and sister. Second patient was recently referred for evaluation of incidentally found leukopenia (2,610 /L). Basophilic inclusions with somewhat floppy appearance were observed in nearly all neutrophils without any recognizable toxic finding in peripheral blood smear. Platelet count was absolutely normal (271,000 /L) and there was not any notable aberration in platelet size. Sea-blue histiocytes were also frequently observed as the first case. Screening for mutation targeting exons of MYH9 gene implicated in MYH9 disorders of previously defined cases was performed for the first case and missense mutation corresponding to K373N was found. The same mutation was reported before in one German family of May-Hegglin anomaly. Increased sea-blue histiocytes may imply increased cellular turn over in these patients and cautiously be generalized for other MYH9 disorder cases warranting careful follow up for possible risk of hematologic malignancy.

Clinical, cellular and neuropathological consequences of *AP1S2* mutations: delineation of a novel recognizable X-linked mental retardation syndrome, MESCH-X. *G. Borck[1], A. Molla Herman[5], N. Boddaert[2], F. Encha-Razavi[3], A. Philippe[1], L. Robel[4], F. Brunelle[2], A. Benmerah[5], A. Munnich[1], L. Colleaux[1]* 1) INSERM U781 and Medical Genetics; 2) Pediatric Radiology; 3) Fetal Pathology; 4) Child Psychiatry, Hôpital Necker-Enfants Malades, Paris, France; 5) INSERM U567, Institut Cochin, Paris, France.

X-linked mental retardation (XLMR) is a clinically and genetically heterogeneous condition. Recently, mutations in the *AP1S2* gene, encoding the 1B subunit of the heterotetrameric clathrin-associated adaptor complex AP-1, have been reported in three XLMR families. Here, we report four patients belonging to two unrelated families in which *AP1S2* truncating mutations segregate. Besides previously reported clinical features such as hypotonia, delayed walking, aggressive behavior, small head circumference and speech delay, we found that autism spectrum disorder, calcifications of the basal ganglia appearing during childhood and highly elevated protein levels in cerebrospinal fluid (CSF) are also part of the disease spectrum. Based on these observations, we propose that *AP1S2* mutations are responsible for a clinically recognizable disease that we have named MESCH-X syndrome (mental retardation, elevated CSF protein, speech delay, cerebral calcifications and hypotonia in infancy, X-linked).

Mice deficient for AP-1 subunits and 1A are embryonic lethal, demonstrating that AP-1 is essential for development. By contrast, no major alteration of the stability, subcellular localization and function of the AP-1 complex was observed in patient fibroblasts. Functional analyses suggested that, in these cells, the absence of 1B protein can be compensated by another 1 subunit. Interestingly, while neither macro- nor microscopic structural defects were observed in the brain of an affected fetus harboring a p.R52X mutation, preliminary results suggest decreased cerebellar staining of synaptophysin, a protein that interacts with the AP-1 subunit. Our results suggest that the observed phenotype is the consequence of a subtle and brain-specific defect of AP-1 dependent intracellular protein traffic.

Molecular basis of the Li-Fraumeni syndrome (LFS): an update from the French LFS cohort. *G. Bougeard[1], S. Baert-Desurmont[1,2], C. Martin[2], S. Vasseur[2], L. Brugières[3], A. Chompret[4], D. Stoppa-Lyonnet[5], C. Bonaïti-Pellié[6], T. Frebourg[1,2], the French LFS Network* 1) Inserm U614, Faculty of Medicine, Rouen, France; 2) Department of Genetics, Rouen University Hospital, Rouen, France; 3) Department of Pediatric Oncology, Institut Gustave Roussy, Villejuif, France; 4) Department of Medicine, Institut Gustave Roussy, Villejuif, France; 5) Department of Genetics, Institut Curie, Paris, France; 6) Inserm U535, Villejuif, France.

The Li-Fraumeni syndrome represents one of the most devastating genetic predispositions to cancers and is characterized by a wide spectrum of early-onset malignancies including sarcoma, brain tumours, adrenocortical tumours and premenopausal breast cancers.We have performed an extensive analysis of *TP53*, based on complete sequencing of the 11 exons and on QMPSF to detect genomic rearrangements, in 396 families suggestive of LFS, fulfilling the French LFS network criteria. We detected in 76 families (19%) germline alterations including 4 complete or partial genomic deletions of the *TP53* locus. These results constitute a definitive argument demonstrating that LFS results from a haploinsufficiency at the *TP53* locus. In this series, we confirm that the mean age of tumour onset in *MDMD2* SNP309 G allele carriers (19.2 years) is significantly different from that observed in patients homozygous for the T allele (29.3 years) and found that the mean ages of tumour onset in *MDMD2* G and *TP53*Arg alleles carriers, and in patients with the *MDMD2* T/T and *TP53* Pro/Pro genotype were clearly different (17.6 vs 39.2 years). The earlier development of tumours in *TP53* wt/mt mice compared to wt/- mice, recently reported, led us to compare the age of tumour onset between patients harbouring *TP53* missense mutations (56 patients) and those carrying other types of alterations (31 patients). As predicted by the murine models, we indeed observed a significant difference between both groups (21.1 years vs. 29.2 years). These results support the hypothesis that missense mutations not only inactivate the transcriptional activity of the wild-type protein but have also an additional oncogenic effect.

Multiple sclerosis-like disorder in OPA1-related autosomal dominant optic atrophy. *P. Amati-Bonneau[1], C. Verny[2], D. Loiseau[1], C. Scherer[2], P. Lejeune[2], A. Chevrollier[1], N. Gueguen[1], V. Guillet[1], M. Ferré[1], P. Reynier[1], D. Bonneau[1]* 1) Département de Biochimie et Génétique, CHU Angers, INSERM U694, Angers, France; 2) Département de Neurologie, CHU Angers, France.

Autosomal dominant optic atrophy is a progressive ophthalmologic disorder caused by mutations in the Optic Atrophy 1 (OPA1) gene, a nuclear gene encoding a mitochondrial protein. We report a patient affected by bilateral optic atrophy associated with multiple sclerosis-like (MSL) features due to a novel OPA1 mutation. A 44 yrs-old man was referred to our neurology unit for a sudden onset of pain in the lower left limb. He presented progressive loss of visual acuity associated with trigeminal neuralgia that appeared two years earlier. Neurological examination revealed proprioceptive dysfunction, brisk tendon reflexes, and ankle clonus in the left lower limb. Ophthalmologic examination indicated bilateral visual acuity of 4/10, cæcocentral scotoma, blue-yellow dyschromatopsia, and moderate bilateral optic atrophy. MRI of the cerebrum and the spinal cord showed T2-weighted high intensity lesions, and fluid-attenuated immersion recovery (FLAIR) revealed white matter hyperintensities predominantly in the calloso-septal interface and in the periventricular region. None of the three main mutations or the seven rare mutations in mitochondrial DNA responsible for Lebers hereditary optic neuropathy was found. The sequencing of the OPA1 gene revealed a novel heterozygous S646L mutation absent in 200 controls. Biochemical studies performed on fibroblasts from the patient showed a significant mitochondrial coupling defect associated with reduced ATP production and respiratory function in comparison to 7 controls. Most OPA1 mutations lead to isolated optic atrophy. MSL features have not been reported so far in association with optic atrophy in patients harbouring OPA1 mutations. A more severe energetic defect was found in fibroblasts from this patient suggesting a relationship between the level of mitochondrial dysfunction and central demyelination. These findings reinforce the hypothesis of the implication of mitochondrial energy metabolism in neurodegenerative disorders, particularly in MS.

KRAS and SOS1 mutations in Noonan and related syndromes. *K. Kalidas, A.H. Crosby, S. Jeffery, A. Shaw, M.A. Patton* Medical Genetics Section, Clinical Developmental Sciences, St George's University of London, London, United Kingdom.

Noonan Syndrome, Cardi-facio-cutaneous syndrome (CFC) and Leopard Syndrome are a group of developmental disorders with overlapping congenital abnormalities. Mutations in the PTPN11 (protein tyrosine phosphatase) genes have been found to account for up to 60% of cases of Noonan syndrome. Mutations in the functionally related KRAS and SOS1 genes gene were recently found to cause Noonan syndrome. We have analysed the KRAS and SOS1 genes in a group of 65 individuals with Noonan syndrome, 15 with CFC syndrome and 2 with LEOPARD syndrome, all of whom have been excluded for variants in the PTPN11 gene. Variants in the KRAS gene, including novel mutations in exon 4, were identified in one CFC patient and four Noonan patients. Three SOS1 variants were also identified in Noonan syndrome, two of which were novel. No mutations were identified in the LEOPARD syndrome patients. Our results indicate that KRAS and SOS1 are responsible for only a small proportion of patients with this clinical spectrum and that mutations in other gene(s) contribute to the pathogenesis of these disorders.

Screening of TMC1 Gene Mutations in DFNB7(11) Locus in Autosomal Recessive Non- syndromic Hearing Loss Iranian Population. *N. Bazazzadegan[1], N. Meyer[2], K. Kahrizi[1], M. Mohseni[1], P. Imani[1], N. Nikzat[1], S. Arzhangi[1], M. Sayfati[1], K. Jalalvand[1], J. Malbin[1], K. Javan[1], M. Farhadi[3], R.J.H. Smith[2], H. Najmabadi[1]* 1) Genetics Research Center, GRC/USWR, Tehran, Tehran, Iran; 2) Molecular Otolaryngology Research Laboratories, Department of Otolaryngology Head and Neck Surgery, University of Iowa, Iowa, IA, United States; 3) Research Centre of Ear, Nose, Throat, and Head and Neck Surgery, Iran university of Medical sciences, Tehran, Iran.

Mutations in the transmembrane channel-like gene 1 (TMC1) cause prelingual autosomal recessive (DFNB7/11) and postlingual progressive autosomal dominant (DFNA36) nonsyndromic hearing loss suggesting that this protein plays an important role in the inner ear. These loci map to the same interval on 9q13-q21. The TMC1 protein is predicted to contain 6 transmembrane domains and to have cytoplasmic orientation of N and C termini. Mutations in this gene have been reported in North America in a family with autosomal dominant inheritance, Sudan, also in our two neighbor countries Pakistan and Turkey. Therefore we decided to study this locus in our population. Thirty nine families with autosomal recessive and one family with autosomal dominant non-syndromic hearing loss that include two or more affected children were screened for DFNB7(11) locus by linkage analysis. These families originated from different ethnic groups of Iranian population and were negative for GJB2 and GJB6 mutations in locus DFNB1 . We used D9S301, D9S175, D9S1876 and D9S1837 STR (short Tandem Repeat) markers for this study. Three out of forty families were linked to this locus. Mutation screening of TMC1 gene in these families revealed a homozygous framshift mutation (P.N150kfrx26) in one of the recessive families and a heterozygous mutation (G417R) in dominant family. Mutation detection for the other recessive family is undergoing. We concluded that after DFNB1 and DFNB21 mutations, TMC1 gene mutations are responsible for the most prevalent cause of non- syndromic hearing loss in Iranian population. Key words : linkage analysis, Iran, TMC1, DFNB7(11).

Point mutations in Spanish Charcot-Marie-Tooth families: relevance to clinical genetic testing. *C. Concheiro-Alvarez[1], P. Blanco-Arias[1], B. Quintáns[3], M.T. Darnaude[5], J. Pardo[3], S. Gómara[4], A. Carracedo[1,2], M.J. Sobrido[2]* 1) Grupo de Medicina Xenómica, Universidad de Santiago de Compostela, Spain; 2) Fundación Pública Galega de Medicina Xenómica, Santiago de Compostela; 3) Hospital Clínico de Santiago de Compostela, Santiago de Compostela; 4) Hospital Xeral Cíes, Vigo, Spain; 5) Hospital de Móstoles, Spain.

Genetic analysis and counseling of CMT families without duplication of the PMP22 region at 17p12 is hampered by the extensive genetic heterogeneity. Knowledge of the genetic epidemiology of CMT in our region is relevant to the rationalisation of a protocol for molecular analysis, diagnostic decision making and genotype-phenotype correlation. A group of 47 Spanish patients (most of them Galician) with a clinical diagnosis of probable CMT and negative for the PMP22 duplication was selected for this study. Systematic sequencing of the coding region and exon-intron junctions of PMP22, MPZ, GDAP1, GJB1, EGR2, NEFL, and LITAF was performed. We found six patients carrying previously described mutations (two in MPZ, three in GJB1, 1 in NEFL). Additionally, we identified three novel coding sequence alterations in PMP22 (L5F), GDAP1 (R224del, two independent patients) and GJB1 (P172H). Four synonimous nucleotide changes were identified in NEFL, EGR2 and GJB1, as well as five nucleotide substitutions in intronic regions not contained in dbSNP. All the new sequence variations were screened in 296 Caucasian controls, 200 of which are Galician individuals without any neurological disorder. In all, 17% of patients (8/47) negative for PMP22 duplication could be diagnosed by sequencing. In addition, 10/47 (21%) patients have changes not seen in controls and therefore with a putative pathogenic effect. The most frequently mutated gene was GJB1 (3 known, 1 probable, 2 possible mutations), followed by MPZ (2 known mutations) and NEFL (1 known, one possible). No definite mutations were identified in PMP22, GDAP1, LITAF and EGR2. In conclusion, mutation screening of GJB1, MPZ and NEFL is cost-efficient in our population and should be offered to patients with demyeliniting or mixed neuropathy who tested negative for PMP22 dosage alterations.

Molecular Analysis of Types 1 and 2 Usher Syndrome in Iranian Patients. *K. Kahrizi[1], N. Meyer[4], G. Assadi Tehrani[1], W.J. Kimberling[4], N. Sadeghpour[1], N. Bazazzadegan[1], M. Mohseni[1], M. Jaberi[2], K. Jalalvand[1], S. Arzhangi[1], H. Emamjomeh[3], H. Najmabadi[1], R.J.H. Smith[4]* 1) Genetics Research Ctr, GRC, USWR, Tehran, Tehran, Iran; 2) Retinitis Pigmentosa Institute, Tehran, Iran; 3) Research Center of Ear, Nose, Throat, and Head and Neck Surgery, Tehran Iran; 4) Molecular Otolaryngology Research Laboratories , Department of Otolaryngology Head and Neck Surgery , University of Iowa, Iowa, IA, United States.

Usher syndrome (USH) is a heterogeneous group of diseases that collectively are the most frequent cause of deaf-blindness. Clinically classified as Type 1, 2 or 3 based on auditory, vestibular and ophthalmologic criteria, Usher syndrome Type 1 and 2 are the most common, with Usher syndrome Type 3 being rare outside of Finland. The objective of this study was to determine the prevalence of Usher syndrome Types 1 and 2 in Iran. Thirty Iranian families with Usher clinical symptom were studied for allele segregation consistent with linkage to the following Usher loci: USH1B, USH1C ,USH1D USH1F and USH2B. One family mapped to USH1B, three families mapped to USH1D, one family mapped to USH1F and one family mapped to USH2C. Mutation analysis of MYOVIIA (USH1B) demonstrated homozygosity for 448C>T: R150X in affected persons and in the USH2C family, a single mutation was found in VLGR1. The remaining families are still being studied. Key words: usher syndrome, Iran, USH1F, USH1B.

***FGFR2* Mutations in Turkish patients with craniosynostosis syndrome.** *O. ALPER[1], E. MIHCI[2], H. KAYSERİLİ[3], M.O. CALISKAN[1], S. TACOY[2], L.J. WONG[4], G. LULECİ[1]* 1) DEPARTMENT OF MEDICAL BIOLOGY-GENETICS, FACULTY OF MEDICINE,AKDENİZ UNIVERSITY, ANTALYA, TURKEY; 2) DEPARTMENT OF PEDIATRICS,FACULTY OF MEDICINE,AKDENİZ UNIVERSITY, ANTALYA, TURKEY; 3) DEPARTMENT OF MEDICAL GENETICS,INSTITUTE OF CHILDREN'S HEALTH, FACULTY OF MEDICINE,İSTANBUL UNIVERSITY,ÇAPA,İSTANBUL, TURKEY; 4) DEPARTMENT OF MOLECULAR AND HUMAN GENETICS, BAYLOR COLLEGE OF MEDICINE, ONE BAYLOR PLAZA,HOUSTON,TEXAS, USA.

Fibroblast growth factor receptor 2 (*FGFR2*) gene mutations have been associated with the craniosynostotic conditions of Apert, Crouzon, Pfeiffer, Jackson-Weiss, Saethre-Chotzen, Beare-Stevenson Cutis Gyrata, and Antley-Bixler syndromes in various ethnic groups. Twenty unrelated Turkish patients (6 Apert syndrome, 6 Crouzon syndrome, 2 Pfeiffer syndrome, 2 Saethre/Chotzen syndrome, and 4 unclassified craniosynostosis) were screened for mutations in exons IIIa and IIIc of the *FGFR2* gene by polymerase chain reaction and direct sequencing. In the present study, *FGFR2* gene mutations are detected in all of 6 patients with Apert syndrome (4 with Pro253Arg; 2 with Ser252Trp) and 4 out of 6 patients with Crouzon syndrome (one with Cys342Tyr, three with Trp290Arg), one patient with Cys342Arg mutation in a Pfeiffer syndrome patient. We did not detect any *FGFR2* gene mutations in patients with Saethre-Chotzen syndrome or unclassified craniosynostosis. As this study provides a preliminary data in Turkish population, elucidation of the *FGFR2* mutations in patients with clinical features suggestive of Apert and Crouzon syndrome offers a significant benefit to those families in terms of genetic counseling and prenatal diagnosis.

Opinions of Japanese Life Scientists on Ethical, Legal and Social Implications of Behavioral Genetics. *J. Higashijima[1], K. Kato[1,2], K. Takahashi[1]* 1) School of Biostudies, Kyoto university, Japan; 2) Institute for Research in Humanities, Kyoto University, Japan.

With recent progress in the life sciences, especially in genome sciences, behavioural genetics related research has come into a new phase, being able to elucidate human nature from genetic information. Historically, behavioural genetics has not only been important in the academic world but also dramatically influenced society, with respect to its close relationship to eugenic social policies. This is why it is particularly significant to tackle research on the Ethical, Legal, and Social Issues (ELSI) of behavioural genetics along with and/or in anticipation of its progress. Then what are the ELSI resulting from behavioural genetics now, and in the future? The problem is that existing controversial issues in behavioural genetics are hindering the formation of general consensus for its reliability and/or interpretation of scientific conclusions of bahavioural genetics. Though there have been some discussions about the ELSI of behavioural genetics in some journals, most of them do not reflect a variety of opinions amongst the basic researchers in the life sciences. In this study, we interviewed 64 Japanese front-line life scientists in basic research to clarify both the heterogeneity and homogeneity of their opinions about putatively hot topics in behavioural genetics related research, especially about higher-brain function related issues within the global context of emphasis on the relationship between science and society. Most respondents agreed with the existence of the potential implications in behavioural genetics related research. They also agreed with the necessity of more global discussions or judgments in/from society about related topics. It seems necessary to consider practical border line to distinct genetic therapy and genetic enhancement in cognitive ability. Moreover, it is strongly suggested to form better relationship between scientists and mass-media to improve the quality of scientific information to the society, and to enrich the social discussion about the ELSI in behavioural genetics.

Homozygous mutation of MYBPC3 associated with severe infantile hypertrophic cardiomyopathy at high frequency amongst the Amish. *H. Cross[1], K. Kalidas[2], K.G. Zahka[3], J. Tumbush[4], B.B. Keller[5], C. Galambos[6], K. Gurtz[7], M.A. Patton[2], A.H. Crosby[2]* 1) Department of Ophthalmology, University of Arizona School of Medicine, Tucson, AZ; 2) Clinical Developmental Sciences, St Georges University of London, London, United Kingdom; 3) Department of Pediatrics, Rainbow Babies and Childrens Hospital, Case Western Reserve University, Cleveland, OH; 4) Das Deutsch Center (DDC) Clinic for Special Needs Children, Middlefield, Ohio; 5) Department of Pediatrics, Hospital of Pittsburgh of UPMC, Pittsburgh, PA; 6) Department of Pathology, Children's Hospital of Pittsburgh of UPMC, Pittsburgh, PA; 7) Windows of Hope Genetic Studies, Kimmeridge Trail, OH.

Familial hypertrophic cardiomyopathy (HCM) is a leading cause of sudden cardiac death amongst young and apparently healthy individuals. Mutations within nine genes encoding sarcomeric proteins have so far been identified to act in an autosomal dominant fashion. We have identified an autosomal recessive form of HCM within a group of Amish children that is associated with very poor prognosis and death within the 1st year of life. Affected patients experienced progressive cardiac failure despite maximal medical therapy. Post-mortem histology revealed myofiber disarray and myocyte loss consistent with refractory clinical deterioration in affected infants. Assuming that a founder mutation was responsible we conducted a genome-wide screen for linkage and identified an autozygous region of chromosome 11 which cosegregates with the infant cardiac phenotype. This region contained the MYBPC3 gene, which has previously been associated with autosomal dominant adult onset HCM. Sequence analysis of the MYBPC3 gene identified a novel splice site mutation in intron 30 which was homozygous in all affected infants. All surviving patients with the homozygous MYBPC3 gene mutations (3330+2T>G) have been treated by orthotopic heart transplantation.

Mutational spectrum of spatacsin-associated spastic paraplegia (SPG11). *P. Bauer[1], U. Hehr[2], B. Winner[3], R. Schuele[4], W. Koehler[5], G. Uyanik[3], A. Engel[1], A. Hehr[2], S. Ploetz[3], J. Gamez[6], A. Rolfs[7], A. Oelmez[8], M. Bonin[1], H. Topaloglu[8], U. Bogdahn[3], B.H.F. Weber[2], L. Schoels[4], O. Riess[1], J. Winkler[3]* 1) Dept Medical Genetics, Univ Tubingen, Tubingen, Germany; 2) Dept of Human Genetics, Univ Regensburg, Regensburg, Germany; 3) Dept of Neurology, Univ Regensburg, Regensburg, Germany; 4) Research Division for Clinical Neurogenetics, Centre of Neurology and Hertie-Institute for Clinical Brain Research, Univ Tuebingen, Tuebingen, Germany; 5) Dept of Neurology, Hospital Hubertusburg, Wermsdorf, Germany; 6) Dept of Neurology, Hospital General Vall d'Hebron, Barcelona, Spain; 7) Dept of Neurology, Univ Rostock, Rostock, Germany; 8) Dept of Pediatric Neurology, Hacettepe University, Ankara, Turkey.

Hereditary spastic paraplegia (HSP) comprise a heterogeneous group of neurodegenerative disorders resulting in progressive spasticity of the lower limbs. One form of autosomal recessive HSP (ARHSP) with thin corpus callosum (TCC) was linked to chromosomal region 15q13-15 (SPG11) and recently associated with mutations in the Spatacsin gene. By means of direct sequencing, a total of 11 causal mutations were identified in the KIAA1840 coding sequence (now designated Spatacsin) including 3 in consanguineous pedigrees from Turkey, one from Saudi Arabia and Germany as well as in 4 sporadic patients of German or Spanish origin. All mutations identified represent truncating mutations and include one previously reported and 6 novel frame-shift mutations as well as two novel nonsense mutations. Furthermore, we report two different splice mutations associated with the SPG11 phenotype. These mutations have been validated by mRNA analyses in peripheral blood cell transcripts. Mutations are distributed throughout the first 30 exons of the Spatacsin gene without obvious clustering in mutational hotspots. In conclusion, we could (i) demonstrate Spatacsin-mutations in our linked SPG11 families, (ii) extend the mutational spectrum for Spatacsin-mutations being scattered throughout the coding sequence, (iii) demonstrate that SPG11 is a recognizable clinical condition even in unlinked sporadic paraplegic patients with thin corpus callosum (TCC).

A whole-genome scan reveals linkage of celiac disease to 6q21-22 and 22q13 in extended pedigrees from Hungary and Finland. *E. Einarsdottir[1], L. Koskinen[1], I. Korponay-Szabo[2], K. Mustalahti[3], K. Kurppa[3], J. Partanen[5], M. Mäki[3], J. Kere[1,4], P. Holopainen[1]* 1) Medical Genetics, Helsinki University, Helsinki, Finland; 2) Heim Pal Childrens Hospital, Budapest and University of Debrecen, Hungary; 3) University of Tampere and Tampere University Hospital, Finland; 4) Karolinska Institute, Huddinge, Sweden; 5) Red Cross Blood Service, Helsinki, Finland.

Celiac disease is a complex genetic disorder caused by inflammatory responses to gluten. Apart from the known susceptibility genes at HLA-DQ locus, the search for additional risk genes continues. We performed a whole-genome linkage scan in two extended four-generation pedigrees consisting of multiple individuals with celiac disease. Our aim was to identify genomic regions shared by the affected individuals within the pedigrees, regions harbouring genetic factors influencing susceptibility to celiac disease. Approximately fifty thousand single-nucleotide polymorphisms were genotyped with the Affymetrix 50K microarray system and analysed by affecteds-only non-parametric linkage analysis. We selected individuals separated by as many meiosis as possible in order to minimise random sharing of genomic segments and to narrow down the disease-linked genetic regions. Our material consisted of one pedigree from central Hungary and one from Finland. Six patients from the Finnish family were genotyped and seven from the Hungarian family. In addition to the well known HLA-DQ risk genes, we identified linkage in both families to a locus on chromosome 6q21-22 (LOD= 2,01 p=0.0012). The Finnish family also showed linkage to a locus on chromosome 22q13 (LOD= 1,29, p=0.007). These regions have previously been suggested to be involved in celiac disease in European populations, but the primary risk genes at these loci remain unknown. Further finemapping in our larger independent family materials will be performed to narrow down the linked region and to identify the disease-associated gene(s). Characterization of novel genetic factors in celiac disease will help us understand the pathogenesis of this complex disorder.

Mutations in TOPORS cause autosomal dominant retinitis pigmentosa with peripheral RPE atrophy. *C. Chakarova[1], M. Papaioannou[1], A. Shah[1], N. Waseem[1], I. Lopez[2], B. Wissinger[3], E. Zrenner[3], C. Ponting[4], R. Koenekoop[2], S.S. Bhattacharya[1]* 1) Molecular Genetics, Institute of Ophthalmology, London, UK; 2) The McGill Ocular Genetics Laboratory, McGill University Health Centre, Montreal, Canada; 3) Department of Pathophysiology of Vision and Neuro-Ophthalmology, University Eye Hospital, Tubingen, Germany; 4) The MRC Functional Genetics Unit, University of Oxford, Department of Human Anatomy and Genetics, Oxford OX1 3QX, UK.

Purpose: To identify the disease-causing mutation in a large French-Canadian family with an autosomal dominant retinal degeneration and perivascular RPE atrophy which maps to 9p (RP31). To explain the molecular basis for photoreceptor cell death due to mutations in the RP31 gene. Methods: Linkage analysis was used on twenty-six individuals from the French-Canadian family after standard ophthalmological evaluations. To identify the disease causing mutation, 53 genes within the critical interval of 14 Mb underwent direct genomic sequencing. A variety of molecular and cell biological techniques were used (bioinformatics, Western blot, immunohistochemistry) in order to explore the disease mechanism involved in this particular retinal degeneration. Results: Here we report the identification of the gene for autosomal dominant retinitis pigmentosa (RP31). TOPOisomerase I - binding - RS protein (TOPORS) is mutated in two families of different origins (French and German). Both mutations cause frameshift leading to premature stop codon and are thus predicted to result in truncated proteins. RNA expression studies indicate the gene to be ubiquitously expressed. Functional studies show a specific cellular localization of TOPORS in the area of the connecting cilium of photoreceptor cells in human and mouse retina. Conclusions: This is the first report of a ubiquitous and multifunctional gene causing only retinitis pigmentosa. Due to the nature of the mutations (leading to truncated protein) we suggest haploinsufficiency as the disease mechanism.

Hereditary cancer syndrome found by aCGH in a patient being evaluated for a Prader-Willi-like syndrome. *B. Heald[1, 2], R. Moran[1], M. Milas[3], C. Garner[3], C. Burke[4], B. Torchia[5], J. Coppinger[5], C. Eng[1, 2, 6]* 1) Genomic Medicine Instit, Cleveland Clinic, Cleveland, OH; 2) Taussig Cancer Center, Cleveland Clinic, Cleveland, OH; 3) Dept of Surgery, Cleveland Clinic, Cleveland, OH; 4) Dept of Gastroenterology, Cleveland Clinic, Cleveland, OH; 5) Signature Genomics Laboratory, Spokane, WA; 6) Dept of Genetics, Case Western Reserve University College of Medicine, Cleveland, OH.

A 22-year-old woman was referred for a genetics evaluation. Several features consistent with Prader-Willi syndrome (PWS) were observed, including mental retardation, short stature, obesity, hypotonia, and small hands and feet. However, the patient lacked many of the key behavioral features of PWS. The patient was adopted and no information is known about her family history. Routine karyotype and chromosome 15 methylation studies were normal. Array comparative genomic hybridization (aCGH) identified a deletion of 5q22 encompassing the APC tumor suppressor locus, resulting in familial adenomatous polyposis (FAP) with mental retardation. A colonoscopy revealed hundreds of polyps throughout the colorectum. Ultrasound of the thyroid detected nodules confirmed on biopsy and operative resection to be papillary carcinoma of the morula type, a type of cancer found in less than 2% of patients with FAP. Only 16 other patients are described in the literature with interstitial chromosome 5 deletions encompassing APC. All patients had mental retardation, dysmorphic facial features, and other developmental abnormalities. The presentation of FAP in these patients is similar to that described in patients with mutations in APC. Our patient is the only case in which the deletion was detected on aCGH and not routine karyotype. The implementation of aCGH into clinical practice has the ability to identify syndromes in patients that were previously unsuspected. The power of this improved technology lies in its genomic assessment of copy number changes at a higher resolution than routine karyotyping. In addition to addressing the cognitive needs of this patient, early identification of a cancer predisposition syndrome and recommendations for appropriate surveillance were made.

Type-2 NF1 deletions are highly unusual by virtue of the absence of non-allelic homologous recombination hotspots and an apparent preference for female mitotic recombination. *H. Kehrer-Sawatzki[1], K. Steinmann[1], D.N. Cooper[2], L. Kluwe[3], N.A. Chuzhanova[4], C. Senger[1], E. Serra[5], C. Lazaro[6], M. Gilaberte[7], K. Wimmer[8], V.F. Mautner[3]*

Five percent of patients with NF1 exhibit gross deletions that encompass the NF1 gene and its flanking regions. The breakpoints of the common 1.4 Mb (type-1) deletions are located within low-copy repeats (NF1-REPs) and cluster within a 3.4 kb hotspot of non-allelic homologous recombination (NAHR). Here we present the first comprehensive breakpoint analysis of type-2 deletions, a second type of recurring NF1 gene deletions. Type-2 deletions span 1.2 Mb and the breakpoints are located within the SUZ12 gene and its pseudogene. Breakpoint analysis of 13 independent type-2 deletions did not reveal any hotspots of NAHR. Intriguingly, 12 of the 13 type-2 deletions are characterized by somatic mosaicism indicating a positional preference for NAHR within the NF1 gene region. All mosaic type-2 deletions were found in females what contrasts with the equal gender distribution noted for type-1 NF1 deletions. Whereas type-1 deletions are caused by interchromosomal meiotic NAHR, type-2 deletions are generated by intrachromosomal NAHR between SUZ12 and its pseudogene during mitosis. Such a clear distinction between the preferred sites of mitotic versus meiotic NAHR is unprecedented in any other genomic disorder.

The LRRK2 G2019S mutation is both common and highly penetrant in a Tunisian non-familial Parkinsons Disease case-control study. *R.A. Gibson[1], J. Kachergus[2], L. Ishihara-Paul[1], M. Hulihan[2], R. Upmanyu[1], L. Warren[1], S. Oldham[1], R. Amouri[3], S. Ben Yahmed[3], M. Kefi[3], M. Zouari[3], S. Ben Sassi[3], P.A. Akkari[1], R. Elango[1], R. Prinjha[1], L. Ragone[1], L.T. Middleton[1], P.M. Matthews[1], F. Hentati[3], M. Farrer[2]* 1) Research and Development, GlaxoSmithKline, USA and UK; 2) Dept of Neuroscience, Mayo Clinic, Jacksonville, Florida, USA; 3) Dept of Neurology, Institut National de Neurologie, Tunis, Tunisia.

Parkinsons disease (PD) is the second most common neurodegenerative disorder after Alzheimer disease, affecting approximately 1% of the population aged over 50. The majority of patients are considered sporadic with age, genetic and environmental risk factors as important determinants of disease penetrance. Studies of multiplex PD families have identified a number of genes in PD, which have provided insights into the mechanisms of the more frequent sporadic form of disease. One such example is the leucine-rich repeat kinase 2 gene (LRRK2) which is implicated in autosomal dominant forms of PD. We previously investigated the frequency of the most common substitution of LRRK2 (G2019S, 6055G>A), in Tunisian-based consanguineous PD families. The G2019S substitution was identified in 39 of the 88 families (44%) examined. To investigate the role of the Lrrk2 G2019S substitution in non-familial forms of PD, an additional 239 individuals with non-familial sporadic PD and 371 unrelated controls were recruited from the Institut National de Neurologie, Tunisia which provides a specialized neurological service to the entire country. All PD patients and controls received neurological examinations and completed standardized questionnaires collecting demographic and clinical information. All cases and controls recruited were screened for the G2019S substitution. In total 35% (73 of the 239) of the sporadic cases recruited and only 1.9% of the controls (7 out of the 371 recruited) were found to have the G2019S mutation. Of the 7 controls that were heterozygous for this change, 5 were younger than 60 and need further evaluation. This finding indicates the high level of penetrance of this substitution its applicability to sporadic PD and the relevance for genetic screening.

Mu-opioid receptor A118G polymorphism is associated with susceptibility to nausea and vomiting in tramadol-treated patients of osteoarthritis. *E. Kim[1], CB. Choi[2], JS. Song[3], YM. Kang[4], CH. Suh[5], J. Lee[6], JY. Choe[7], CK. Lee[8], WT. Chung[9], HA. Kim[10], SC. Bae[2], C. Kang[1]* 1) Dept Biological Sci, KAIST, Daejon, Korea; 2) Dept Int Medicine, Hosp Rheumatic Diseases, Hanyang Univ Coll Medicine, Seoul, Korea; 3) Dept Rheumatology, Chung-Ang Univ Coll Medicine, Seoul, Korea; 4) Dept Int Medicine, Kyungpook National Univ Sch Medicine, Daegu, Korea; 5) Dept Int Medicine, Ajou Univ Sch Medicine, Suwon, Korea; 6) Dept Int Medicine, Ewha Womans Univ Coll Medicine, Seoul, Korea; 7) Dept Int Medicine, Catholic University of Daegu School of Medicine, Daegu, Korea; 8) Dept Int Medicine, Yeungnam Univ Coll Medicine, Daegu, Korea; 9) Dept Int Medicine, Dong-A Univ Coll Medicine, Busan, Korea; 10) Dept Int Medicine, Hallym Univ Coll Medicine, Chuncheon, Korea.

Tramadol used for the treatment of moderate to severe pains is also effective in treatment of osteoarthritis but can cause various adverse events. Clinically active metabolites of tramadol act as agonists against mu-opioid receptor distributed in the chemoreceptor trigger zone, which then activates the vomiting center possibly leading to emetic responses. Mu-opioid receptor plays a key role in pain control as a primary target of opioid drugs. The A118G polymorphism in mu-opioid receptor gene (*OPRM1*), although encoding for an Asn40Asp substitution, has been shown to drastically alter translation efficiency of mRNA and hence the protein level. In this study, 193 patients with osteoarthritis who had been treated with tramadol were recruited. Among them 106 patients did not show any side effects and the remaining 87 patients showed one or more side effects including nausea, dizziness, and vomiting. The A118G polymorphism was significantly associated with susceptibility to nausea and vomiting in tramadol-treated patients of osteoarthritis (P = 0.025, OR = 0.579, 95% CI = 0.358-0.937) in comparison between the patients (n = 54) having suffered from nausea or vomiting and those (n = 139) not having suffered from either. The results suggest that the minor-allele G118 carriers are better protected from the tramadol-caused emetic responses possibly by reducing the protein level.

Cutis Laxa Type II associated with craniosynostosis, joint contractures and corpus callosum agenesis. *R. Garcia, F. Suarez* Inst de Genetica Humana, Pontificia Univ Javeriana, Bogota, D.C., Colombia.

We presented a new born of masculine sex with Cutis Laxa type II, associated with craniosynostosis, joint contractures and corpus callosum agenesis. Product of first pregnancy, mother of 25 year old, parents were not known to be related. He presents to the physical examination weight of 2800 grams, height of 48 centimeters, OFC of 41 centimeters. The skin is loose with redundant folds, with a slow return on stretching, but the facial skin were unaffected. Head: microcephaly, brachycephaly, wide anterior fontanel. Extremities: rhizomelic shortness of upper and lower limbs, elbow and wrist contractures, finger flexion contractures, bilateral equinovarus. Abdominal wall: bilateral inguinal hernia. Neurologic: Marcus Gunn phenomenon and hypotonia. Radiological images: widened metaphyses, congenital hip dislocation; cerebral MRI: corpus callosum agenesis and colpocephaly. Skin Biopsy showed a diminution of elastic fibers throughout the dermis. High resolution cytogenetic analysis showed no abnormality. No evidences of abnormalities in copper. The clinical characteristics, with facial skin unaffected, let us classifies the patient as an affected by Cutis Laxa type II with neurological abnormalities not described before.

HIGH INCIDENCE OF DHPR DEFICIENCY IN SOUTH ITALY : REPORT OF THREE PATIENTS WITH THE SAME MUTATION (L14P). *D. Concolino, L. Muzzi, M. Rapsomaniki, M.G. Pascale, M.T. Moricca, F. Ceravolo, P. Strisciuglio* Dept Pediatrics, Univ Catanzaro, Catanzaro, Italy.

Deficiency of dihydropteridine reductase (DHPR) causes a variant form of phenylketonuria associated with a devastating neurological disease. Hyperphenylalaninaemias (HPA) with BH4 deficiency are about 3% of all HPA. We describe three patients from Calabria, a southern region of Italy, affected by DHPR caused by same mutation. We used serum prolactin levels as a marker for optimal dosage of hydroxylated precursors in long-term treatment monitoring. All patients were children of unrelated parents DHPR diagnosis were made by BH4 oral loading test (20mg/Kg) and the measurement of DHPR activity in erythrocytes. None of patients showed neurological signs before the beginning of pharmacological treatment. In the case 1 the annual median dosage of L-Dopa was of 5,19mg/Kg/die. Other two patients showed increase of serum levels of prolactin that required adjustments of L-dopa independently of the body weight. Actually, case 2 (5 years and 3 months) needs L-Dopa at the dosage of 6.0mg/Kg/die and case 3 (4 years) needs L-Dopa at the dosage of 5.8 mg/Kg/die. The outcome of three patients is until now very favourable. Molecular analysis on QDPR gene on these three patients showed the mutation pL14P in homozygosity on exon 1. This mutation has been found in Mediterranean populations and a founder effect has been hypothesized. Thus our molecular data seem to confirm this hypothesis and could explain high incidence of DHPR deficiency in our region. In conclusion we found an high incidence of DHPR deficiency in our region and we show that the prolactin could be a good indicator of optimal dosage of neurotransmitter precursors.

Multiple rare non-synonymous variants in APC predispose to colorectal tumours. *J.P. Cheadle[1], D. Azzopardi[1], A.R. Dallosso[1], K. Eliason[2], B.C. Hendrickson[3], N. Jones[1], E. Rawstorne[1], J. Colley[1], V. Moskvina[4], C. Frye[2], J.R. Sampson[1], R. Wenstrup[2], T. Scholl[3]* 1) Institute of Medical Genetics, Cardiff University, Cardiff, UK; 2) Myriad Genetic Laboratories, Inc., 320 Wakara Way, Salt Lake City, UT; 3) Genzyme Genetics, 3400 Computer Drive, Westborough, MA; 4) Biostatistics and Bioinformatics Unit, Cardiff University, Cardiff, UK.

It has been proposed that multiple rare variants in numerous genes collectively account for a substantial proportion of multifactorial inherited predisposition to a variety of chronic diseases including colorectal cancer (CRC). We have studied this hypothesis by re-sequencing the adenomatous polyposis coli (APC) gene in 691 unrelated North American patients with colorectal tumours and 969 matched healthy controls. Rare inherited non-synonymous variants were significantly over represented in patients who did not carry conventional pathogenic mutations in the APC or MUTYH genes (non-FAP non-MAP patients) (81/480, 16.9%) as compared to FAP/MAP patients (20/211, 9.5%; P=0.0113). Furthermore, significantly more non-FAP non-MAP patients carried rare non-synonymous variants as compared to healthy controls (P=0.0166). Seven out of sixteen non-synonymous variants were shown to alter -catenin-regulated transcription and in silico analyses predicted that over half of the 61 different variants identified were likely to affect function. These data show that multiple rare non-synonymous variants in APC play a significant role in predisposing to colorectal tumours.

In vivo screen for enhancer activity using lentivirus-mediated transgenesis. *M. Friedli[1,5], I. Barde[2,5], C. Attanasio[1,5], M. Arcangeli[1,5], A. Quazzola[2,5], S. Verp[2,5], F. Spitz[3,4,5], D. Duboule[3,5], D. Trono[2,5], S.E. Antonarakis[1,5]*
1) Department of Genetic Medicine and Development,University of Geneva,Switzerland; 2) School of Life Sciences, EPFL,Lausanne,Switzerland; 3) Department of Zoology and Animal Biology,University of Geneva, Switzerland; 4) EMBL Heidelberg,Heidelberg,Germany; 5) National Research Centre Frontiers in Genetics.

Finding sequences that control spatial and temporal expression of genes is important to understand genome function. In this study, we aim to perform an in vivo unbiased screen for enhancer activity in a 200-kilobase DNA fragment using lentiviral-mediated transgenesis. While previous studies have used evolutionary conservation as an indicator of regulatory potential, our study is without any bias towards a particular sequence feature. We chose a mouse BAC corresponding to a region of human chromosome 21; this region was selected because it contains the olig1 and olig2 genes that are expressed specifically in the CNS and thus potentially interesting for Down Syndrome. In order to screen this fragment systematically for enhancer activity, we generated a library of overlapping clones by digesting the BAC with CviJ and cloning upstream of a LacZ reporter in a lentiviral vector. The library contains 87 clones to date, with sizes ranging from 2-4 kb covering 70 percent of the BAC sequence. We are generating lentivectors for each segment of the library and injecting them in pools of 10 in mouse oocytes. E11 Embryos are recovered from foster mothers and stained for LacZ in order to identify expression patterns. The first three pools injected yielded 10 of 62 LacZ positive embryos with an average of 3.5 transgene integrations per embryo. The inserted segments were sequenced from all embryos in order to correlate a pattern of expression with a specific sequence. Different fragments, (some containing evolutionary conserved sequences) were identified that potentially contain gene expression regulators. Injection of individual sequences will be used to confirm enhancer activity of candidate clones. This approach will enable us to probe a substantial genomic segment for enhancer activity in mouse embryos.

Molecular analysis of the SHOX gene in 409 children with short stature. *C. Huber[1], M. Rosilio[2], A. Munnich[1], V. Cormier-Daire[1], The French SHOX Genesis Module* 1) Department of Medical Genetics and INSERM U781, Necker Hospital, Paris, France; 2) Lilly France, Suresnes, France.

We present the results of the molecular analysis of the SHOX gene and the PAR1 region in a series of short stature children with normal endocrine screening. This study was part of GeNeSIS, the international observational study conducted by Eli Lilly and Company. The aim of the study was to determine 1) the prevalence of SHOX anomalies in short stature children who were followed by pediatric endocrinologists, 2) the frequency of clinical evidence of Madelung Deformity (MD) in children with SHOX anomalies and 3) the value of a family history of short stature for deciding on whether SHOX testing should be performed. The only inclusion parameter was height SDS below -2. 409 children were included by 38 participating centres (from January 2003 to February 2007). The series comprises 248 girls and 161 boys with age ranging from 2 to 17 years, 172 were at a prepubertal stage. The SHOX molecular screening included extensive microsatellite analysis of the PAR1 region and direct sequencing of the SHOX gene. We observed a total of 103 SHOX anomalies including 49 deletions of variable sizes encompassing SHOX, 37 deletions located downstream of the SHOX gene and 17 point mutations. Among the 103 anomalies, 50 were identified in children with clinical evidence of MD, with a large preponderance of girls. In the 53 others, the proportion of boys and girls was similar. The absence of MD in this group may reflect the difficulty to clinically diagnose dyschondrosteosis (DCS) in young children before puberty and in males. 78 SHOX anomalies were inherited and short stature was observed in 69 parents highlighting the importance of evaluating the family. We conclude that SHOX deficiency is a frequent cause of short stature. Evaluation of the family history, taking especially signs of DCS such as MD into account, may guide the physician to identify subjects who should undergo SHOX testing. Finally, the observation of a large proportion of deletions located downstream of the SHOX gene emphasizes the necessity of an extensive microsatellite analysis of the PAR1 region.

Intrathecal delivery of iduronate 2-sulfatase to the CNS of cynomolgous monkeys. *A.R. Garcia, J. Pan, A. Stronge, M. Tonini, M. Alessandrini, C. Neal, J. Lieb, Y. Lu, M. Wiles* Preclinical Research, Shire Human Genetic Therapies, Cambridge, MA.

Hunter syndrome, or Mucopolysaccharidosis (MPS) II, is an inherited X-linked disorder caused by a deficiency of the lysosomal enzyme iduronate 2-sulfatase (I2S), resulting in the accumulation of undegraded glycosaminoglycans (GAG). In contrast to the attenuated form, the severe form of MPS II adversely affects CNS function. Intrathecal (IT) injection of I2S in cynomolgous monkeys was performed to examine the effect of dose on distribution in the CNS. Eleven normal monkeys received 3 monthly IT bolus injections of 3 mg (n=3), 30 mg (n=3), 100 mg (n=2), or 150 mg (n=3) I2S via an implanted lumbar port/catheter assembly; 3 monkeys served as vehicle controls. Brain and spinal cord were collected 24 hr after the final injection. I2S levels were determined by a sensitive activity assay. Distribution of human I2S within the CNS was verified by immunohistochemistry (IHC). All IT injections were well tolerated with no visible adverse reaction. At the 3 mg dose there was no increase in I2S activity in the brain compared to endogenous levels measured in controls. At 30, 100, or 150 mg doses, I2S activity was significantly elevated (4X, 8X, and 10X of endogenous levels, respectively). IHC for I2S revealed a dose dependent delivery of enzyme throughout the brain. At the 3 mg dose, I2S staining was seen in meningial and some glial cells but not neurons. At higher doses, many cerebral neurons, meningial, glial, and perivascular cells were stained more intensely for I2S. Deep penetration of enzyme in cerebral neurons from layer I (surface) near the meninges to layer VI (near the deep white matter) was seen by I2S IHC. Neuronal I2S staining was equivalent between frontal, middle, and rear sections of the brain. Similarly, brain I2S activity was evenly distributed along the brains rostro-caudal axis. In summary, repeated IT injection of I2S results in dose dependent, widespread delivery to many cell types of the CNS and in deep penetration of the enzyme in cerebral cortex. Therefore, IT injection of I2S may represent a useful approach for the treatment of CNS manifestations of MPS II.

Association of RF and anti-CCP positivity, but not carriage of shared epitope or *PTPN22* susceptibility variants, with response to anti-TNF treatment in RA. *A. Barton[1], K.L. Hyrich[1], BRAGGSS[2], A. Morgan[3], A.G. Wilson[4], J. Isaacs[5], J. Worthington[1], C. Potter[1]* 1) University of Manchester, UK; 2) Biologics in Rheumatoid Arthritis Genetics and Genomics Study Syndicate; 3) University of Leeds, UK; 4) University of Sheffield, UK; 5) Newcastle University, UK.

Purpose: To determine whether rheumatoid factor (RF), anti-CCP antibodies, or carriage of shared epitope (SE) and *PTPN22* susceptibility variants predict response to anti-TNF therapy in a large UK cohort of patients with rheumatoid arthritis (RA).

Methods: UK-wide multi-centre collaborations were established to recruit 642 patients treated with anti-TNF drugs for RA (46% received Infliximab, 43% Etanercept and 11% Adalimumab). Serum RF, anti-CCP antibody and SE status were determined using commercially available kits. *PTPN22* R620W genotyping was performed using a Sequenom MassArray platform. Linear regression analyses were performed to investigate association between these 4 factors and drug response at 6 months, defined as the absolute change in disease activity score (DAS28). Analyses were performed in the entire cohort and also stratified by anti-TNF agent.

Results: Eighty nine per cent of patients tested positive for RF and 82% positive for anti-CCP. Patients who tested negative for RF had a 0.48units greater mean improvement in DAS28 compared to RF positive patients (95% CI: 0.08, 0.87, p=0.02). A better response was also seen among patients who tested negative for anti-CCP (Coef: 0.39, 95% CI: 0.07, 0.71, p=0.02). Upon stratification, association of both antibodies was restricted to the Infliximab-treatment group. No association was demonstrated between drug response and SE or *PTPN22* carriage.

Conclusion: The presence of RF or anti-CCP antibodies was associated with a reduced response to anti-TNF drugs as a whole and Infliximab, in particular. However, the presence of these antibodies only accounts for a small proportion of the variance in treatment response. It is likely that genetic factors will contribute to treatment response but these do not include the 2 genes known to confer susceptibility to RA.

From Stüve-Wiedemann syndrome to Crisponi syndrome. *N. Dagoneau[1], S. Bellais[1], B. Leheup[2], P. Blanchet[3], P. Sarda[3], L.I. Al Gazali[4], M. Di Rocco[5], A. Munnich[1], V. Cormier-Daire[1]* 1) Department of Medical Genetics and INSERM U781, Necker Hospital, Paris, France; 2) Department of Clinical Genetics, Children Hospital, Vandoeuvre les Nancy, France; 3) Department of Genetics, Arnaud de Villeneuve Hospital, Montpellier, France; 4) Department of Pediatrics, Faculty of Medicine and Health Sciences, Al Ain, United Arab Emirates; 5) Department of Pediatrics, Gaslini Institute, Genoa, Italy.

Stüve-Wiedemann syndrome (SWS) is characterized by bowing of the long bones with internal cortical thickening and flared metaphyses, trismus in response to stimuli and camptodactyly. These last features are shared by Crisponi syndrome which is distinct from SWS by the absence of congenital limb bowing. The clinical course of both syndromes is characterized by major feeding and respiratory difficulties and temperature instability usually leading to death in the first months of life.We have collected the samples of 45 SWS families and identified mutations in the Leukemia Inhibitory Factor gene (LIFR) in 33/45 SWS families. We have then excluded the LIFR in three families with Crisponi syndrome but identified mutations in the Cytokine Receptor-like Factor 1 (CRLF1) in all. Following this initial study, we identified homozygote CRLF1 mutations (c.178TG, G60S) in two sibs from Morocco with Crisponi syndrome. We also considered CRLF1 as a candidate gene in the SWS patients without any LIFR mutation but we found no mutation. CRLF1 forms a heterodimer complex with Cardiotrophin Like Cytokine Factor 1 (CLCF1) and this heterodimer competes with Ciliary Neurotrophic Factor (CNTF) for binding to the ciliary neurotrophic factor receptor complex which is composed of CNTFR, gp 130 and LIFR. These findings suggest a key role of the CNTFR pathway in the function of the autonomic nervous system while the specific impairment of the LIFR pathway is presumably involved in the bone manifestations characteristic of SWS.

Prediction of osteoporosis candidate genes by computational disease gene identification strategy. *Q. Huang[1], G. Li[1], W. Cheung[1], Y. Song[2], A. Kung[1]* 1) Dept Medicine, Univ Hong Kong, Hong Kong, Hong Kong; 2) Genome Research Center, Univ Hong Kong, Hong Kong, Hong Kong.

Osteoporosis is a complex disease with strong genetic component. To date, more than twenty genome wide linkage scans across multiple populations have been launched to hunt for osteoporosis susceptibility genes. Some significant or suggestive chromosomal regions of linkage to bone mineral density have been identified and replicated in genome-wide linkage screens. However, identification of key candidate genes within these confirmed regions is challenging. Now some bioinformatics tools are available for disease gene identification. These tools use information extracted from public online databases, such as sequence data, medical literature, gene ontology and function annotation, and information on biology, function and gene expression. In this study we used five freely available bioinformatics tools (Prioritizer, Geneseeker, PROSPECTR and SUSPECTS (PandS), Disease Gene Prediction (DGP) and Endeavour) to analyze the thirteen well replicated osteoporosis susceptibility loci (1p36, 1q21-25, 2p22-24, 3p14-25, 4q25-34, 6p21, 7p14-21, 11q14-25, 12q23-24, 13q14-34, 20p12, 2q24-32 and 5q12-21) and identify a subset of most likely candidate osteoporosis susceptibility genes that are largely involved in TGF- signaling, GM-CSF signaling, axonal guidance signaling, PPAR signaling, and Wnt/-catenin signaling pathway. The list of most likely candidate genes and the associated pathway identified might assist researchers in prioritizing candidate disease genes for further empirical analysis and understanding of the pathogenesis of osteoporosis.

Segregation and pathogenesis of balanced/unbalanced homologous Robertsonian translocations, t(13;13), t(14;14); t(15;15), t(21;21) and t(22;22) - Case reports and review. *D.S. KrishnaMurthy[1], F.M. Al Kandari[1,2], M.A. Redha[1], K.K. Naguib[1], L.A. Bastaki[1], S.A. Al-Awadi[1]* 1) Cytogenetics Laboratory, Kuwait Medical Genetics Centre, Al Sabah, Kuwait; 2) Department of Allied Health, Kuwait University, KUWAIT.

One in 900 humans is born with a Robertsonian translocation. The most frequent forms of Robertsonian translocations are between chromosomes 13 and 14, 13 and 21, and 21 and 22. Robertsonian translocations (balanced or unbalanced) involving acrocentric chromosomes, 13,14,15 and 21, 22 are well known chromosomal abnormalities leading to multiple congenital anomalies, infertility, repeated fetal loss, dysmorphism and mental retardation. However, homologous Robertsonaian translocations, t(13;13q),t(14;14),t(15;15) and t(22;22) are relatively rare. Carriers of balanced ROBs are at an increased risk of having chromosomally unbalanced, phenotypically abnormal offspring. These individuals are trisomic for one of the chromosomes involved in the translocation, with three copies instead of the normal complement of two. Carriers of ROBs are also at an increased risk of uniparental disomy (UPD), the inheritance of both chromosome copies from a single parent. Uniparental inheritance of some chromosomes has been shown to be deleterious due to the effects of imprinting (the differential expression of genes depending on the parent of origin). Risk estimates vary depending on the type of rearrangement. Carriers of homologous acrocentric rearrangements are at very high risk of having multiple spontaneous abortions and chromosomally abnormal offspring. Parents of fetuses and children with unbalanced homologous acrocentric rearrangements are rarely found to be carriers or mosaic for the same rearrangement.

Investigation of genetic variants within candidate genes of the TNF signalling pathway on the response to anti-TNF agents in a UK cohort of RA patients. *J. Bowes[1], C. Potter[1], K. Hyrich[1], BRAGGSS[2], A. Morgan[3], A.G. Wilson[4], J. Isaacs[5], J. Worthington[1], A. Barton[1]* 1) ARC-EU, University of Manchester, UK; 2) Biologics in Rheumatoid Arthritis Genetics and Genomics Study Syndicate; 3) University of Leeds, UK; 4) University of Sheffield, UK; 5) Newcastle University, UK.

Purpose: To investigate genetic variants within candidate genes of the tumour necrosis factor (TNF) signalling pathway in determining response to anti-TNF therapy in a UK population of rheumatoid arthritis (RA) patients.

Methods: A panel of single nucleotide polymorphisms (SNPs) were selected to span six candidate genes (DUSP1, HRB, IKBKAP, MAP3K1 MAP3K14 and TANK). Pairwise tag SNPs were selected from the HapMap phase II. Samples from RA patients (n=642) treated with anti-TNF agents (Etanercept, Infliximab and Adalimumab) were recruited by a UK-wide, multi-centre collaboration and genotyped on a Sequenom MassARRAY platform. Linear regression was performed to determine if candidate SNPs could predict the response to anti-TNF therapy at six months, defined as the absolute change in disease activity score (DAS28). The regression model was adjusted for baseline DAS28, HAQ score and concurrent DMARD therapy. SNPs demonstrating genotypic association ($p<0.05$) were analysed under additional genetic models.

Results: A total of 71 SNPs were genotyped in 630 patient samples. Linear regression analysis identified two tag SNPs associated with treatment response in the cohort. Further analysis revealed stronger associations under a dominant genetic model. Carriage of the minor allele of rs96844 (MAP3K1) was associated with improved treatment response (genotypic $p = 0.037$, dominant $p = 0.011$). Carriage of the minor allele of rs4792847 (MAP3K14) was associated with a reduced treatment response (genotypic $p = 0.044$, dominant $p = 0.016$).

Conclusion: Association was found to two SNPs in candidate genes of the TNF signalling pathway in a large cohort of UK RA patients receiving anti-TNF therapy. These findings will be explored further when more samples from the on-going collection become available.

Evaluation of linkage disequilibrium in the Azores Islands and mainland Portugal. *C.C. Branco[1,2], E. Cabrol[1], M. São Bento[1], C.T. Gomes[1], R. Cabral[1,2], A.M. Vicente[2,3], P.R. Pacheco[1,2], L. Mota-Vieira[1,2]* 1) Dept Molec Gen, Pathology Unit, Hosp Divino Espirito Santo, Azores Islands, Portugal; 2) Instituto Gulbenkian de Ciência, Oeiras, Portugal; 3) Centro de Biopatologia, Instituto Nacional de Saúde Dr Ricardo Jorge, Lisboa, Portugal.

The study of the extent of LD and population structure is a good starting point for the investigation of complex traits. Here, we characterize the LD extent in the Azores and mainland Portugal populations. The sample distribution per Azorean group and island was the following: Eastern group, 207 (São Miguel 185; Santa Maria 22); Central group, 150 (Terceira 54; Pico 29; São Jorge 23; Faial 25; Graciosa 19) and the Western group, 75 (Flores 59; Corvo 16). In addition, 97 individuals from mainland Portugal were analysed. LD was evaluated in the Xq13.3 region by genotyping eight STR markers. Pairwise LD calculation demonstrates higher number of significant associations in the Western group (10 out of 28 comparisons), in contrast to the 3 found in the Central and Eastern groups. Additionally, D analysis indicates that the Western group presents higher values when compared with the other two groups. However, all islands groups show values of D lower than 0.33, suggesting no extensive LD in these populations. As expected, the highest D values are found for shorter distances for all populations. Taken together, the data show that the Azorean population presents a lower average D (0.142) compared with mainland Portugal (0.226). These results suggest that the identification of identical by descent (IBD) regions surrounding disease susceptibility or other complex trait loci in the Azorean, as well as in the mainland populations, would require a very high density of markers. On the other hand, the easy reconstruction of large pedigrees in the Azorean population is a valuable resource for the fine mapping of disease genes.

Racial/ethnic disparity and regional variation in participation in buccal DNA collection - The National Birth Defects Prevention Study. *K. Crider[1], J. Reefhuis[1], A. Woomert[2], S. Rasmussen[1], P. Romitti[3], C. Hobbs[4], M. Royle[5]* 1) Centers for Disease Control and Prevention, NCBDDD, Atlanta, GA; 2) Battelle/CPHRE, Durham, NC; 3) University of Iowa, Iowa City, IA; 4) University of Arkansas, Little Rock, AR; 5) New Jersey Department of Health, Trenton, NJ.

The National Birth Defects Prevention Study is a multicenter, case-control study (begun in 10/97) to examine environmental and genetic risk factors for birth defects. A 1-hour telephone interview was completed by 70% of mothers, 56% of whom returned the buccal DNA cell collection kit mailed to them after the interview. We assessed demographic characteristics associated with return of the kits to investigate possible factors related to participation rates for DNA collection. This analysis was limited to mothers with an estimated delivery date on or before 12/31/03. A total of 15,920 interviewed mothers were eligible to receive a buccal DNA kit (11,805 case mothers, 4,115 control mothers). Of these, 60% were non-Hispanic white (NHW), 11% were non-Hispanic black (NHB), 23% were Hispanic (H), and 6% were other (O) races. Rates for DNA collection were highest among NHW (60%) mothers, followed by H (53%), O (49%), and NHB (39%). The Iowa center had the highest overall participation rate (74%), while the New Jersey center had the lowest (41%). Participation ranged from 76% in Iowa to 45% in New Jersey among NHW mothers; from 52% in California to 27% in New York among NHB mothers; and from 64% in Arkansas to 34% in New Jersey among H mothers. DNA collection rates were slightly higher overall among cases (57%) than among controls (52%). Participants who received a $20 incentive with the kit had higher participation rates than those who did not (56% vs. 41%). Maternal age, income, and education had little effect on overall participation rates. Among women who were willing to participate in an extensive interview, participation in the genetic component varied, limiting both the study power and generalizability. We found substantial variation in buccal collection participation rates by region and by race/ethnicity. Incentives increased participation.

***FOXC1*/*PITX2* mutations and copy number changes in a Belgian-Dutch cohort of patients with Axenfeld-Rieger malformations.** *B.N. D'haene[1], F. Meire[2], T. de Ravel[3], I. Casteels[4], B.P. Leroy[1,5], P. Kestelyn[5], A.S. Plomp[6], M. Joosten[7], A. De Paepe[1], E. De Baere[1]* 1) Center for Medical Genetics, Ghent University Hospital, Belgium; 2) HUDERF, Brussels, Belgium; 3) Center for Human Genetics, Catholic Leuven University, Belgium; 4) Dept of Ophthalmology, Catholic Leuven University, Belgium; 5) Dept of Ophthalmology, Ghent University Hospital, Belgium; 6) Dept of Medical Genetics, AMC, Amsterdam, The Netherlands; 7) Clinical Genetics, University Rotterdam, The Netherlands.

Axenfeld-Rieger (AR) malformations comprise a spectrum of rare autosomal dominant congenital structural malformations of the anterior eye segment. A primary purpose of this study was to determine the prevalence of disease-causing *FOXC1*/*PITX2* mutations and copy number changes in a Belgian-Dutch cohort of patients with AR malformations. A second goal was to evaluate the contribution of three candidate genes: *FIBULIN-4*, *P32* and *FOXC2*. Thirty-six probands with AR, mainly of Belgian-Dutch origin, were examined for copy number changes of *FOXC1*/*PITX2* with MLPA and screened for subtle *FOXC1*/*PITX2* mutations by sequencing. Array CGH with a tiling BAC array for the *FOXC1* region was carried out for patients with a known *FOXC1* deletion and for all patients without identified mutation. In addition mutation screening of *FIBULIN-4*, *P32* and *FOXC2* was performed in the latter group. This revealed no disease-causing mutations so far. In conclusion, a disease-causing genetic defect was found in 44% of the probands in this study. The majority of these are *FOXC1* mutations (69%) and one third *PITX2* mutations (31%). Thirty-eight percent of these defects are genomic rearrangements: 5 *FOXC1* deletions and 1 *PITX2* deletion. Our data sustain a major role of the *FOXC1*/*PITX2* genes in the molecular pathogenesis of the AR spectrum in the Belgian-Dutch population. Screening of other candidate genes is currently ongoing.

A Genome-wide association study using DNA pooling identifies evidence for novel susceptibility genes for Alzheimer's Disease. *R. Abraham[1], G. Kirov[1], V. Moskvina[1], A.R. Morgan[1], P. Hollingworth[1], L. Georgieva[1], S. Lovestone[2], M. O'Donovan[1], M. Owen[1], J. Williams[1]* 1) Dept Psychological Medicine, Cardiff University, UK; 2) Institute of Psychiatry, Kings College London, UK.

Late-onset Alzheimer's Disease has a strong genetic component but the only replicable genetic risk factor identified to date is the ()4 allele of APOE. To identify additional susceptibility loci we have conducted a genome-wide association study using DNA pooling to reduce costs. DNA pools were constructed from 1000 LOAD cases and 1200 age, gender and ethnicity matched controls. Pools were hybridised to Illumina HH300 and HH240S arrays, assaying over 550,000 SNPs. For each SNP the ratios of intensities for allele A and allele B (A/(A+B)) were used to predict allele frequencies. To reduce technical error each hybridisation was replicated between 4 and 8 times and predicted allele frequencies averaged over high quality replicates.(
)In order to prove that our experiment was capable of detecting a true genetic association, we examined whether we were able to detect the known association at the APOE locus. Eight SNPs were identified in the APOE region with predicted allele frequency differences between cases and controls of 5-14%. Four of these 8 SNPs have been individually genotyped and show significant association with LOAD (p-values ~ 7 x 10-9 to 4 x 10-15), demonstrating the accuracy of our pooling method.(
)We are currently individually genotyping 100 SNPs with the greatest predicted differences in allele frequencies. Initially we focused on SNPs in clusters with other significant SNPs. To date we have identified 16 significant SNPs in our case / control sample (p ()0.02). Our most significant SNP has p=0.00002 (Odds Ratio 1.298 CI: 1.151-1.463) and displays linkage disequilibrium with SNPs in a gene showing putative functional candidacy for AD. We are currently individually genotyping functional and tagging SNPs in this and other promising genes in addition to SNPs from the pooled experiment dataset.

Transmission of class I / II multi-locus MHC haplotypes and multiple sclerosis susceptibility: accounting for linkage disequilibrium. *M.J. Chao[1], M.C.N.M. Barnardo[2], G.Z. Liu[1], M.R. Lincoln[1], S.V. Ramagopalan[1], B.M. Herrera[1], D.A. Dyment[1], A.D. Sadovnick[3], G.C. Ebers[1]* 1) Department of Clinical Neurology, University of Oxford, John Radcliffe Hospital, Oxford, OX3 9DU, UK; 2) Nuffield Department of Surgery, Churchill Hospital, Oxford, OX3 7LJ, UK; 3) Department of Medical Genetics, University of British Columbia, Vancouver, V6T 1Z4, Canada.

The human MHC class II region is associated with genetic susceptibility to MS. Roles for HLA class I loci have been supported in several case-control studies, but this methodology does not consider the known LD between class I and II loci. In 1258 individuals from 294 MS families we analysed class I and II interactions. Using haplotype TDT, we found positive associations between MS and several *HLA-DRB1*15-HLA-A* haplotypes including *HLA-DRB1*15-HLA-A*02* (P=2.41x10^{-05}) and *-HLA-A*03* (P=8.42x10^{-06}), and several *HLA-DRB1*15-HLA-B* haplotypes including *HLA-DRB1*15-HLA-B*07* (P=2.23x10^{-10}).

*HLA-DRB1*15* haplotypes divergent for reported *HLA-A* allelic associations were equally over-transmitted, illustrating no detectable effect of *HLA-A* or *-B* alleles in *cis* on susceptibility. *HLA-A* and *-B* alleles on haplotypes not bearing *HLA-DRB1*15* were not over-transmitted. Similarly, general over-transmission of *HLA-DRB1*15* haplotypes was independent of the *HLA-B* allele present. Furthermore, *HLA-B*07* haplotypes from *HLA-DRB1*X-HLA-B*X/HLA-DRB1*X-HLA-B*07* heterozygous parents were transmitted per random expectation giving no indication of *HLA-B* independence or *trans* complementation of *HLA-DRB1*15* by *HLA-DRB1*X-HLA-B*07* haplotypes. These results imply that many reports of class I allelic associations in MS are class II dependent, secondary to LD with class II loci. The lack of independent class I associations suggests that virus-related class I-antigen complexes are not T-cell targets in MS. The inability to replicate confirmed case-control associations highlights the importance of family-based analyses. The high frequency that allelic associations cannot be replicated emphasises the requirement for constructing multi-locus haplotypes in dissecting associations in regions of tight LD as illustrated by these results.

Pure partial trissomy 4q32q34: a familial report with the associated phenotype. *A. Guichet[1], E. Colin[1], O. Ingster[1], D. Bonneau[1,2]* 1) Department of Biochemistry and Genetics, CHU, Angers, France; 2) INSERM U694, Angers, France.

Duplication of the long arm of chromosome 4 has been described in more that 60 patients. In most cases, the duplication resulting from an unbalanced segregation of a balanced translocation in one of the parents is associated with partial monosomy for other chromosomal material. This leads to wide phenotypic variability complicated by the number and size of the breakpoints reported. However, partial duplication of chromosome 4q has been very rarely reported. We present a case of familial pure partial duplication of 4q32q34, affecting a mother and her two sons, characterized by distinctly dysmorphic features and mental retardation. The index case was a boy referred for developmental delay at 18 months of age. The pregnancy had been uneventful. The child had dysmorphic features but showed no growth retardation. Bilateral convergent strabismus had appeared at the age of 12 months. At the time of consultation, the psychomotor delay was such that the child could neither walk nor talk. Cytogenetic analysis performed on a peripheral blood sample revealed a 46,XY, der(6)ins(6;4)(q26;q32.1q35) abnormality. FISH analysis (using commercial, BAC, and MultiFish probes) confirmed the pure trisomy 4q32q34. When the parental karyotyping was done, the mother's karyotype showed the same 46,XX, der(6)ins(6;4)(q26;q32.1q35) abnormality. She also had distinctively recognizable dysmorphic features, and suffered from moderate mental retardation and strabismus. The couple had a second child for which they refused a prenatal cytogenetic diagnosis. Eventually, at birth they allowed the child to be karyotyped. He was then discovered to have the same karyotype as the mother and his older brother. He too had dysmorphic features but no strabismus as yet. As simple duplications are more useful for defining the trisomy 4q phenotype, this case of familial pure partial trisomy 4q32q34 should contribute to the karyotype/phenotype correlation for this critical region.

Association of AGGF1 gene polymorphisms with susceptibility for Klippel-Trenaunay syndrome. *Y. Hu[1], S.B. Seidelmann[1], L. Li[1], A.A. Timur[1], D.J. Driscoll[2], Q.K. Wang[1]* 1) Molecular Cardiology, Cleveland Clinic, Cleveland, OH; 2) Department of Pediatrics, Mayo Clinic, Rochester, MN.

Klippel-Trenaunay syndrome (KTS) is a severe congenital disorder that results in mixed vascular malformations. It is characterized by capillary malformations, venous malformations or varicose veins, and hypertrophy of the affected tissues. Our molecular genetic dissection of one KTS- associated translocation involving chromosomal segments 5q and 11p identified a strong candidate gene, AGGF1 (previously known as VG5Q), which increases KTS susceptibility. To further analyze the genetic relationship between AGGF1 and KTS, we examined whether common variants in AGGF1 were associated with susceptibility to KTS. We analyzed HapMap data and selected two SNPs, rs13155212 in exon 7 and rs7704267 in intron 11 that capture information for all common variants in the one haplotype block that covers the entire AGGF1 gene. The two SNPs were genotyped in 173 Caucasian KTS patients and 477 Caucasian non-KTS controls. AGGF1 variants rs7704267 and rs13155212 were significantly associated with susceptibility for development of KTS (P = 0.004 and 0.013, respectively). Permutation testing also showed a significant empirical P value for the association (empirical P = 0.006 and 0.015, respectively). These results suggest that common AGGF1 variants confer risk of KTS.

Non-disjunction of chromosome 13. *A. Collins[1], M. Bugge[2], M.B. Petersen[3]* 1) Dept Human Genetics, Univ Southampton, Southampton, United Kingdom; 2) Wilhelm Johannsen Centre for Functional Genome Research, Department of Cellular and Molecular Medicine, University of Copenhagen, Denmark; 3) Department of Genetics, Institute of Child Health, Athens, Greece.

We performed a molecular study with 21 microsatellites on a sample of 82 trisomy 13 conceptuses, the largest number of cases studied to date. The parental origin was determined in every case and in 89% the extra chromosome 13 was of maternal origin with an almost equal number of maternal MI and MII errors. The latter finding is unique among human autosomal trisomies, where maternal MI (trisomies 15, 16, 21, 22) or MII (trisomy 18) errors dominate. Of the 9 paternally derived cases 5 were of MII origin but none arose from MI errors. There was some evidence for elevated maternal age in cases with maternal meiotic origin for liveborn infants. We find clear evidence for reduced recombination in both maternal MI and MII errors and the former is associated with a significant number of tetrads (33%) that are nullichiasmate, which do not appear to be a feature of normal chromosome 13 meiosis. This study supports the evidence for subtle chromosome-specific influences on the mechanisms that determine non-disjunction of human chromosomes, consistent with the diversity of findings for other trisomies.

Long-term phenotypic correction of murine Hemophilia A and immunological differences of bioengineered FVIII variants delivered by helper-dependent adenoviral vectors. *V. Cerullo[1], M.P. Seiler[1], R. Garcia[1], C. Clarke[1], R.J. Kaufman[4,2], S.W. Pipe[3], B. Lee[1,2]* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Howard Hughes Medical Institute; 3) Pediatrics and Communicable diseases, University of Michigan; 4) Biological Chemistry and Internal Medicine, University of Michigan.

Bioengineering of the factor VIII (FVIII) molecule has produced variants that overcome secretion and/or inactivation in vitro, but their value for in vivo gene therapy has not been evaluated. We tested six modified FVIII variants for in vivo efficacy by expressing them from helper dependent adenoviral (HD-Ad) vectors. We constructed wild type (WT), B-domain deleted (BDD), a point mutant for improved secretion (F309S), a variant with a partial B-domain deletion for improved secretion (N6), a combination of the point mutant and partial B-domain deleted variant (F309N6), and an inactivation resistant (IR8) FVIII variant. All constructs expressed functional protein after injection of high dose HD-Ad. However, activity improved from 20-50% with WT, to nearly 100% with the N6 and F309N6 variants. Interestingly, mice treated with N6 showed long-term FVIII activity for 64 weeks with reduced anti-FVIII antibody titer. Importantly, the N6 and F309N6 vectors resulted in therapeutic levels of FVIII activity after a 50% lower viral dose, indicating that transgene modification itself can considerably improve the dose efficacy of HD-Ad; a key impediment to clinical application. In summary, bioengineering of the FVIII molecule may be an attractive measure to augment the safety profile of HD-Ad gene therapy for hemophilia A.

Improving Utility of Circulating DNA for Prenatal Genetic Testing: Fragment Size and Purity. *C. Jorgez, F. Bischoff* Department of Obstetric and Gynecology, Baylor College of Medicine, Houston, TX.

Objetive Among the pitfalls of using cell-free-fetal DNA from plasma for prenatal diagnosis is the quality of recovered DNA fragments and abundance of maternal DNA (>95%). Our objective was to explore an alternative method for achieving enrichment and high-quality fetal DNA from plasma. **Methods** Cell-free DNA from 31 pregnant-women and 18 controls (10 males and 8 females) were size separated using agarose gel electrophoresis. DNA from sections containing fragments of 100-300; 500-700; and 1500-2000bp were excised and extracted, followed by whole genome amplification (WGA) of recovered fragments. Levels of globin and DYS1 for total and fetal DNA, respectively, were measured. **Results** Higher quality enriched fetal DNA was obtained following electrophoresis and WGA. Distribution of globin size-fragments was similar among pregnant-women and controls. Among the control-male cases, distribution of size-fragments was the same for both globin and DYS1. However, among pregnant women smallest size fragment (100-300bp) accounted for nearly 50% (39.7617.55%) of the recovered DYS1-DNA but only 10% (10.406.49%) of globin DNA. After WGA of plasma fragments from pregnant-women, DYS1 sequence amplification was best observed when using the 100-300 bp fragments as template. As measured by the 260/280 ratio, quality of DNA also improved after WGA (0.960.22 before vs. 1.600.14 after). **Conclusions** Combination of gel-extraction and WGA could lead to enrichment of fetal-DNA from plasma for improvement of clinical applications. These methods will better enable high-throughput screening for more comprehensive testing of prenatal genetic abnormalities.

Detection of copy number variation from high-density SNP arrays: An integrated Bayesian hidden Markov model approach incorporating pedigree information. *Z. Chen[1], M. Taddesse[1], K. Wang[2], M. Li[1]* 1) Department of Biostatistics and Epidemiology, University of Pennsylvania School of Medicine, Philadelphia, PA; 2) Department of Genetics, University of Pennsylvania School of Medicine, Philadelphia, PA.

Copy number variations (CNVs) refer to gains and losses of genomic elements compared to a reference genome assembly. CNVs are common in humans and some CNVs are associated with human phenotypic variation and susceptibility to disease. Recent advances in genotyping technologies have made it possible to make high-resolution CNV calls using whole-genome SNP arrays. Various studies have demonstrated the heritability of CNVs, however, few have incorporated family structures in the analysis. Here we develop an integrated Bayesian approach that aims to incorporate family relationships when inferring CNVs in the context of parents-offspring trios. We assume that the copy number sequence along the chromosome follows a Markov model with transition probabilities dependent on genetic distances between adjacent SNPs. Specifically, we model parental CNVs through a standard hidden Markov model; given parental copy numbers at a SNP, the offsprings copy number is then modeled through Mendelian inheritance and the dependence on the copy number at the previous SNP is modeled through recombination fraction between the two SNPs. Due to cell-line artifacts or segmental mutation events during recombination, many CNVs might be non-Mendelian inherited. To accommodate such CNVs, we allow for de novo events in offsprings CNV calls and use another HMM to account for the dependence with neighboring SNPs in the same de novo CNV region. By incorporating both family data and allowing for de novo events, our method provides flexibility for the analysis of a wide range of settings, and is expected to improve the accuracy of CNV calls as compared to methods that ignore family relationships. We evaluate the performance of the proposed method and illustrate its practical utility by applying it to the analyses of simulated datasets and the CEU trio data from HapMap.

Unbalanced derivative chromosome 7 with mild phenotypic features. *S.A. Berend[1], J.B. Ravnan[2], R.E. Bruce[3], M.J. Sutcliffe[4, 5], M.L. Loscalzo[4, 5]* 1) Genzyme Genetics, Tampa, FL; 2) Genzyme Genetics, Santa Fe, NM; 3) Florida Perinatal Associates, Tampa, FL; 4) All Children's Hospital, St. Petersburg, FL; 5) University of South Florida, Tampa, FL.

Cytogenetically visible unbalanced chromosome rearrangements involving the euchromatic regions most often result in relatively severe phenotypic features. We present an unbalanced chromosome rearrangement resulting in mild phenotypic features in a family. The patient was referred for an amniocentesis due to Tetralogy of Fallot with pulmonary atresia seen on ultrasound. Cytogenetic analysis revealed an abnormal chromosome 7 with additional material of unknown origin located on the long arm. Fluorescence in situ hybridization (FISH) analysis with chromosome 7 specific probes showed that the subtelomere region of the long arm of chromosome 7 was deleted. There was a portion of the long arm that did not hybridize with the whole chromosome painting probe for chromosome 7, indicating that there was material present from an additional chromosome. The banding pattern suggested involvement of chromosome 18. Chromosome 18 specific probes confirmed that the material had originated from the long arm of chromosome 18. This rearrangement results in monosomy for the terminal region of chromosome 7 (appears to only involve the subtelomere region), and trisomy for the distal region of the long arm of chromosome 18, from 18q21.3--qter. Cytogenetic and FISH analysis on the father of this fetus indicated he had the same unbalanced derivative chromosome 7. He had mild phenotypic features and normal mental capacity. Previous reports of similar deletions of chromosome 7 report severe mental retardation with short stature and other minor anomalies. Previous reports of similar duplications of chromosome 18 also suggest a more involved phenotype, reporting intrauterine growth retardation, dysmorphic features, and severe to profound mental retardation. The mild phenotype associated with the derivative chromosome 7 in this family is unusual and appears to be discordant with what is reported in the literature.

Variants in the FANCF gene are associated with Type 2 Diabetes in Pima Indians. *L. Bian, Y.L. Muller, R.L. Hanson, S. Kobes, C. Bogardus, L.J. Baier* PECRB, NIDDK, NIH, PHOENIX, AZ.

A genome-wide association (GWA) study with the Affymetrix Mapping 100K chip was used to identify susceptibility genes for type 2 diabetes mellitus (T2D) in Pima Indians. Results from this GWA showed that rs10500938 on Chr11p14.3 was associated with early-onset T2D (onset age less than 25 yrs) in both a case-control analysis (N= 300 cases and 329 controls; p = 0.001 adjusted for age and sex) and a within-family analysis (N= 482 discordant siblings; p = 0.04 adjusted for age and sex). This variant is positioned within the 3UTR of FANCF. FANCF encodes the Fanconi anemia (FA) complement group F, and patients with Fanconi anemia have been reported to have endocrine and metabolic abnormalities, such as abnormal glucose/insulin metabolism and obesity. In addition, FA patients also have an increased prevalence of diabetes mellitus. Therefore, the FANCF gene was directly analyzed as a positional candidate gene for T2D. The coding region, UTRs and 2 kb of the promoter region of the FANCF gene were sequenced in 24 non-first degree related Pima Indians, and 10 SNPs were identified, including rs10500938. Among these SNPs, SNP1 (rs7109087), SNP4 (rs7112345) and SNP6 (rs2307895) were in perfect linkage disequilibrium (LD) defined as D=1 and r2 = 1. SNP2 (novel), SNP3 (rs4442551) and SNP10 (rs10500938) were also in perfect LD. Therefore SNPs 1 (rs7109087), 5 (novel), 7 (novel), 8 (novel), 9 (rs4447177) and 10 (rs10500938) were selected as representative SNPs and were further genotyped for association analysis in a population-based sample of 3230 full-heritage Pima Indians. The 3 UTR variant rs10500938 remained associated with T2D in the larger population sample using either a general analytical model (OR = 1.36, 95% CI: 1.18-1.58, p = 0.00004, adjusted for age, sex, and birth year) or a within-family model (OR = 1.41, 95% CI: 1.11-1.79, adjusted p = 0.005). Since this 3UTR variant is in perfect LD with the SNP2 (novel) and SNP3 (rs4442551) which map to the promoter region of FANCF, in vitro expression studies are ongoing to determine the functional variant. An additional Native American cohort is also being genotyped to attempt replication of these associations.

Screening for dup7q11.23 in children with expressive language delay. *J.O. Cardy[1], M.J. Somerville[2], E.J. Young[3], S. Bamforth[2], M. Lilley[2], L.R. Osborne[3]* 1) Comm Sciences and Disorders, University of Western Ontario, London, Ontario, Canada; 2) Medical Genetics, University of Alberta, Edmonton, Alberta, Canada; 3) Medicine, University of Toronto, Toronto, Ontario, Canada.

The association of duplication of the Williams-Beuren syndrome region on chromosome 7q11.23 with deficits in expressive language in a few individuals led us to initiate a search for additional subjects. We decided to perform both a genetic and phenotypic screen. For the genetic screen, we recruited children with a primary diagnosis of expressive language delay or apraxia through speech-language pathologists and interactive web sites for families with apraxia. Informed consent was obtained, saliva collected, DNA extracted and duplication of the WBS region tested using real-time SYBR Green amplification of fragments from *GTF2I*, *ELN* and *BAZ1B* on an AB 7900 instrument. An initial screen of 150 subjects did not identify any with a duplication of 7q11.23. In conjunction, we have been carrying out a phenotypic screen of individuals attending genetics clinics, to identify patients who bear similar facial and/or clinical characteristics to the patient with dup7q112.3 that we originally reported in 2005. We identified a 5-year old boy with a diagnosis of severe receptive and expressive language delay. His younger sibling also had severe language delay, and both children were globally developmentally delayed. A third, older sibling had a mild speech impairment. All three children attended school with the help of teachers aids. Real-time PCR analysis demonstrated that the two younger siblings had a 1.55 Mb duplication of the WBS region, but that the eldest sibling, who showed the mildest symptoms, did not. Their mother, who also had academic difficulties, showed a similar facial dysmorphism to our original dup7q11.23 patient but no DNA sample was available for analysis. We conclude that careful phenotypic screening of patients attending genetics clinics may identify more individuals with dup 7q11.23 than a more general genetic screen of subjects with speech and expressive language delay. This is likely due to the enormous genetic and environmental heterogeneity of speech and language impairment.

Dissecting the origins of (ATTCT)n expanded chromosomes in Brazilian SCA10 families through a haplotype study. *T. Almeida[1], I. Alonso[1], L. Saraiva-Pereira[2], L. Jardim[2], P. Magalhães[3], S. Martins[1,4], J. Sequeiros[1,5], I. Silveira[1]* 1) Unigene, IBMC, Univ. Porto, Portugal; 2) Hosp. Clínicas de Porto Alegre, Brasil; 3) CCGen, IBMC, Univ. Porto, Portugal; 4) IPATIMUP, Univ. Porto, Portugal; 5) ICBAS, Univ. Porto, Portugal.

Spinocerebellar ataxia type 10 (SCA10) is an autosomal dominant neurodegenerative disorder caused by a dynamic mutation in intron 9 of the *ATXN10* gene, at chromosome 22q13.3. A large expansion of 400 to 4500 ATTCT repeats is found in SCA10 patients, whereas normal alleles vary usually from 10 to 29 repeats. To date, the mutation has only been found in families of Mexican or Brazilian origin. We found three SCA10 Brazilian families with patients carrying expanded SCA10 alleles. These families have a mixed Portuguese and Amerindian ancestry. In this study, we aim to determine the origin of these expanded alleles. The identification of new polymorphisms within a region of 800 bp flanking the repeat was performed in 50 Brazilian individuals, by PCR followed by DHPLC. Three new SNPs were identified in this region and haplotypes were reconstructed in our SCA10 Brazilian families. G-G-C was the most common haplotype found in the Brazilian population and was also shared by all expanded chromosomes. Our preliminary results suggest that the SCA10 expansion in these Brazilian families may have arisen in a common ancestral haplotype, but the study of additional polymorphisms in the region is still needed to assess the origin of expanded chromosomes.

Improved homozygote detection through internal calibration of high-resolution melting data. *C.N. Gundry[1], S.F. Dobrowolski[1], Y.R. Martin[1], T.C. Robbins[1], L.M. Nay[1], C.T. Wittwer[1,2], D.H-F. Teng[1]* 1) Biochemistry R&D, Idaho Technology, Salt Lake City, UT; 2) University of Utah, School of Medicine, Department of Pathology, Salt Lake City, UT.

Background: Genotyping techniques using high-resolution DNA melting are both simple and powerful, but they can be limited by sample-to-sample variations in temperature, buffer and volume. Heterozygotes are easiest to detect in melting because of the presence of heteroduplexes, which alter the shape of the transitions significantly, within the re-annealed product. Homozygote differentiation, however, often depends more on temperature reproducibility for accurate genotyping because of similar melting shapes. In addition, some types of homozygotes (e.g., A/T or G/C) are inherently difficult to detect, even with the best instruments because of small Tm differences. Methods: Calibrator oligonucleotides were synthesized and included at equimolar concentrations with their complementary sequences. 96 well PCR was performed in conventional thermocyclers with LC Green Plus dye in the presence of calibrators. PCR plates were moved to the LightScanner and melts were performed from 55 to 97 C. Calibrator melting signitures were aligned, within each reaction, and used to transform the fluorescence data. Genotypes were determined by sequencing and/or probe-based genotyping for each sample. We assessed homozygote genotyping error rates before and after calibration by measuring the distance (C) of each samples apex to the mean Tm value of the group to which its genotype corresponded. Errors were observed when the Tm of a sample was closer to the mean Tm of the incorrect group. Results: Across multiple plates and PCR targets calibration improved the homozygote genotyping error from 10% to less than 1%. Tm standard deviations lowered from approximately 0.056 to 0.027 C, after calibration. Conclusion: Internal calibration improved discrimination of homozygotes. Our calibration system enabled the correct genotyping of symmetric base-pair neutral homozygotes, in apparent exception to nearest neighbor thermodynamic assumptions.

Gastroschisis and Genitourinary Infections. *M.L. Feldkamp[1], L.D. Botto[1], J. Reefhuis[2], J. Kucik[2], S. Krikov[1], A. Wilson[1], C. Moore[3], J.C. Carey[1]* 1) Pediatrics, University of Utah, Salt Lake City, Ut; 2) Center on Birth Defects and Developmental Disabilities; 3) Office of Genomics and Disease Prevention, Centers for Disease Control and Prevention, Atlanta, Ga.

Gastroschisis is a pathogenetic and epidemiologic dilemma. Competing pathogenetic views consider gastroschisis as a late fetal disruption (after normal morphogenesis), or, alternatively, a primary malformation of ventral wall closure. Epidemiologically, gastroschisis is unique for its strong association with very young maternal age and its recent increase in occurrence. We focused on genitourinary (GU) infections as a possible risk factor for gastroschisis, because such infections, which include urinary tract infections (UTI) and sexually transmitted infections (STI), are common in sexually active young women and their frequency may be increasing. We analyzed data from the National Birth Defects Prevention Study, an ongoing multi-center, population-based case-control study of risk factors for major birth defects. The study included 515 case-infants with gastroschisis and 5008 unaffected controls. Women were considered exposed if they reported a GU infection at any time from one month prior through the third month after conception. An STI was reported by 21 cases (4.1%) and 99 controls (2.0%), and a UTI was reported by 68 cases (13.2%) and 341 controls (6.8%). Odds ratios for gastroschisis, adjusted for maternal age, were 1.2 (95% confidence interval: 0.7, 2.2) for STI alone, 1.4 (1.1, 1.9) for UTI alone, and 3.8 (1.3, 10.5) for STI with UTI. Within maternal age strata, the risk for STI with UTI was highest for women <25 years: 2.9 (0.6, 14.4) for women <20 years and 5.7 (1.4, 22.9) for women 20-24 years. The risk for gastroschisis remained elevated for STI with UTI at 4.6 (1.4, 15.4) after controlling for many covariates. These findings suggest that GU infections, particularly as a combination of an STI and a UTI, are risk factors for gastroschisis. If the association is causal, and the rate of infections is increasing, GU infections may account for some of the increase in reported rates of gastroschisis. The role of a specific susceptibility in young women, fever, or medications, remains unclear.

Fine Mapping of The 15q Glioma Susceptibility Locus And Candidate Gene Analysis. *H. Jiao[1], N. Paunu[2], I. Fransson[1], H. Haapasalo[2], J. Kere[1]* 1) Karolinska Institute, Sweden; 2) University of Tampere, Finland.

Gliomas are the most common brain tumors. The incidence and mortality of gliomas increase in many developing countries. Gliomas occasionally occur as familial with a likely genetic component, but no single gene has been identified as a causative factor. We mapped a low-penetrance locus for familial glioma on chromosome 15q23 (Paunu et al. 2002; OMIM 607248). Current work is focused on the fine-mapping and candidate gene studies on the 15q region. Four possibly functionally relevant candidate genes, NTRK3 (OMIM191316), SIAT8B (OMIM602546), NR2F2 (OMIM107773), and ADAMTS17 (OMIM607511), have been sequenced and studied. We did not detect putative mutations in exons or exon-intron boundaries in any of these genes, but identified a set of previously unknown variants. To pinpoint new candidate gene we have performed more intensive genome-wide scan using high-density Affymetrix GeneChip Human Mapping 500K Array. Fifteen individuals, 4 trios and one affected sibling with one parent were selected for genotyping. Based on linkage analysis and TDT, a new functional candidate gene has been found, and sequencing of the gene is on the way. All variants found by sequencing analysis will be evaluated in case-control samples for association to understand their roles in the development of brain tumors, in particular gliomas.

Deciphering Synergistic Heterozygosity in the Fatty Acid Oxidation Pathway. *K.M. Griffin[1], S. Ji[1], D. Matern[2], P. Rinaldo[2], J.D. Sharer[1], T.R. Schoeb[1], J. Vockley[3], P.A. Wood[1]* 1) Dept. of Genetics, University of Alabama at Birmingham; 2) Dept. of Laboratory Medicine and Pathology, Mayo Clinic College of Medicine; 3) Dept. of Human Genetics, University of Pittsburgh.

Usually considered monogenic traits, mitochondrial -oxidation (FAO) disorders may involve two or more mutant genes in a heterozygous state contributing to the disease phenotype; a concept called synergistic heterozygosity (SH). We hypothesize that SH is revealed when genetic combinations shift the control of pathway flux from key regulatory sites and alter metabolite pool sizes. Recent experiments introduced heterozygous deficiencies of a transcriptional regulator of FAO, peroxisomal proliferator activated receptor- (PPAR), or the rate limiting enzyme of liver FAO, carnitine palmitoyltranserase-1a (CPT-1a, liver isoform) with long-chain acyl-CoA dehydrogenase (LCAD). Using mice 6-9 weeks of age and cold tolerance as a metabolic challenge, we observed ~33% cold intolerance in LCAD +/-//PPAR +/- (n=20, $p<0.01$), and also in PPAR +/- (n=6) mice. No detrimental interaction was detected in LCAD +/-//CPT-1a +/- mice (n=5). Acylcarnitine analysis revealed a significant increase of $C_{18:1}$ and C_{16} species only in the PPAR +/- group (n=5), and fatty liver scores were considerably decreased in LCAD +/-//PPAR +/- compared to wild-type, as if the double heterozygotes were protected. Similar studies were also conducted with carnitine palmitoyltranserase-1b +/- (CPT-1b, muscle isoform)//CPT-1a +/- mice. Cold intolerance or fatty liver was not detected in CPT-1 single (n=20 for CPT-1a, n=14 for CPT-1b) or double heterozygotes (n=22). Since the CPT-1 isoforms are reciprocally expressed, they demonstrate some mechanistic specificity to the heterozygous combinations and development of metabolic intolerance. Overall, heterozygous enzyme deficiencies may synergize to increase susceptibility to environmental triggers of metabolic decompensation, whereas other combinations may have little effect or perhaps provide a novel increased resistance to metabolic disease phenotypes.

Evaluation of glycerol homeostasis and metabolism in glycerol kinase (Gyk) knockout (KO) heterozygous mouse using intraperitoneal glycerol tolerance test (IPGlyTT). *M. Kosuga[1], N.K. Maclennan[1], Y.H. Zhang[1], B.L. Huang[1], E.R.B. McCabe[1,2]* 1) Pediatrics, UCLA, Los Angeles, CA, USA; 2) Human Genetics, UCLA, and Bioengineering, Henry Samueli School of Eng and App Sci, UCLA, and Mattel Children's Hospital at UCLA, Los Angeles, CA, USA.

Glycerol kinase deficiency (GKD) is an X-linked inborn error of metabolism with phenotypes, ranging from asymptomatic hyperglycerolemia to a severe metabolic disorder with vomiting, acidosis and central nervous systems crises. Because glycerol kinase (GK) activity and the GK genotype do not predict phenotype in GKD patients, it is essential to examine glycerol homeostasis and metabolism in a murine model to understand pathogenesis and to evaluate treatment efficacy. We designed an intraperitoneal glycerol tolerance test (IPGlyTT) and studied glycerol tolerance in vivo using Gyk KO heterozygous and wild type (WT) female mice. Mice were weighed to determine the dose of glycerol (2mg/g body weight from a 20% solution) and fasted for 8 hours. The glycerol solution was injected ip into mice and blood samples were collected before injection and then at 30, 60, 90, 120, 180 minutes after injection. Serum glycerol concentrations and hepatic GK activities in Gyk KO heterozygous mice and WT mice were measured using radioassay. Hepatic GK activities in Gyk KO heterozygous female mice were from 30% to 50% of WT female mice. In the IPGlyTT, Gyk KO heterozygous mice had normal serum glycerol concentrations before glycerol injection. Serum glycerol concentrations reached maximum at 30 minutes after injection in both KO heterozygous and WT mice. Serum glycerol concentration in WT mice and GKD KO heterozygous mice remained similarly elevated through 90 min and then began to diverge. The WT mice returned to normal at 120 min, whereas the GKD KO heterozygous mice continued to have elevated glycerol levels through 180 min. Glycerol tolerance was impaired in GKD KO heterozygous mice compared to WT mice. IPGlyTT is useful in assessing glycerol homeostasis and metabolism GKD KO heterozygous mice. We will utilize this test for evaluating the efficacy of cell transplantation and lentiviral gene therapy for GKD KO mice.

Statistical issues when multipoint linkage analysis is performed at only one position. *S.E. Hodge[1,2], L. Rodriguez-Murillo[1], L.J. Strug[1], D.A. Greenberg[1,2]* 1) Psychiatry & Biostatistics, Columbia University, New York, NY; 2) NY State Psychiatric Institute, New York, NY.

(1) Methods: Following Xing & Elston (2006; X&E), we performed simulations of multipoint linkage analysis at a single position (i.e., not maximized over position). We calculated both lods (i.e., analyzing the data under the correct or generating model, and mods (maximizing the multipoint lod scores over 18 models). These models were dominant (D) and recessive (R), with penetrances of 0.10, 0.20, ... 0.90, signified by D10, D20, ..., D90, R10, ..., R90. Data were generated under D20, D50, D80, and R20, R50, R80. Disease allele frequency was 0.01 for D models, 0.14 for R. Phenocopy rate was set to 0.001. Each simulation involved 1000 datasets; each dataset contained *n* four-child families, ascertained to have 2 affected children. Parental markers were fully informative, and parental affectedness was included in the analyses. *(2) For the lods:* We demonstrate by theoretical arguments, and also confirm via simulation, that as datasets become more informative, *type I error approaches zero* (unlike for usual statistical analyses). E.g., for D50 data, type I error dropped from .013 for n=10 to .000 for n=30; for R50 data, it dropped from .040 to .000. *(3) For the mods:* We demonstrate a similar pattern via simulation, though less straightforward for R than for D. For D50, type I error dropped from .045 to .007, for R50, from .040 to .024, as n increased from 10 to 30. We also investigate which models yielded the false positive mod scores, as did X&E, but we argue that this question is fundamentally irrelevant to analysis of complex data. *(4)* Finally, we argue that multipoint lods and mods evaluated at a single position presumably have different statistical properties than multipoint lods or mods that are maximized over position. Since most investigators maximize their multipoint scores over position, relying on results from single-position simulations is potentially misleading.

ATTCT repeat interruptions in Brazilian patients with SCA10. *I. Alonso[1], T. Almeida[1], L.B. Jardim[2], O. Artigalas[2], M.L. Saraiva-Pereira[2], T. Matsuura[3], J. Sequeiros[1,4], I. Silveira[1]* 1) UnIGENe - IBMC, University of Porto, Porto, Portugal; 2) Hosp. Clínicas de Porto Alegre, Porto Alegre, Brasil; 3) Center for Neurological Diseases and Cancer, Nagoya University Graduate School of Medicine, Nagoya, Japan; 4) ICBAS, University of Porto, Porto, Portugal.

Spinocerebellar ataxia type 10 (SCA10) is an autosomal dominant neurodegenerative disorder caused by the expansion of an $(ATTCT)_n$ located in intron 9 of the *ATXN10*, a gene of still unknown function. SCA10 was first described in Mexican families presenting with cerebellar ataxia and seizures. Afterwards, Brazilian families were also described presenting spinocerebellar ataxia, but without seizures. We have previously described the presence of an expansion of the polymorphic ATTCT repeat, responsible for SCA10, in two Brazilian families presenting spinocerebellar ataxia without seizures. In these families we detected reduced penetrance alleles of 360-370 repeats, in elderly asymptomatic subjects. To investigate a previous hypothesis of interruptions in the $(ATTCT)_n$ tract functioning as a disease modifier, we assessed the interruption motif in an additional family with ataxia and seizures. By a modified PCR technique an abnormal discontinuous ladder, exceeding the range observed for normal alleles, was detected in this Brazilian family, presenting progressive cerebellar ataxia with associated seizures and onset during or after the 3rd decade of life. This suggested the presence of interruptions within the ATTCT expansion. Comparison of the expanded ladder pattern detected by modified PCR with the previously described suggests that this interruption is located more close to the 5 end of the repeat expansion, probably having 40-50 bp, followed by an additional stretch of ATTCT motif and a new interruption. We are now cloning the larger PCR products, obtained by the modified PCR technique for sequencing of the interrupted alleles and identification of the interruption motif present in this family.

Hypomethylation of H19 differentially methylated region in a patient with a 46,XX,t(8;11)(q24.1;p15.4)pat karyotype and a Silver-Russell syndrome phenotype. *K. Izumi[1,2], Y. Morinishi[3], M. Hattori[1], K. Kosaki[1]* 1) Dept Pediatr, Keio Univ, Tokyo, Japan; 2) Dept Genetics, Case Western Reserve Univ., Cleveland, OH; 3) Dept of Pediatr, National Defence Med Coll,Tokorozawa, Japan.

Silver-Russell syndrome (SRS) is characterized by severe intrauterine growth retardation and relative macrocephaly with triangular facies and other minor malformations. Recently, a subgroup of SRS patients has been found to exhibit aberrant imprinting at the H19 differentially methylated region (DMR) on chromosome 11p15. The underlying mechanism leading to the aberrant methylation has not yet been delineated. Here we report an aberrant hypomethylation of H19 DMR in a 2-year-old girl with SRS features and a de novo balanced reciprocal translocation of which breakpoint was near the H19 locus. The patient was born at 35 weeks of gestation and had a birth weight of 1060 g. She fulfilled the Preece diagnostic criteria of SRS. G-banding analysis revealed a 46,XX,t(8;11)(q24.1;p15.4) karyotype. Reiterative FISH experiments and genome walking revealed that the breakpoint on chromosome 11 resided in an intron 1 of the MRPL23 gene, while the breakpoint on chromosome 8 resided in the midst of a large gene desert. Analsys of SNPs near the breakpoint revealed that the translocation occurred during the spermatogenesis. Methylation analysis of the H19 DMR using bisulfite sequencing revealed that only 3 (13%) of 23 randomly chosen clones were methylated across the 18 CpG sites. The observation that the presently reported proband with an SRS phenotype and a balanced translocation, of which the breakpoint was only 25K bases from the H19, had an H19 DMR that was mostly unmethylated strongly suggests that the translocation event is causally related with the aberrant matylation pattern. The balanced translocation might have separated H19 from a putative cis-acting regulatory element that is responsible for the methylation of the paternally derived H19 DMR allele. The successful precise localization of the translocation breakpoint in the present case has yielded a promising clue to the identification of such a regulatory element whose existence on the telomeric side to of H19 has never been previously.

Surfactant-based Rapid DNA Extraction from Archived Blood Spots on Filter Paper for Molecular Analysis. *U. Bhardwaj[1], F. Mashayekhi[2], D.T. Kamei[2], E.R.B. McCabe[1,2,3]* 1) Pediatrics, David Geffen School of Medicine at UCLA, Los Angeles, CA, USA; 2) Bioengineering, Henry Samueli School of Engineering and Applied Science, UCLA, Los Angeles, CA, USA; 3) Human Genetics, David Geffen School of Medicine at UCLA, Los Angeles, CA, USA.

Dried blood spots (DBS) are widely used in neonatal screening for metabolic and genetic diseases in the United States and elsewhere. DBS on filter paper facilitate the collection, transport, and storage of blood samples for laboratory use. We present a new surfactant-based method to extract DNA from DBS that had been stored for over 10 years. Specifically, we tested the performance of the nonionic surfactants Triton X-100 and Triton X-114, which are comprised of a hydrophilic polyethylene oxide chain followed by a hydrophobic 4-(1,1,3,3-tetramethylbutyl)phenyl group. Various Triton X-100 and 114 solutions were compared with the commonly used Chelex method regarding their ability to improve detection with polymerase chain reaction (PCR) primers for dystrophin exon 20. In our method, DNA was extracted from the 3 mm filter paper punch samples with solutions containing different concentrations of the two surfactants, and subjected to PCR amplification. The 5% Triton X-100 and 7% Triton X-114 solutions increased the yield of DNA relative to the Chelex-100 method. These results suggest that the surfactants enhance the ability to remove DNA from the paper by improving the wetting properties of the solution through altering surface and interfacial tensions. This rapid, simple, and inexpensive extraction method generated superior results from archived specimens compared with the standard method and may represent a useful tool in newborn screening and molecular epidemiologic studies.

Mutation of *RRM2B*, encoding p53-controlled ribonucleotide reductase (p53R2), causes severe mitochondrial DNA depletion. *A. Bourdon[1], L. Minai[1], V. Serre[1,2], J-P. Jais[3], E. Sarzi[1], S. Aubert[1], D. Chrétien[1], P. de Lonlay[1], V. Paquis-Flucklinger[4], H. Arakawa[5], Y. Nakamura[5], A. Munnich[1], A. Rötig[1]* 1) U781, INSERM, PARIS,France; 2) Université Paris 7, PARIS, France; 3) Service de biostatistique et informatique médicale, PARIS, France; 4) Département de génétique médicale, NICE, France; 5) Human Genome Center, Institute of Medical Science, TOKYO, Japan.

Mitochondrial DNA (mtDNA) depletion syndrome (MDS; MIM 251880) is a prevalent cause of oxidative phosphorylation disorders characterized by a reduction in mtDNA copy number. The hitherto recognized disease mechanisms alter either mtDNA replication (POLG) or the salvage pathway of mitochondrial deoxyribonucleotides 5-triphosphate (dNTPs) for mtDNA synthesis (DGUOK, TK2, SUCLA2). A last gene, MPV17, has no known function. Yet, the majority of cases remain unexplained. Studying seven cases of profound mtDNA depletion (1-2% residual mtDNA in muscle) in four unrelated families, we have found nonsense, missense, splice-site mutations and in-frame deletions of the p53R2 gene encoding the cytosolic p53-inducible ribonucleotide reductase small subunit. Accordingly, severe mtDNA depletion was found in various tissues of the p53R2-/- mouse. The mtDNA depletion triggered by p53R2 mutations in both human and mouse suggests that p53R2 has a crucial role in dNTPs supply for mtDNA synthesis.

Congenital diaphragmatic hernia (CDH) associated with deletion of chromosome 15q26: genotype -phenotype correlations. *A. de Klein[1], M. Klaassens[1,2], B. Eussen[1], R. Galjaard[1], D. Scott[3], B. Lee[3], B. Oostra[1], D. Tibboel[2]* 1) Dept Clinical Genetics, Erasmus MC, Rotterdam, Netherlands; 2) Department of Pediatric Surgery, Erasmus MC, Rotterdam, the Netherlands; 3) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, USA.

Congenital diaphragmatic hernia (CDH, MIM 142340) is a severe birth defect characterized by a defect in the diaphragm, associated lung hypoplasia and postnatal pulmonary hypertension. Approximately 50% of the CDH cases are associated with other congenital anomalies and in 5-10% of the cases there is a chromosomal etiology. Deletion of 15q26 is the most frequently described structural chromosomal anomaly in patients with non-isolated CDH. recently we have reported two additional prenatally detected patients with a deletion of 15q26. The phenotype is similar to other patients with CDH caused by 15q26 deletions and includes intra-uterine growth retardation, left-sided CDH, cardiac anomalies and distinct dysmorphic features, as seen in Fryns Syndrome. Here we would like te present a genotype - phenotype correlations of these 25 CDH and compare these with other known genotype-phenotype associations as for example the chromosome 1q anomalies. We believe that when these combination of birth defects are diagnosed, either pre- or post-natally, further investigations to identify or exclude a deletion of 15q26 or other CDH loci are indicated, since this will have major consequences for prognosis.

Use of dried blood spots in ELISA detection of IL-7. *K. Chen[1], S.A. McGhee[1], E.R.B. McCabe[1,2]* 1) Pediatrics, David Geffen School of Medicine at UCLA, Los Angeles, CA, USA; 2) Human Genetics, David Geffen School of Medicine at UCLA, and Department of Bioengineering, Henry Samueli School of Engineering and Applied Science, UCLA, Los Angeles, CA, USA.

IL-7 is a 25 kDa cytokine with a nonredundant role in T cell homeostasis. Due to abnormal T-cell development, patients with untreated severe combined immunodeficiency (SCID) have elevated levels of IL-7. Patients with SCID benefit substantially from hematopoietic stem cell transplantation in the first month of life. We proposed to determine if ELISA detection of IL-7 in dried blood spots would be useful in the development of a newborn screening test for SCID. Blood samples were obtained from healthy adults. Using commercially available ELISA kits (R&D Systems), IL-7 levels were measured in (1) plasma, (2) dried plasma spots, and (3) dried blood spots. As positive controls, samples were spiked with recombinant human IL-7. IL-7 levels in dried plasma spots correlated with levels detected in fresh frozen plasma. Using Western blot analysis, IL-7 antibody was able to detect immunoreactive proteins in each sample type. We identified a low molecular weight protein that contributes to a high background in ELISA detection of IL-7 in dried blood spots. We examined a variety of strategies to reduce the high background by removing the low molecular weight protein prior to analysis, and by using different antibodies to detect IL-7. IL-7 can be recovered from dried plasma spots. Because IL-7 is present in picogram levels in the blood, there are multiple factors that can interfere with highly sensitive ELISA detection in dried blood spots. Reduction of these interfering factors will be required for use of dried blood spots for IL-7 detection as a newborn screening method for SCID.

OSTM1 and NR2E1: Positional candidate genes for psychosis in Alzheimers and Schizophrenia. *V. Kodavali*[1], *R.A. Sweet*[1], *R.I. Kamboh*[2], *V.L. Nimgaonkar*[1,2] 1) Dept Psychiatry, Univ Pittsburgh, Pittsburgh, PA; 2) Dept Human Genetics, Univ Pittsburgh, Pittsburgh, PA.

Psychotic symptoms, i.e., hallucinations and delusions, are common among patients with late onset Alzheimers Disease (LOAD), with a reported three-year cumulative incidence of 51%. Psychotic symptoms define a more severe sub-group of LOAD that has more rapid cognitive decline, causes greater caregiver distress, and results in greater societal burden due to premature institutionalization. Current treatments for LOAD with psychosis (LOAD+P) are inadequate. We have found LOAD+P to be familial, with a heritability of 61-70%. We found suggestive linkage using data from the NIMH Alzheimer Disease Genetics Initiative, at chromosome 6q near marker D6S1021. This region may also harbor psychosis liability genes for schizophrenia and bipolar illness. We conducted follow-up genetic association studies of the Chr 6q region in a cohort of 200 subjects with LOAD+P and 350 unrelated individuals with LOAD without psychosis, using pooled DNA analysis. We detected significant association with a Single Nucleotide Polymorphism (SNP, rs218291) which is located in the upstream region of Osteopetrosis-associated Transmemberane Protein 1 (OSTM1) and Tailless (NR2E1) genes (p=0.009). This polymorphism could be potentially regulating the transcription of both OSTM1 and NR2E1 genes. Importantly, increased amyloid b protein deposition and neuronal loss was observed in osteopetroic mice. Similarly, Monaghan et al (2003) showed that disruption of the NR2E1 locus leads to impaired development of supragranular layers of neocortex, layers that may be selectively affected in psychosis. In order to further understand the genetic association and the role of the regulatory regions of OSTM1 and NR2E1 in psychosis, here, we are systematically characterizing OSTM1 and NR2E1 polymorphisms and their functional effects in US Alzheimers and schizophrenia samples.

Adjustment for sex and age may conceal significant sex- and age- specific genomic determinants of physiological traits. *P. Hamet[1], O. Seda[1], D. Gaudet[2], P.-L. Brunelle[1], A. Gurau[1], E. Merlo[3], L. Pilote[4], T. Kotchen[5], A.W. Cowley[5], J. Tremblay[1]* 1) CR CHUM, Montreal, Quebec, Canada; 2) Complexe Hospitalier, Chicoutimi, Quebec, Canada; 3) École Polytechnique de Montreal, Quebec, Canada; 4) MUHC, Montreal, Quebec, Canada; 5) MCW, Milwaukee, Wisconsin, USA.

Sex and age are recognized factors affecting pathogenesis of complex traits. Their effects on the underlying genetic architecture received only limited attention so far. From over 500 collected traits in 120 French-Canadian families (n = 810 subjects) from the Saguenay-Lac-St-Jean region of Quebec, Canada, about 50% were sex- and age- independent, remaining ones were sex- and age-specific to a variable degree. We assessed, among other traits, the sex- and age-specific linkage of systolic (SBP) and diastolic (DBP) blood pressures and heart rate recorded also by 24h ambulatory blood pressure measurement. Multipoint and two-point sex-specific linkage analysis was performed with a variance components approach implemented in SOLAR in 3 settings: all, males and females. Age-specific two-point linkage analysis was performed by S.A.G.E. SIBPAL in all sibpairs, younger than 55 years and older than 55 years. The genetic information was represented by 437 microsatellite markers and >58,000 single nucleotide polymorphisms by Affymetrix GeneChip 50k Xba240 array. The results of linear regression confirmed significant contribution of age to the temporal change of SBP but not DBP. Heritability was higher in women for HR and DBP, conversely, most SBP measures were more heritable in men. In age-specific analysis, we observed several significant linkage signals specific for <55-year sib-pair group, e.g. SBP (peak at D8S1100, p=5.6x10-6) or pulse pressure (peak at D12S1064, p=4.3x10-6). Sex-specific linkage analysis revealed locus on chromosome 2 linked to SBP exclusively in men with no evidence of linkage in the female and combined sets. The fine genotyping pointed to rs10497097 in an intron of STAM2 gene at the peak of male-specific signal. We report identification of several age- and sex-specific genetic determinants of blood pressure and heart rate, none of which would have been observed in fully sex- and age-adjusted models.

A Variant in ENPP1 is Associated with Obesity and Insulin Action in Pima Indians. *T. Guo, M. Traurig, Y. Muller, L. Ma, R. Hanson, K. Sayuko, C. Bogardus, L. Baier* PECRB, NIDDK/NIH, Phoenix, AZ.

ENPP1, Ectonucleotide Pyrophosphatase/Phosphodiesterase 1, also known as PC-1 (Plasma Cell Membrane Glycoprotein), maps to a chromosome 6q23-24, previously shown to have suggestive linkage to type 2 diabetes (T2D) in a genome-wide linkage scan for genetic determinants of T2D among Pima Indians. ENPP1 inhibits insulin-induced conformational changes of the insulin receptor, thereby affecting its activation and downstream signaling. Prior studies have reported that a Gln121Lys in ENPP1 is associated with type 1 diabetes, T2D and obesity in some populations. To investigate the potential role of ENPP1 in the pathophysiology of T2D and obesity in Pima Indians, all 25 exons, the 5 and 3-UTRs and more than 2kb of the putative promoter region of ENPP1 were sequenced in DNA from 24 non-first-degree related Pima Indians. Among the 21 single nucleotide polymorphisms (SNPs) that were identified, two were nonsynonymous (Gln121Lys and Phe656Leu), but neither were associated with T2D or Body Mass Index (BMI) among a population-based sample of 3500 full-heritage Pima Indians. In contrast, one common SNP (rs17060795) located in a conserved non-coding sequence (CNS) was associated with BMI in this population sample (general analysis p=0.03; within family analysis p=0.02, both p adjusted for age, sex, and birth-year). In addition, among 358 non-diabetic Pima subjects who had been studied in our Clinical Research Center, this SNP was also associated with percent body fat, fat mass and fat-free mass (adjusted p=0.02, 0.002 and 0.002, respectively) as well as measures of insulin action, where subjects with the obesity risk allele (G) had a lower mean glucose uptake rate in response to both physiologic and high dose insulin infusions during a hyperinsulinemic, euglycemic clamp (adjusted p=0.005 and p= 0.0007, respectively). The CNS encompassing this variant is a retroposed gene of LRRC8B. We determined that this retroposed gene itself is not expressed in human tissues, but propose that the retroposed sequence may have acquired regulatory activity that is affecting expression of ENPP1 or another nearby gene, resulting in variation in body composition and insulin action.

Nitisinone (OrfadinR) reduces the massive fractional excretion of homogentisic acid in alkaptonuria patients. *M. Kayser, W. Introne, K. O'Brien, I. Bernardini, R. Kleta, W. Gahl* Human Biochemical Genetics Section, Medical Genetics Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD.

Alkaptonuria (AKU), a rare metabolic disorder of impaired tyrosine catabolism, is due to deficiency of homogentisic acid oxygenase. An organic compound, homogentisic acid (HGA), accumulates and binds to connective tissue causing darkened urine, darkened cartilage (ochronosis), joint destruction, and cardiac valve deterioration. Homogentisic acid is actively secreted through organic anion transporters in the renal tubules at levels 3-4 times the glomerular filtration rate. In AKU patients, mean plasma levels of HGA are 6.6 ug/ml and urinary HGA excretion averages 4.2 grams per day, more than 100 times normal. Nitisinone (NTBC), a potent reversible inhibitor of p-hydroxyphenylpyruvic acid dioxygenase, was shown in two separate, small studies to reduce urine homogentisic acid excretion in AKU patients up to 95%. We measured urine and plasma HGA levels in 42 AKU patients enrolled in either a natural history or a long-term treatment trial evaluating the clinical efficacy of nitisinone. Plasma HGA, measured using an HPLC/UV method, was 0.355 ug/ml (0.148-0.815) in the 6 patients receiving nitisinone and 5.65 ug/ml (2.62-11.2) in the 36 patients not receiving nitisinone. and Urine HGA, measured using a stable isotope dilution GC/MS technique, was 9.9 mg/dl (1.13-24.8) in the nitisinone-treated patients and 255.4 mg/dl (42-585.9) in those not receiving nitisinone. The average fractional excretion of HGA was 276% (90-520) in the nitisinone-treated patients vs 422% (80-1328) in those not receiving nitisinone. In conclusion, nitisinone reduces the filtered load of HGA, resulting in decreased tubular secretion through the organic anion transporter systems and, consequently, decreased urine HGA excretion.

Central nervous system impairment in mouse saposin C deficiency. *G.A. Grabowski, H. Ran, M. Zamzow, B. Quinn, Y. Sun* Div Human Genetics, Cincinnati Childrens Hosp, Cincinnati, OH.

Saposin C has unique activation and proteolytic protective functions for acid -glucosidase (GCase), the enzyme that cleaves glucosylceramide, a glycosphingolipid in the lysosomal degradation pathway. Saposin C as well as saposins A, B and D is processed from a common precursor, prosaposin. The few patients with saposin C deficiencies developed a Gaucher-like phenotype due to diminished glucosylceramide cleavage activity. To explore the *in vivo* effects of saposin C, saposin C null mice (C-/-) were generated by introducing a point mutation into the cysteine codon in exon 11 of prosaposin locus. Prosaposin and saposin A, B and D were expressed at normal levels whereas saposin C protein was not detected in C-/- mice. Inclusions in dorsal root ganglion and loss of Purkinje cells were evident at 25 weeks. The neurological phenotype in C-/- mice developed at about 1 year and those mice exhibited wobbly walking and weakness of the hind limb. Activated microglial cells and astrocytes were present in thalamus, brain stem and hind brain, demonstrating restricted regional proinflammatory response in C-/- mice. Deficiency of saposin C resulted in decreases of *in vitro* GCase activity in liver, kidney and brain due to the decrease in proteolytic structure of the wild type GCase. No storage cells or glucosylceramide were found in visceral organs in C-/- mice. These results support the notion that saposin C has a predominant function in the central nervous system. The further elucidation of saposin Cs *in vivo* function will advance the study of glycosphingolipid storage diseases.

LGMD2B (Dysferlin-deficiency) shows compensatory upregulation of vesicle trafficking pathway Rab27A and its effector Synaptotagmin like protein 2. *A. Kesari[1], M. Fukuda[2], S. Knoblach[1], EP. Hoffman[1]* 1) Center of Genetic Medicine, Children's National Medical Center, Washington, DC; 2) Department of Developmental Biology and Neurosciences, Tohoku University Miyagi, Japan.

Mutations in the dysferlin gene (DYSF) on chromosome 2p13 cause Limb girdle muscular dystrophy 2B (LGMD2B) and Miyoshi Myopathy (MM). Dysferlin-deficient patients show a relatively acute onset with marked muscle inflammation in late teens. Dysferlin-deficient muscle shows abnormalities of vesicle trafficking. We hypothesized that the late yet acute onset of LGMD2B could be associated with compensatory up-regulation of alternative vesicle traffic pathways, and inflammatory signals. Twenty-five patients showing Dysferlin-deficiency on muscle biopsy were used for mutation screening, and 19 mutation-positive patients identified. Ten of these biopsies were used for genome-wide mRNA profiling, and data compared to a disease control (FKRP mutation-positive subjects [LGMD2I]), and normal volunteer muscle. Two inflammatory-associated genes, Tenascin and Versican, were found highly expressed in Dysferlin-deficient muscle, at both the mRNA and protein levels. These two interacting proteins may respond to the vesicle traffic and monocyte abnormalities, leading to over-aggressive inflammatory cascades. A vesicle trafficking pathway involving two interacting proteins, Synaptotagmin-like protein (Slp2a) and a small GTPase (RAB27A), were highly induced in dysferlin-deficient muscle, while not expressed in normal muscle, Becker muscular dystrophy, or FKRP. We suggest that the C2-containing Slp2a protein shows disease-specific compensatory up-regulation in Dysferlin-deficiency, leading to induction of an alternative vescicle trafficking pathway.

Fine-mapping of 42 hereditary prostate cancer families narrows the interval for a susceptibility locus on chromosome 22q12.3. *B. Johanneson[1], S.K. McDonnell[2], D.M. Karyadi[1], S.J. Hebbring[3], L. Wang[3], K. Deutsch[6], L. McIntosh[4], E.M. Kwon[1], M. Suuriniemi[1], J. Stanford[4,5], D.J. Schaid[2], E.A. Ostrander[1], S.N. Thibodeau[2]* 1) Institute, National Institutes of Health, Bethesda, MD 20892; 2) Department of Health Sciences Research, Mayo Clinic, Rochester, MN 55905; 3) Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN 55905; 4) Division of Public Health Sciences, Fred Hutchinson Cancer Research Center, Box 19024, Seattle, WA 98109; 5) School of Public Health and Community Medicine, University of Washington, Seattle, WA 98115; 6) Institute for Systems Biology, Seattle, WA 98103.

Genetic studies suggest that hereditary prostate cancer is a genetically heterogeneous disease with multiple contributing loci. Studies of high-risk prostate cancer families selected for aggressive disease, analysis of large multigenerational families, and a meta-analysis from the International Consortium for Prostate Cancer Genetics (ICPCG), all highlight chromosome 22q12.3 as a susceptibility locus. Our study is the most detailed fine-mapping analysis of this region to date. Of 173 high-risk families from the Mayo Clinic and 254 from the Prostate Cancer Genetic Research Study (PROGRESS), 42 were identified as having a shared haplotype among all affected men that overlapped the 22q12.3 region. In 35 of the families, an overlapping consensus region of 8.73 Mb is defined. However, in the subset of 14 families with 5 affected men per family, a 2.53 Mb shared consensus segment is identified in 12 of the families that overlaps with previously published intervals. Combining these results with data from the other published studies, a three-recombinant consensus interval is found in 52 of 54 families which narrows down the region to 1.36 Mb between 33.72 Mb and 35.08 Mb. Overall, our results provide the most comprehensive framework achievable for candidate gene testing. Ongoing studies are aimed at evaluating genes in this region for variants associated with prostate cancer risk.

Race-Marketing: BiDil and the Race Debate in Popular Media. *S. Harry, T. Caulfield* Health Law Institute, Edmonton, Alberta, Canada.

The Food and Drug Administrations approval of the race-specific drug BiDil, marketed as a heart failure medication specifically for African-Americans or individuals who self-identify as black, has triggered the re-emergence of the race debate in genetic research literature and in the popular media. Supporters of the drug including the National Association for the Advancement of Colored People (NAACP) and the Association of Black Cardiologists have lauded the medication as the first step in decreasing health disparities within ethnic minority groups (Lerner, 2004). Critics have been very vocal in questioning the methodology of the drug trials and interpretation of the results, arguing that the trials were unduly influenced by commercial considerations (Gellene, 2005). Given the important role the media plays as a source of information and as a means of shaping public perceptions, exploring popular representations of race in this context seems essential.

This study examines popular representations of BiDil including major newspapers, magazines, and periodicals using a coding frame successfully implemented in other media studies. Preliminary observations show that while the popular press portrays both sides of the race controversy, a significant portion uncritically accept the existence of genetic differences between races despite extensive scientific evidence to the contrary. Only a few articles discuss socio-economic factors as contributors to heart failure in African Americans, but emphasize the significance of genetic predisposition. This data helps to inform the debate regarding the representations of race in the context of genetic research. While some have suggested that the development of BiDil is the first constructive step toward the pharmacogenomic goal of personalized medication (Roylance, 2005), others commentators have countered that race does not accurately reflect individual variation or variation within a sub-population. Future research should explore the degree to which popular representations accurately reflect this debate and the degree to which they result in the racialization of medicine (Stein, 2005).

.

Evaluation of Genetic Services in Ontario: Patient Satisfaction and Health Care Utilization. *M. Cappelli[1], N. Barrowman[1], J. Carroll[2], N. Carson[1], C. Gilpin[1], F. Miller[3], M. Mullen[1], L. Velsher[4], B. Wilson[5]* 1) Dept Psychology, Children's Hosp Eastern Ont, Ottawa, ON, Canada; 2) Univ of Toronto, Toronto, Canada; 3) MacMaster Univ, Toronto, Canada; 4) North York Gen Hosp, Toronto, Canada; 5) Univ of Ottawa, Ottawa, Canada.

In 2000, publicly funded clinics were established in Ontario to provide comprehensive cancer genetic counseling services. Considerable interest in genetic testing, coupled with increasing knowledge of the availability of these services has to led to greater demand on these services. This ongoing study, which began in 2003, evaluates cancer genetic services in Ontario for hereditary breast, ovarian and colorectal cancers. Emphasis is on patient satisfaction with these services, and patient knowledge and practices following genetic counseling. A prospective, repeated measures design was used. Patients were recruited from five regional sites across Ontario. All participants complete a self-report survey (Time 1) following their genetic counseling appointment. Patients who underwent genetic testing completed two additional surveys: a telephone interview at Time 2 (4-6 weeks after receiving genetic test results), and a mail-out survey at Time 3 (one year after receiving genetic test results). To date, 640 surveys (Time 1) have been mailed and 489 returned (response rate = 76.4%). Preliminary data demonstrate that 95.7% of patients were satisfied with the manner in which they were received by the staff at the genetic clinic. As well, 93% felt that they were given the information they wanted about the risks and benefits of genetic testing. A notable area showing decreased satisfaction is communication between the genetic counselor and the physician about genetic test results (72.2%) as well as recommended screening (62.1%). By identifying current deficiencies in the services provided, cancer genetics services can improve and evolve which, in light of anticipated future demands, is critical for sustainability. These results have implications for policy formulation regarding cancer genetics programs in Ontario and elsewhere.

Genetic association of the CHRNA6 and CHRNB3 genes with tobacco dependence in a nationally representative sample. *N. Hoft[1], I. Schlaepfer[1], R. Corley[1], S. Young[1], B.C. Haberstick[1], D. Huizinga[2], S. Menard[2], M. Ehringer[1]* 1) Inst Behavioral Genetics, University of Colorado, Boulder, CO; 2) Inst Behavioral Science, University of Colorado, Boulder, CO.

The family of neuronal nicotinic acetylcholine receptors show regulation of activity by both endogenous acetylcholine and exogenous nicotine, making sequence variations in these receptors likely candidates for association with tobacco phenotypes. Our group has previously identified a significant association between SNPs in the genomic region containing the CHRNA6 genes and dependence for tobacco use in a young adult Colorado-based sample (Zeiger et al, submitted). Similarly in that same region SNPs in CHRNB3 have been found to be associated with tobacco dependence in regular smokers (Beirut et al 2007). In this study, we were able to replicate both these findings in the National Youth Survey Family Study wave 10, a nationally representative sample of households. Eight single nucleotide polymorphisms (SNPs) in the CHRNA6 and CHRNB3 genomic region were genotyped in 1002 subjects, approximately half of whom are members of sibling pairs. Association was assessed using a family-based approach as implemented in the statistical package PBAT (FBAT-PC, principal components). Individual SNPs were tested for association with a composite phenotype of frequency and quantity of tobacco use and dependence, and followed by testing of individual phenotypes to validate results from the composite. Variation in CHRNA6 was found to be associated with a composite dependence-frequency-quantity phenotype ($p = 0.02$) as well as with dependence in regular smokers ($p=0.025$). Additionally, multiple SNPs adjacent to rs6474413, the SNP identified in Beirut et al (2007), were shown to be associated with dependence in regular smokers ($p=0.004$). Together these results further implicate the region upstream of CHRNB3 in susceptibility/resistance to nicotine dependence.

A common polymorphism in the CARD domain of RIG-I modifies the innate immune response of human dendritic cells. *J. Hu, A. Voho, Y. Ding, A. Ganee, M. Kumar, A. Pendleton, J. G. Wetmur* Microbiology, Mount Sinai School of Medicine, New York, NY.

Infection of human dendritic cells (DCs) by negative-stranded RNA viruses leads to activation of the RNA helicase RIG-I, exposing its CARD domain. The CARD domain binds to MAVS and initiates downstream signaling resulting in the induced transcription of the interferon beta gene (*IFNB1*). Interferon beta expression is a crucial step in both induction of innate immunity and in the DC maturation response leading to induction of adaptive immunity. Transcription of the RIG-I gene (*DDX58*) is itself induced by interferon beta signaling through the type-1 interferon receptor. A common and potentially functional SNP, rs10813831 (A/G), encodes a Arg7Cys polymorphism in the RIG-I CARD domain. qRT-PCR analysis of the total RNA extracted from 130 DC samples infected by Newcastle disease virus revealed a significant association of Arg7Cys with increased *IFNB1* transcription (p=0.05 for heterozygous and p=0.019 for homozygous variants; p_{trend}=0.021) and *DDX58* transcription (p=0.067 for heterozygous and p=0.034 for homozygous variants; p_{trend}=0.023), particularly in homozygous variants. RNA allelic imbalance (AI) analysis on these infected DC samples showed that the Arg7Cys polymorphism was not associated with AI (p=0.845), ruling out linkage disequilibrium and demonstrating that the observed association between Arg7Cys and transcription originated from the structural change of RIG-I CARD domain, possibly affecting RIG-I folding or interaction with MAVS. In a separate experiment, single-cell level transcription of *IFNB1* and *DDX58* in individual DCs was examined by nested multiplex real time qPCR. This single cell analysis revealed a much stronger association between *IFNB1* and *DDX58* transcription in the presence than in the absence of blocking antibodies (R^2=0.60 vs. 0.28). Taken together, these data indicate that the innate immune response to viral infection in human DCs is strongly dependent on the basal level of *DDX58* transcription and is modified by a functional polymorphism in its CARD domain. Support: NIAID HHSN266200500021C and U19AI06231.

GSTT1: Clinical Biomarker Assay Development for Copy Number Variation. *A.B. Freeman, C. Taylor, L. Gautier, Y. Xiang, C. Lopez-Correa* Integrative Biology and Lilly Systems Biology, Eli Lilly and Company, Indianapolis, IN.

Glutathione S-transferase (GSTT1) is a Phase II metabolizing enzyme responsible for the conjugation of environmental carcinogens, pollutants, drugs and other xenobiotics. GSTT1 contains a deletion that reduces enzyme activity, is highly variable in the human population and therefore results in a Copy Number Variant (CNV). The GSTT1 copy number genotype correlates with conjugation phenotype; individuals with two gene copies have a high conjugator phenotype whereas individuals with no copies of GSTT1 (null genotype) have a nonconjugator phenotype. Therefore, a GSTT1 CNV assay could serve as a key clinical biomarker for tailored therapies and patient stratification.

We assessed the ability of PCR and Quantitative PCR (qPCR) technologies to detect the GSTT1 deletion status in 263 HapMap and 23 cancer cell lines. The two PCR assays used to genotype the GSTT1 CNV were optimized from previously described methods while the qPCR assay was similar to that described by McCarroll et al (2006). In an independent effort, we also utilized array Comparative Genomic Hybridization (aCGH) to detect the GSTT1 copy number in the cancer samples.

Using the qPCR assay in the HapMap cell lines, our GSTT1 CNV genotypes were in 100% agreement with McCarroll et al (2006) as compared to 90% agreement with the PCR assay. In the cancer samples, however, there was only 70% consistency between the qPCR and PCR assay results, while the aCGH genotypes had even less consistency with all of the above.

We conclude the qPCR assay is the most accurate and reliable for the detection of GSTT1 copy number in clinical patients. We further hypothesize that the high rate of discrepant GSTT1 CNV genotypes observed with all assays in the cancer samples is attributed to increased genomic rearrangements and instability within these cell lines. Cell heterogeneity within the cancer samples would directly affect the analysis of CNV genotypes with one or two copies. This is substantiated by the consistency among all four assays to identify the GSTT1 null genotype in both normal and cancer samples.

MicroRNA expression profiling in human embryonic stem cells using universal bead arrays. *J. Fan[1], J. Chen[1], J. Loring[2], L. Laurent[2]* 1) Dept Genetic Analysis, Illumina, Inc, San Diego, CA; 2) Burnham Institute for Medical Research, La Jolla, CA.

We have developed a very sensitive and reproducible method for microRNA expression profiling. The method is a modification of the high throughput gene expression profiling assay, the DASL Assay that we developed previously (Fan et al., Genome Research 14:878-885. 2004). It applies a solid-phase primer extension (after target hybridization) to enhance the discrimination among homologous miRNA sequences. In addition, universal PCR is used to amplify all targets prior to array hybridization. Currently, assays are designed to simultaneously analyze 470 well-annotated human miRNAs (miRBase: http://microrna.sanger.ac.uk/), and additional 273 human miRNAs compiled from the literature. Highly reproducible miRNA expression profiles (R^2 >0.98) were generated with as little as 200 ng total RNA input. Furthermore, very similar expression profiles were obtained between total RNA and enriched small RNA species (R^2 = 0.96). High concordance (R^2 = 0.8) was obtained between the array results and quantitative RT-PCR results, when fold-difference was compared.

We have used this method for global miRNA profiling of human embryonic stem cells (hESC), neural stem cells (NSC), and differentiated cells to probe the differences in miRNA usage leading to self-renewal and pluripotence. Unsupervised clustering analysis separated all samples into four distinct groups: hESCs, fetal NSCs, adult NSCs and differentiated cells. Interestingly, miRNAs differentially regulated in hESCs are distributed in large genomic clusters. Moreover, previously described oncogenic miRNAs are over-expressed in hESCs, while tumor suppressor miRNAs are depleted in hESCs compared to the differentiated cell types. Let-7, a miRNA shown to be necessary for cellular differentiation in *c. elegans*, is strongly down-regulated in hESCs. This suggests that miRNAs play important regulatory role in maintaining the stem cell state, and in directing stem cell differentiation.

QUANTIFICATION OF microRNA DURING CENTRAL NERVOUS SYSTEM DEVELOPMENT. *D.B. Dogini, P.A.O Ribeiro, T.C. Pereira, C.S. Rocha, I. Lopes-Cendes* Medical Genetics, FCM - UNICAMP, Campinas, Sao Paulo, Brazil.

MicroRNAs (miRNAs) are a recently discovered class of non-coding RNA molecules of 21-24nt that regulate the expression of target genes in a post-transcriptional manner. This regulation is likely to be mediated by translational repression or target mRNA degradation. miRNAs are though to be involved in several important biological processes, including cell differentiation and embryonic development. In order to better investigate the role of miRNAs in central nervous system (CNS) development, we quantified 104 different miRNAs in mouse brain during development. We obtained RNA from mouse in four stages of development (E15, E17, P1 and P7) and used it in real-time PCR reactions with a stem-loop RT based TaqMan MicroRNA Assay. Bioinformatics analysis identified four clusters (C1, C2, C3 and C4) of miRNAs expression. In addition, we found a significant decrease in expression of 12 miRNAs (Cluster C1; $p<0,05$) in latter stages of development. Our results suggest the presence of a specific expression pattern in cluster C1, indicating that these miRNAs are involved in regulation of genes related to neurogenesis. Supported by CAPES and FAPESP.

Algorithm for conversion of TaqMan genotyping assays to unlabeled probe assays. *D. de Silva[1], M. Wall[1], J. Blackett[1], F. le Calvez[2], S. Tavtigian[2], J. McKinney[1], D. Teng[1]* 1) Idaho Technology, Inc, Salt Lake City, UT; 2) International Agency for Reasearch on Cancer, Lyon, France.

In the past, using PCR methods for genotyping has required fluorescently labeled oligonucleotides. These methods can be costly and time consuming. TaqMan probes are one such example where a different probe is required for each allele. LunaProbes, an extension of the high-resolution DNA melting technique, now provides a simple, inexpensive alternative for genotyping. With LunaProbes, all three possible genotypes that result from a given polymorphism can be detected with a single unlabeled oligonucleotide probe. A LunaProbe is a simple oligonucleotide blocked at the 3 end to prevent extension. LunaProbes are designed to sit over a SNP of interest and are included in the PCR reaction prior to amplification. Genotyping is accomplished by monitoring the melting of the probe-target duplex post PCR. Key to the success of this method is the use of asymmetric PCR, where one primer is used in excess resulting in the over-production of the target strand recognized by the probe and the use of LCGreen Plus dye that is capable of producing a strong fluorescent signal from the probe-target interaction. A simple decision tree is presented that allows rapid assessment of an existing fluorescent probe design for conversion to a LunaProbe assay. The steps required take into consideration: the sequence and Tm of oligonucleotides being used to amplify region of interest, and the sequence and Tm of the probe in use. This assessment will also define which DNA strand is optimal for the probe to anneal to, helping a user design the asymmetric PCR reaction. LunaProbes are a simple inexpensive alternative for genotyping, easily replacing current expensive methods of genotyping. The algorithm presented was validated on ten TaqMan assays where a single LunaProbe replaced two fluorescently labeled probes with a 100% success rate.

Adult onset congenital erythropoietic porphyria, an extra challenge in the diagnosis of porphyria. *S. Gustafson[1], A. Lichtin[2], K. Astrin[3], C. Eng[1]* 1) Genomic Medicine Institute, Cleveland Clinic Foundation, Cleveland, OH; 2) Department of Hematology, Cleveland Clinic Foundation, Cleveland, OH; 3) Mt Sinai School of Medicine Porphyria DNA Testing Laboratory, New York, NY.

The porphyrias are a group of metabolic diseases of heme biosynthesis for which clinical and laboratory findings show significant heterogeneity. Congenital erythropoietic porphyria (CEP) is a rare autosomal recessive porphyria, caused by germline mutations in the uroporphyrinogen III synthase gene (UROS), typically presenting in childhood with severe photosensitivity, urine discoloration, and erythrodontia. Rare cases of adult-onset CEP have been reported, with homozygous germline UROS mutations causing reduction in enzyme production. In some cases of late-onset CEP associated with hematologic abnormalities suggestive of myelodysplastic syndrome, somatic loss-of-heterozygosity or acquisition of a second loss-of-function mutation within bone marrow cells has been suggested as a cause. A 47 year-old woman who first presented in her late 20s with mild cutaneous photosensitivity resembling porphyria cutanea tarda, a family history suggesting AD inheritance, and urine, blood and stool porphyrin levels consistent with CEP, was referred to genetics for clarification of the diagnosis and discussion of treatment options. Mutation analysis of UROS identified germline compound heterozygosity for a common CEP missense mutation (C73R), and a novel missense change (R138H). This is the first report of R138H, which, based on the presentation of our patient, is suspected to be a mild CEP mutation. Literature review revealed at least 17 cases of adult-onset CEP, with male predominance; 9 (52.9%) were associated with thrombocytopenia or myelodysplasia. Age at diagnosis ranged from 23 years of age to 72 years, and presentation varied from mild to severe in skin findings, urine discoloration, and other organ involvement. Our patient, with a mild phenotype, adds to the limited literature reporting adult-onset CEP and helps to expand the clinical spectrum of CEP. Further studies are needed to define whether UROS testing should be included as a diagnostic adjunct in atypical CEP and CEP-like presentations.

Age of diagnosis vs. outcome of infants with Severe Combined Immunodeficiency. *J. Davis[1], K. Chan[1], J. Puck[2]* 1) NHGRI,NIH Bethesda, MD; 2) Dept.of Pediatrics, UCSF, San Francisco, CA.

Severe combined immunodeficiency(SCID)is a rare disorder characterized by lack of T cells and antibody responses. Though genetic etiologies are diverse, all affected infants have very few T cells. SCID is asymptomatic at birth. Unless family history is positive, SCID infants are diagnosed only after serious infections arouse suspicion; those not recognized in time for intervention die of infections. Bone marrow transplantation (BMT) for SCID is life-saving if performed early; Buckley et.al (2004) reported 95% vs 70% survival, respectively, for BMT before vs after 3.5 m of age. We have developed a SCID newborn screening test based on quantitative PCR of T-cell receptor excision circles (TRECs), which are abundant in normal neonatal blood, but absent in SCID blood regardless of genotype(Chan and Puck, 2005). To examine whether universal newborn screening for SCID would be beneficial, we designed a structured interview for parents that reviewed each month of their affected infants first 2 years. Parents of 39 SCID patients born from Jan 2000 through Dec 2004 consented to sharing their infants history either after enrolling in our mutation study or by responding to our notice on the website www.scid.net. Based on their vivid recollections, we recorded numbers of clinic visits for infections, hospital stays, treatments, age at SCID diagnosis, age at BMT, and outcome. A recognized family history, present in only 7 cases (18%), led to early diagnosis (mean age of 2 m). These infants all received antibiotics and immunoglobulin, had BMTs at a mean age of 3 m, and were surviving at least 2.5 y post-BMT. In contrast, the 32 SCID infants (82%) with no known family history had a mean age of diagnosis of 9 m, with one diagnosed only at autopsy. Eight sporadic SCID infants died of infections before treatment could be instituted, and 10 others died after receiving BMT or PEG-ADA enzyme treatment, yielding an overall survival of only 44% for this group. We suggest that testing all newborns for TRECs could rescue SCID infants by giving sporadic cases access to early care currently available only to those with prior affected relatives.

Deducing source population HLA composition in US ethnic groups. *W. Klitz[1,2], L. Gragert[3], M. Maiers[3]* 1) Sch Public Health, Univ California, Berkeley, CA; 2) Public Health Institute, Oakland, CA; 3) National Marrow Donor Program, Minneapolis, MN.

The USA is indeed a nation of immigrants, ranging from the first prehistoric arrivals from Asia to the sea, land and air additions of more recent times. Despite admixture since arrival, the unique genetic record of the source populations of US ethnic groups awaits revelation. We uncover the parental population contributions of two major admixed US ethnic groups, African Americans and Hispanics, utilizing HLA (Human Leukocyte Antigen) variation from the A, B and DRB1 loci. HLA typing of donor samples from the National Marrow Donor Program was used to estimate three locus haplotypes with more than 90,000 samples in each group, including European Americans as representative of one of the parental populations of each of the admixed groups. The results showed that Europeans contributed to both the African Americans and Hispanics, as is well known from demographic history. Each of the admixed populations had less than 40% haplotype similarity to the European Americans. Remarkably, HLA haplotypes demonstrated nearly complete separation according to continental source (Africa, America and Europe) with nearly all haplotypes being discretely assignable to place of origin. This work recovers the original HLA types of the founding populations, populations which typically are no longer coherent and available for study after the original founder events often centuries ago. We conclude that minimal overlap in HLA haplotypes is present between populations having different continental origins. This is unlike other genetic systems, including genomic surveys of SNPs and microsatellites in which summaries of contrast between human populations reveal only statistical tendencies of population differentiation. In contrast, HLA haplotypic variation has evolved rapidly among human populations as they spread across the globe, producing the nearly complete separation among groups.

Molecular mapping of a balanced translocation involving 11q24.2 associated with severe bipolar affected disorder. *S.T. Holden[1], A.S. Davies[2], S. Bint[2], A. Dunlop[3], R. Blennerhassett[4], R.C. Trembath[5], W. Reardon[3]* 1) Clinical Genetics, Guy's and St Thomas' NHS Trust, London, United Kingdom; 2) Cytogenetics, Guy's and St Thomas' NHS Trust, London, United Kingdom; 3) National Centre for Medical Genetics, Our Lady's Hospital for Sick Children, Crumlin, Dublin 12, Ireland; 4) St Ita's Psychiatric Hospital, Portrane, Co. Dublin, Ireland; 5) Medical and Molecular Genetics, King's College, London, United Kingdom.

The molecular characterization of the breakpoints of chromosome rearrangements associated with disease phenotypes, in conjunction with data from linkage and association studies, is a powerful approach to identifying candidate genes for complex genetic disorders. This approach has led to the identification of candidate genes for schizophrenia and bipolar disease, conditions associated with episodes of psychosis, and has highlighted pathways which begin to explain how these phenotypes, which show overlapping features and can be manifest within the same kindred, might be related at the molecular level. Linkage and association studies have shown that the region 11q22-24 is a disease locus for schizophrenia, and have highlighted FXYD6 and GRIK4 as candidate susceptibility genes. Interestingly, two patients have been reported, one with recurrent episodes of psychosis, and a second with severe bipolar disease, who have unbalanced chromosome deletions of 11q (Jacobsen syndrome) encompassing the interval of this disease locus. We report our progress in mapping the chromosome breakpoints in an intellectually normal patient with an apparently balanced chromosome rearrangement, 46,XX,t(11;15)(q24.2;q26.3), who has had recurrent episodes of severe bipolar disease associated with psychosis. The chromosome 11 breakpoint maps close to, but is distinct from, GRIK4, raising the possibility of further genetic heterogeneity for susceptibility at this disease locus.

An illustrative case of a mosaic deletion of FMR1 in a mildly affected male. *M. Ikeda[1], B. Coffee[1], D. Budimirovic[2], L. Hjelm[1], W. Kaufmann[2], S.T. Warren[1]* 1) Dept Human Genetics, Emory Univ, Atlanta, GA; 2) Kennedy Krieger Institute, Johns Hopkins University, Baltimore, MD.

Fragile X syndrome (FXS) is a common form of inherited mental retardation and is most often due to the loss of the FMR1 gene expression by expansion of a 5 UTR CGG-repeat. However, other sequence specific mutations such as missense changes and deletions involving FMR1 can also abrogate gene function. We report here the characterization of a 1 Mb mosaic deletion encompassing both FMR1 and FMR1NB in an 11 year-old male showing cognitive delay and social avoidance. Although a normal length 23 CGG repeat allele was present, PCR amplification of the repeat tract and a Southern blot probing for FMR1 in patient DNA returned signal intensities that were decreased relative to controls. Use of a comparative genomic hybridization microarray for the X-chromosome, probing at an average intermarker distance of 330 bp, identified a possible 1 Mb deletion spanning FMR1 and the next downstream gene, FMR1NB. A PCR based assay, using primers immediately outside the boundaries of the deletion, amplified a breakpoint junction fragment and confirmed a deletion of 1,013,395 bp. The fragment sequence revealed L1 elements immediately flanking the breakpoint with a common 4 bp sequence at each edge, indicating non-homologous end joining utilizing this microhomology. This case illustrates issues regarding FMR1 gene testing. The patient had a relatively mild FXS phenotype (IQ of 73 but without facial features of FXS) due to his 10% mosaicism of the intact X-chromosome in lymphocytes. Moreover, this large deletion resulting in weaker, but normally sized fragments on PCR and Southern blot testing could be interpreted as normal. Thus, for patients with mild FXS phenotypes and normal clinical testing results, FMR1 copy number variation should also be considered.

Paternally Transmitted Haplotypes of the Imprinted Insulin Gene are Associated with Size for Gestational Age and Umbilical Cord IGF-II Levels. *R.M. Adkins[1], J. Krushkal[2], C. Klauser[3], E.F. Magann[4], J.C. Morrison[3], J. Fain[5], G. Somes[2]* 1) Pediatrics, University of Tennessee Health Science Center, Mephis, TN; 2) Preventive Medicine, UTHSC; 3) Obstetrics & Gynecology, Univ. MS Medical Center; 4) Naval Medical Center Portsmouth, VA; 5) Molecular Sciences, UTHSC.

Objective: To test the association between haplotypes in the insulin-IGF2 locus and both risk of small for gestational age birth and umbilical cord IGF-II levels, as well as the effect of the parental origin of haplotypes. **Subjects:** 207 pairs of healthy African-American full-term newborns and mothers were recruited from Memphis TN and Jackson MS with birth weights ranging from 2210g to 4735g. **Methods:** Six single nucleotide polymorphisms (SNPs) located in the insulin (INS) and insulin-like growth factor 2 (IGF2) genes were genotyped in all mothers and newborns. Associations of individual SNPs and inferred haplotypes in the newborns and mothers with risk of small for gestational age (SGA) birth were tested using logistic regression, and mean umbilical cord IGF-II levels were compared by ANOVA. The risk of SGA and differences in cord IGF-II were also compared according to the parental origin of haplotypes. **Results:** In newborns three INS SNPs exhibited significant ($p<0.01$) association with reduced SGA risk. Two of these SNPs also were significantly associated with umbilical cord IGF-II levels. The alternate alleles at these SNPs were associated with reduced risk of SGA when present in the mother. No maternal SNPs associated with cord IGF-II levels. When analyzed according to parental origin of haplotypes, paternally-transmitted haplotypes significantly associated with risk of SGA and cord IGF-II levels, but maternally-transmitted haplotypes were not significantly associated. **Conclusion:** Newborn genotypes for polymorphisms near the 5 end of the insulin gene are significantly associated with size for gestational age and cord IGF-II levels, with a major effect due to the paternally inherited allele, which is preferentially expressed due to imprinting. There is some evidence that complementary haplotypes confer reduced risk of SGA in mothers and newborns.

Risk assessment of acute vascular events in Congenital Disorder of Glycosylation type Ia. *J.B. ARNOUX[1], V. VALAYANNOPOULOS[1], N. BODDAERT[2], F. BRUNELLE[2], N. SETA[4], M.D. DAUTZENBERG[3], P. DE LONLAY[1]* 1) Pediatric Metabolism Unit, Hôpital Necker - Enfants Malades, Paris, France; 2) Pediatric Radiology, Hôpital Necker - Enfants Malades, Paris, France; 3) Hematology Laboratory, Hôpital Necker - Enfants Malades, Paris, France; 4) Department of Biochemistry, Hôpital Bichat, Paris, France.

Background: The congenital disorder of glycosylation type Ia (CDG-Ia) presents a broad clinical spectrum. Some patients suffer from acute vascular events (AVE; thrombosis and bleeding) and stroke-like events. No correlations have been made between the marked haemostasis abnormalities of CDG-Ia and the occurrence of acute vascular events.

Methods: We report on 6 patients with CDG-Ia presenting vascular events, then we analyzed the clinical and haemostasis data of 39 CDG-Ia patients described in the literature, 17 with vascular events (E) and 21 unscathed of any event (EF), to determine risk factors for acute vascular events in CDG-Ia.

Results: Acute vascular events occurred in patients younger than 15 years, especially when there was fever and prolonged immobilization. Haemostasis and liver cytolysis were statistically abnormal in patients younger than 5 years whatever the occurrence of vascular events, and they normalized with time. Higher factors VIII and IX activities were statistically observed in the E cluster ($p=0.03$) compared to the EF cluster. The activity/antigenicity ratio for Protein C ($p=0.02$) was also higher in the E group.

Conclusion: CDG-Ia patients younger than 15 years old are at risk of acute vascular events. The paradoxical results - abnormal VIII and IX factors in EF patients and normal results in E patients, while XI, AT, PC and ASAT, ALAT are abnormal in both groups - could suggest a disequilibrium between prothrombotic and antithrombotic factors in the E group. Vascular events may also occur in patients where glycoproteins are proportionally more hypoglycosylated, particularly Protein C.

Telomere length is increased in women with premature ovarian failure. *K.L. Bretherick[1,2], C.W. Hanna[1,2], M.R. Fluker[3,4], W.P. Robinson[1,2]* 1) Dept of Medical Genetics, University of British Columbia; 2) Child & Family Research Institute; 3) Genesis Fertility Center; 4) Dept of Obstetrics & Gynecology, BC Childrens and Womens Hospital; Vancouver, BC, CANADA.

Women with premature ovarian failure (POF) experience menopause before the age of 40, and may therefore be considered prematurely reproductively aged. Rate of reproductive aging may be related to overall rate of aging, a suggestion that is supported by human epidemiologic studies reporting that late child bearing is associated with longer lifespan. We therefore hypothesized that indicators of cellular aging, such as short telomere length, would be more common in women with POF than in controls. DNA was obtained from peripheral blood of POF patients (N=54), control women between the ages of 17 and 55 (control group 1, N=92), and women who have had a healthy pregnancy after the age of 37 and have not had a miscarriage (control group 2, N=41). Average telomere length was determined by quantitative PCR amplification of the telomeric repeat expressed relative to amplification of a single copy gene. Surprisingly, age-adjusted mean telomere length was significantly longer for POF patients than both control groups (0.968 for POF patients vs. 0.893 for control group 1 and 0.931 for control group 2, p=0.02, two tailed ANCOVA). There is evidence that estrogen exposure may positively affect telomere length, and we have previously reported that haplotype at the estrogen receptor alpha gene (*ESR1*) was significantly associated with risk for POF. However, there was no association between telomere length and genotype at *ESR1* or genotype at a polymorphism in the estrogen receptor beta (*ESR2*) gene in either patient or control group, or in all data combined. Longer telomeres may nonetheless be the result of abnormal hormone exposure in this group, either due to elevated estrogen levels as a result of recruitment of large cohorts of follicles prior to POF onset, or as a result of hormone replacement therapy following diagnosis. Regardless, the increase in telomere length observed in POF patients does not support a pathogenic role for an increased rate of cellular aging in POF.

Correlation of phenylalanine levels with intellectual outcome and executive functioning in patients with phenylketonuria. *L.V. Furtado[1], N.L. Cantor[2], S.L. Ernst[3], J.B. Fulton[2], N. Longo[1,3]* 1) Dept Pathology, Univ Utah ARUP Laboratories, Salt Lake City, UT; 2) Primary Children's Medical Center, Salt Lake City, UT; 3) Dept Pediatrics, Univ Utah ARUP Laboratories, Salt Lake City, UT.

Background: Phenylketonuria (PKU) is characterized by elevated phenylalanine levels that can impair brain development and functioning. It is treated with a diet restricted in phenylalanine. It is unclear whether there are certain periods in which phenylalanine levels have a stronger effect on psychometric cognitive measures. Here we correlate phenylalanine levels at specific ages to subsequent or concomitant intellectual and executive functioning in patients with PKU. Methods: Phenylalanine levels at time of diagnosis, time at which therapy was initiated, and average phenylalanine levels for different periods (<1 year, 1-3 years, 3-5 years, 5-10 years, 10-18 years, >18 years) were correlated to the results of psychometric testing (Wechsler Intelligence Scale for Children (WISC-III, WISC-IV); Wide Range Achievement Test (WRAT-3, WRAT-4); Wechsler Adult Intelligence Scale (WAIS-III); and Childrens Category Test (CCT-2)) in 52 patients with PKU over 5 years of age (average age 14.45.9 years, range 5.6-30 years). Data were analyzed by regression analysis, using $p<0.05$ as level of significance. Results: In our group of patients, the highest phenylalanine level at diagnosis did not correlate with later IQ or functional outcome. By contrast, there was a negative correlation between the time at which dietary treatment was initiated and later reading and spelling scores. Average plasma phenylalanine levels at ages 3-5 years and 5-10 years negatively correlated with average final IQ and verbal performance, while no significant correlation was noted with other age periods. Part of the correlation in the 5-10 year old group could be explained by the known relationship between phenylalanine levels and performance at time of testing. Conclusions: Time at which therapy is initiated and phenylalanine levels between 3 and 10 years of age negatively correlated with long-term measure of intellectual functioning and with performance on verbal academic measures in patients with PKU.

Determining pathogenicity of a BRCA1 missense variant - a multi-modal approach. *N. Hamel[1], M.A. Carvalho[2,3], G. Birrane[4], A. Soni[4], E.H. van Beers[5], S. Joosse[5], D. Novak[1], P.M. Nederlof[5], S. Grist[6], D. Goldgar[7], S. Tavtigian[8], A.N.A. Monteiro[2], J.A.A. Ladias[4], W.D. Foulkes[1], M. Tischkowitz[1]* 1) McGill University, Montreal, Canada; 2) H. Lee Moffitt Cancer Center & Research Institute, Tampa, USA; 3) Centro Federal de Educação Tecnológica de Química, Rio de Janeiro, Brazil; 4) Harvard Institutes of Medicine, Harvard Medical School, Boston, USA; 5) Netherlands Cancer Institute, Amsterdam, The Netherlands; 6) Flinders Medical Centre and Flinders University of South Australia, Adelaide, Australia; 7) University of Utah School of Medicine, Salt Lake City, USA; 8) IARC, WHO, Lyon, France.

New BRCA1 variants of unknown significance are regularly detected in clinical practice and create serious management problems in the families concerned. BRCA1: M1775K was identified through BRCA1/BRCA2 mutation screening by full sequencing in 2 unrelated families with a history of breast cancer. Position M1775 is invariant in a sequence alignment including 9 mammals, chicken, frog and pufferfish. Combining sequence alignment results, Grantham variation and deviation scores, SIFT scores, logistic regression results for co-segregation in both families and histopathological data from M1775K tumors, the probability that M1775K is a high-risk variant exceeds 0.99. LOH data shows partial loss of the wild-type allele in the M1775K tumor and CGH analysis of these tumors closely resembles the aberrations present in BRCA1-related tumors. The M1775K variant was evaluated for transactivation activity in the context of stringent reporters and displayed markedly reduced activity with 20% and <5% of the wild type activity in yeast and mammalian cells, respectively. M1775K resides within the C-terminal BRCT binding domain and protein crystallography showed that it specifically disrupts the phosphopeptide binding pocket, thereby inhibiting BRCA1 interaction with BRIP1. This result suggests that the integrity of the BRCA1 phosphopeptide binding pocket is required for tumor suppression. Importantly, we demonstrate that multiple lines of evidence are required to confirm the pathogenicity of very rare variants in any susceptibility gene.

Duplication 9p and Prader-Willi syndromes in an infant resulting from a de novo unbalanced 9;15 translocation.

M.T. Carter[1], F.D. Jacob[2], R. Ray[1], J.E. Allanson[1] 1) Medical Genetics, Children's Hospital of Eastern Ontario, Ottawa, Ontario, Canada; 2) Pediatric Neurology, University of Alberta, Edmonton, Alberta, Canada.

Duplication 9p has a well-described dysmorphic syndrome associated with it. The physical features include hypertelorism, down-slanting palpebral fissures, deep set eyes, down-turned corners of the mouth, and mild skeletal anomalies including hypoplastic terminal phalanges. We report an infant born with some of the typical features of duplication 9p syndrome, as well as the unusual features of extreme joint hyperlaxity with subluxation of the knees and elbows, arachnodactyly and total anomalous pulmonary venous return (TAPVR). Karyotype revealed a de novo unbalanced (9;15) translocation resulting in duplication of 9pter-9q13 and deletion of 15q distal to band q13. Methylation analysis and FISH studies revealed deletion of the SNRPN locus on the paternally derived chromosome 15, consistent with Prader-Willi syndrome. This infant represents the first reported case of duplication 9p syndrome with TAPVR, with the additional interesting finding of Prader-Willi syndrome resulting from an unbalanced 9;15 translocation.

Rhabdomyosarcoma in Costello syndrome: Clinical review and molecular studies. *K.W. Gripp[1], L. Nicholson[1], D.L. Stabley[2], K. Sol-Church[2]* 1) Medical Genetics, A.I. duPont Hosp, Wilmington, DE; 2) Biomed. Research, A.I. duPont Hosp, Wilmington, DE.

Costello syndrome (CS) is a rare anomaly and tumor predisposition syndrome, with rhabdomyosarcoma (RMS) being the most common malignancy. Tumor screening was proposed. CS is due to germline mutations in *HRAS*, an oncogene at 11p15.5. The CS causing missense *HRAS* mutations are identical to those found in isolated tumors, and result in gain-of-function. While it appears obvious that a germline mutation in an oncogene should be the first hit in tumorigenesis of CS pts, Kratz (2007) showed that in the development of isolated RMS loss of heterozygosity (LOH) for 11p15.5 precedes *HRAS* changes. In light of the discovery of *HRAS* mutations in CS and the new information on RMS initiation, we reviewed RMS in presumed CS pts.

Results: Screening didn't identify any RMS, but 2 pts became symptomatic between screenings. While all reported pts presented with RMS age 6, we report here a 16 year old presenting with RMS. In 12/20 pts information about the *HRAS* change is known: G12S in 9 (75%); G12A in 2 (16%); G12C in 1. This is comparable to the distribution in CS overall with G12S in 80% and G12A in 9%. Previously we reported that most, but not all, CS mutations occur in the paternal germline (Sol-Church 2006). This may be relevant to the RMS risk in this population. Information on the parental origin of the mutation is available on 2, both paternal. LOH for 11p15.5 was previously reported in 5 tumors (Kerr 2003), but parental status of LOH was not identified. We now prove LOH and loss of the maternal allele in 2 novel cases. If LOH of the maternal allele with overexpression of the paternal allele is the initiating event, then maternally derived *HRAS* mutations may imply a reduced RMS risk. No pts with maternal mutation had RMS.

Conclusions: While most CS associated RMS occurs in young children, adolescents are at risk. Our data suggest a similar tumor risk associated with G12S and other *HRAS* changes. Parental origin of the germline mutation may impact RMS risk.

Identification of genes silenced by methylation on head and neck tumor cell lineages. *C. Kaneto[1], G. Molfetta[1], M. Calmon[3], R. Moura[2], J. Kaiano[2], R. Rodrigues[4], C. Zanelli[5], H. Brentani[6], A. Camargo[2], E. Tajara[4], D. Carraro[2], P. Rahal[3], S. Valentini[5], W. Silva-Jr.[1]* 1) Depto Genética, Faculdade de Medicina de Ribeirão Preto/USP. Abnormalities in the normal pattern of DNA methylation have been characterized as an important mechanism on carcinogenesis. It is called epigenetic modification as it does not change DNA sequence and can be defined as a heritable change in gene expression. Epigenetic alterations observed in cancer include hypermethylation of selected CpG island gene promoters and simultaneous global hypomethylation. The aim of this project was to identify, by Rapid Subtraction hybridization (RaSh) method, putative genes silenced by methylation in four head and neck cancer lineages. These lineages were also treated with demethylating agent in order to evaluate changes in gene expression after treatment. A total of 480 genes were analysed, 186 genes had enhanced expression after treatment with demethylating agent and, of these, 169 present CpG island in their promoter region. RT-PCR assay was chosen to validate differential expression of genes selected by RaSH. The genes that showed differential expression were: PLAU, CD82, RBBP4, AOF2, TMSB10, HSPA5, LAMC2 and POU2F3. For all the selected genes an enhanced expression was observed after treatment with demethylating agent on, at least, one of the analysed lineages. POU2F3 showed enhanced expression after treatment in FaDu and UM-SCC-38A lineages. In UM-SCC-14, the genes CD82, RBBP4, AOF2, HSPA5 and LAMC2 showed the same effect, but HSPA5 and LAMC2 had their expression enhanced in UM-SCC-17 too. In UM-SCC-38, all genes showed enhanced expression after treatment with demethylating agent. Our work is another evidence that these genes may be regulated by methylation and silenced by epigenetic changes in head and neck cancer. Financial Support: CNPq, FAPESP.

Genetic association of *PLAUR* with autism spectrum disorder and possible gene-gene interactions in the MET signaling pathway. *D.B. Campbell[1], J.S. Sutcliffe[2,3], C. Li[4], R. Sacco[5,6], A.M. Persico[5,6], P. Levitt[1,3]* 1) Pharmacology, Vanderbilt Univ, Nashville, TN; 2) Mol Physiology & Biophysics, Vanderbilt Univ, Nashville, TN; 3) Vanderbilt Kennedy Center for Research on Human Development, Vanderbilt Univ, Nashville, TN; 4) Biostatistics, Vanderbilt Univ, Nashville, TN; 5) Lab of Mol Psychiatry & Neurogenetics, Univ Campus Bio-Medico, Rome, Italy; 6) Fondazione S Lucia, IRCCS, Rome, Italy.

We recently described association of a functional variant of *MET* with autism spectrum disorder (ASD). The ASD-associated variant resides in the promoter and alters the affinity of transcription factors encoded by *SP1* and *SUB1*. MET functions to influence development of the cerebral cortex and cerebellum. Analyses of transcript levels in ASD postmortem cortical tissue revealed decreased expression of *MET* and increased expression of three genes encoding proteins that activate MET signaling, *HGF*, *PLAUR* and *SERPINE1*. Because the *SP1*, *SUB1*, *HGF*, *PLAUR* and *SERPINE1* genes lie within chromosomal regions that have shown evidence for linkage to ASD, we hypothesized that these genes may contribute to ASD susceptibility. We screened all exons and regulatory regions for variants in each of the five genes in 48 individuals with ASD. Identified variants were genotyped in 629 ASD pedigrees and 312 unrelated controls. The *MET* promoter variant rs1858830 allele C was associated with ASD in this sample by family-based association test (FBAT; P=0.008) and case-control analyses (P=0.015). The *PLAUR* promoter variant rs344781 allele G was also associated with ASD by both family-based (FBAT; P=0.006) and case-control analyses (P=0.007). The *PLAUR* promoter rs344781 relative risk was 1.932 (95% CI: 1.128, 3.308) for genotype GG and 2.422 (95% CI: 1.380, 4.251) for genotype AG compared to genotype AA. Exploratory gene-gene interaction analyses suggested interactions of *MET* with *PLAUR* and *HGF* and interactions of *PLAUR* with *HGF, SERPINE1* and *SP1*. Although functional variants have not yet been identified, the evidence of association of *PLAUR* provides further support that disruption of the MET signaling pathway contributes to ASD susceptibility.

Bioenergetical analysis of mouse neuronal mitochondrial DNA during aging. *Y. Bai, Q. Zhao, Y. Li, T. Song*
Cellular & Structural Biol, Univ Texas Health & Sci Ctr, San Antonio, TX.

There is a significant amount of evidence suggesting that aging affect, particularly in neuronal cells, mitochondrial structure and function. The mitochondrial theory of aging thus proposes that there is a vicious cycle in which somatic mtDNA mutations cause defective electron transfer, increasing the generation of damaging reactive oxygen species (ROS) that, in turn, induce further mtDNA mutations. Compromised mitochondrial function, including a decrease in energy supply and tissue degeneration, leads to various aging-related phenotypes. However, there have been no comprehensive studies of overall mutation loads in the tissues during the aging process or of the bioenergetics consequences resulting from these mutations. To address these issues, we developed approaches to transfer mtDNA from mouse brain into established cell lines, and improved methods to isolate mutations in the cultured cell lines. In particular, we established 60 cell lines each in groups carrying near homoplasmic mitochondrial DNA from synaptosomes of old (25 months) and young (5 months) mice. Baseline respiration, maximal respiratory capacity and uncoupled respiratory activity were measured in those cells. Interestingly, there is no significant difference between young and old groups in the base line respiration and maximal respiration capacity. However, we found that the uncoupled respiratory activities in the aged group were significantly increased by 33%. Furthermore, the ratio of maximal respiratory capacity to uncoupled respiratory activities in the old group were lower by 27%, indicating a aging-dependent decrease in the control of respiration by the mitochondrial membrane potential. We also measured the growth capacity in galactose medium where cells were predominantly relied on mitochondrial oxidative phosphorylation for ATP production. The cell numbers after 4 days culturing in galactose medium were 18% lower in the old group compared with the young group. Theses findings pointed to an alteration of mitochondrial function associated with changes in mtDNA during aging.

Overexpression of mitochondrial Leucyl-tRNA synthetase restores the mitochondrial dysfunctions caused by the MELAS-associated tRNALeu(UUR) A3243G mutation. *M. Guan[1,2], R. Li[1]* 1) Div Human Genetics, Children's Hosp Medical Ctr, Cincinnati, OH; 2) Department of Pediatrics, University of Cincinnati College of Medicine, Cincinnati, Ohio 45229.

The A3243G mutation in the tRNALeu(UUR) gene causes mitochondrial encephalomyopathy, lactic acidosis, stroke-like symptoms (MELAS) and other disorders including diabetes and deafness. Cytoplasmic hybrids (cybrids) cell studies demonstrated that this mutation results in decreased level and aminoacylation capacity of the tRNALeu(UUR), thereby leading to a decrease in the steady-state levels of affected tRNA. A failure in the tRNALeu(UUR) metabolism is responsible for the reduced rate of mitochondrial protein synthesis and the respiration defects. However, attempts to correct the mitochondrial dysfunctions caused by this mtDNA mutation have so far been unsuccessful. We hypothesized that overexpression of mitochondrial Leucyl-tRNA synthetase (LeuRS) in the cybrids carrying the A3243G mutation can correct the defects in mitochondrial tRNA metabolism, consequently increasing the level of mitochondrial translation. For this purpose, human LeuRS cDNA was cloned into a pcDNA3 vector and transfected into 43B cell line carrying nearly homoplasmic A3243G mutation and a cell line derived from same subject but lacking this mutation. Resultant stable transfectants expressing the LeuRS cDNA exhibited an increase in the level of aminoacylated and steady-state tRNALeu(UUR) as well as other mitochondrial tRNAs, compared with parental cybrids carrying the A3243G mutation. These are likely responsible for an increasing of in the rates of mitochondrial protein synthesis and respiration in these resultant stable transfectants expressing the LeuRS cDNA, relative to the parental cybrids carrying the A3243G mutation. This suggests that the overexpression of mitochondrial Leucyl-tRNA synthetase restore the mitochondrial dysfunctions caused by the MELAS-associated tRNALeu(UUR) A3243G mutation.

Genetic Association Analysis of Pyruvate Carboxylase, a Positional Candidate Gene for Acute Insulin Response: The IRAS Family Study. *P.A. Antinozzi[1], N.D. Palmer[1], C.D. Langefeld[1], M. Bryer-Ash[2], D.W. Bowden[1]* 1) Wake Forest Univ., Winston Salem, NC; 2) Univ. of California, Los Angeles, CA.

Impaired pancreatic -cell function is a hallmark of type 2 diabetes. Acute insulin response (AIR) is a quantitative measure of first phase insulin secretion in response to glucose stimulation. IRAS Family Study previously reported linkage of AIR in 284 African American (AA) subjects (21 pedigrees) on 11q and replicated this finding in an additional 214 AA subjects (22 pedigrees). Combined analysis yielded a bimodal peak with a LOD-1 support interval from 54-84cM (LOD=2.77 at 58cM and LOD=2.54 at 76cM). Among more than 300 annotated genes, pyruvate carboxylase (PC) was identified as a strong positional candidate. PC catalyzes the conversion of pyruvate to oxaloacetate, the initial reaction of gluconeogenesis and is involved in neurotransmitter synthesis and insulin secretion. The PC gene is encoded by two transcripts; a large, 110kb transcript found to be highly abundant in gluconeogenic tissues in animal models and a short 59kb transcript. Based on coverage and LD metrics from the HapMap Yoruban dataset, 36 SNPs were chosen for genotyping on 605 AA participants. In the Yoruban dataset, 20 of 37 SNPs with MAF >5% genotyped in HapMap for PC captured 88.0% of SNPs with r2 > 0.8 (mean r2=0.94). Using SOLAR, 4 and 6 SNPs were associated ($P<0.05$) with AIR in MGS set 1 and 2 respectively. This exceeds the number expected by chance (1.9). In the combined analysis, three SNPs were significantly associated with AIR (P=0.007-0.02). Of these SNPs, rs7119676 was highly significant (P=0.007) and was also associated using the Quantitative Pedigree Disequilibrium Test which is robust to population stratification. Variation at this locus confers a protective effect following an additive model with the variant having a 1.5X increased AIR (1335 vs. 914 pmol/L). This SNP is located ~3kb upstream of exon 1 of the short transcript. Based on these findings, it is proposed that this SNP, or a linked variant, could modulate the expression of the short PC transcript and confer a protective advantage which could compensate for deficiencies in individuals with impaired pancreatic -cell function.

An Intragenic Genomic Duplication Resulting in Loss of Function and other Novel Mutations in *NLRP7* in Women with Recurrent Biparental Hydatidiform Moles. *Y. Kou[1], L. Shao[1], R. Rosetta[1], D. Del Gaudio[2], H. Peng[1], T. AL-Hussaini[3], I. Van den Veyver[1, 2]* 1) Depts of Ob-Gyn, Baylor College of Medicine, Houston, TX; 2) Depts of Molecular Human Genet, Baylor College of Medicine, Houston, TX; 3) Dept of Ob-Gyn, Assiut University, Assiut, Egypt.

Hydatidiform mole (HM) is an abnormal development of the placenta with hyperproliferative trophoblast. Biparentally inherited HM (BiHM) have normal diploid biparental inheritance and are not androgenetic. Linkage using consanguineous pedigrees of women with BiHM refined a major locus to chromosome 19q13.42. Recently, mutations in the NACHT, leucine rich repeat (LRR) and PYD containing 7 (*NLRP7*) gene were identified in DNA of women with recurrent BiHM whose mutation maps to this region. We studied kindreds with several affected women and isolated cases of recurrent BiHM of confirmed biparental inheritance and first performed bisulfite genome sequencing of regulatory DMRs at several imprinted loci (*NESP55*, *KCNQ1OT1*, *PEG3*, *H19*, *SNRPN*) on DNA from BiHM tissue. We found failure to acquire or maintain DNA methylation that is established at imprinted DMRs during oogenesis. We sequenced coding exons of *NLRP7* using DNA of women with recurrent BiHM and found new missense and splice-site mutations in isolated cases. We identified a homozygous missense mutation c.2234C>G (p.L745V) affecting a conserved leucine in the 2nd LRR of *NLRP7*, a compound heterozygous c.2234C>G, an exon 9 splice donor mutation (c.2796+2T>G) and a previously described c.2457+1G>A mutation. Southern analysis and quantitative RT-PCR (qPCR) revealed a 4Kb tandem intragenic duplication spanning exons 2-5 of *NLRP7* in 5 patients from 3 unrelated Egyptian families but not in unaffected controls, suggesting the presence a founder effect in this population. The resulting mutant mRNA is predicted to translate into a truncated protein containing a frameshift of six amino acids and a stop codon after Thr710 and lacking all LRRs. This is second report confirms that *NLRP7* deficiency is a major cause of BiHM.

High resolution array comparative genomic hybridization (aCGH) in individuals with Prader-Willi syndrome.
M.G. Butler, N. Kibiryeva, W. Fischer, D.C. Bittel Children's Mercy Hospital and University of Missouri-Kansas City, MO.

Prader-Willi syndrome (PWS) is a neurodevelopmental obesity disorder caused by a loss of expression of imprinted genes from the paternal 15q11-q13 region usually due to a deletion. The proximal deletion breakpoint occurs at one of two sites located within either of two large duplicons. The larger type I (TI) deletion involving breakpoint 1 (BP1) is nearer to the centromere and located proximal to D15S1035 while the smaller type II (TII) deletion involves breakpoint 2 (BP2) and distal to D15S1035. Breakpoint 3 (BP3) is located at the distal end of 15q11-q13 and common to both typical deletion subgroups. Using high resolution oligonucleotide aCGH analysis (244K DNA microarray, Agilent Technologies), we examined the position of the chromosome 15 breakpoints in 12 PWS subjects with TI deletions (mean age 24.7y) and 13 with TII deletions (mean age 18.6y). BP1 spanned a region from 18.68 to 20.20 Mb (mean 19.89) from the p terminus while BP2 spanned from 20.81 to 21.36 Mb (mean 21.19). BP3 spanned the region from 25.94 to 27.29 Mb for both deletion subgroups; however, a bimodal distribution of breakpoints was observed. The size of the TI deletion ranged from 5.72 to 8.15 Mb (mean 6.58) and 4.77 to 6.40 Mb (mean 5.31) for TII deletions. The BP1 region (1.52 Mb) was larger than BP2 (0.55 Mb). The BP3 region was 1.35 Mb for the combined TI and TII subgroups. A subset of the TI subjects (e.g., breakpoint at 18.68 Mb) includes the loss of three genes/transcripts (i.e., *LOC283755, POTE5, OR4N4*) in addition to the four genes previously recognized between BP1 and BP2 (i.e., *GCP5, CYFIP1, NIPA1, NIPA2*). Thirteen of the 25 PWS subjects showed copy number variation of other chromosomes particularly deletions and duplications of chromosome 8p (clustered at approximately 39 Mb from the p terminus). Additional studies are required to further characterize the regions of copy number variation among PWS and control subjects. The use of high resolution oligonucleotide microarrays should allow for more detailed genomic data for genotype - phenotype correlations and more precise breakpoint location and assignment of duplications and deletions.

Potential role of *p63* in human bladder exstrophy. *B.J. Ching[1], M. Ludwig[2], H. Reutter[3], C. Nauta[1], J.P. Gearhart[4], S.A. Boyadjiev[1,4]* 1) Section of Genetics, Dept. of Pediatrics, University of California Davis, Sacramento, CA; 2) Dept. of Clinical Biochemistry, University of Bonn, Bonn, Germany; 3) Dept. of Human Genetics, University of Bonn, Bonn, Germany; 4) Dept. of Urology, The James Buchanan Brady Urological Institute, Johns Hopkins University, Baltimore, MD, United States.

The Bladder-Exstrophy-Epispadias-Complex (BEEC) represents a spectrum of urogenital anomalies in which part or all of the distal urinary tract fail to close and are exposed on the outer abdominal wall. Clinically, this rare congenital anomaly ranges from epispadias (EP) to classic bladder exstrophy (CBE), to its most severe form - cloacal exstrophy (CE). *p63*, a homolog of the *p53* tumor-suppressor gene, encodes multiple tissue-specific isoforms acting as transcription factors vital for correct embryologic development. *N-p63-/-* null mice manifest bladder exstrophy in addition to severe craniofacial, limb, and skin anomalies. Human *p63* mutations are associated with at least five autosomal dominant genetic syndromes with anomalies of the urogenital system, but not BEEC. We have initiated *p63* analysis in a cohort of 15 CBE and five CE patients. Direct sequencing of the entire coding region of *p63* from genomic DNA did not yield obvious mutations. RT-PCR of COOH-terminal cDNA fragments derived from normal and exstrophic human bladder and lymphoblast RNA did not identify abnormal p63 expression and several novel isoforms were identified and validated. Sequencing of the COOH-terminal isoform specific RT-PCR products did not show nucleotide changes. N-terminal isoform specific RT-PCR, northern blot and quantitative real-time PCR analyses are underway to further assess if *p63* plays causal role in BEEC.

Genetic and functional characterization of BRCA1 and BRCA2 variants of uncertain significance. *D. Goldgar[1], D. Easton[2], S. Tavtigian[3], C. Frye[4], M. Agarwal[5], D. Farrugia[5], F. Couch[5]* 1) University of Utah, Salt Lake City, UT; 2) Strangeways Research Laboratories, University of Cambridge, Cambridge, UK; 3) International Agency for Research on Cancer, Lyon France; 4) Myriad Genetic Laboratories, Inc. Salt Lake City UT; 5) Mayo Clinic, Rochester MN.

Mutation screening of the breast and ovarian cancer predisposition genes BRCA1 and BRCA2 is becoming an increasingly important part of clinical practice. Classification of rare non-truncating sequence variants in these genes is problematic because it is not known whether these subtle changes alter function sufficiently to predispose cells to cancer development. Using data from the Myriad Genetic Laboratories database of nearly 70,000 full-sequence tests, we have assessed the clinical significance of 1433 sequence variants of uncertain significance (VUS) in the BRCA genes. Three independent measures were employed in the assessment: co-occurrence in trans of a VUS with known deleterious mutations; detailed analysis of personal and family history of cancer in VUS-carrying probands by logistic regression; and in a subset of probands, an analysis of co-segregation with disease in pedigrees. For each of these factors a likelihood ratio was computed under the hypothesis that the VUS were equivalent to an average deleterious mutation compared to neutral with respect to risk. The likelihood ratios derived from each component were combined to provide an overall assessment for each VUS. Logistic regression based on family history was shown to be a powerful discriminator of neutral vs. deleterious variants. Statistical analysis of heterogeneity within classes of VUSs showed that deleterious variants were those that were predicted to affect splicing, fell at positions that are highly conserved among BRCA orthologs, and were more likely to be located in specific domains of the proteins. We characterized a subset of the BRCA2 missense mutations using functional assays that measure the ability of wildtype and mutant forms of BRCA2 to repair DNA damage by homologous recombination and to control centriole amplification. Overall, both assays displayed strong correlations with the results of the genetic studies.

Investigating Protein-Protein Interactions Relevant to SCA6 and SCA7 Pathogenesis. *J.J. Kahle[1], J. Lim[1], H.Y. Zoghbi[1, 2]* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Howard Hughes Medical Institute.

Several dominantly inherited Spinocerebellar ataxias (SCAs) are caused by expansion of a translated CAG repeat encoding a polyglutamine (polyQ) tract in the respective proteins. The normal function of the ataxia proteins is proving relevant to pathogenesis, suggesting that disease proteins and their interacting partners play a role in neuronal health and survival. We generated an interactome using ataxia-causing proteins, however, we did not identify interactors for some full-length bait proteins, including CACNA1A (calcium channel alpha-1A subunit) and ataxin-7, the proteins mutated in SCA6 and SCA7, respectively. Our data suggest that rescreening with multiple fragments of these proteins may yield more interactions. CACNA1A is a large protein that has different splice forms, including one that expresses a polyQ tract in the cytoplasmic tail of the channel, and another, that has a stop prior to the polyQ tract. Using different wild-type splice isoforms of CACNA1A, as well as constructs containing different polyQ lengths we generated seventeen fragments of the cytoplasmic domain of the protein. We also generated eleven protein fragments of ataxin-7 with different length polyQ repeats. These baits were used in a high-stringency yeast 2-hybrid screen against an adult human brain cDNA library. We identified 254 total different interacting proteins; surprisingly, a subset of these are common to both ataxin-7 and CACNA1A. Ataxin-7 fragments interacted with many proteins reported to be expressed in the retina and a few that are suspected to have a role in eye disease, which is interesting given that patients with SCA7 exhibit macular degeneration in addition to ataxia. We identified 161 proteins interacting with CACNA1A, of these, 23 were in common to both splice forms. Currently, we are validating the interactions by co-affinity purification. Adding the new data to the existing ataxia interactome will enable us to look for additional common points of convergence for the various ataxias and will provide further insight about the normal function of the disease proteins and perhaps pathways involved in neurodegeneration.

The genetic structure of Pacific Islanders. *J.S. Friedlaender[1], F.R. Friedlaender[2], F.A. Reed[3], K. K. Kidd[4], J.R. Kidd[4], G. Chambers[5], R. Lea[5], J.H. Loo[6], G. Koki[7], J.A. Hodgson[8], D.A. Merriwether[9], J.L. Weber[10]* 1) Anthropology,Temple University, Philadelphia, PA; 2) Independent Researcher, Philadelphia, PA; 3) Biology,University of Maryland, College Park, MD; 4) Genetics,Yale University, New Haven, CT; 5) Biological Sciences,Victoria University, Wellington, NZ; 6) Transfusion Medicine, Mackay Memorial Hospital, Taipei, Taiwan; 7) I.M.R., Goroka,Papua New Guinea; 8) Anthropology, New York University, NY; 9) Anthropology, Binghamton University, Binghamton, NY; 10) Marshfield Clinic Research Foundation, Marshfield, WI.

Human genetic diversity in the Pacific has not been adequately sampled. As a result, population relationships there have been open to debate. A genome scan of 687 autosomal microsatellites and 203 insertion/deletions on 936 individuals from 40 populations now shows the remarkable nature of Melanesian variation, and allows for a more complete comparison of Pacific populations with groups from other regions. While genetic diversity within individual Pacific populations is shown to be low, the diversity among Melanesian groups is very high. There is considerably more variation among groups in the island of New Britain than among East Asian or European populations.Melanesian diversity varies with island size and topographical complexity. The greatest distinctions are among the isolated groups in large island interiors. The pattern also follows language distinctions. Papuan-speaking groups are the most distinctive, and Austronesian groups, which tend to live along the coastlines, are more intermixed.In contrast, the Polynesian, Taiwan Aboriginal, and Micronesian groups are similar to each other and to East Asian populations. They have weak associations with Melanesians. An Austronesian genetic signature exists in less than half the Melanesian groups that speak Austronesian languages. This signature was not detected in any Papuan-speaking group. These findings provide a resolution to the debates over Polynesian origins and interactions with Melanesians; the debates had heavily relied on the evidence from single locus mitochondrial DNA or Y chromosome variation.

A genomic approach to studying repeat instability in schizophrenia. *D.E. Dickel[1], M-C. King[1,2], J.M. McClellan[3]* 1) Dept of Genome Sciences; 2) Dept of Medicine (Medical Genetics); 3) Dept of Psychiatry, University of Washington, Seattle, WA 98195.

Schizophrenia is a severe, debilitating psychiatric disorder of unknown cause. Some cases of schizophrenia may be caused by rare, often de novo, highly penetrant mutations. Sporadic cases of schizophrenia in previously unaffected families may most likely harbor such mutations. Potentially unstable oligonucleotide repeats are among the most vulnerable of genomic features. Repeat expansions are potentially intriguing in schizophrenia given the disorders neurological phenotype, paternal age bias, and possible anticipation.

The purpose of this project is to identify repeat expansions with large effect on schizophrenia. Using a bioinformatics search, we identified 327 tri-, tetra-, or pentanucleotide repeats that overlap transcribed features and are sufficiently long to likely be polymorphic. By screening genomic DNA from individuals with schizophrenia, we are identifying repeats with more apparent homozygotes than expected based on Hardy-Weinberg equilibrium (HWE) criteria. To exclude loss of heterozygosity due to technical artifacts, we genotype repeats that fail HWE using multiple primer pairs, in cases and ancestry-matched controls.

In preliminary experiments, we identified a repeat with a significant excess of homozygosity among cases but perfect fit to HWE among controls. This excess is observed with multiple non-overlapping primer pairs and after identifying short repeats by capillary electrophoresis and medium length repeats by long-range PCR. We screened cases and controls at this locus by Southern blot to identify any expansions >300 repeats and any deletions of the entire repeat.

We will evaluate repeats elsewhere in the genome in the same way. If either large expansions or deletions are associated with schizophrenia at any repeat, we will sequence genes harboring schizophrenia-associated repeats in multiple unrelated cases to identify other classes of mutations such as frameshifts or point mutations. We will also undertake preliminary experimental characterization of the mutant sequences.

Long-term oral cysteamine therapy attenuates the morbidity and mortality of nephropathic cystinosis in adults.

W. Gahl[1], J.Z. Balog[1], K. O'Brien[1,2], G. Golas[1,2], R. Kleta[1,2], I. Bernardini[1] 1) Section on Human Biochemical Genetics, Medical Genetics Branch, NHGRI, NIH, Bethesda, MD; 2) Office of Rare Diseases, NIH, Bethesda, MD.

Nephropathic cystinosis, a lysosomal storage disorder due to defective transport of cystine out of lysosomes, results from mutations in CTNS. Almost half the patients in North America and Europe are homozygous for a 57-kb deletion in CTNS. Without treatment, children with cystinosis suffer from renal Fanconi syndrome and its complications, growth retardation, photophobia, and end-stage renal failure requiring kidney transplantation. Treatment with oral cysteamine (Cystagon), which can reduce cellular cystine levels by 95%, dramatically slows glomerular deterioration and normalizes growth; Cystagon is approved by the FDA for use in pre-transplant cystinosis patients. Based upon our examinations of 100 adult cystinosis patients between 1985 and 2006, we report striking rates of mortality (33%; mean age 29 years) and morbidity (24-75% for each complication), specifically related to hypothyroidism, hypergonadotropic hypogonadism (in men), pulmonary insufficiency, swallowing abnormalities, myopathy, retinopathy, vascular calcifications, and diabetes. Homozygosity for the 57-kb CTNS deletion did not correlate with these individual complications, but did correlate with mortality and with the overall severity of the morbidity. In adults, long-term (>8years) oral cysteamine therapy was associated with significantly greater height and weight, older age at renal transplant, lower serum cholesterol levels, and lower rates of morbidity and mortality. In fact, as duration of cysteamine therapy increased, the frequencies of myopathy, diabetes mellitus, pulmonary dysfunction, swallowing abnormalities, vascular calcification, retinopathy and death decreased. We conclude that all cystinosis patient should receive oral cysteamine therapy, and the registration for Cystagon should be amended to include post-transplant cystinosis as an indication. In addition, we should redouble our efforts to diagnose and treat cystinosis early, including attempts at newborn screening.

Experiences of genetic discrimination are common in persons at risk for Huntington disease. *Y. Bombard[1], L. Currie[1], G. Veenstra[1], J. Paulsen[2], J. Bottorff[1], M. Hayden on behalf of the Canadian Respond-HD resear[1]* 1) University of British Columbia, CAN; 2) University of Iowa, USA.

Genetic discrimination (GD) is a potential risk associated with genetic testing (GT). GD is the perceived differential treatment of asymptomatic individuals (AI) on the basis of their actual or presumed genetic differences. The fear of GD has prevented individuals from undergoing GT and participating in genetic research. Such effects are significant as GD directly hinders potentially beneficial engagement with genetic medicine as well as important scientific advances. Although the concern for GD is widespread, there is paucity of evidence indicating whether GD exists in general and in HD in particular. The aims of this study were to examine the nature & extent of GD and to assess whether GT is associated with increased levels of GD. A cross-sectional survey of 293 AI from families at risk for HD was undertaken using a self-report questionnaire. The sample comprised 233 AI (response rate of 80%): 167 AI who underwent GT (83 who have the mutation & 84 who do not) and 66 AI who chose not to be tested. GD was reported by 93 respondents (40%) and occurred most often in life & disability insurance, by friends, when making reproductive decisions and establishing relationships. GD did not differ in prevalence between tested & untested respondents (p=0.236). Family history (FH) rather than GT was reported as the major reason for GD. Predictors of GD included: discovering the FH under the age of 19 (OR:4.5, p=0.001), being aware of the FH for > 10 years (OR:2.0, p=0.004) and knowing people with HD symptoms or who have died (OR: 1.5, p=0.033). Distress was found to be associated with the experience of GD (p=0.011). CONCLUSIONS: GD is common in this sample. FH is the major determinant of GD. Those that discover their FH at a younger age and know of their FH for longer are at greater risk for GD. Overall, participating in GT is not associated with increased levels of GD. GD is a significant mental health and social issue for persons at-risk for HD. To our knowledge, this is the first study to report GD among AI who have participated in GT compared to those who chose not to be tested.

Absence of dementia in Down syndrome. *E. Doran[1], T. Tirosh-Wagner[2], L. Dai[2], F. Ezgu[2], L.G. Shaffer[3], J.O. Korbel[4], A.E. Urban[4], M. Snyder[4], I.T. Lott[1], J.R. Korenberg[2]* 1) Pediatrics, University of California, Irvine, Orange, CA; 2) Cedars-Sinai Medical Center, Los Angeles, CA; 3) Signature Genomic Laboratories, Spokane, WA; 4) Yale University, New Haven, CT.

Down syndrome (DS) is associated with an increased risk of Alzheimer-like dementia (AD). Studies have shown that up to 75% of people with DS at age 60 years have AD. Usually caused by trisomy 21, rare individuals with partial trisomy 21 and DS features provide opportunities to identify the genes whose variation in copy number is incompatible with normal human development. In order to understand the genetic contribution to the risk of AD in DS, we have characterized the clinical and molecular features of individuals with partial trisomy 21. We now report a 65 year-old male with 47XY,+del(21)(q11.2q22.1)[18]/46XY[2]. Relevant clinical history includes: hypertension, pulmonary stenosis, and an episode of paranoid ideation and auditory hallucinations. Family history was remarkable for dementia in the patients mother and 2 maternal aunts. Physical examination: brachycephaly, flat occiput, round face, upslanted palpebral fissures, Brushfield spots, flat nasal bridge, anteverted nostrils, down-turned corners of the mouth, short philtrum, highly vaulted palate, furrowed tongue, and short and broad webbed neck. Cognitive testing: WAIS-III; full scale IQ 69, verbal IQ 71 and performance IQ 72. Neurological exam and standardized dementia assessments revealed no clinical signs of dementia. Brain MRI revealed mild central atrophy, consistent for age. Molecular analysis using 1887 BAC clones microarray, FISH and high resolution isothermal microarray (tiled at~1/100bp), reveled increase in copy number from 28.1Mb-qter of chromosome 21 including genes for GRIK1, SOD1, HUNK, DYRK1A, DSCAM, SNF1LK. These results suggest that in this individual increased copy number of these specific genes is not sufficient to increase risk for AD in DS and supports the hypothesis that increase copy number of the gene encoding APP and other genes in the region, may be responsible for the risk of AD in DS. The results support our proposal of APP being a principle target for prevention of dementia in DS.

Evidence Of Common Genetic Determinants For Insulin Resistance And Thrombosis. *J. Cui[1], X. Guo[1], K.D. Taylor[1], S. Cheng[2], R. Hughes[2], J. Li[2], W. Hsueh[3], J.I. Rotter[1]* 1) Cedars-Sinai Med Ctr, Los Angeles, CA; 2) Roche Molecular Systems, Inc., Alameda, CA;; 3) UCLA, Los Angeles, CA.

The metabolic syndrome (MS) is characterized by the clustering of a number of metabolic abnormalities in the presence of underlying insulin resistance, with a strong association with diabetes and cardiovascular disease morbidity and mortality. It has been suggested that MS may contribute to the development of venous thromboembolism and may act as a link between venous thrombosis and atherosclerosis. MS and thrombosis have been shown to have underlying genetic determinants individually. However, no data is available regarding the possibility of a common genetic basis for the association between MS and thrombosis. In this study, we evaluated the association between insulin resistance and 7 variations in 5 genes (F7, FGB, ITGA2, ITGB3, and SERPINE1) that were previously implicated in thrombosis. Families were ascertained via a coronary artery disease proband in the Mexican-American Coronary Artery Disease Project. Mexican Americans have been shown to be the population with the highest risk for MS. 656 individuals from 100 Mexican-American families were genotyped for 7 literature-associated thrombosis SNPs in the 5 genes (2 SNPs in F7 and SERPINE1, and 1 in all others). 449 adult offspring and offspring spouses were phenotyped for insulin sensitivity by the hyperinsulinemic euglycemic clamp and the insulin sensitivity index (SI) was derived. The generalized estimating equation method was utilized to evaluate the associations. Both SNPs (I/D and R353Q) in F7 were found to be associated with SI (p=0.038, 0.048), as was SNP L33P in gene ITGB3 (p=0.027). SNP G(-455)A in gene FGB was not significantly associated with SI, however a significant association (p=0.016) with homeostasis model assessment (HOMA) was identified. Our results suggest that genes in the thrombosis pathway, including F7, FGB, and ITGB3 are associated with insulin resistance/sensitivity. This supports the hypothesis that there might be genes that link insulin resistance and thrombosis in Mexican Americans, a group at high risk for the metabolic syndrome.

Apolipoprotein E Proximal, Promoter and Distal SNPs and Associations with Cerebrospinal Fluid Apolipoprotein E Protein Levels. *L.M. Bekris, N.M. Galloway, S. Millard, D. Tsuang, E. Peskind, C.E. Yu* Medicine, Univ Washington, Seattle, WA.

Apolipoprotein-E (ApoE) is involved in lipid transport. The APOE 4 polymorphism is associated with an increased risk of Alzheimers disease. Associations between APOE regulatory SNPs and ApoE expression in human populations independent of APOE 4 genotype has been difficult to establish and may be in part due to strong linkage disequilibrium (LD) in the APOE gene region. The aim of this investigation was to generate hypotheses regarding the regulatory potential of SNPs in a large 70 kb region surrounding the APOE gene, while taking into account the strong LD in the region, as well as age, gender and APOE 4. Cerebrospinal Fluid (CSF) was collected from control subjects 21-87 years of age (n=148). CSF ApoE levels were measured and genotypes were determined for several SNPs (n=22) surrounding the APOE gene. SNPs genotyped include; promoter SNPs, APOE proximal SNPs, and APOE distal enhancer SNPs (ME1, HCR2, BCR). Backward linear regression models were performed to evaluate the influence of these SNPs on CSF ApoE levels while taking into account age, gender, APOE 4 and correlation between SNPs (LD). The results indicate that CSF ApoE levels increase significantly with age and are influenced by a subset of APOE proximal SNPs (within the TOMM40 gene), APOE promoter SNPs, and distal enhancer SNPs. R2 values indicate that these SNPs are not in strong LD with each other or with APOE 4. In support of these results, the distal hepatic control region SNP (HCR2) did not show an influence on CSF ApoE levels which would be expected given that hepatic ApoE should not contribute to CSF ApoE levels. In summary, utilizing backward linear regression models to investigate the influence of APOE proximal, promoter and distal SNPs on CSF ApoE levels, we found an influence by a subset of proximal, promoter and distal SNPs, on CSF ApoE levels, that vary in their contribution to CSF ApoE levels according to age, gender and the presence of APOE 4. A combined influence by these SNPs on CSF ApoE levels implicates APOE regulatory haplotypes as playing a role in ApoE expression. *APOE.*

High Resolution Melt Curve Analysis of Genomic and Whole Genome Amplified DNA. *M.H. Cho[1,2,3], B.J. Klanderman[1], D. Ciulla[1], B.A. Raby[1,2,3], E.K. Silverman[1,2]* 1) Channing Laboratory, Department of Medicine, Brigham and Women's Hospital, Boston, MA; 2) Division of Pulmonary and Critical Care Medicine, Department of Medicine, Brigham and Women's Hospital, Boston, MA; 3) Division of Pulmonary and Critical Care Medicine, Department of Medicine, Beth Israel Deaconess Medical Center, Boston, MA.

Background: High resolution melt curve analysis is a post-PCR technique that can be used for mutation detection. Recent advances in instrumentation and double strand specific DNA dye have improved the accuracy of this method. To our knowledge, this method has not been tested on whole genome amplified (WGA) DNA. Methods: Whole genome amplification (REPLI-g, Qiagen) was successfully performed on genomic DNA samples from 39 subjects from the Boston Early-Onset COPD study. 24 amplicons from 9 genes were PCR amplified in paired genomic and WGA samples and subsequently analyzed by high resolution melt curve analysis using the LightScanner (Idaho Technology). Selected samples from each melt curve were bidirectionally resequenced. Results: Melt patterns were concordant between the genomic and WGA samples in 92% of successfully analyzed sample pairs. Of the discordant patterns, there was an overrepresentation of alternate melt curve patterns in the WGA samples suggesting the presence of a mutation (false positives). Targeted resequencing was performed in 140 genomic and 136 WGA samples and revealed 43 SNP. Heterozygous variants were identified by non-wild type melt pattern in 100% of genomic and 92% of WGA samples. Wild types were correctly classified in 93% of genomic and 54% of WGA samples. As expected, the technology lacked sensitivity for homozygous variants. Conclusion: High resolution melt curve analysis is a sensitive tool for SNP discovery in genomic DNA. Performance appears to be substantially less in whole genome amplified DNA.
Acknowledgments: We thank all the study participants. Work was supported by U.S. National Institutes of Health (NIH) grants R01 HL075478 (Silverman) and K08 HL74193 (Raby).

Rapid prenatal confirmation of ultrasound-impressed Beckwith-Wiedemann syndrome caused by hypomethylation of LIT1 by quantitive endonuclease-polymerase chain reaction. *S.P. Chang[1], G.C. Ma[1], C.W. Yang[1,2], D.J. Lee[1], M. Chen[1,3,4]* 1) Center for Medical Genetics, and Department of Medical Research, Changhua Christian Hospital, Changhua, Taiwan; 2) Graduate Institute of Molecular Medicine, College of Medicine and Hospital, National Taiwan University, Taipei, Taiwan; 3) Department of Obstetrics and Gynecology, and Department of Medical Genetics, College of Medicine and Hospital, National Taiwan University, Taipei, Taiwan; 4) Department of Obstetrics and Gynecology, Changhua Christian Hospital, Changhua 500, Taiwan.

Beckwith-Wiedemann syndrome (BWS) is a rare congenital overgrowth disorder associated with abnormalities of imprinted gene expression at chromosomal region 11p15. We propose a rapid molecular test for evaluating the statuses of DNA methylation at 11p15 by using methylation-sensitive endonuclease-coupled quantitative polymerase chain reaction (E-Q-PCR) in fetuses affected with BWS. E-Q-PCR involved two steps: (1) methylation-sensitive endonuclease NotI treatment, and (2) quantitative real-time PCR performance. PCR was achieved by use of two pairs of primers that specified amplifications of 2 distinct regions (with and without NotI cutting sites, respectively) surrounding an imprinting center LIT1/KCNQ1OT1 of 11p15. PCR-amplification ratio of the NotI-cut region to the NotI-uncut region was calculated as a methylation index in LIT1. We tested this novel strategy (E-Q-PCR) in 2 fetuses clinically diagnosed with BWS and 9 unaffected fetuses from cultured amniocytes.The E-Q-PCR analysis can assess DNA methylation changes in LIT1 between unaffected individuals and BWS fetuses. The methylation indices detected in both BWS fetuses (9.0% and 9.1%)were apparently lower than that of unaffected fetuses (56.9%~67.8%). E-Q-PCR is a novel method for quantitative analysis of methylation status of LIT1, which accounts for 60% detectable molecular pathology of BWS cases. This methodology is easily performed and suitable for rapid confirmation of BWS fetuses impressed by obstetric ultrasound.

Frequent loss of heterozygosity at the IRF-1 gene locus in breast cancer. *L.R. Cavalli, R.B. Riggins, R. Clarke, B.R. Haddad* Lombardi Comprehensive Cancer Center, Georgetown University, Washington, DC.

Several key observations indicate that the interferon regulatory factor-1 gene (IRF-1) localized on 5q31.1 may be a potentially important breast cancer tumor suppressor gene. IRF-1 is mutated or rearranged in several cancers, including some hematopoietic and gastric cancers. IRF-1 can reverse the oncogenic transformation of cells induced by the overexpression of oncogenes including both RAS and MYC in mouse models. Since functional roles for RAS and MYC are established in human breast cancer, a loss of IRF-1 function might also be important in this disease. IRF-1 can induce apoptosis through both p53-dependent and p53-independent signaling. Loss of 5q12-31 was reported in 11% of sporadic breast cancers and 5q deletion was detected in 86% of BRCA1 positive tumors. More recently, high-resolution array CGH studies have shown loss at 5q31.1, in 50% of BRCA1 positive breast cancers. Taken together, these observations offer a rationale to investigate the hypothesis that the IRF-1 gene plays an important role in breast cancer and to explore the usefulness of evaluating its loss of function in breast cancer. For this reason, we initiated a study in order to determine the frequency of IRF-1 allelic loss in breast tumors. Towards this end, we designed and optimized an approach to determine loss of heterozygosity (LOH) at the IRF-1 locus using an intrageneic dinucleotide polymorphic marker. Using this approach, we analyzed breast tumor specimens from 42 women with invasive breast cancer. 30 cases were informative and LOH at the IRF-1 locus was detected in 9/30 cases (30%). Our findings are consistent with a tumor suppressor role of the IRF-1 gene in breast cancer and justify further studies to confirm our initial LOH findings in a larger cohort of patients and to demonstrate functional inactivation of the IRF-1 gene in breast cancer (e.g. via gene mutations and/or an epigenetic process).

CLINICAL-GENETIC STUDY AND FOLLOW-UP OF INSTITUTIONALIZED PATIENTS FOR ESTABLISHING DIAGNOSIS AND RISK FACTORS FOR MENTAL RETARDATION. *L. Batista, L. Giuliani, J.M. Pina, G. Molfetta* Dept Medical Genetics, Hosp das Clinicas - USP, Sao Paulo, Brazil.

In developed countries, mental retardation (MR) occurs in 2-3% of general population, this figure reaches up to 10% in developing countries. It is important to define the etiopathogenesis of this disorder in order to improve the treatment, to try to establish an accurate recurrence risk and to provide correct genetic counseling to families. Also, for inherited causes of MR, X-linked mental retardation is responsible for about 20-25% of cases in males, which the most common causes are FRAXA and FRAXE Syndromes. Screening for these syndromes is recommended for all children with learning disabilities or MR of unknown etiology associated to behavior disturbances or late language development. We have studied 430 institutionalized patients diagnosed as MR in a school for patients with learning disabilities. We have done an accurate birth and familial history as well as pedigree and physical examination; neuroimaging and cytogenetics exams are requested when necessary. Of the 430 patients, 70% were mild to moderate MR; 12% were severe and in the remaining 18% of patients we were not able to classify the MR severity because they had delayed neuropsychomotor development and we could not define yet if it would evolve into a MR. Etiopathogenic diagnosis was possible in 49% of the patients: 18.5% had genetic diseases divided in chromosomal disorders (15.4%) and monogenic disorders (20.2%); 3.2% had a single CNS anomaly; 16.2% showed environmental causes; 9.5% presented CNS multiple dysfunctions (MR with epilepsy or MR with brain palsy) and 0.9% had MR associated to psychosis. In order to screen for FRAXA and FRAXE syndromes, PCR technique were carried out in all male patients with unknown etiology. The laboratorial tests did not reveal positives cases for FRAXA or FRAXE syndromes. This work is important for defining the correct cause of the MR as well as defining better preventive approaching strategies for the families of the affect patient. It is also important to perform genetic counseling to every family and explain their accurate recurrence risks.

Endothelial dysfunction improved by l-arginine supplementation in the patient with Noonan syndrome, moyamoya-like vascular changes, and antiphospholipid syndrome. *Y. Akita, S. Yatsuga, J. Nishioka, Y. Koga* Dept Pediatrics & Child Health, Kurume Univ Sch Medicine, Kurume, Japan.

We report a 12-year-old Japanese female with Noonan syndrome who had antiphospholipid syndrome and moyamoya-like vascular changes. She presented choreic movements in her face and extremities. She manifested clinical features that resemble those of Turner syndrome and has a normal karyotype. Tests for anticardiolipin antibody and lupus anticoagulant were positive. Magnetic resonance angiography revealed occlusion of bilateral internal carotid arteries and moyamoya-like vascular changes in the basal ganglion region. Moyamoya-like vascular changes are characterized by collateral vessels formation in the basal cerebral vasculature caused by chronic thrombosis or stenosis. We evaluated endothelial function in the patient by flow-mediated vasodilation (FMD) and found a significant decrease vs controls. We started l-Arginine supplementation therapy in the patient. l-Arginine is known to be an important precursor of nitric oxide (NO), which improved endothelial dysfunction in MELAS (mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke) in our study. In this case, l-Arginine supplementation may reduce damage of focal brain ischemia by increasing microcirculation in cerebral blood flow(CBF).

Preimplantation Genetic Diagnosis (PGD)/Screening (PGS) in carriers of structural chromosome abnormalities: The Genzyme Genetics experience. *A. Hajianpour, L. Dong, B. Huang, B. Herbert, D. Burkhardt, S.Y. Kou, Q.Q. Huang, R. Habibian* Dept Cytogenetics, Genzyme Genetics, Monrovia, CA.

PGD/PGS is now an established procedure for the detection of single gene disorders by PCR, and chromosome aneuploidy /rearrangements by FISH, in cleavage stage blastomeres. Reciprocal translocations are the most common form of chromosome abnormalities observed (1 in 500 live births), followed by Robertsonian translocations and inversions (1 in 1000 each). There has been an increase in demand for PGD/PGS by patients who carry chromosome rearrangements in order to increase their chances of normal pregnancies. Genzyme Genetics is one of the leading laboratories performing PGD/PGS by FISH. A retrospective data analysis performed on 51 couples carrying chromosome rearrangements, using blastomeres fixed on slides, are presented here. When applicable, we used three differentially labeled probes: two subtelomere probes appropriate to the chromosome arms involved in the rearrangement, combined with a centromere probe (or any other probe mapping proximal to the breakpoints). When differentially labeled centromere or proximal probes were not available, we performed two sequential hybridizations with subtelomere probes specific to each arm of the chromosome involved. Using these strategies it is possible to identify all 16 segregation products of reciprocal translocations, all six possible outcomes of Robertsonian translocations, and all major recombinant products of inversions, excluding the recombinant products within the inversion loop. We perform pre-PGD chromosome and FISH analysis on all couples with chromosome rearrangements unless they have been tested by our laboratories previously. Using this protocol we have identified two discrepant results. Therefore, it is recommended that laboratories performing PGD/PGS for chromosomal rearrangements also perform cytogenetic and FISH analysis on parental blood. This is to confirm the rearrangements and identify any possible polymorphisms (by FISH) in order to select the most appropriate probes for PGD/PGS analysis.

Weird animal genomes and the evolution of sex chromosomes. *J. Graves* Research Sch Biol Science, Australian National Univ, Canberra, ACT, Australia.

In humans and other therian mammals, females have two X chromosomes and males a single X and a Y that bears the testis-determining gene SRY. Birds and reptiles have completely different triggers for sex determination; either genes on unrelated sex chromosomes (Z and W in snakes and birds), or environmental triggers like temperature. Or both, as we recently discovered in dragon lizards. X and Y chromosomes evolved from an ordinary pair of autosomes as the Y progressively degraded (the bird Z and W evolved independently from a different autosome pair). Our strategy is to compare the chromosomes, genes and DNA between distantly related mammal groups, as well as birds and reptiles. The genomes of Australias unique kangaroos and platypus, now being completely sequenced, are particularly valuable because these alternative mammals are distant enough to provide informative variation, but not too distant to compare DNA sequences. Kangaroo sex chromosomes reflect the original mammal sex chromosomes and define evolutionary layers in the X. The bizarre multiple platypus sex chromosomes are related to the bird Z, implying that our sex chromosomes are relatively young. The human X contains more than a thousand genes biased toward functions in male reproduction, and intelligence, and often both, perhaps because of positive selection for male-advantage genes on the hemizygous X in males, and selection by females of intelligent mates, acting independently on X-borne genes. The small human Y bears only 45 different protein-coding genes, 27 (mostly testis-specific) in the male-specific region. Most Y genes (even those with functions in sex determination and spermatogenesis) evolved from widely expressed partners on the X. Comparisons between mammals shows that the Y degraded independently in different lineages. For instance, the kangaroo Y contains several novel testis-specific genes with X-borne partners. Degradation is ongoing, and if it continues at the same rate, will wipe out the human Y in 7 million years.

A comparison of human and chimpanzee recombination landscapes in the pseudo-autosomal regions. *A. Fledel-Alon[1], D. Serre[2], M. Przeworski[1]* 1) Department of Human Genetics, University of Chicago, 920 East 58th Street, Chicago, Illinois 60637, USA; 2) McGill University and Genome Quebec Innovation Center, Montreal, Quebec H3A 1A4, Canada.

Recent studies have revealed a rapid evolution of recombination hotspot locations between humans and their closest living evolutionary relative, chimpanzees. Over larger genetic distance, however, genetic maps estimated in extant humans and historical rates estimated from human patterns of linkage disequilibrium are highly concordant. These observations led to the suggestion that while fine scales evolve rapidly, broader scale rates are conserved, either because of constraint on recombination rates or competition among hotspots. We tested this model by comparing rates of recombination in humans and chimpanzees in the pseudo-autosomal regions (PARs): PAR1, a 2.7 Mb region experiences obligate crossing-over in males and which therefore serves as a miniature model of a chromosome, and PAR2, a 0.33 Mb region that is human-specific. To do so, we resequenced over 200 amplicons spanning the PAR regions in 32 unrelated chimpanzees and estimated recombination rates from patterns of linkage disequilibrium. We then compared the inferred chimpanzee recombination rates to those estimated from human sperm typing, and from human phase II HapMap data. Here, we discuss the results of this comparison, and the implications for the evolution of recombination rates.

CYTOGENETIC FINDINGS IN WOMEN WITH AMENORRHEA. *R. Baez-Reyes, G. Razo-Aguilera* Department of Genetics, National Institute of Perinatology, Mexico City, MEXICO.

INTRODUCTION: Amenorrhea is the absence or abnormal cessation of the menses, resulting from ovarian malfunction and the etiology include in some cases chromosomal alterations. OBJETIVE: To study the frecuency of the chromosomal abnormalities(CA) in women referred for counseling and karyotyping with primary amenorrhea(PA) and secundary amenorrhea(SA). METHODS; We report a cytogenetic study of 136 women with primary(87) or secundary(49) amenorrhea was performed at Genetics of Reproduction of the National Institute of Perinatology from January,1997 to June,2007. RESULTS: The frecuency of the CA in primary amenorrhea was 13.2% and secundary amenorrhea was 7.35%. Numerical alterations in the karyotypes observed were: 45,X ; 47,XXX ; X mosaicism (45,X/46,XX ; 45,X/46,XX/47,XXX ; 46,XX/47,XXX ; 46,XX/47,XXX/48,XXXX), Y mosaicism (45,X/46,XY). The presence of 46,XY female condition in 3 cases detected to be associated with PA. The structural chromosomal anomaly were: X,autosomal translocations (X;1, X;4, X;6 and X;8), one reciprocal translocation: t(2;8) and other alterations: 46;Xi(Xq) and mos 45,X/46,Xi(Xq). CONCLUSION: The present study show the importance of the karyotype in the investigation of the causal factor in the evaluation of patients with amenorrhea for a early diagnosis and the possibility of treatment.

Competitive allele-specific short oligonucleotide hybridization (CASSOH) method: Applications to genotyping of clinically important SNPs in pharmacogenetics. *S. Kure[1], M. Hiratsuka[2], A. Ebisawa[2], F. Kamada[1], S. Komatsuzaki[1], J. Kanno[1], A. Narisawa[1], Y. Aoki[1], M. Mizugaki[2], Y. Matsubara[1]* 1) Department of Medical Genetics, Tohoku University School of Medicine, Tohoku University Scholl of Medicine, Sendai, Japan; 2) Department of Clinical Pharmaceutics, Tohoku Pharmaceutical University, Sendai, Japan.

Pharmacogenetics involves determining the genetic polymorphisms influencing drug exposure levels. We have developed a simple genotyping method of single nucleotide polymorphisms (SNPs) using immunochromatographic strip, CASSOH, which detects a SNP within 10 min after the competition of PCR by forming a visible gold-particle line on a chromatographic test strip (Matsubara Y and Kure S, Hum Mutat, 2003;22:166-172, Hiratsuka et al, Drug Metab Pharmacokin., 2004;19:303-307). The CASSOH method dose not demand either technical expertise or expensive instruments, and is readily performed in local clinical laboratories. We have applied this method for detection of ten SNPs that are clinically important in drug metabolism, ALDH2*2, CYP2C19*2, CYP2C19*3, NAT2*5, NAT2*6, NAT2*7, TPMT*3C, UGTT1A1*6, UGT1A1*27, and mitochondrial DNA 1555A>G. All the SNPs were successfully detected by the CASSOH method. The system developed here would facilitate poin-of-care genetic testing in local hospitals and out-patient clinics, promising potentially diverse clinical applications.

Evidence for T(Brachyury) as a Candidate Gene for Vertebral Malformations. *P. Giampietro[1], C. Raggio[2], J. Staubli[1], E. McPherson[1], L. Ivacic[1], K. Rasmussen[1], F.S. Jacobsen[1], F. Faciszewski[1], R.M. Pauli[3], J. Burmester[1], I. Glurich[1], O. Boachie-Adjei[2], R. Blank[3]* 1) Marshfield Clinic, Marshfield, WI; 2) Hospital for Special Surgery, New York, NY; 3) University of Wisconsin, Madison, WI.

No major genes for sporadically occurring congenital vertebral malformations (CVM) in humans have been identified. In contrast, multiple mouse mutations feature abnormal vertebral phenotypes. We have identified body patterning genes in mice as candidates for causing human CVM. T is a critical gene to establish mesodermal identity. In mice, T mutations act as recessive lethals and have a dominant abnormal tail phenotype. In humans, some, but not all, investigators report that the C allele of a T/C polymorphism in intron 7 has been reported to be preferentially transmitted to offspring with spina bifida. We therefore hypothesized that mutations in T (Brachyury) contribute to the pathogenesis of other human vertebral malformations. To test this idea, we sequenced the complete coding region and 500 bp of the T gene in 50 thoroughly characterized patients with CVM. Three patients were heterozygous for an A338V missense mutation in exon 7 that did not occur in an ethnically diverse, 443 person reference population. Alanine is conserved at this residue in mouse, rat, rabbit, dog, and Xenopus tropicalis, but not in armadillo, elephant, opossum, chicken, or tetraodon. Valine did not occur at this residue in any of the species in which alanine was not conserved. The individuals harboring the A338V mutation had diverse spinal phenotypes, including Klippel-Feil syndrome, sacral agenesis, and spondylothoracic dysplasia. A fourth patient, with T12 and L1 hemivertebrae, harbored an exon 7 splice junction C to T variant. This previously unreported variant was tested in 347 control subjects, and 11 heterozygotes and 2 T/T individuals were found. We believe that the A338V mutation is pathogenic and that the splice junction variant may increase CVM risk. Presumably, epistatic interactions between the T protein and other developmental genes and the environment modulate the phenotypic consequences of T mutations.

High-resolution SNP array analysis of epithelial ovarian cancer reveals numerous micro-deletions and amplifications. *I.G. Campbell[1], E.R. Thompson[1], A. Sridhar[1], W. Qiu[1], S. Jacobs[2], D.Y.H. Choong[1], K.L. Gorringe[1]* 1) Research Division, Peter MacCallum Cancer Centre, East Melbourne, Victoria, Australia; 2) Affymetrix, Inc, Santa Clara, California.

Genetic changes in sporadic ovarian cancer are relatively poorly characterized compared with other tumor types. We have evaluated 31 primary ovarian cancers and matched normal DNA for loss of heterozygosity and copy number alterations using 500K SNP arrays. In addition to identifying the expected large-scale genomic copy number changes, over 380 small regions of copy number gain or loss (<500kb) were identified among the 31 tumors including 33 regions of high level gain (>5 copies) and 26 homozygous deletions. The existence of such a high frequency of small regions exhibiting copy number alterations had not been previously suspected since earlier genomic array platforms lacked comparable resolution. Interestingly, many of these regions harbor known cancer genes. For example, one tumor harbored a 350 kb high-level amplification centered on FGFR1 and three tumors showed regions of homozygous loss 109 kb - 216 kb in size involving the RB1 tumor suppressor gene only. These data suggest that novel cancer genes may be located within the other identified small regions of copy number alteration. Analysis of the number of copy number breakpoints and the distribution of the small regions of copy number change indicate high levels of structural chromosomal genetic instability in ovarian cancer.

Position-dependent cancer hyper- and hypomethylation in a DNA repeat array linked to FSH dystrophy. *M. Ehrlich[1], L. Qi[1], K. Jackson[1], C. Shao[1], K. Tsumagari[1], M. Lacey[2]* 1) Hayward Genetics Prog, SL31, Tulane Medical Sch, New Orleans, LA; 2) Dept. of Mathematics, Tulane University, New Orleans, LA.

Short subtelomeric arrays of tandem 3.3-kb units, called D4Z4, are linked to the enigmatic facioscapulohumeral muscular dystrophy (FSHD). D4Z4 arrays with 1 to 100 units are on 4q35 and 10q26 but only a 4q35 array of 1-10 units is pathogenic. D4Z4 is normally dependent on DNMT3B for most of its methylation. By blot-hybridization analysis with various CpG methylation-sensitive restriction endonucleases, we found hypomethylation of D4Z4 in some ovarian carcinomas and Wilms tumors and hypermethylation in others, as previously seen for NBL2, another tandem repeat that is normally methylated mostly by DNMT3B. Surprisingly, in cancers with D4Z4 hypermethylation, there seems to be a barrier to spreading of methylation to the beginning of the repeat array despite the very high sequence conservation throughout the array. This suggests differences in chromatin structure affecting methylation at the interface of the (G+C)-rich D4Z4 array and the proximal sequence. In addition, several unusual CpG methylation patterns correlated with atypical local sequences. A tenaciously methylated CpG site proximal to the array is surrounded by repeated T-containing oligonucleotide motifs. Conversely, resistance to cancer-associated hypermethylation was seen at D4Z4 CpG sites near runs of G that can form G-quadruplexes, a non-B DNA structure. G-quadruplexes can regulate transcription and interactions between DNA duplexes in vivo. Therefore, G-quadruplexes in D4Z4 may not only decrease the probability of cancer-linked DNA hypermethylation, but more importantly, also play a central role in the topological constraints that confer pathogenicity on short 4q D4Z4 arrays and make long ones phenotypically neutral. (Supported in part by NIH Grant NS048859 and an FSH Society Grant.).

Applications of Next-Generation Sequencing in Genetic Epidemiology. *F.M. De La Vega[1], J. Sorenson[1], F. Hyland[1], K. McKernan[1], W. Kim[2], S.J. Finch[2], D. Gordon[3]* 1) Applied Biosystems, Foster City, CA; 2) Stony Brook University, Stony Brook NY; 3) Rutgers University, Piscataway, NJ.

An important application for next-generation sequencing (NGS) is the deep resequencing of targeted regions and whole genomes for the discovery of a range of sequence variants including SNPs, rare mutations, indels, copy number, and large scale genomic rearrangements. Ultimately one goal is to provide genometypes of individual patient samples for identification of disease susceptibility alleles. In such experiments, a shotgun sequencing of template DNA is performed, where reads are derived from clonal fragments and genotypes are derived by counting. We sought to understand the relationships between number and length of reads and per-base sequencing error to the overall genotyping accuracy through simulations and through experimental results from the Applied Biosystems SOLiD system. Since NGS platforms typically produce short reads (25-35bp), coverage needs to increase to 15-20X to reduce heterozygous misclassification errors to acceptable rates, whereas homozygote calling requires less coverage (10-15X). Error rate significantly influences coverage requirements highlighting its importance in genometyping. Due to shotgun coverage some missing data will persist, suggesting a role for statistical imputation methods. A critical question in association studies is the power to detect genetic association with a fixed sample size. Recent work has focused on two-stage designs, where subsets of individuals and markers are typed each in screening and replication stages. A typical assumption is that the disease variant is contained in the screening SNP panel. Here, we examined situations where the disease variant is initially not typed (as is more typical), but can be discovered and simultaneously typed by NGS of the leading candidate regions in cases and controls. We discover that while significant power loss may occur when the disease variant is absent from the screening phase, power can be recovered by full SNP ascertainment by resequencing. These results suggest that NGS could become a valuable tool in the identification of susceptibility genes for complex disease.

Diagnostic testing for Duchenne/Becker Muscular dystrophy using Dual Priming Oligonucleotide (DPO) system.

J.H. Kim[1], G.H. Kim[1,2], J.J. Lee[2], D.H. Lee[3], J.K. Kim[3], H.W. Yoo[1,2,4] 1) Genome Research Center for Birthe Defects and Genetic Disorders, Asan Institute for Life Sciences,; 2) Medical Genetics Clinic and Laboratory, Asan Medical Center; 3) Seegene Institute of Life Science; 4) Department of Pediatrics, Asan Medical Center, University of Ulsan College of Medicine, Seoul, Korea.

Duchenne and Becker type muscular dystrophy (DMD and BMD, OMIM #310200, 30076) are common X-linked heritable muscle diseases in children caused by mutations in the dystrophin gene. Large exon deletions in the gene are found in about 60% of DMD patients. A serial set of multiplex PCR has been employed to detect the deletion mutation, which frequently generates noise PCR products due to the presence of multiple primers in single test tube as well as the stringency of PCR conditions. This often leads to a false-negative or false-positive result. To address this problematic issue, we introduced the Dual Primer Oligonucleotide (DPO) system. DPO contains two separate priming regions joined by a polydeoxyinosine linker, which serve high PCR specificity even under less optimal PCR conditions. We tested 50 healthy controls, 50 patients with deletion mutation as deletion-positive patient controls, and 20 patients with no deletions as deletion-negative patient controls using DPO-multiplex PCR. Both the presence and extent of deletion were verified by simplex PCR spanning promoter region(PM) and 18 exons including exons 3-4, 6, 8, 12-13, 17, 19, 43-48, 50-52, 60 in all 120 controls. DPO-multiplex PCR showed 100% of both sensitivity and specificity for the detection of presence of deletion. However, it shows 71.2 % of sensitivity and 100% of specificity in determining the extent of deletions. In conclusion, DPO-multiplex PCR method is another useful molecular testing modality for the diagnosis of patients with DMD/BMD since it is easy to perform, fast and cost-effective as well as the result shows relatively high analytical validities.

Presence of a familial translocation t(7;15)(p22;q14) and de novo deletion of the 15q11-q13 region in a 12 month old girl with Angelman syndrome. *L. Jenkins[1], D. Delgado[1], R. Roshan[2], J. Kobori[1]* 1) The Permanente Medical Group, Inc. Genetics Department, San Jose, CA; 2) The Permanente Medical Group, Inc. Department of Pediatric Neurology, San Francisco, CA.

A 12 month old girl with developmental delay, hypotonia, happy demeanor, and delayed speech was identified prenatally to have a maternally inherited balanced translocation: t(7;15)(p22;q14). Postnatal DNA methylation studies confirmed the clinical suspicion of Angelman syndrome. Further diagnostic testing by FISH methods detected a de novo chromosomal deletion in the 15q11q13 region in the der(15) chromosome, with the loss of the SNRPN and UBE3A locus. A human oligo-based array was used to refine the size and the location of the deletion. The translocation breakpoints map to a newly described breakpoint cluster region at 15q14 and the distal subtelomeric end of the short arm of chromosome 7. Similar rearrangements involving 15q14 and the terminal ends of the recipient chromosome have been reported to result in an unbalanced karyotype of 45 chromosomes due to the loss of the der(15). This is the first reported case of Angelman syndrome in which the 15q11q13 de novo deletion is found in a familial balanced translocation involving 15q14 in a "balanced" complement of 46 chromosomes. Non-allelic homologous recombination between 15q-specific low copy repeats (LCRs) could result in the deletion observed in the der(15), and the reciprocal duplication of this region in the "normal" 15 homolog during maternal meiosis. The mother has a history of multiple miscarriages with no other significant clinical findings. Risk assessment for a de novo deletion of the 15q11q13 region in carriers of a balanced reciprocal translocation involving chromosome 15 is limited due to few reported cases. These findings have important implications for prenatal diagnosis. When a fetus from a carrier parent is found to have the same balanced translocation or normal appearing 15 homologs, FISH analysis should be considered to rule-out a submicroscopic deletion or duplication of the 15q11q13 region. Depending on the parental origin, the defect could lead to Angelman syndrome, Prader Willi syndrome, or dup(15)(q11q13).

A novel intronic point mutation of CPS1 gene in a Korean family with CPS1 deficiency. *G.H. Kim[1], J.M. Ko[2], J.J. Lee[1], H.W. Yoo[1,2]* 1) Med Genetics Clinic & Laboratory, Asan Medical Center; 2) Department of Pediatrics, Asan Medical Center, University of Ulsan College of Medicine, Seoul, Korea.

Carbamoyl phosphate synthetase I (CPS1) deficiency (OMIM#237300) is a rare autosomal recessive inborn error of the urea cycle causing hyperammonemia. The mutations of CPS1 gene located on 2q35 are responsible for CPS1 deficiency. To date, about 50 mutations have been reported. We encountered a 7-day-old Korean female infant with hyperammonemia and the diagnosis was confirmed by CPS1 gene mutation analysis as well as biochemical findings including low plasma citrulline level and absence of orotic aciduria. The patient was born to healthy parents of non-consanguineous marriage. Her previous 3 elder siblings died during neonatal period because of hyperammonemic encephalopathy. The mutation analysis was performed with reverse transcriptation (RT)-PCR and sequence analysis using cDNA isolated from liver tissue. Two different transcripts were found; one showed normal sequences and the other 60 bp insertion of intronic sequences. Subsequently, the sequence variations were confirmed in genomic DNA isolated from peripheral leukocytes. Mutations of the CPS1 gene were identified in the patient and her parents. The patient carries both a deletion mutation c.1529del, resulting in a frame-shift p.Gly510AlafsX4, and a novel intronic mutation, c.3666+64T>G, a base change at 64 bp down stream from the end of exon 30, making a base c.3666+61 more efficient 5 new splice donor site for intron 30. Automated splice site analysis using this base change revealed that it generated 1.4 fold more efficient splice site than the original one. Therefore, c.3666+64T>G mutation results in the retention of 60 intronic bases into mRNA during RNA processing, leading to a truncated mutation p.Val1223delins(Val-Ile-Ile-Tyr-Lys_X). The mutation c.1529del was inherited from her father, and the novel c.3666+64T>G from his mother. We report a novel intronic mutation of the CPS1 gene in a Korean family with CPS1 deficiency.

Analysis of methylation status in the promoter of interferon regulatory factor-2 gene in patients with late-onset psoriasis. *N. Hosomi[1,2], K. Fukai[1], N. Oiso[3], Y. Kira[4], T. Ohshimo[1], A. Umekoji[1], M. Ishii[1]* 1) Dermatology, Osaka City University, Osaka, Japan; 2) Dermatology, Kashiwara Municipal Hospital, Kashiwara, Japan; 3) Dermatology, Kinki University, Osakasayama, Osaka, Japan; 4) Central Laboratory, Osaka City University, Osaka, Japan.

Interferon regulatory factor 2 (IRF2) is a transcriptional regulatory protein which represses the expression of interferon-alpha/beta genes. In mice lacking IRF2, the inflammatory skin disease very similar to human psoriasis develops spontaneously. In addition, IRF2 gene is located at human chromosome 4q35, where a familial psoriasis susceptibility locus has been mapped. Thus, the IRF2 gene is a strong candidate gene for psoriasis. We hypothesized that the methylation of the promoter of the gene is associated with type 2 psoriasis in Japan. To analyze IRF2 promoter methylation status, we investigated genomic DNA in peripheral leukocytes of patients with late-onset psoriasis and healthy controls using bisulfite-sequencing method. We enrolled ten late-onset psoriasis patients (mean age; 72.4 years, mean affected age; 49.8years) and five healthy controls (mean age; 63 years) in this study. The genomic DNAs were treated by sodium bisulfite, and the region from -508 to -22 of the IRF2 promoter was amplified by PCR in two fragments. They were cloned into TA-cloning vector, and fifteen clones for each fragment were sequenced. We identified 16 methylated CpG sites (-78, -122, -126, -153, -157, -232, -240, -261, -290, -306, -364, -369, -377, -407, -430 and -456; numbered from the transcriptional initiation site) in the IRF2 promoter of late-onset psoriasis. We also identified 7 methylated CpG sites in the promoter of healthy controls (-126, -167, -232, -235, -253, -306 and -379). The frequencies of the methylated CpGs were approximately 5% both for the psoriasis patients and the normal controls.

Functional consequence of a common and a novel *CYP17A1* promoter polymorphism for association studies. *V.M. Hayes* Cancer Genetics Group, Garvan Institute of Medical Research, Sydney, NSW, Australia.

Cytochrome P450c17 is a key enzyme in sex hormone production and is encoded by the *CYP17A1* gene. A single nucleotide polymorphism (SNP) located 34-bases upstream of translation initiation, rs743572T>C, has been studied extensively for its potential role, although often controversial, in conferring risk to a large number of hormone-related diseases and conditions. The majority of these studies are based on the assumption that this polymorphism directly influences gene transcription. In prostate cancer, numerous studies have reported associations with increased/decreased risk, or lack of association. In our large European-Australian cases-control study (n=1,563) we report a lack of association between this marker and prostate cancer risk (1) in agreement with a meta-analysis (n=5,159) for European-based populations (2). The latter study did however suggest a potential influence of this marker in African-based populations. We have identified a novel SNP at the -34 position, resulting in a T to A nucleotide change, in two African-based populations using denaturing gradient gel electrophoresis. We demonstrate how commonly used genotyping methods, restriction fragment length polymorphism analysis and TaqMan allelic discrimination, result in genotype misclassification. Although the common C- and the novel A-allele variants create putative SP-1 and AP-4 transcription factor binding sites, respectively, we show no biological effect of these polymorphic alleles on transcription factor binding or gene expression compared to the wild-type allele. The implication of our findings on association studies of the *CYP17A1* -34T>C SNP are apparent, not only with respect to genotype misclassification in Africans, but also the lack of evidence supporting its role as a functional (direct association) polymorphic marker.

There are gender differences in attitudes toward the genomic studies applied to medicine and genomic literacy in Japan. *I. Ishiyama[1], A. Nagai[1], K. Muto[2], A. Tamakoshi[3], K. Mimura[4], M. Kokado[5], T. Tanzawa[6], Z. Yamagata[1]* 1) Department of Health Sciences, School of Medicine, University of Yamanashi, Japan; 2) Institute of Medical Science, University of Tokyo, Japan; 3) Department of Clinical Research Management, National Hospital for Geriatric Medicine, Japan; 4) Ochanomizu University Graduate School of Humanities and Sciences, Japan; 5) Kyoto University, Japan; 6) Department of Science Education, Shizuoka University, Japan.

The aim of this study was to assess gender differences in public attitudes toward the promotion of genomic studies applied to medicine, the level of genomic literacy and the relationship between attitudes and literacy , analyzing the data of nationwide opinion survey. The participants of 4,000 people (age 20-69) were selected using the stratified two-step randomization from Japanese public. They were asked the following items by postal questionnaire. Pros and cons of the promotion of genomic studies applied to medicine, level of genomic literacy, demographic and socioeconomic background, and attitudes about science in general. We examined the relationship between approval of the promotion and the level of genomic literacy, using logistic regression models stratified by gender. The response rate was 54.3% (male 51.1%, female 58.6%), and 69.4% of all respondents were in favor of the promotion (male 73.8%, female 65.6%). Males were more likely to approve of the promotion than females. The mean score of genomic literacy was 20.2 (range 0-30). There was a significant difference between the score of males and females (male 20.4, female 20.0). Multivariable analysis showed that approval was related to the high score of literacy. This relationship was stronger in male than in female (for the highest quintile of score versus the lowest, male: adjusted odds ratio (OR) 3.36; 95% confidence interval (CI) 1.88-5.98, female: adjusted OR 1.86; 95% CI 1.17-2.95). It also showed that a relationship between approval and income was stronger in female than in male. We need further discussions and research to analyze the factors that affect the attitudes toward genomic studies in male and female.

Therapeutic dosage of valproic acid may not increase survival motor neuron protein in fibroblasts from patients with spinal muscular atrophy type I and II. *.. Gunadi[1], T.H. Sasongko[1], S. Yusoff[1], A.H. Sadewa[3], R. Sutomo[4], M.J. Lee[1], M. Matsuo[2], H. Nishio[1]* 1) Department of Genetic Epidemiology, Kobe University Graduate School of Medicine, Kobe, Japan; 2) Department of Pediatrics, Kobe University Graduate School of Medicine, Kobe, Japan; 3) Department of Biochemistry, Gadjah Mada University School of Medicine, Yogyakarta, Indonesia; 4) Department of Pediatrics, Gadjah Mada University School of Medicine, Yogyakarta, Indonesia.

Homozygous absence of the survival motor neuron 1 gene (*SMN1*) is the most frequent cause of spinal muscular atrophy (SMA). Clinical severity may be modified by the presence of the *SMN2* gene, almost identical to *SMN1*. Administration of valproic acid (VPA), a well-known drug for epilepsy, is a potential treatment of SMA, since it has been reported to increase the full-length (FL) *SMN2* expression. VPA may have splicing modulation activity, as well as histone deacetylase (HDAC) inhibitor activity. However, it is controversial whether it can increase the *SMN2* expression in SMA patients. In this study, we analyzed *SMN2* transcripts and SMN protein levels in SMA fibroblasts cultured in the medium with therapeutic concentration of VPA. Fibroblasts from two SMA patients lacking *SMN1* were used. One patient was an SMA type I (2 *SMN2* copies) and the other one was an SMA type II patient (3 *SMN2* copies). Semi-quantitative RT-PCR analysis showed neither significant difference in *SMN2* splicing patterns nor in total *SMN2* transcript amounts between mock and VPA-treated fibroblasts from both patients. Western blotting analysis also demonstrated that SMN protein levels were not changed at various concentrations of VPA. In conclusion, VPA within therapeutic dosage may not increase *SMN2* transcripts and SMN protein levels in fibroblasts from patients with SMA type I and II. Our study did not test the VPA effects on fibroblasts from SMA type III and IV patients, although there have been reported that VPA ameliorate their symptoms. Further studies are necessary to select SMA patients who will respond to therapeutic dosages of VPA.

Mutations in insulin-like factor 3 receptor are associated with osteoporosis. *A. Ferlin[1], A. Pepe[1], L. Gianesello[1], A. Garolla[1], S. Feng[2], R. Morello[3], A.I. Agoulnik[2], C. Foresta[1]* 1) University of Padova, Department of Histology, Microbiology and Medical Biotechnologies, Centre for Male Gamete Cryopreservation, Padova, Italy; 2) Department of Obstetrics and Gynecology, Baylor College of Medicine, Houston, TX 77030, USA; 3) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX 77030, USA.

Background: Insulin-like factor 3 (INSL3) is produced primarily by testicular Leydig cells. It acts by binding to its specific G-protein coupled receptor RXFP2 (Relaxin family peptide 2) and is involved in testicular descent during fetal development. The physiological role of INSL3 in adults is not known. The aim of the study was to verify whether reduced INSL3 activity could cause or contribute to some signs of hypogonadism, such as reduced bone density, currently attributed to testosterone deficiency. This was possible by the availability of the largest series of men with mutations in the RXFP2 gene. Methods: Extensive clinical investigation, including bone densitometry by DEXA, was performed on 25 young men (age 27-41) with the T222P mutation in the RXFP2 gene. Expression analysis of INSL3 and RXFP2 on human bone biopsy and human and mouse osteoblast cell cultures was performed by RT-PCR and immunohistochemistry. Real-time cAMP imaging analysis was performed on these cells. Lumbar spine of Rxfp2-deficient mice was studied by histomorphometric analysis. Results: Sixteen out of 25 young men with RXFP2 mutations have significantly reduced bone density. No other apparent cause of osteoporosis was evident in these subjects, whose testosterone plasma concentrations were in the normal range. Expression analyses showed the presence of RXFP2 in human and mouse osteoblasts. Stimulation of these cells with INSL3 produced a dose- and time-dependent increase in cAMP, confirming the functionality of the RXFP2/INSL3 receptor-ligand complex. Consistent with the human phenotype, bone histomorphometric analysis of Rxfp2-/- mice showed decreased bone volume. Conclusions: This study suggests a role for INSL3/RXFP2 signaling in bone metabolism and link RXFP2 gene mutations with human osteoporosis.

FAF1 a new gene for Cleft Palate and Pierre Robin Sequence. *M. Ghassibe[1], L. Desmyter[1], O. Boute[2], B. Bayet[3], Ph. Pellerin[4], N. Revencu[1], H. Poirel[5], J. Vermeesch[6], L. Backx[6], R. Vanwijck[3], M. Vikkula[1]* 1) Laboratory of Human Molecular Genetics, Christian de Duve Institute and Université catholique de Louvain, Brussels, Belgium; 2) Centre de Génétique, CHU de Lille, Lille, France; 3) Centre Labiopalatin, Division of Plastic Surgery, Cliniques universitaires St Luc, Brussels, Belgium; 4) Service de chirurgie plastique et reconstructives, CHU de Lille, Lille, France; 5) Center for Human Genetics, Cliniques universitaires St Luc and Université catholique de Louvain, Brussels, Belgium; 6) Center for Human Genetics, Leuven University Hospital, Leuven, Belgium.

Cleft lip and/or cleft palate is the most frequent craniofacial malformation in humans (~ 1/700). Genetic factors involved in cleft lip with or without the palate (CL/P) are thought to be different from those having a role in cleft palate only (CPO). There is a significant challenge in identifying genetic and environmental components of isolated clefts since it is a multifactorial disease with complex etiology. We show that the FAF1 gene (Fas-Associated Factor 1) is disrupted, by a reciprocal translocation, in a patient with Pierre Robin sequence (PRS), characterized by a cleft of the palate and a micrognathia resulting in glossoptosis. Moreover, association study showed that FAF1 predisposes to cleft palate and Pierre Robin sequence. Screening of the gene revealed several substitutions occurring in highly conserved domains which might thus be responsible of the cleft condition in five separate families. Finally, by in-situ hybridization we show high levels of Faf1 mRNA along the medial edge epithelium of the fusing palate, at the fusing superior lips and the tongue. This expression declines after fusion. Human FAF1 is a Fas-associating molecule with the ability to initiate apoptosis. It is a member of the Fas death-inducing signaling complex and a suppressor of NF-kB activity. Taken together, our observations demonstrate that FAF1 is a novel gene playing an important role in the ethiopathogenesis of syndromic and non-syndromic cleft palate by preventing the medial edge epithelial cells (MEE) from undergoing apoptosis. (vikkula@bchm.ucl.ac.be).

Single nucleotide polymorphisms of follicle-stimulating hormone receptor gene are associated with testicular cancer susceptibility. *C. Foresta, M. Pengo, R. Selice, A. Garolla, A. Ferlin* University of Padova, Department of Histology, Microbiology and Medical Biotechnologies, Centre for Male Gamete Cryopreservation, Padova, Italy.

Testicular germ cell tumour (TGCT) is the most common cancer in young adult men. Epidemiological and clinical features suggest that TGCT development is under endocrine control but definitive proofs are lacking. FSH levels are increased in numerous conditions associated with increased risk of TGCT and some single nucleotide polymorphisms (SNPs) in the FSH receptor (FSHR) gene influence the sensitivity of the receptor to FSH. However, a possible effect of FSH on testicular carcinogenesis has never been explored. Here we studied the association of FSHR SNPs with TGCT. Analysis of 12 potential SNPs of the FSHR gene in 188 TGTC cases and 152 controls, revealed 4 informative SNPs, represented by two polymorphisms in exon 10 (Ala307Thr and Ser680Asn), and two polymorphisms in the promoter region (-114 T/C and -29 G/A). Specific haplotypes and genotypes determined by the association between two or more of these SNPs were associated with TGCT. In particular, the Ala307/Ser680 allele lowers the risk of TGCT, especially in combination with the -29 G allele and the -114 T allele (P = 0.009, relative risk 0.73; 95% confidence interval 0.57-0.92). The genotype homozygous for the Thr307-Asn680 allele increases the risk of TGCT, especially in combination with the -29 A/G alleles and the -114 T allele (P = 0.018, relative risk 2.20; 95% confidence interval 1.14-4.29). The associations were stronger for non seminoma than seminoma. These data provide evidence that FSHR gene polymorphisms modulates susceptibility to TGCT. The variants associated with higher risk are those with higher activity of the FSHR, suggesting a role for FSH in the carcinogenesis process of this tumour.

Clinical and molecular genetics of Lebers congenital amaurosis (LCA): a multi-center study of Italian patients. *S. Banfi[1], C. Ziviello[1, 2], F. Testa[3], S. Rossi[3], S. Signorini[4], S. Galantuomo[5], E.M. Valente[6, 7], E. Rinaldi[3], F. Simonelli[3]* 1) Telethon Institute of Genetics and Medicine (TIGEM), Naples; 2) Institute of Genetics and Biophysics "A. Buzzati-Traverso", CNR, Naples; 3) Department of Ophthalmology, Second University of Naples, Naples; 4) Department of Child Neurology and Psychiatry of the IRCCS C. Mondino Foundation, Pavia; 5) Department of Ophthalmology University of Cagliari, Cagliari; 6) IRCCS CSS-Mendel Institute, Rome; 7) Department of Medical and Surgical Pediatric Sciences, University of Messina, Messina, Italy.

Lebers congenital amaurosis (LCA) is a group of hereditary retinal dystrophies characterized by severe loss of visual function early in life. We investigated the molecular basis of Lebers congenital amaurosis (LCA) in a cohort of Italian patients and we performed genotype-phenotype analysis. Overall, we carried out mutation analysis, by using an integrated approach including microarray and sequencing analyses, in 95 patients for nine LCA genes. Disease-causing mutations were identified in 28% of patients and twelve novel mutations were identified. Mutations occurred more frequently in the RPE65 (8.4%), CRB1 (7.4%), and GUCY2D (5.2%) genes. Mutations in CEP290 were found in only 4.2% of the patients analyzed. Overall, we found that RPE65 gene mutations represent a significant cause of LCA in the Italian population while GUCY2D and CEP290 mutations have a lower frequency in the Italian population, as compared to other reports. These findings confirm that the genetic epidemiology of LCA in Italy, similar to what has been observed for other forms of inherited retinal degenerations, is different from what reported in the U.S. and in other Northern European countries.

Performance of whole genome amplified DNA in genome-wide association studies. *M. Inouye[1], Y.Y. Teo[2], K.S. Small[2], A.E. Fry[2], S.C. Potter[1], S.J. Dunstan[3], M. Seielstad[4], I. Barroso[5], N.J. Wareham[6], K.A. Rockett[2], D.P. Kwiatkowski[1,2], P. Deloukas[1]* 1) Human Genetics, Wellcome Trust Sanger Institute, Hinxton, Cambridgeshire, United Kingdom; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, United Kingdom; 3) Oxford University Clinical Research Unit, Hospital for Tropical Diseases, Ho Chi Minh City, Vietnam; 4) Agency for Science, Technology and Research, Singapore; 5) Metabolic Disease Group, Wellcome Trust Sanger Institute, Hinxton, Cambridgeshire, United Kingdom; 6) MRC Epidemiology Unit, Strangeways Research Laboratories, United Kingdom.

Research into the genetic basis of common diseases is expanding rapidly with the advent of genome-wide association studies. Experimental success in these studies relies on accurate SNP typing with high-density probe arrays thus requiring high quality DNA, which is often irreplaceable and available in finite amounts. Whole genome amplification allows nanogram quantities of DNA to be rescued for SNP genotyping. However, previous studies have not accurately reflected how robustly panels of 300,000 to 1 million SNP sets will perform with amplified DNA, thus highlighting the importance of a genome-wide map of amplified DNA performance on high-density genotyping arrays. We performed an extensive comparison of amplified DNA with genomic DNA from 4,995 individuals from 4 separate cohorts genotyped at three facilities in America, Britain and Singapore. These samples were run on multiple genome-wide arrays from both Affymetrix's GeneChip and Illumina's BeadArray. Amplified DNA exhibited a substantial decline in call rates when compared against genomic DNA, and in selected regions of the genome we observed correlated differential rates of probe hybridization and signal loss on both platforms. These regions are highly dependent on GC content and segmental duplications, thus resulting in a biased set of lower quality SNPs which lowers genome coverage. We also highlight the promise of genotype imputation to recover lost performance.

Deficiency of PORCN, a regulator of Wnt signaling, causes focal dermal hypoplasia. *K.-H. Grzeschik[1], D. Bornholdt[1], F. Oeffner[1], A. Koenig[2], M. Boente[3], H. Enders[4], B. Fritz[1], M. Hertl[2], U. Grasshoff[4], K. Hoefling[5], V. Oji[6], M. Paradisi[7], C. Schuchardt[8], Z. Szalai[9], G. Tadini[10], H. Traupe[6], R. Happle[2]* 1) Human Genetics, University of Marburg, Germany; 2) Dermatology, University of Marburg, Germany; 3) Dermatology, Hospital San Miguel de Tucumán, Argentina; 4) Human Genetics, University of Tuebingen, Germany; 5) Medical Microbiology, University of Bonn, Germany; 6) Dermatology, University of Muenster, Germany; 7) Pedatric Dermatology, IDI, Roma, Italy; 8) Klinik Pieper. St. Blasien-Menzenschwand, Germany; 9) Pediatric Dermatology, Children's Hospital, Budapest, Hungary; 10) Dermatological Science, University of Milan, Italy.

Focal dermal hypoplasia (FDH, Goltz syndrome, MIM 305600) is an X-linked dominant, male-lethal, mostly sporadic multisystem birth defect affecting a multitude of tissues of ectodermal and mesodermal origin.

Using a stepwise, generally applicable approach employing i) genetic mapping of FDH in rare familial cases, ii) comparative genome hybridization on custom made high resolution arrays (HR-CGH) to search sporadic cases for small deletions in candidate chromosome areas associated with this Mendelian trait, iii) point mutation analysis in genes highlighted by overlapping deletions, we identify *PORCN*, located in Xp11.23, as the gene mutated in FDH. Focusing the CGH analysis by independent methods, such as genetic mapping, on restricted candidate areas eliminates ambiguities which might arise from the wealth of copy number variants in the human genome unrelated to the phenotype under study. Contiguous gene deletions or stop mutations affecting PORCN result in loss of function of this putative O-acyltransferase, crucial for cellular export of Wnt signaling proteins. The defect is detectable at the cellular level. Hence, FDH is a human developmental disorder caused by deficient Wnt signal production. Extreme skewing of X-inactivation or postzygotic mosaicism reduce the deleterious consequences of mutations in female patients. Due to the severity of the PORCN deficiency in cells with active mutant X-chromosome, effects of missing neighbouring genes in contiguous deletions are covered by epistasis.

Complex balanced translocation t(1;5;7)(p32.1;q14.3;p21.3) and two microdeletions del(1)(p31.1p31.1) and del(7)(p14.1p14.1) in a patient with features of Greig cephalopolysyndactyly and mental retardation. *E. Bocian[1], K. Borg[1], B. Nowakowska[1,2], E. Obersztyn[1], S.W. Cheung[2], L. Korniszewski[3], T. Mazurczak[1], B. Wiśniowiecka-Kowalnik[1], P. Stankiewicz[1,2]* 1) Department of Medical Genetics, Institute of Mother and Child, Warsaw, Poland; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, USA; 3) Institute of Physiology and Pathology of Hearing Outpatient Genetic Clinic, Warsaw, Poland.

Complex chromosome rearrangements (CCRs) are rare structural abnormalities that involve at least two chromosomes and more than two breakpoints and are often associated with developmental delay, mental retardation and congenital anomalies. Additional microdeletions localized on derivative translocation chromosomes yet not directly at the translocation breakpoints have been described very rarely. We report a de novo, apparently balanced translocation t(1;5;7)(p32.1;q14.3;p21.3) in a 7-year-old boy with severe psychomotor retardation, neonatal muscular hypertonia, congenital heart defect, polysyndactyly of hands and feet, and dysmorphic features resembling Greig cephalopolysyndactyly syndrome (GCS). Analysis of the chromosome breakpoints using FISH with locus-specific BAC clones and long-range PCR products did not identify chromosome imbalance at the interrogated regions. High-resolution comparative genomic hybridization (HR-CGH) and array CGH (aCGH) revealed two additional cryptic de novo deletions del(1)(p31.1p31.1) and del(7)(p14.1p14.1) that are not associated with the translocation breakpoints. FISH and polymorphic marker analyses showed that both deletions are located on the derivative chromosomes, are 4.2-6.1 Mb and 5.1 Mb in size, respectively, and are paternal in origin, suggesting that the described CCR arose during spermatogenesis. The deletion on chromosome 7p encompasses the GLI3 gene that is causative for the GCS, Pallister-Hall and Acrocallosal syndrome. We hypothesize that the intellectual disability and cardiac defects in our patient may be due to deletion or disruption of other genes localized either at the translocation breakpoints regions or within the deletions. We discuss the potential mechanisms of formation of the described CCR.

Diagnosis of t(9;14)(p13;q32) in post-transplant lymphoproliferative disorder. *S.L. Betz[1], M.A. Vigil[1], K.W. Rao[1,2]*
1) Department of Pathology, McLendon Clinical Laboratories, University of North Carolina Hospitals, Chapel Hill, NC; 2) Departments of Pediatrics and Genetics, University of North Carolina School of Medicine, Chapel Hill, NC.

Post-transplant lymphoproliferative disorder (PTLD) is a diverse group of lymphoid proliferations that arises in immunosuppressed recipients of solid organ or bone marrow allografts. Clonal cytogenetic abnormalities are frequent in monomorphic PTLD, however, there are few reports of 14q32 rearrangements. Here we report a 3 year old patient with a history of renal transplant, a high EBV titer, lymphadenopathy, and a high clinical suspicion for PTLD. A bone marrow biopsy and fine needle liver aspiration were performed. Liver aspirate demonstrated strong diffuse positive staining for CD20, BCL-2, and EBV (ISH) EBER stains within large malignant cells, and was classified as monomorphic PTLD, diffuse large B-cell lymphoma subtype. G-banded cytogenetic analysis demonstrated the presence of del(9)(p13), add(11)(q23), and add(14)(q32) in 5 of 20 metaphase cells. In order to further identify the origin of material on the abnormal chromosomes, analysis with Vysis MLL, p16, and CCND1/IGH FISH probes was performed. This analysis, using interphase and metaphase FISH, demonstrated the presence of a t(9;14) and a der(11) with loss of the MLL locus and 14q and 9p material attached to the distal long arm. Final cytogenetics were reported as 46,XY,t(9;14)(p13;q32),der(11)t(11;14)(q21;q12)t(9;14)(p13;q32)[5]/46,XY[14]. The t(9;14)(p13;q32) is a rare recurrent chromosomal aberration, detected in B cell lymphoproliferative disorders, and results in translocation of PAX5 to chromosome 14. While limited information exists about the t(9;14) and PTLD, the 2 reports in the literature suggest the presence of this rearrangement may be associated with a poor outcome. Our patient, diagnosed with PTLD 5 months after transplant, developed severe respiratory distress with pulmonary hemorrhage and expired 5 weeks after the initial PTLD diagnosis. This report provides further evidence that the t(9;14) is associated with PTLD, and that this rearrangement may be associated with a particularly aggressive variant of PTLD.

Molecular Genetic Diagnosis of Haemophilia A from Jammu region of J&K State, India. *P. Kumar[1], V. Dogra[1], W.K. Balwan[1], M. Idris[2], G.R. Chandak[2], S. Gupta[1]* 1) HGRCC, Zoology, University of Jammu, Jammu, Jammu, India; 2) Centre for Cellular and Molecular Biology, Uppal Road, Hyderabad, Andhra Pradesh, India.

Hemophilia A is one of the most common X-linked Genetic disease caused by different mutations in the factor VIII gene. It is estimated that about 50% of severe haemophilia A cases are the result of an inversion in factor VIII gene. In the work we present an analysis of 33 haemophilia A patients and 35 family members (Mothers and Sisters) of the 33 patients by using both the direct and indirect mutation detection techniques. Direct mutation analysis of inversion Intron 22 has been carried out by Conventional Southern Hybridization technique, Of the 33 patients, 22 were severely affected by the disease haemophilia A. 9 of these 22 severely affected patients had inversion in intron 22 of distal type and 2 had inversion in intron 22 of Proximal type. Amongst the 10 moderately affected patients 3 had inversion in intron 22 of Distal type, while in the remaining 7 patients none of the two i.e. Distal or Proximal type of inversion could be detected. In a single case of mild type neither Distal nor Proximal type of inversion could be detected. Only one mother of moderately affected patient was found carrier for distal type of inversion mutation. For indirect mutation analysis, two intragenic markers BclI and XbaI located in intron 18 and 22 respectively were taken up. Specific regions of factor VIII gene were amplified followed by restriction digestion in order to find out the informativeness of the marker. BclI marker intron 18 RFLP was informative for 24/51 X-chromosomes and allele frequency was 47.05%, whereas the heterozygosity rate was 9/16 (56.25%) for women studied and XbaI marker on intron 22 RFLP was informative for 14/51 individuals and allele frequency was 27. 45%.the heterozygosity rate was 6/16 (37.50%) for females studied.

An intronic SNP affects the HTR2a gene expression in the human brain and outcome of antidepressant treatment. *S.H. Hashemi, T. Arentzen, S. Haugbol, D. Erritzoe, V. Frokjaer, J. Madsen, G.M. Knudsen* Neurobiology Research Unit and Center for Integrated Molecular Brain Imaging, Rigshospitalet, Copenhagen University Hospital, Section 9201, Blegdamsvej 9, DK-2100 Copenhagen, Denmark.

BACKGROUND: The single nucleotide polymorphism (SNP) rs7997012, a result of a transition mutation from a G to an A in the second intron of the gene encoding the serotonin 2a receptor (HTR2a), was recently found to be associated with lower risk of no response to antidepressant treatment (McMahon et al, Am J Hum Genet. 2006.78(5):804-14). The biological impact of this polymorphism is, however, unknown. MATERIAL AND METHODS: To functionally characterize rs7997012 a cohort of 97 unrelated healthy Caucasian volunteers (39 women and 58 men; age range: 18.47 - 79.62 years, mean age 41.45 years, SD = 17.06) underwent positron emission tomography scanning with [18F]-altanserin for assessment of the cerebral HTR2a-binding and was subjected to 5-exonuclease Taqman SNP genotyping by applying specific primers/probes. RESULTS: The distribution of the three genotypes (AA, AG, GG) were in Hardy-Weinberg equilibrium (Chi-square = 0.66, df=2, P= 0.72). The frequencies of AA, AG and GG were 14.4%, 52.6%, and 33.0%, respectively which were similar to those of Caucasians reported by HapMap (Chi-square=1.03, df=2, P=0.60). A reduction of HTR2a receptor binding in neocortex (RBN) was found to be age-dependent (slope: -0.01002 0.004198, p= 0.019). In a linear regression analysis with age as covariate the polymorphism was found to impact RBN significantly in an additive fashion (GG>AG>AA) (df=1, p=0.03). CONCLUSION: The ancestral G-allele of rs7997012 is associated with higher HTR2a-binding in neocortex and the transition mutation generating the A-allele may lead to reduction of the receptor gene expression at both mRNA and protein levels. We speculate that this reduction in cortical HTR2a receptor density is related to better outcome after antidepressive treatment.

Systematic search for placental epigenetic markers on chromosome 21: towards noninvasive prenatal diagnosis of fetal trisomy 21. *S.S.C. Chim[1], S. Jin[2], T.Y.H. Lee[2], F.M.F. Lun[2], W.S. Lee[2], L.Y.S. Chan[2], Y. Jin[2], N. Yang[2], Y.K. Tong[2], T.Y. Leung[1], T.K. Lau[1], C. Ding[3,4], R.W.K. Chiu[2,3], Y.M.D. Lo[2,3]* 1) Dept of Obstetrics & Gynaecology; 2) Dept of Chemical Pathology; 3) Li Ka Shing Institute of Health Sciences; 4) Centre for Emerging Infectious Diseases, The Chinese University of Hong Kong, Hong Kong SAR, China.

The presence of fetal DNA in maternal plasma has offered a source of fetal genetic materials for noninvasive prenatal diagnosis. However, co-existing background maternal DNA complicates the analysis of such fetal DNA for aneuploidy detection. Recently, differential methylation patterns between the placenta and maternal blood cells have been shown for *SERPINB5* on chromosome (Chr) 18. Fetal trisomy 18 was further shown to be detectable noninvasively based on the allelic ratio of hypomethylated *SERPINB5* in maternal plasma. To develop a similar method for the noninvasive detection of trisomy 21, we systematically searched 114 CpG islands (CGIs), representing 76.5% of all 149 CGIs on Chr21, for differential DNA methylation patterns in the placenta and maternal blood cells. Most of the CGIs not studied contained repetitive DNA. Extent of CpG methylation in 5 placentas and 5 maternal blood cells were determined by methylation-sensitive single nucleotide primer extension and/or bisulfite sequencing. The methylation index (MI) of a CpG site was estimated as the ratio of the methylated to the total population of molecules. Thirteen CGIs were shown to contain 1 CpG site completely unmethylated (MI=0.00) in maternal blood cells and methylated in the placenta (MI range 0.22-0.65). Nine CGIs were shown to contain 1 CpG site completely methylated (MI=1.00) in maternal blood cells and hypomethylated in the placenta (MI range 0.00-0.75). One of these placental epigenetic markers was detected in 100% of 12 maternal plasma samples and another marker in 8 samples during pregnancy. Both markers exhibited postpartum clearance. Epigenetic differences between the placenta and maternal blood cells were found on 22 of 114 (19.3%) CGIs studied on Chr21. Epigenetic alterations may therefore provide a rich source of markers for noninvasive prenatal diagnosis.

Analysis of a candidate region on chromosome 6 detected by genome-wide association study for human narcolepsy. *M. Kawashima[1], K. Numazawa[1], M. Honda[2], J. Ohashi[3], Y. Honda[4], T. Ebisawa[1], K. Tokunaga[3]* 1) Dept Sleep Disorder Research (Alfresa), Univ Tokyo, Tokyo, Japan; 2) Tokyo Institute of Psychiatry, Tokyo Metropolitan Institute for Medical Research, Tokyo, Japan; 3) Department of Human Genetics Graduate school of Medicine, University of Tokyo, Tokyo, Japan; 4) Sleep Disorder Clinic of Seiwa Hospital, Tokyo, Japan.

Human narcolepsy is a multifactorial disorder, involving both genetic and environmental factors. A genetic factor strongly associated has been found in the human leukocyte antigen (HLA) class II region: most Japanese narcoleptic patients possess the HLA-DRB1*1501-DQB1*0602 haplotype. To find out associated genetic factors other than HLA, a genome-wide association study using about 23,000 microsatellite markers with pooled DNAs has been performed. The subjects were all Japanese living in the Tokyo area (case: 220, control: 420). From the 1st and 2nd screening using pooled DNAs, one of the associated markers which showed difference between the allele frequencies of cases and controls by Fishers exact test ($P<0.005$): D6S0129i, is located near the HLA region. This marker was assessed by individual genotyping and three alleles reached significant level. To avoid the effect of linkage disequilibrium with HLA-DRB1*1501-DQB1*0602 haplotype, HLA-DRB1*1501 heterozygous cases and controls were then used (case: 170, control: 112). In the analysis, one allele still showed significant association ($P=0.0022$). Therefore, the surrounding region of marker D6S0129i was applied to the high-density association mapping. Forty Tag SNPs and eighteen SNPs were analyzed by direct sequencing. As a result, thirty-three SNPs reached the significant level. These SNPs were subjected to the association analyses using HLA-DRB1*1501 heterozygotes, and 7 SNPs still showed significant association by permutation test ($P<0.005$). In contrast, the associations observed in HLA class I region disappeared when HLA-DRB1*1501 heterozygous cases and controls were used. These observations indicate that the region is one of the newly associated loci which are independent from HLA class II haplotype.

PDE4D and ALOX5AP are not major risk factors for stroke in the Portuguese population. *T. Krug[1], H. Manso[1,2], B.V. Fonseca[1], L. Gouveia[3], S. Violante[1], R. Taipa[4], I. Albergaria[2], G. Gaspar[2], M. Correia[4], M.V. Baptista[5], A. Pinto[6], R. Silva[6], F. Gonçalves[7], G. Lopes[4], J.P. Gabriel[8], I. Matos[9], J.M. Ferro[3], A. Vicente[1,2], S.A. Oliveira[1]* 1) Inst Gulbenkian de Ciência, Portugal; 2) Instituto Nacional de Saúde Dr. Ricardo Jorge, Portugal; 3) H. de Santa Maria, Portugal; 4) H. Geral de Santo António, Portugal; 5) H. Garcia de Orta, Portugal; 6) H. Fernando Fonseca, Portugal; 7) H. Univ. de Coimbra; 8) H. de São Pedro, Portugal; 9) H. Distrital de Mirandela, Portugal.

Stroke is the third cause of death in developed countries and is even more disabling than lethal. The most common form of stroke is a complex disorder resulting from the interplay of environmental and genetic factors, but its genetic underpinnings remain elusive. Recent whole-genome linkage screens followed by fine-mapping association studies have strongly implicated phosphodiesterase 4D (PDE4D) and arachidonate 5-lipoxygenase-activating protein (ALOX5AP) as susceptibility genes for stroke in the Icelandic population. PDE4D degrades second messenger cAMP, a key signal transduction molecule in different cell types, including inflammatory, vascular endothelial and smooth muscle cells. ALOX5AP is required for the synthesis of the leukotrienes secreted by various types of inflammatory cells clustering at the injured sites in blood vessels. The risk conferred by these genes in other populations is unclear since replication studies have reported conflicting results. Our aim was to test the association of these genes with stroke in a Portuguese sample of 533 patients (82% with ischemic stroke) and 507 unrelated controls. We genotyped 52 SNPs in the 5end of PDE4D and 21 SNPs in ALOX5AP and 10kb flanking region on each side (SNPs are either tagging SNPs from HapMap or SNPs previously found associated), and performed single-marker and haplotype association tests. We found only weak evidence for association (0.02p-value0.05) of 3 SNPs and 1 haplotype in PDE4D, and 2 SNPs in ALOX5AP. This study suggests that variants in PDE4D and ALOX5AP are not major risk factors for stroke in the Portuguese population.

Fatigue and Sleep Disturbances in Asymptomatic BRCA1/2 Mutation Carrier Women: Preliminary Study. *E. Dagan[1,2], T. Shochat[2], R. Gershoni-Baruch[1,3]* 1) Rambam Medical Center, Haifa, Israel; 2) Nursing, Faculty of Social Welfare and Health Sciences, University of Haifa, Haifa, Israel; 3) Bruce Rappaport Faculty of Medicine, Technion-Institute of Technology, Haifa, Israel.

Aim: To investigate whether asymptomatic BRCA1/2 mutation carriers exhibit high levels of fatigue and sleep disturbances. Methods: Asymptomatic BRCA1/2 mutation carriers (n=11) and non-carriers (n=15) from the oncogenetic clinic in Rambam Medical Center in Israel and low-risk controls (n=36) were recruited. Participants completed a battery of clinical, psychological (Brief Symptoms Inventory, BSI; Cancer Related Worry, CRW) and fatigue (Fatigue Symptoms Inventory, FSI) and sleep quality (Pittsburgh Sleep Quality Index, PSQI) questionnaires. Activity monitors (actigraphs) were worn for one week, for objective assessment of sleep quality. Results: Mean ages at interview were not statistically different between groups as well as psychological assessment by the BSI. CRW was significantly different between groups (carriers 0.830.49, non-carriers 0.700.52, controls 0.430.42; p=0.027); post-hoc analysis revealed significant differences between carriers and controls. Subjective sleep quality showed borderline significance between carriers (6.734.45) and controls (4.262.78); (p=0.087). Sleep duration (minutes) based on actigraphy was significantly different between groups (carriers 44950, non-carriers 39958, controls 43452; p=0.047); post-hoc tests revealed borderline significance between carriers and non-carriers (p=0.071). Actigraphic measures of sleep efficiency (percentages) showed borderline significance between carriers (9313) and controls (973); (p=0.085). Wake-time after sleep onset (minutes) showed borderline significance between carriers (2328) and controls (1210); (p=0.084). No group differences for sleep latency or specific and overall measured of fatigue were found. Conclusions: These preliminary results indicate that asymptomatic BRCA1/2 carrier women exhibit sleep disturbances compared to controls. Sleep disturbances in non-carriers were similar to carriers. Early screening for sleep disturbances may allow early management in women undergoing genetic testing.

Bone mass in children with Type I Gaucher Disease treated with low dose imiglucerase. *R. Heitner[1], J.M. Pettifor[2], S. Lipshitz[3]* 1) Pediatrics, Johannesburg Hospital University Witwatersrand South Africa; 2) Paediatrics;MRC Mineral Metabolism Research Unit. Chris Hani Baragwanath Hospital University Witwatersrand South Africa; 3) Linksfield Clinic South Africa.

Purpose:To assess bone mass in children with Type I Gaucher Disease treated with low dose imiglucerase over a period of 4.5-15 years. The haematological manifestations and organomegally of the disease are well managed with enzyme replacement therapy (ERT)using imiglucerase.Data shows that long term, irrespective of the dose used(15-60u/kg.body mass)there is normalization of the haematological and organ parameters. The effect of the dose on bone disease is less clear. High dose ERT is recommended to normalize bone mineral density(BMD)in patients with Type I Gaucher Disease. Previous studies have all been done in adults. **Methodology**: BMD was measured in 10 patients (age range 7-20 years)who had been on treatment for 4.5 to 13 years on a dose of 10u/kg.body mass fortnightly.BMD was measured using DXA (Discovery W Hologic Inc) at the lumbar spine and proximal femur and at the distal 1/3 and ultradistal forearm in 5 patients over the age of 18y using the same machine.Z-scores for each site were calculated using the manufacturers reference values. **Results**:Besides one patient who started on treatment after developing clinical bone pathology,none of the children complained of bone pain,had bone crises,pathological fractures or bone remodelling changes on MRI scan or standard radiology. Normal growth was achieved in all patients.Mean BMD Z score at the total hip was 0.44+0.94, at the spine -1.64+0.82,and at the distal 1/3 forearm -2.54+0.96. BMD Z score at the hip was inversely correlated with age.This association was not found at the spine.There was an almost significant inverse relationship between the age of the subject and BMD Z score at the lumbar spine (R^2=0.4.p=0.054)This relationship was not noted at other sites. **Conclusion** Low dose imiglucerase in children appears to preserve bone mass at the hip.This is possibly not so at the spine or distal 1/3 radius.Further longitudinal studies are required. In resource poor countries low dose imiglucerase may provide a means of preserving bone integrity.

Association analysis of human cAMP-GEFII gene polymorphisms with Japanese schizophrenia patients. *H. Kawasaki, H. Mitsuyasu, L. Gotoh, Y. Kobayashi, N. Oribe, A. Takata, S. Kanba* Dept Neuropsychiatry, Kyushu Univ, Fukuoka, Japan.

We have previously reported novel genes of second-messenger regulated Rap1-GEF (guanine nucleotide exchange factor) gene family whose GEF activities are positively regulated by the binding of second-messenger molecules such as cAMP, calcium and diacylglycerol (DAG), indicating that three major second messengers transduce their signals to target molecules different from protein kinases. A part of this gene family includes cAMP-GEFI and cAMP-GEFII, CalDAG-GEFI and CalDAG-GEFII. Both cAMP-GEFI and cAMP-GEFII have binding domains for cAMP as well as GEF domains. Since antipsychotics have antagonistic actions for dopamine receptors regulating intracellular cAMP concentrations in central nervous system, cAMP-GEFs can be good candidates for molecular studies of schizophrenia. In order to investigate the contribution of cAMP-GEFII to the pathophysiological mechanisms of schizophrenia, we carried out a genetic analysis of single nucleotide polymorphisms (SNPs) of the cAMP-GEFII gene. Information of a total 21 SNPs was collected based on the databases of both dbSNP and JSNP and our genotyping experiments, which included 3 coding SNPs and 17 intron SNPs and one regulatory SNP. We found two novel non-synonymous ones. We genotyped 96 schizophrenic patients and 140 healthy controls with the 21 SNPs by direct sequencing method. Two SNPs were shown to be significant difference between schizophrenia and healthy controls in Japanese population. However, after Bonferroni correction, those were disappeared. We are now trying to genotype more samples. The results of haplotype prediction, linkage disequilibrium calculation, and multi-variate statistical analysis are now being analyzed. Although there was slightly different distribution of the regulatory SNP between schizophrenia and controls, no statistical significant association were found. All subjects were given informed consent based on the ethical regulations of Kyushu University.

Contribution of complement factor H Y402H polymorphism to stroke risk. *L. Gouveia[1], T. Krug[2], H. Manso[2,3], I. Albergaria[3], G. Gaspar[3], R. Taipa[4], M.R. Silva[5], M. Correia[4], M.V. Baptista[6], A. Pinto[7], R. Silva[7], C. Ferreira[8], J.P. Gabriel[5], I. Matos[9], G. Lopes[4], A.M. Vicente[2,3], S.A. Oliveira[2], J.M. Ferro[1]* 1) H. de Santa Maria, Portugal; 2) Instituto Gulbenkian de Ciência, Portugal; 3) Instituto Nacional de Saúde Dr. Ricardo Jorge, Portugal; 4) H. Geral de Santo António, Portugal; 5) H. de São Pedro, Portugal; 6) H. Garcia de Orta, Portugal; 7) H. Fernando Fonseca, Portugal; 8) H. São Marcos, Portugal; 9) Distrital de Mirandela, Portugal.

The evidence that inflammation is an important mechanism in atherogenesis and stroke is growing with recent data from human and animal studies, and both complement factors and complement regulatory factors have been linked to cardiovascular diseases. Complement inhibitor factor H (CFH) is a plasma protein essential in the regulation of the alternative complement pathway and has been suggested to play a part in complement inhibition in atherosclerotic lesions. The Y402H (rs1061170) polymorphism in the CFH gene has been firmly established as a risk factor for age-related macular degeneration. This exonic polymorphism seems to alter the ability of CFH to suppress excess complement activation, ultimately leading to complement-related damage to arterial walls and vessel injury. There are inconsistent findings regarding the CFH role in susceptibility to myocardial infarction. To investigate the role of CFH in stroke susceptibility we assessed the association of the Y402H genetic variant in a Portuguese dataset of 533 stroke patients (82% with ischemic stroke) and 507 unrelated controls. We found a weak allelic association of this polymorphism with ischemic stroke (OR=1.23, 95%CI:1.00-1.50, p=0.043), but no association when ischemic and hemorrhagic stroke were combined (OR=1.21, 95%CI:0.99-1.46, p=0.054). These results suggest that the polymorphism Y402H in CFH is, at best, a minor stroke risk factor.

Association Analysis of Adenosine A1 receptor (ADORA1) and Dopamine D1 receptor (DRD1) genes with schizophrenia in the Japanese population. *L. Gotoh, H. Kawasaki, H. Mitsuyasu, Y. Kobayashi, N. Oribe, A. Takata, S. Kanba* Dept Neuropsychiatry, Kyushu Univ, Fukuoka, Japan.

Antipsychotic agents used for the treatment of schizophrenia affect dopamine D2 receptor (DRD2) mediated neurotransmissions, suggesting that dopaminergic dysfunction plays an important role in the pathophysiology of schizophrenia. On the other hands, it is shown that SCH23390, a selective DRD1 antagonist, inhibited PCP-induced schizophrenia-like behaviors. It is also reported that adenosine neurotransmitter system has functional interaction with dopaminergic neurotransmission. It is also known that N6-cyclopentyladenosine, ADORA1 agonist functionally involved in inhibition of PCP-induced behavior of schizophrenia model rats, as well as DRD1 antagonist. Therefore, it is possible to hypothesize that the functions of ADORA1 and DRD1 could be some part of the pathophysiological mechanisms of schizophrenia. To clarify the relationship between ADORA1, DRD1 and schizophrenia, the single nucleotide polymorphisms (SNPs) of these two receptor genes were analyzed in both schizophrenia patients and normal controls. For genotyping experiments, total 16 fragments were amplified by PCR from each subject consisting of the schizophrenia patients (n=200) and normal controls (n=210). Primers were designed according to the positions of SNPs and the database of JSNP (Japanese Single Nucleotide Polymorphisms). Using the amplified DNA fragments, all the subjects were genotyped with 27 SNPs and 2 deletions in ADORA1 gene, 1 SNP in DRD1 gene. Based on the results, genotyping and allele frequencies were calculated. Association analysis of each polymorphism was performed between schizophrenia patients and normal individuals. Two SNPs indicated statistically significant difference between the two populations ($P>0.05$). However, after Bonferroni correction, those were disappeared. Further analysis such as haplotype prediction, linkage disequilibrium calculation, sliding window analysis and multi-variate statistical analysis will be carried out. All subjects were given informed consent before blood collection strictly based on the ethical regulations of Kyushu University.

Dopamine Transporter 3'-UTR VNTR Genotype and Migraine. *F.B. Atac[1], U. Can[2], H. Verdi[1], A.C. Yazici[3], G. Celiker[2], R. Ocal[2], U.S. Benli[2]* 1) Dept Medical Biol & Genetics, Baskent Univ Fac Medicine, Ankara,Turkey; 2) Dept Neurology,Baskent Univ Fac Medicine,Ankara,Turkey; 3) Dept Biostatistics,Baskent Univ Fac Medicine,Ankara,Turkey.

Migraine is a debilitating neurovascular disease characterized by nausea vomiting, photophobia, phonophobia, neurological disturbances and severe recurrent headache. Although environmental factors could influence migraine susceptibility, the evident data indicates the importance of the genetic component. However, the pathophysiological mechanisms causing migraine is still remained to be elucidated. Therefore the continuing molecular identification of key proteins involved in migraine will refine our understanding of this common disease that strikes during the most productive years of a person's life. Recent pharmacological studies points out the effect of dopamine receptor antagonist in treatment. This treatment improves the involvement of the dopaminergic system in migraine. Dopamine uptake is mediated by dopamine transporter (DAT). Therefore the polymorphisms in DAT gene may be the candidates as migraine susceptibility modifier. In this study we aimed to elucidate the role of 40-bp variable number of tandem repeats (VNTR) in the 3' untranslated region (3'UTR) of the DAT gene (DAT3'UTR) in 100 migraine cases and 81 healthy controls. The G test and two proportion z test results indicate that DAT3'UTR polymorphism is a susceptibility factor for migraine in our population ($p<0.001$) since, the 10/11 ($p<0.01$), 11/12 and 12/12 ($p<0.001$) genotypes are strongly associated with migraine. When we performed allele comparison a significant difference was found between migraine cases and healthy controls (Fisher exacts $p <0.001$) with respect to allele 11 and 12 (OR= 2.872, 95% CI 1.828-4.514; OR= 56,568, 95% CI 7.723-414.347) respectively. In contrast to previous reports from other ethnic groups, our result may suggest that the genetic variability at the DAT gene is involved in the predisposition to migraine.

Apo-1/Fas gene polymorphisms and multiple sclerosis in Southern Italy. *V. Andreoli[1], P. Valentino[2], F. Trecroci[1], F. Condino[1], A. La Russa[1], F. Scionti[1], R. Cittadella[1]* 1) Institute of Neurological Sciences, National Research Council, Piano Lago di Mangone. Cosenza; Italy; 2) Institute of Neurology, University Magna Graecia, Catanzaro, Italy.

The pathogenesis of multiple sclerosis (MS) is under strong genetic control involving several or more genes each of modest effect. Whilst the mechanisms underlying the pathogenesis of MS remain unknown, it has been hypothesised that either decreased apoptosis of autoreactive T cells in the central nervous system (CNS), or increased apoptosis of oligodendrocytes may play an important role. Physiologic regulation of cell death is essential for removal of potentially autoreactive lymphocytes during development and excess cells after the completion of an immune response. Apo-1/Fas, an apoptosis-signaling cell surface receptor belonging to the Tumor Necrosis Factor Receptor Super Family 6 (TNFRSF6), is considered to have an important role in the regulation of the immune system by deleting autoreactive T-lymphocytes. Several studies have shown aberrant expression of this molecule in MS, correlating with a decrease in T cell apoptosis or increase in CNS tissue damage. Moreover, Apo-1/Fas maps to the long arm of chromosome 10q23/10q24.1 in humans. Positive lod scores with microsatellite markers near this region were identified in the United States and Canadian genome screens. These two criteria, pathobiological and positional, make the Apo-1/Fas antigen an interesting candidate for an association with MS. To address these findings, we have tested two SNPs in a set of 286 MS patients from Southern Italy (Calabria region) and 271 healthy controls subjects from the same geographical area: a G to A polymorphism at position (-670) in the enhancer region of the promoter and a single nucleotide change from C to T 74 nucleotides from the beginning of exon 7 in the Apo-1/Fas gene. Our results showed no significant differences in the allele and genotype distribution of the polymorphisms between MS patients and controls suggesting that, despite a biological plausibility, Apo-1/Fas gene is not significantly associated with MS in Italian patients. In conclusion, the present findings from Italian population suggest that there was no association between these polymorphisms and susceptibility to MS. Therefore, in the absence of conclusive data, we cannot exclude the possibility that our results are only partially indicative in the wish to identify Apo-1/Fas as a susceptibility-gene to MS, because the association between genetic polymorphisms and MS may also vary with ethnicity.

A multiple founder effect of HFE C282Y mutation explains the hereditary hemochromatosis in Azorean island of Sao Miguel (Portugal). *C.T. Gomes[1], P.R. Pacheco[1,2], M. Sao-Bento[1], R. Cabral[1,2], C.C. Branco[1,2], L. Mota-Vieira[1,2]*
1) Molecular Genetics Pathology Unit, Hospital of Divino Espirito Santo, Ponta Delgada, Azores, Portugal; 2) Institute Gulbenkian of Science, Oeiras, Portugal.

Hereditary hemocromatosis (HH) is an autosomal recessive disorder of the iron metabolism. It is typically associated with homozygosity for the C282Y mutation of the HFE gene, which is located on the HLA region (6p21.3). Generally, this mutation lies within the celtic ancestral HLA-A*03-B*07 haplotype. Here, C282Y mutation was selected as a model to study the diversity and origin of recessive mutations in a geographic isolated population. A total of 130 individuals from Sao Miguel Island (Azores) were genotyped for HLA-A and -B by PCR-SSP, and for HFE mutations (C282Y, H63D and S65C) by PCR-RFLP. Data analysis was performed using Arlequin v3.1 and Graphpad Prism v5.0 softwares, after dividing the sample in two groups: 48 homozygous or carriers for the C282Y mutation and 82 with no mutations. Statistical analysis revealed that four alleles - HLA-A*03 (20.8%), HLA-A*26 (2.1%), HLA-B*29 (10.4%) and HLA-B*45 (9.4%) - protrude in the C282Y mutation group, when compared to the control subjects ($p<0.05$). Moreover, three haplotypes, identified by computational inference, were found to be significantly associated with the C282Y: HLA-A*02-B*58 (5.2%; OR=19.78, 95% CI: 1.08-362.0), HLA-A*03-B*07 (5.2%; OR=8.96, 95% CI: 1.03-77.84) and HLA-A*29-B*45 (7.3%; OR=27.57, 95% CI: 1.56-488.70). Another haplotype HLA-A*24-B*15 (3.1%) was also identified by direct inference in an individual homozygous for HLA region and C282Y mutation. These haplotypes probably have several geographical origins. Overall, these findings suggest that HH in the São Miguel Island can be explained by a multiple founder effect. (lmotavieira@hdes.pt), Azorean Government founded.

Simultaneous analysis of genome-wide SNP data and candidate region sequence data. *C.J. Hoggart[1], J.C. Whittaker[2], M. De Iorio[1], D.J. Balding[1]* 1) Department of Epidemiology & Public Health, Imperial College, Norfolk Place, London W2 1PG; 2) Non-communicable Disease Epidemiology Unit, London School of Hygiene & Tropical Medicine, Keppel Street, London WC1E 7HT.

The ideal analysis of a genome-wide association study for a complex disease would involve analyzing all the SNP genotypes simultaneously to find a set of SNPs most associated with disease risk. The computational challenge of handling up to one million SNPs simultaneously is daunting, but it could greatly improve performance over single-SNP analyses, since a weak effect may be stronger and a false signal weakened when other causal effects are accounted for. Our algorithm estimates regression coefficients for each SNP by maximizing the likelihood subject to a penalty that strongly favors zero values, corresponding to no association. For each causal variant our algorithm typically reports one SNP that best captures the association and not other SNPs in strong LD with it. By default the algorithm searches for additive effects but can also search for recessive and dominant effects. We consider two forms for the penalty corresponding to the Laplace and normal-exponential-gamma prior distributions. The Laplace prior improves SNP selection in comparison with single-SNP tests, and the normal-exponential-gamma prior improves selection further. We demonstrate the performance of the algorithm using simulated and real genome-wide datasets and simulated sequence data of up to 500K SNPs. These analyses require only a few hours on a desktop workstation, exploiting an approximate calibration of the type-I error that avoids the need for permutation analyses.

MicroRNAs influence gene expression phenotypes of ataxia telangiectasia carriers. *V.G. Cheung, D.A. Smirnov*
Pediatrics & Genetics, ARC 516G, Univ Pennsylvania/Child Hosp, Philadelphia, PA.

Ataxia Telangiectasia (AT) is an autosomal recessive disorder caused by mutations in the *ATM* gene. Previously, we showed that the gene expression phenotype of AT carriers is distinct from non-carriers and also from carriers of a similar disorder, Nijmegen Breakage Syndrome. Even though patients with an autosomal recessive disease like AT are rare, carriers are not. Therefore, carriers for recessive mutations can contribute significantly to phenotypic diversity.

The goal of this study is to characterize gene expression phenotypes of AT carriers and to study the underlying mechanism. We chose gene expression as the phenotype since many diseases are due to altered expression levels of genes. Knowing that ATM plays a key role in radiation response, we compared the radiation-induced gene expression responses of non-carriers, AT carriers and AT patients. We found 22 gene expression phenotypes that behaved in a recessive manner, where the radiation-induced expression response of carriers is similar to that of non-carriers, but differs significantly from AT patients ($P<0.01$). In addition, we found 29 gene expression phenotypes that behaved in a dominant manner, where the expression response of AT carriers differed significantly from that of non-carriers ($P<0.01$), but not from AT patients. To account for these patterns, we examined microRNAs that regulate gene expression. When we compared these among the three AT genotypes, we observed 15 microRNAs with recessive pattern and 7 with dominant pattern. Finally, we showed that the gene expression patterns can be explained by microRNAs that regulate the genes. For example, the dominant expression pattern of *TNFSF4* mRNA is due to the dominant pattern of expression of miRNA-125b that regulates its expression.

To our knowledge, this is the first report that implicates the role of microRNA in a human Mendelian disorder and offers a mechanism that accounts for the phenotypic manifestation in carriers of recessive mutations.

Interleukin-6 (IL-6) promoter and C-reactive protein (CRP) gene polymorphisms and levels compared to Mainz Severity Score Index (MSSI) in Fabry disease. *G. Chicco[1], G. Altarescu[2], C. Whybra[3], S. Delgado-Sanchez[3], N. Sharon[4], M. Beck[3], D. Elstein[1]* 1) Gaucher Clinic, Shaare Zedek Medical Center, Jerusalem, Israel; 2) Genetics Unit, Shaare Zedek Medical Center,Jerusalem, Israel; 3) Universitäts-Kinderklinik, Mainz, Germany; 4) Department of Statistics, School of Public Health, Hebrew University, Jerusalem, Israel.

Objectives: Fabry disease is a multi-system disorder with phenotypic hetereogeneity partially explained by genotype. Elevated IL-6 and CRP plasma levels are associated with increased risk and worse outcome of ischemic events, serious prognostic signs in Fabry disease. Methods: 56 patients (34 hemizygous males, 22 females) were studied. A promoter polymorphism (-174 GC) of IL-6 gene associated with serum IL-6 levels was compared to the Mainz Severity Score Index (MSSI) in patients. C-reactive protein (CRP) serum levels and polymorphism (1059 GC) were evaluated as inflammation markers to ascertain a possible inflammatory etiology. Non-parametric ANOVA, Fishers exact, Bonferroni, and Hardy-Weinberg (HW) statistics were used. Results: Mean age of adults = 42 (range: 26-58) years; 29 patients received enzyme therapy (ERT). Mean total MSSI = 26.7 (moderate disease) but females were lower (total: 23.412.6 vs 32.213.6). Controls but not patients were in HW equilibrium. Significant correlations existed between all MSSI scores and IL-6 genotypes in females but only 3 MSSI scores in males. IL-6 C/C genotype was significantly correlated with 3 MSSI sub-scores, generally two-fold higher. There were no significant correlations with CRP levels/polymorphisms and MSSI scores or with IL-6 polymorphisms. CRP levels decreased after ERT in patients with a G allele in IL-6 but increased in patients with C/C (p=0.003). Conclusions: Prevalence of C allele in IL-6 significantly influences MSSI i.e. clinical severity, especially in females. This is unrelated to IL-6 as a pro-inflammatory marker as demonstrated by lack of correlations with CRP levels/genotypes. IL-6 may be a prognostic marker in Fabry disease, especially the presence of a C allele and especially in females.

NOS3 gene Polymorphysims in Turkish Stroke Patients. *U. Can[1], H. Verdi[2], A.C. Yazıcı[3], K. Beksac[2], G. Celiker[1], E. Derle[1], U.S. Benli[1], N. Ozbek[4], F.B. Atac[2]* 1) Neurology, Baskent University School of Medicine, Ankara, Turkey; 2) Dept Medical Biology and Genetics,Baskent University School of Medicine, Ankara, Turkey; 3) Dept Biostatistics,Baskent University School of Medicine, Ankara, Turkey; 4) Dept Pediatric Heamotology,Baskent University School of Medicine, Ankara, Turkey.

Impaired endothelial-mediated vasodilation is a common feature of many vascular risk factors, and experimental evidence strongly supports a role for impaired NO-dependent vasomotor reactivity in the pathophysiology of stroke. Nitric oxide (NO), synthesized by endothelial constitutive NO synthase (ecNOS-NOS3) plays a key role in vascular regulation and atherosclerosis. There are contradictory results existing on concerning the role of the ecNOS gene as a risk factor for brain infarction. In view of the location and proposed biological effect of NO we felt it was prudent to evaluate further the relation NOS3 gene intron 4 VNTR and exon 7 894 G/ T polymorphysims in Turkish Stroke Patients. 118 stroke cases and 100 controls were included in this study. There was an insignificant relationship between the intron 4 VNTR genotype distribution and allele frequencies in the stroke and control group. In contrast to this finding the distribution of exon 7 894 G/T genotype was significantly different between cases and controls, the TT genotype was more frequent in stroke cases (35.65%) than in controls (16.84 %); where as GG genotype was more frequent in controls (32.63 %) than in stroke cases (15.65%) ($p<0.001$). This data may suggest the importance of NOS3 exon 7 894 TT genotype as a pre-disposition factor for stroke in our population. Stroke is likely to be a multifactorial disease, several genes with weak or moderate effects are likely to be involved, and other candidate genes should also be investigated in order to understand the cause of the arteriolopathy which may have have future implications in treatment and prevention.

Family based association analysis of TGFB1 as modifier gene in Cystic Fibrosis. *M.D. Bettin[1], C. Bombieri[1], G. Malerba[1], L. Xumerle[1], F. Belpinati[1], C. Castellani[2], B.M. Assael[2], P.F. Pignatti[1]* 1) Sec. Biology and Genetics, Dpt. Mother Child & Biology-Genetics, University of Verona, Verona, Italy; 2) Cystic Fibrosis Veneto Regional Centre, Hospital of Verona, Italy.

Cystic fibrosis (CF) is a lethal, multi-system autosomal recessive genetic disorder primarily affecting Caucasian populations, caused by mutations in the cystic fibrosis transmembrane conductance regulator (CFTR) gene. Severity of clinical presentation in CF, particularly the pulmonary manifestation, are highly variable, even among CF patients presenting the same genotype. This variability is only partially explained by allelic heterogeneity at the CFTR gene. Literature data suggest that the severity in CF may be correlated with other genetic factors. Two polymorphisms (-509C/T and Leu10Pro) of the TGFB1 gene, which encodes for a cytokine involved in inflammation and tissue repair and expressed by several cells, have recently been associated to a more severe CF pulmonary manifestation in the American population (Drumm et al, NEJM 353:1443; 2005). We here report the results of TDT and haploscore association analyses of three TGFB1 functional polymorphisms (-509C/T, Leu10Pro e Arg25Pro) in Italian CF patients. Eightytwo family trios with a CF child and 52 unrelated CF patients were collected through the Veneto Regional CF Centre of Verona. All the patients were clinically evaluated for respiratory parameters, gastrointestinal and nutritional status parameters, and other clinical variables related to the common CF complicances (diabetes, DIOS, etc). TDT test result showed evidence of association between Pro25 and FEV1 ($p=0.018$). No association was found among other polymorphisms and studied clinical parameters. Single locus and haplotype analyses performed in all the unrelated CF patients confirm the association of TGFB1 gene polymorphisms with FEV1%. These results compared to literature data indicate that further studies are necessary to characterized the involvement of TGFB1 gene as modifier of disease severity in cystic fibrosis.

A NOVEL MISSENSE MUTATION OF THE NF2 GENE IN A SEVERELY AFFECTED BOY AND HIS HEALTHY FATHER. *A.L. Gabriele[1], M. Ruggieri[2,3], C. Nucifora[3], A. Patitucci[1], T. Sprovieri[1], A. Magariello[1], R. Mazzei[1], F.L. Conforti[1], C. Ungaro[1], M. Muglia[1], A. Quattrone[1,4]* 1) Institute of Neurological Sciences (ISN)-CNR, Mangone , Cosenza, Italy; 2) ISN, CNR, Section of Catania, Italy; 3) Department of Paediatrics, University of Catania, Italy; 4) Institute of Neurology, University of Magna Graecia, Catanzaro, Italy.

Neurofibromatosis type 2 (NF2) is an autosomal dominant disease characterised by the development of multiple nervous system tumours and skin and ocular abnormalities. Inactivating mutations in the NF2 tumour-suppressor gene, located on 22q12, causes the disease. We studied the NF2 gene in a severely affected boy and his family. An 8-year-old boy was referred because of multiple cutaneous café-au-lait spots and scoliosis. General examination revealed besides the café-au-lait spots, a moderate scoliosis and NF2-plaques. Magnetic resonance imaging (MRI) of the brain and spine, revealed a massive high signal lesion extending over almost the entire spine (ependymoma). At age 11 years, MRI revealed bilateral vestibular schwannomas and spinal schwannomas in the lumbar spine. There were no other NF2 stigmata after full clinical and imaging NF2 screening in the boy and his 12-year-old sister and in both parents. Screening of the entire coding region sequence of the NF2 gene by DHPLC analysis showed a modified pattern for exon 12. Direct sequencing revealed a heterozygous missense mutation at the nucleotide 1127 resulting in an aminoacid substitution arginine-376 by glutamine (R376Q). The mutation was also detected in the fathers patient and was not found in 100 normal chromosomes. Impairment of the functional domain of the missense mutation here reported could abolish the NF2 tumour- suppressor activity determining the NF2 clinical phenotype we recorded. Notably, however, missense mutations are usually mild, often causing the mildest form of NF2. Remarkably, in this family we observed an early onset and severe phenotype in the boy and lack of clinical/imaging signs in his father who harboured the same NF2 gene mutation.

Evidence that oxidative stress is increased in plasma of patients with peroxisome biogenesis disorders. *M. Deon[1,3], A. Sitta[1,3], A.G. Barschak[1,3], T. Terroso[1,2], M. Pigatto[1,2], A. Barden[1,2], A.B. Oliviera[1], G.O. Schmitt[1], D.M. Coelho[1], L.B. Jardim[1], R. Giugliani[1,3], M. Wajner[1,3], C.R. Vargas[1,2,3]* 1) Medical Genetics Service, HCPA, Porto Alegre, RS, Brazil; 2) Department of Clinical Analysis, Pharmacy Faculty, PPGCF, UFRGS, Porto Alegre, RS, Brazil; 3) Department of Biochemistry, ICBS, UFRGS, Porto Alegre, RS, Brazil.

The peroxisome is a single membrane organelle present in nearly all eukaryotic cells with different metabolic functions. The importance of the peroxisome became more evident by the existence of various severe genetic disorders associated by the failure of the functions of peroxisomes. Defects in peroxisomal functions are associated with major, and often fatal, changes at the neurological level during human development. The peroxisomal disorders are subdivided into two major categories: those in which the organelle is not formed normally (the peroxisomal biogenesis disorders - PBDs) and those that are associated with defects of a single peroxisomal proteins [the single peroxisomal enzyme (transporter) deficiencies - PEDs]. Neurological symptoms and brain abnormalities are characteristic of patients with PBDs. However, very little is known about the pathomechanisms involved in the tissue damage of these disorders. Considering that peroxisome is involved in oxidative reaction and that in a previous study we showed evidence that oxidative stress is probably involved in pathophysiology of other peroxisomal disease - X-linked adrenoleukodystrophy, in the present study we evaluated two oxidative stress parameters, namely as membrane protein thiol content and thiobarbituric acid-reactive species (TBA-RS) in plasma of patients with PBD. It was observed a significant decrease of membrane protein thiol content, indicating a possible protein oxidation, and a significant increase of plasma TBA-RS measurement, indicating a stimulation of lipid peroxidation. It is therefore proposed that oxidative stress may be involved in the pathophysiology of the disorders of peroxisome biogenesis. A novel gene is disrupted in a patient with balanced translocation t(3;X)(q12.3-q22.3) associated with Cerebral Cavernous Malformations. *F. Gianfrancesco[1], T. Esposito[1], S. Penco[2], V. Maglione[3], F. Letizia[1], C.L. Liquori[4], M.C. Patrosso[2], O. Zuffardi[5], A. Ciccodicola[1], D.A. Marchuk[4], F. Squitieri[3]* 1) Institute of Genetics and Biophysics, Italian National Research Council,Naples, Italy; 2) Medical Genetics Laboratory, Niguarda Ca' Granda Hospital, Milan, Italy; 3) Neurogenetics Unit, IRCCS Neuromed, Pozzilli (IS), Italy; 4) Department of Molecular Genetics and Microbiology, Duke University Medical Center, Durham, NC, USA; 5) Department of Pathology and Medical Genetics, University of Pavia, Pavia, Italy.

Cerebral Cavernous Malformations (CCM) exhibit autosomal dominant inheritance, and accounts for 10-20% of all cerebrovascular abnormalities with prevalence in the general population between 0.1% and 0.5%. The past few years have seen rapid advances in our understanding of the genetics and molecular biology of CCM with the identification of the CCM1, CCM2, and CCM3 genes. A discrepancy in the frequencies of mutations in the three CCM genes between the values originally predicted by linkage in families and the values obtained by DNA mutation-analysis screens of probands suggest that another CCM gene exists on the chromosome 3. Recently, we have recruited a patient with a X/3 balanced translocation that exhibits CCM. We refined the critical region to an interval of 200-kb and identified the interrupted gene. Quantitative real-time PCR was used to quantify the amounts of this transcript in the lymphoblastoid cell line of our patient. We detected that the mRNA expression level of this gene is consistently decreased 2.5 fold versus control (P= 0.0006) with allelic loss of gene expression. Because CCM2 is required as a scaffold for MEKK3-mediated p38 MAPK phosphorylation during osmotic shock by sorbitol, we also investigated a possible role for our protein in the p38 MAPK pathway. We observed that the phosphorylation status of activated p38 MAPK was altered in response to mechanical stress associated with medium change. These data indicate that this protein may be part of the complex signaling pathway that, when perturbed, causes abnormal vascular morphogenesis in the brain, leading to CCM.

Neonatal hepatoblastoma in Beckwith-Wiedemann syndrome: which role for imprinting alteration of the 11p15.5 region? *L. de Sanctis, MC. Russo, C. Marinaccio, A. Testa, D. Farinasso, L. Costa, F. Cresi, M. Silengo, L. Silvestro, R. Miniero* Dept. Pediatric Sciences, Univ Torino, Torino, Italy.

Beckwith-Wiedemann syndrome (BWS) is an overgrowth disease caused by alteration in the 11p15.5 region (paternal UPD, hypo/hypermethylation of the differential methylated regions, duplications, traslocations, point mutations), where H19, IGF2 and other imprinted genes involved in growth reside. BWS is characterized by macrosomia with hemihypertrophy, macroglossia, omphalocele or umbilical hernia, neonatal hypoglicemia, ear and renal abnormalities. 10-15% of BWS children early develops an intrabdominal neoplasia: Wilms tumor (67%), hepatoblastoma (11%), rabdiomiosarcoma (5%) and neuroblastoma (4%). Hemihypertrophy is the clinical sign significantly associated to an increased relative risk (IRR) of neoplasia. A genotype/epigenotype correlation has recently been evoked between paternal UPD and H19 hypermethylation with cancer IRR. G.M., born at term, 4290g, came to our observation for respiratory distress syndrome, showing macroglossia, macrosomia with hemihypertrophy, umbilical hernia, neonatal hypoglicemia, suggestive for BWS, for which molecular analysis of the 11p15.5 region has been performed. During pregnancy increased alphafetoprotein (AFP) levels were recorded, polihydramnios, hypergrowth and renal US hyperechogenicity. At birth AFP was 58.690 kUI/l, abdominal US showed bilateral renal dysplasia. At 24 days it has been repeated for the worsening clinical conditions showing a 8x5 cm mass in hypochondrium, confirmed by TC scan. AFP was 245532 kUI/l; fine needle biopsy allowed to define a hepatoblastoma, for which a reductive pre-surgery chemiotherapy was begun. Molecular analysis revealed a paternal UPD. This case report: - is the first report of a very early onset of hepatoblastoma in BWS - confirms the usefulness of serial AFP determinations as hepatoblastoma marker - underscores how a definite and early molecular characterization of the 11p15.5 region alteration can drive the physicians in the correct management of each epigenetic BWS subgroup.

Investigation of the Association between Trinucleotide Repeat at the First Exon of Androgen Receptor Gene and A/G Polimorphism in Prostate Specific Antigen Gene Promoter Region. *D. Alptekin[1], M. Izmirli[2], Y. Bayazit[3], H.U. Luleyap[1], B. Soyupak[3], Z. Tansu[3]* 1) Department of Medical Biology, Cukurova University, Medical Faculty, Adana, Balcali, Turkey; 2) Department of Radiology, Cukurova University, Medical Faculty, Adana, Balcali, Turkey; 3) Department of Urology, Cukurova University, Medical Faculty, Adana, Balcali, Turkey.

Number of polymorphic repeats (CAG-Poigulutamine, GGN-Polyglycine) at the first exon of androgen receptor (AR) gene is known to be related with prostate cancer. Moreover, it is also associated with the A/G polymorphism at the ARE I region of Prostate Specific Antigen (PSA) gene. This study aims to search if the malformations in AR and PSA gene found in the individuals with prostate cancer are also detected in the patients son. To estimate this 10 ml blood samples were collected from the patients with prostate cancer and this sons. The DNA was isolated and amplified using PCR. The products of PCR were separated in agarose gel electrophoresis and the number of trinucleotide repeats was determined. The amplified PCR product is digested with Nhe I enzyme to identify AA, AG and GG genotypes for PSA gene A/G polymorphism. Vast majority of the individuals with prostate cancer manifested less than 20 CAG trinucleotide repeats (75.8 %) while their sons had low number of the repeat number below 20 (11.1 %). Number of GGN trinucleotide repeats was less than 20 (67.2 %) in most of patients, however, unlike CAG, the repeat number was not diminished in their sons. PSA gene A/G polymorphism was remarkably high in AA homozygote (41.4%) and AG heterozygote (44.8 %) in the patients with prostate cancer. Their sons also manifested high AA homozygote (38.9 %) and AG heterozygote (44,4 %) forms. Taken together, we report AA and AG polymorphism is associated with prostate cancer, and their sons comprise the risk group. Therefore the individuals with prostate cancer above the age of 40 and their sons are recommended for annual medical check up.

Possible post-meiotic origin of the constitutional t(11;22). *T. Kato[1], H. Inagaki[1], H. Kogo[1], T. Ohye[1], M. Tong[1], B.S. Emanuel[2], H. Kurahashi[1]* 1) Division of Molecular Genetics, Fujita Health University, Toyoake, Japan; 2) Division of Human Genetics, Children's Hospital Philadelphia, Philadelphia, PA.

The constitutional t(11;22) is the only known recurrent non-Robertsonian translocation in humans. The translocation breakpoints occur within palindromic AT-rich repeats on chromosomes 11q23 and 22q11. In our previous studies, we established translocation-specific PCR by using the sequence of the translocation junction fragments from both derivative translocation chromosomes. Using this method, we successfully detected *de novo* t(11;22)s in sperm samples from normal healthy males, but not in lymphoblasts or fibroblasts. To understand how this translocation occurs during spermatogenesis, we divided sperm samples into small aliquots prior to DNA extraction and directly performed translocation-specific PCR. Multiplex PCR allowed us to detect der(11) and der(22)-specific PCR products of *de novo* origin, which were amplified concomitantly from the same aliquots. This result suggests that the *de novo* t(11;22) occurs as a reciprocal translocation. Further, we changed the combinations of primer pairs, which allowed us to identify dicentric and acentric translocation derivative chromosomes. Interestingly, these two unusual derivative chromosomes also appear concomitantly in the same aliquots. Based on the fact that no unbalanced translocation products were identified, we speculate that *de novo* t(11;22) translocations are likely to arise at post-meiotic stages of spermatogenesis.

Models, Test Statistics, and Designs for Genetic Association Studies with Pooled Genotyping. *S.Y. Cheong*[1], *E. Feingold*[2,1] 1) Department of Biostatistics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 2) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA.

Although most genetic association studies use individual genotyping, it is possible that many studies can be performed more efficiently using pooled DNA, particularly at the initial screening stage. Pooled studies are challenging, however, because there are unresolved issues of how to incorporate pooling error into the designs and test statistics. We develop several models for the bias and variance introduced by pooling and then use those models to consider optimal case-control test statistics and designs. We consider several different case-control study designs with the same chip number for each cohort group, in order to find out which design is most powerful. In addition, we consider designs that incorporate covariate information. We investigate test statistics for each design theoretically, and also verify the results with simulation studies.

A rapid flow cytometry test based on histone H2AX phosphorylation for the sensitive and specific diagnosis of Ataxia Telangiectasia. *C. Giachino[1], V. Turinetto[1], A. Brusco[2], S. Cavalieri[2], E. Lantelme[1], L. Orlando[1], U. Ricardi[3], M. De Marchi[1], A. Amoroso[2], D. Gregori[4], P. Porcedda[1]* 1) Department of Clinical and Biological Sciences, University of Turin, Italy; 2) Department of Genetics Biology and Biochemistry, University of Turin, Italy; 3) Department of Medical and Surgical Disciplines, University of Turin, Italy; 4) Department of Public Health and Microbiology, University of Turin, Italy.

Background: Ataxia Telangiectasia (A-T) is a progressive neurodegenerative disease with onset in early childhood, caused by mutations in the ATM (ataxia-telangiectasia mutated) gene. Clinical diagnosis relies on laboratory tests showing high levels of serum alphafetoprotein (AFP), cell sensitivity to ionizing radiation (IR) and absence or reduced levels of ATM protein. Many tests, however, are not sufficiently sensitive and/or specific for A-T, have long tournaround times or require large blood samples. We have therefore developed a new flow cytometry method for the diagnosis of A-T through the measurement of histone H2AX phosphorylation. Methods: Forty-six healthy donors, 20 genetically proven A-T patients, 19 with suspected A-T and 1 with Friedreich Ataxia were recruited. Histone H2AX phosphorylation in T-cell lines, lymphoblastoid cell lines (LCLs) and peripheral blood mononuclear cells (PBMCs) was evaluated by flow cytometry after 2 Gy IR. Results: Phosphorylated histone H2AX mean fluorescence intensity of irradiated A-T cells was significantly lower than that of healthy donors. The intra-staining, intra-assay and inter-assay imprecisions were 15.5%. Sensitivity and specificity were virtually 100% when the test was performed on PBMCs. Screening of the 19 patients with suspected A-T classified fifteen patients as non-A-T. The four classified as A-T were subsequently confirmed by ATM mutation analysis. The Friedreich Ataxia patient was classified as non-A-T. Conclusions: This flow cytometry test is very sensitive, specific and rapid (two days), and requires only 1-2 ml of blood. It may thus be proposed for the early differential diagnosis of A-T.

Rapid genotyping methods for detection of the novel *CYP2A6*12* hybrid allele and *CYP2A6* copy number variation using Pyrosequencing technology. *D. Koontz, A. Spencer, J. Huckins, M. Gallagher* CDC, NCEH, DLS, Molecular Biology Branch, Atlanta, GA.

CYP2A6 is the primary enzyme that metabolizes nicotine to cotinine. Genetic variability in this gene contributes to much of the inter-individual variability in *CYP2A6* enzyme activity. Several allelic variants arise from unequal crossover events that occur between the *CYP2A6* gene and the inactive *CYP2A7* gene. The *CYP2A6* deletion allele is created by such an event with *CYP2A6* gene duplication as the reciprocal outcome. A *CYP2A7/CYP2A6* hybrid (*CYP2A6*12*) is another variant created by an unequal crossover. Traditional methods for genotyping these variants are laborious, unreliable and not suitable for large sample sizes. We developed Pyrosequencing assays for each of these variants that use sets of PCR primers to co-amplify common regions of these genes. To detect copy number variation, the *CYP2A7*-specific peak heights serve as the reference by which to compare *CYP2A6*-specific peak heights. Genotype calls are derived from quantitative peak height ratios that give unique values for each genotype. To detect the *CYP2A6*12* hybrid allele, both *CYP2A6* wild-type and hybrid sequences are co-amplified and the presence of the hybrid sequence is determined by sequence analysis. We genotyped 4 ethnic groups: Hispanic (N=32), Asian (N=42), African American (N=35), and European Caucasian (N=43) from the Coriell Human Variation Collection. Samples were previously genotyped by 2-step long range-PCR for *CYP2A6*12* and by PCR-RFLP and TaqMan for *CYP2A6* copy number. Results were 100% concordant with the Pyrosequencing assays. Despite small sample sizes, a striking inter-ethnic difference in the distribution of the *CYP2A6* deletion allele was noted and is consistent with previous reports of a higher prevalence in Asian populations. These assays will be used to assess *CYP2A6*12* and *CYP2A6* copy number variation in a large-scale study of 7,300 multi-ethnic DNA samples from the U.S. population for prevalence estimates and associations with variability in nicotine metabolism. With appropriate robotics, over 1,900 samples can be genotyped in 8 hours.

An association analysis of 13 anxiety disorder candidate genes. *I. Hovatta[1,2,3], J. Donner[1,2], S. Pirkola[4], K. Silander[1], L. Kananen[1,2], J. Lönnqvist[4], L. Peltonen[1,3,5]* 1) Department of Molecular Medicine, National Public Health Institute, Helsinki, Finland; 2) Research Program of Molecular Neurology, Biomedicum Helsinki, Finland; 3) Department of Medical Genetics, University of Helsinki, Finland; 4) Department of Mental Health and Alcohol Research, National Public Health Institute, Helsinki, Finland; 5) Broad Institute of MIT and Harvard, Boston, MA.

We have taken a cross-species approach to identify susceptibility genes for anxiety disorders. As a model, we used inbred mouse strains that differ in their innate anxiety levels. We chose an unbiased gene expression-based approach to identify candidate genes. We first assessed anxiety behavior of six inbred strains by behavioral tests, and conducted gene expression profiling using microarrays of seven brain regions. We identified 17 genes that had an expression pattern that correlated significantly with the behavioral phenotype across all strains. We carried out functional studies and showed by lentivirus-mediated gene transfer that two candidate genes, glyoxalase 1 and glutathione reductase 1, regulate anxiety-related behavior in mouse in vivo (Hovatta et al. Nature 2005). We have now investigated if any of the identified genes predispose humans to anxiety disorders as part of the Finnish population-based Health 2000 study. A representative sample (n=6005) of Finlands adult population was interviewed with CIDI for the presence of anxiety disorders. In addition, blood samples were collected for DNA extraction. The annual prevalence for the studied anxiety disorders was 5.7% (n=339) (Pirkola et al. 2005). Controls were matched according to age, sex, and home province. Thirteen of the 17 genes we identified in mouse have a homolog in the human genome. We have genotyped 207 SNPs including all non-synonymous SNPs, SNPs that alter potential microRNA binding sites, and additional gap-filling SNPs selected from the HapMap data in our anxiety disorder cohort. Statistical analyses using both allele and haplotype based methods are currently being carried out in order to investigate whether the studied SNPs associate to anxiety disorders in the Finnish population.

Familial Noncompaction Cardiomyopathy: A Novel Genetic Cardiomyopathy. *Y.M. Hoedemaekers[1, 2], K. Caliskan[2], F.J. ten Cate[2], M. Michels[2], D. Dooijes[1], D.F. Majoor - Krakauer[1]* 1) Clinical Genetics, Erasmus Medical Center, Rotterdam, the Netherlands; 2) Thoraxcenter, Erasmus Medical Center, Rotterdam, the Netherlands.

Background: Noncompaction cardiomyopathy (NCCM) has recently been recognized as a novel cardiomyopathy characterised by an excessively thickened endocardial layer with deep intertrabecular recesses. Cardiac symptoms include heart failure, lethal arrhythmias and/or thrombo-embolic complications, mostly affecting young adults. Sporadic and familial forms of NCCM exist. Genetic NCCM is heterogeneous, mostly inherited as an autosomal dominant trait. Previously we described the occurrence of two sarcomeric gene mutations in two NCCM families. To investigate recurrence of NCCM in families, cardiologic screening of first-degree relatives of 30 NCCM patients was performed. Methods: Cardiologic screening of 52 relatives consisted of an ECG, two-dimensional echocardiography and physical examination. In some relatives contrast echocardiography or MRI and/or exercise ECG was also performed. Relevant medical records deceased relatives were ascertained to establish the cause of death. DNA analysis was performed of relatives in families with sarcomeric mutations. Results: In 17 of the 30 families (57%) a cardiomyopathy was detected in relatives; 30/52 (58%) relatives had NCCM, 8/52 (15%) of relatives had another cardiomyopathy: 2 with dilated cardiomyopathy (DCM), 4 with hypertrophic cardiomyopathy (HCM) and 2 with an unspecified cardiomyopathy. Most affected relatives were asymptomatic and severity of the cardiomyopathy was highly variable. Additional molecular screening of relatives in four families identified two mutation carriers without any cardiac features of NCCM or other cardiomyopathy and allowed exclusion of the mutation in three relatives. Conclusion: The majority NCCM is genetic. Therefore, cardiologic screening of all first-degree relatives of patients is important to reveal the variable features including NCCM, DCM and HCM. When appropriate, presymptomatic DNA testing is valuable to identify asymptomatic carriers, who are at risk developing manifestations of cardiomyopathy.

Dinucleotide polymorphism upstream SNCA gene determines susceptibility to Parkinsons disease. *Y. Fang[1], P. Rizzu[1], D. Sondervan[1], D.J.H. Deeg[2], B. Post[3], J.J. van Hilten[4], P. Heutink[1]* 1) clinical genetics, Free University Medical Center Amsterdam; 2) Institute for Research in Extramural Medicine (EMGO institute)), VUMC; 3) Dept. Of Neurology, Academic Medical Center, University of Amsterdam; 4) Department of Neurology, Leiden University Medial Center, Leiden, The Netherlands.

Parkinsons disease(PD) is a complex genetic disorder for which several genetic risk factors have been proposed. Mutations in the SNCA gene are responsible for PD in some families with Mendelian inheritance. Two meta-analyses reported that a dinucleotide repeat(REP1) upstream SNCA gene was associated with PD. The expression of the SNCA gene was found to be correlated with the length of the REP1 repeat providing a explanation of the biological effect of the risk factor. To replicate the association in our population, we tested the REP1 polymorphism in 2 PD cohorts from the Netherlands (total 498 patients), 317 cases from a clinimetric research cohort, Scales for Outcome in PD(SCOPA),and 181 from a clinical PD cohort from the Academic Medical Center Amsterdam(AMC). As control cohort we used the Longitudinal Aging Study Amsterdam(LASA,n=1693). 5 alleles(264,266,268,270 and 272bp) were found, 3(266,268 and 270bp) of them were common in our populations (covering 99% genotypes). The 266-allele was underrepresented and 270-allele was overrepresented in PD cases(p=2.4x10-7 for SCOPA,and 0.003 for AMC cohorts, respectively), compared to the LASA cohort. The association was present in both early (<50 yrs)and later (>50 yrs) onset PD case of SCOPA (p=0.0014 and 0.0024, respectively). Adjusting for age and gender, the 270/270 was found to significantly increase the risk of PD comparing to 266/266 with OR(95%CI) of 15.0(3.8-59.1). The age distribution in LASA cohort was significantly different by the genotype of common alleles (p=0.01), the 266-allele was associated with old age. While the PD-risk allele, 270-allele, was associated with young age. We concluded that the REP1 polymorphism increases susceptibility to PD in our population. Further studies are warranted to determine the survival effect of the polymorphism in the LASA population-based cohort.

CSI-OMIM - Clinical Synopsis Search In OMIM. *R. Cohen[1], A. Gefen[1], O. Birk[1], A. Melkman[2]* 1) Developmental Genetics (The Morris Kahn Laboratory of Human Genetics), Ben-Gurion University, Beer-Sheva, Israel; 2) Department of Computer Sciences), Ben-Gurion University, Beer-Sheva, Israel.

Note: AG and RC contributed equally to this project.

The OMIM database is a tool used daily by geneticists. Each syndrome page includes a Clinical Synopsis section containing a list of known phenotypes comprising the syndrome. The phenotypes are in free text and many different phrases are often used to describe the same phenotype, the difference originating in different spelling variations or typing errors, varying sentence structures and use of a verbal phenotype description as well as medical name.
Using natural language processing, an information vector was constructed for each phrase using Miriam-Webster online dictionary and medical dictionary, Princeton's Wordnet dictionary and NIH's MESH. The vectors were used to cluster the similar phenotypes into synonymous groups. This was followed by manual curation for weeding out the false positives. The syndromes listed in OMIM were organized using a linear clustering technique (SPIN) based on the frequencies of Clinical Synopsis phrases described in the syndrome.
This allows a better search for matching syndromes by choosing exact search terms to focus the search on the best matching syndromes.

Molecular bases and clinical delineation of the Pitt-Hopkins syndrome, a severe epileptic encephalopathy associated with autonomic dysfunction. *L. de Pontual[1], M. Rio[2], R. Redon[3], V. Malan[1], N. Boddaert[4], P. Plouin[5], NP. Carter[3], S. Lyonnet[1,2], A. Munnich[1,2], L. Colleaux[1], J. Amiel[1,2]* 1) INSERM U-781, PARIS, France; 2) Departement of Genetics; 3) 3The Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, Cambridge, UK; 4) Pediatric Radiology and INSERM U-797; 5) Clinical Neurophysiology Unit and INSERM U-663.

Pitt-Hopkins syndrome (PHS) is a syndromic encephalopathy characterised by severe psychomotor delay, epilepsy and daily bouts of diurnal hyperventilation starting in infancy, mild postnatal growth retardation, postnatal microcephaly and distinctive facial features. A systematic 1Mb resolution genome wide BAC array in 4 PHS cases first identified a 1.8 Mb de novo microdeletion on chromosome 18q21.1 in 1 case. We subsequently identified de novo heterozygous missense mutations of a conserved amino acid in the basic region encoded by the TCF4 gene in the three additional PHS cases. These findings provide the first evidence of a human disorder related to class I basic helix-loop-helix transcription factor defects (also known as E-proteins). Haploinsufficiency is the most likely disease-causing mechanism but dominant-negative effect is an alternative hypothesis currently being tested for missense mutations of the basic domain. Expression analysis of the TCF4 gene during human embryonic development will also be presented. More recently, we identified further PHS cases by reviewing files for which PHS differential diagnoses had been excluded i.e. Rett, Angelman, and Mowat-Wilson syndromes. This novel series of patients will be presented. The facial gestalt of patients with PHS is extremely valuable for clinicians to consider the diagnosis before the onset of distinctive features such as bouts of hyperventilation and epilepsy that, although distinctive, may not be fully penetrant. EEG and brain MRI may also give valuable clues that will be discussed. Patients diagnosed with PHS display a broad spectrum of dysautonomic features that will be detailed. These data may shed new light on the normal processes underlying autonomic nervous system development and maintenance of an appropriate ventilatory neuronal circuitry.

Detection of human copy number variations using a collection of Japanese complete hydatidiform moles. *Y. Kukita[1], K. Higasa[1], S. Ishikawa[2], T. Tahira[1], K. Hayashi[1]* 1) Division of Genome Analysis, Research Center for Genetic Information, Medical Institute of Bioregulation, Kyushu University, Fukuoka, Japan; 2) Division of Genome Science, Research Center for Advanced Science and Technology, University of Tokyo, Tokyo, Japan.

Copy number variations (CNVs) of DNA segments in the human genome can confer phenotypic variations such as risk to complex disease traits. Because there is an abundance of CNVs with population differentiation, cataloging CNV regions for each ethnic population is biomedically important. We carried out genome-wide high resolution CNV mapping using a collection of complete hydatidiform moles (CHMs) as samples, and analyzing the intensity values of a high-density DNA oligonucleotide hybridization experiments (Affymetrix 500K SNP Array). The advantage of using CHM for CNV detection is that the relative change in the hybridization signal caused by the copy number change is expected to be larger for CHM sample than for usual diploid sample (thus, larger S/N ratio), because CHM has the genome of single sperm origin, and its genome is haploid. Our results are being compared with the CNVs reported in the Database of Genomic Variants and validation by wet experimental methods is ongoing. We will present an integrated haplotype map of SNPs and CNVs, and discuss about the features of analyses using CHMs.

Identification of novel mutations in NEMO in a cohort of Incontinentia Pigmenti. *F. Fusco[1], A. Pescatore[1], M. Paciolla[2], F. Ottobre[1], M. D'Urso[1], M.G. Miano[1], M.V. Ursini[1]* 1) Dpt Human Molecular Genetics, IGB-ABT-CNR, Naples, Italy; 2) University of Basilicata, Potenza, Italy.

Incontinentia Pigmenti (IP) is an X-linked dominant disease caused by mutation in the NEMO gene located in the Xq28 chromosomal region. NEMO encodes for a key subunit of the crucial IKK regulatory complex required for the activation of NF-kB pathway. Therefore, the remarkably heterogeneous and often severe clinical presentation reported for IP is due to the pleiotropic role of this transcriptional signalling pathway. Previous reports from us and from others have demonstrated that >70% of the IP cases are due to a recurrent exon 4-10 genomic rearrangement in the NEMO gene. Beside the NEMO rearrangement, about 39 small mutations (missense, frameshift and nonsense mutations) scattered all along the NEMO gene, have been reported. We will present an update and a report of 10 novel small mutations in NEMO that we identified in a cohort of IP patients from Europe and Mediterranean area. In this cohort, we confirm that the recurrent exon 4-10 NEMO rearrangement accounts for 70% of cases and we will present genotype-phenotype correlation, obtained applying a phenotype score based on clinical features of IP. The updated distribution of all the small mutations associated to IP along the NEMO gene highlights a secondary hot spot mutation in a conserved exon/domain of NEMO and reveals that all small alterations found in IP are private mutations. Furthermore, we found an unexpected high incidence of sporadic cases (about 65%). In summary, those observations might aid in determining the molecular basis of IP disease and also genetic counselling in patients with IP will benefit from an updated analysis of NEMO mutations.

First 503 Human Subjects of Genetics of Left Ventricular Outflow Tract Malformation Study. *S.M. Fitzgerald-Butt, G.A. Zender, K.L. McBride* Center for Molecular & Human Genetics, Children's Research Inst, Columbus, OH.

Congenital heart defects are among the most common of all medically significant birth defects and are a leading cause of infant mortality. Left ventricular outflow tract (LVOT) obstruction malformations, include aortic valve stenosis (AS), coarctation of the aorta (CoA), mitral valve stenosis (MS), hypoplastic left heart syndrome (HLHS), Shone complex (SC) and bicuspid aortic valve (BAV). They are thought to arise embryologically from reduced flow through the LVOT and therefore likely have related genetic and environmental etiologies. We are actively recruiting probands with an LVOT defect and both parents in a study to define these etiologies. LVOT diagnoses, family history, pregnancy exposures, and maternal health are obtained on each proband and other affected relatives using the National Birth Defects Prevention Study questionnaire as a template. An investigator-designed Microsoft Access database is used to gather, store and analyze the data. We have enrolled 503 subjects in 183 families over 25 months of recruiting; 36% of subjects are probands (65% male and 93% white), 33% mothers, 25% fathers and 6% other relatives. 25 (14%) families have a family history of LVOT malformation and 6% of enrolled relatives are affected. Of probands, 20% have HLHS, 5% SC, 2% IAA-A, 42% CoABAV, 21% ASBAV, 9% BAV and 1% MS. We have collected blood samples for lymphocyte EBV transformation on 78% of the all subjects and 77% of probands. For the last six months we have offered a $25 gift card as incentive for completion of the study which resulted in approximately a 10% increase in blood samples. The pregnancy exposure questionnaire has been completed by 124 families or 69%. Reported prenatal exposures include: medication (63%), alcohol (56%), cigarette smoking (26%), second hand smoke (16%), chemical (16%), radiation (12%), hot bath/Jacuzzi (10%), fever (6%), recreational drugs (4%) and heavy metal (2%). Similar collection of a matched control group should provide us with adequate power to define the etiologies of LVOT malformations.

FXTAS: a descriptive study of premutation carriers from fragile X families. *E.G. Allen[1], J. Juncos[2], M. Rusin[1], G. Novak[1], D. Hamilton[1], L. Shubeck[1], R. Letz[3], S.L. Sherman[1]* 1) Department of Human Genetics, Emory University, Atlanta, GA; 2) Department of Neurology, Wesley Woods Center, Emory University School of Medicine, Atlanta, GA; 3) Department of Behavioral Science and Health Education, Rollins School of Public Health, Emory University, Atlanta, GA.

We are conducting a study to further examine the symptoms, penetrance, and risk factors associated with the tremor/ataxia syndrome (FXTAS) among carriers of premutation alleles of the FMR1 gene. Our study population includes all siblings of premutation carrier males over the age of 50 identified through a survey of families with fragile X syndrome. We conducted a comprehensive battery of tests including a medical history, a neuropsychological test battery, and quantitative neurological assessment. Within the neurological assessment, we use a series of tests to obtain objective, quantitative measures of key features observed in FXTAS cases to date: postural or intention tremor and postural stability. We have obtained these measures on 25 control males (mean age=64.9), 56 premutation males (mean age=64.4), 18 control females (mean age=67.6) and 15 premutation females (mean age=64.1). Subjects were scored as expressing the above phenotypes if they scored greater than one standard deviation above age-adjusted standards. Male premutation carriers showed a significantly increased incidence of tremor compared to male controls (66.0% compared to 33.3%; p=0.008). In addition, premutation carrier males showed a significantly increased frequency of ataxia compared to controls (61.1% compared to 22.2%; p=0.007). These phenotypes were not significantly increased among female premutation carriers. Among males, a significant association was seen between repeat size and VIQ and PIQ when adjusting for age at testing and education. When premutation carriers were divided into those that show motor symptoms and those that do not, only premutation carriers with motor symptoms were significantly different from controls for these IQ measures. Premutation carriers with motor symptoms also showed some deficits in visual scanning and attentional abilities.

Analysis of the Myb Oncogene and its Cooperation in Nf1 Leukemogenesis. *A.G. Hadjipanayis[1], B. Sack[1], J. Walrath[1], J. Zucali[1], V. Kelley[1], J. Guerts[3], D. Largaespada[3], S. Kogan[4], J. Resnick[1], K. Shannon[2], P. Wallace[1]* 1) Molecular Genetics, University of Florida, Gainesville, FL; 2) UCSF Pediatrics, San Francisco, CA; 3) University of Minnesota; 4) UCSF Laboratory of Medicine, San Francisco, CA.

Juvenile myelomonocytic leukemia (JMML) is an aggressive myeloproliferative disease characterized by leukocytosis, monocytosis, thromobocytosis, splenomegaly, and lymphadenopathy. Children with neurofibromatosis (NF1), a dominant tumor syndrome, are at a 200-500-fold increased risk for JMML. Twenty percent of children with JMML have NF1, which may not be clinically evident at time of diagnosis. Tumor cells show loss of the normal NF1 allele, fulfilling the two-hit mechanism. Based on this and other research, it has been hypothesized that somatic mutations at other genes are necessary to cause JMML to progress to a more acute form. To search for such loci, the Nf1Fcr mouse knockout mutation was crossed onto the BXH2 mouse background, which develops AML due to retroviral mutagenesis. Nf1Fcr/BXH2 mice developed acute myeloid leukemia (AML) at an earlier onset, and common sites of viral integration were mapped in the tumors. The first locus to be analyzed is termed Epi1, and these integrations were downstream of the Myb oncogene. We hypothesized that this causes increased Myb function. To test this, we constructed a mouse reconstitution model that over-expresses Myb simultaneous with inactivation of Nf1 in bone marrow used these cells to engraft lethally irradiated mice. These mice have leukocytosis and are dying with evidence of myeloid dysplasia and organ infiltration. We are analyzing tissues and data to determine whether this is an acute disease, and whether Myb hyperactivation accelerates onset of the disease compared to Nf1 mutant only. In addition, bone marrow cells (presumably tumor) from the Myb/Nf1 mice have been engrafted into new sub-lethally irradiated recipient mice. If these mice develop disease, then Myb in fact cooperates with Nf1 in acute myeloid leukemia. The experiments will be finished soon, and we will present our complete data analysis.

Evidence for interaction between *DCDC2* and *KIAA0319* in dyslexia. *P. Hoffmann[1], K.U. Ludwig[1], D. Roeske[1,2], J. Schumacher[3], G. Schulte-Körne[4], I.R. König[5], A. Ziegler[5], B. Müller-Myhsok[2], M.M. Nöthen[1]* 1) Dept Genomics, Life & Brain Ctr, Bonn, Germany; 2) MPI Psychiatry, Munich, Germany; 3) Inst Hum Genet, Univ Bonn, Bonn, Germany; 4) Dept Child & Adolesc Psychiatry, Univ Munich, Munich, Germany; 5) IMBS, Univ Lübeck, Lübeck, Germany.

Independent linkage studies for dyslexia have pointed towards a susceptibility locus on chromosome 6p21-p22 (DYX2) (1). This region harbours two candidate genes in close proximity to each other, namely *DCDC2* and *KIAA0319* (1). Unfortunately, no single study to date has sufficiently covered both genes, which would be necessary to understand the relative contribution of both genes and to identify possible interactions between them. Harold et al.(2) recently reported a combined analysis of both genes in two UK samples, supporting their previously observed findings for *KIAA0319* and showing evidence for an interaction between the two genes. We have previously reported strong association of variants in the *DCDC2* gene with dyslexia in German families, but did not obtain any evidence for a contribution of the *KIAA0319* gene (3). In the present study we expanded the marker set from our previous study by six markers in order to obtain a more comprehensive picture of the contribution of *KIAA0319*. None of these markers showed significant association with dyslexia, neither in the total sample, consisting of 244 German families with a severely affected child, nor when stratifying for the subdimensions or severity. When testing for interaction between markers in *KIAA0319* and our previously identified risk haplotype in *DCDC2* (3), we obtained no evidence for interaction for dyslexia itself, but identified a nominally significant association for the subdimension word reading, which was the core phenotype in the study of Harold et al. This may be seen as supportive evidence for an interaction between *KIAA0319* and *DCDC2*. However, an effect of *KIAA0319* alone, as reported for the UK samples, could not be demonstrated in our sample of German origin.

Enzyme Replacement Therapy for MPS II: Developing a Pre-medication Protocol. *M. Descartes[1], J. Franklin[1], T.L. Hanvey[2]* 1) Dept Genetics, Univ Alabama, Birmingham, Birmingham, AL; 2) Children's Hospital of Alabama, Birmingham, AL.

MPS II is an X-linked, lysosomal disease that is caused by deficiency of iduronate-2-sulfatase (I2S). Elaprase (Idursulfase), the first product for the treatment MPS II was approved in July 2006. Infusion reactions are commonly reported in patients on Elaprase. We report the management approach of a patient with persistent infusion reactions. Our patient was diagnosed with MPS II at 4 years of age and started on Elaprase at 4.3 years. The patient received Elaprase at 1mg/kg/dose once per week. The Elaprase was prepared and administered following manufacturer recommendations. Our patients first infusion-related adverse event occurred on his fourth infusion. He developed general malaise and fever after the infusion. The patient was being pre-medicated with acetaminophen PO and diphenhydramine IV. He developed flushing, whelps, and irritability on the fifth infusion. The infusion was stopped, methylprednisolone IV administered, and infusion re-started at a slower rate. With each infusion the patient had nausea, emesis, flushed face, and pruritic rash. During the sixth infusion, ranitidine IV was given in addition to diphenhydramine due to a rash. The premedication regimen was then changed to include methylprednisolone IV. The patient developed a rash but resolved with additional diphenhydramine. With infusion eight, the premedication regime was changed to include PO prednisone to be given 2 hours prior to infusion. The IV methylprednisolone pre-infusion was stop and acetaminophen PO and diphenhydramine IV were given upon patient arrival. The maximum flow rate was also decreased. Irritability, gagging and rash were noted. The symptoms resolved by stopping the infusion and by giving additional diphenhydramine. With the ninth infusion, coughing and crying were noted. With the tenth infusion, the patient remained irritable. These last symptoms resolved untreated. This patient transitioned to care at a local hospital due to the time traveled (over 4 hours one way each week). The family was anxious for care closer to home. This patients response to the infusions represents the difficulty in determining the best pre-medication protocol for these patients.

Searching for an embryonic lethal mutation associated with DNA methylation. *K.M. Baumgarner[1], M.J. Cramer[1], M.J. Justice[2], A.C. Lossie[1]* 1) Animal Science, Purdue University, West Lafayette, IN; 2) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Virtually all human diseases result from genetic mutations and/or errors in gene expression that can be studied using mouse models, which are important tools for identifying disease-causing and developmentally regulated genes. The peri-implantation window is crucial for DNA methylation and subsequent determination of an individuals epigenome; disruptions in this process often cause embryonic lethality in mammals. This project utilized the *l11Jus1* line of embryonic lethal, homozygous mutant mice, which were derived from an ENU mutagenesis screen targeted to a 35 Mb region of MMU11. Homozygotes die shortly after implantation and demonstrate defective DNA methylation at the *Commd1/U2af1-rs1* locus. The phenotype of the mutants is much more severe than what would be predicted from disruption of these reciprocally imprinted genes. Therefore, we hypothesize that the mutated gene will either disrupt global DNA methylation imprinting or be essential for embryonic development. The goal of this project is to positionally clone *l11Jus1* in order to better understand the epigenetic factors that are involved in epigenome establishment during early mammalian development. The first objective was to narrow the region by meiotic mapping of recombinant animals derived from an F_2 intercross. The second objective was to sequence the best candidate genes in the critical interval (CI), including: *Ap2b1*, *Suz12*, *Evi2a*, *Cct6b*, *Riffl*, and the *Slfn* family of genes. After mapping 527 animals, we narrowed the CI to a 4.3 Mb region flanked by *Wsb1* and *D11MIT120*. During sequence analysis, we identified many single nucleotide polymorphisms (SNPs) between the two background strains (129S6/SvEvTac and C57BL/6J). We have yet to locate the mutation, but have found 25 expressed SNPs, 35 intronic SNPs, and 9 small deletions to date. These SNPs and deletions will be added to the SNP databases, expanding the coverage of the 129S6/SvEvTac genome. We are further narrowing the CI by generating more recombinant animals, and sequencing additional candidate genes.

A description of the first oncogenetic clinic for BRCA1/2 mutation carriers in London: The Carrier Clinic. *E. Bancroft[1], A. Ardern-Jones[1], K. McReynolds[1], S. Shanley[1], Z. Kote-Jarai[2], R. Eeles[1,2], Carrier Clinic Collaborators* 1) Royal Marsden NHS Foundation Trust, London; 2) Institute of Cancer Research, London.

A specialist oncogenetic clinic was established in 1996 at the Royal Marsden NHS Foundation Trust for families harbouring mutations in *BRCA1* and *BRCA2* to offer expert advice and specialist follow-up. The remit of this multidisciplinary clinic is provide individualised screening recommendations, psychological support, cascade testing, risk reduction strategies and offers an extensive research portfolio. METHODS: We have performed a retrospective analysis on uptake of prophylactic surgery, uptake of *BRCA1/2* testing and cancer incidence in 347 families identified with *BRCA1/2* mutations between January 1996 and December 2006. A total of 661 individuals have attended this clinic and 406 mutation carriers identified (239 *BRCA1*, 165 *BRCA2* and 2 *BRCA1* and *BRCA2*). RESULTS: Out of 406 gene positive individuals 85.8% choose to attend the Carrier Clinic for annual follow-up. Out of 476 individuals eligible for a predictive test 411 have proceeded to testing. The incidence of prophylactic bilateral mastectomy (PBM) contralateral mastectomy (PCM) and oophorectomy (PBO) is as follows: 70.4% mutation carriers aged 40-70 chose PBO; 32.3% unaffected women chose PBM at a mean age of 37.4 years; 22% of women chose PCM at the time of a breast cancer diagnosis; 14.3% of unaffected women chose both PBM and PBO. In unaffected women the mean time to surgery post-test was 11 months for PBM and 12.5 months for PBO. 95.6% of individuals approached to take part in research are enrolled in at least one study. The number of families identified is increasing annually both through clinical and research testing. Cancer incidence amongst these individuals matches the incidence reported in the literature. CONCLUSION: The results indicate a high demand for both prophylactic surgery and genetic testing in women from *BRCA1/2* families. This clinic model has subsequently been adopted in other centres and this will facilitate translational studies in this group. The Carrier Clinic Collaborators: Locke I, Walker L, Barwell J, Mitchell G, Dorkins H, Thomas S, Doherty R, Lynch E, Mitra A, Javhar S, Izatt L, Pichert G.

An integrated genome visualization tool for diagnostics and research. *B. Eussen, M. Moorhouse, T.A. Knoch, F. Grosveld, A. de Klein* Clinical Genetics and Cell Biology, ErasmusMC, Rotterdam, South Holland, Netherlands.

In the past cytogenetics has illustrated that specific chromosomal regions are linked to genome structure related components of the DNA. The first genome wide approach was achieved with the identification of the first human duplicon set by E. Eichler et al 2002. These duplicons were not randomly spread on the genome but clustered on centromere and telomere regions. Also common microdeletion regions like Prader Willi and DiGeorge syndrome are flanked by these duplicon clusters. In principle all these duplicons regions can be pitfalls in the interpretation of genomic assays, a recent report of the HapMap project showed a nice correlation between duplicon regions and polymorphic regions in two different platforms: a tiled human BAC array and the Affymetrix 500K SNP (Redon et al. 2006). To visualize the actual complexity at array hotspots or candidate regions related to specific diseases, an integrated view on genomic and experimental data must be available in a customized way. For this we developed a generic visualization tool called 3D genome viewer. In a few examples we will show the flexibility, customization and the intuitive integration of experimental data from different diagnostic platforms (SNP/BAC arrays, QPCR, MLPA) with a selection of currently available public data sources like; segmental duplicons(Eichler et al. 2002), Genomic Variants data (Iafrate et al. 2006) and syndrome locations (DECIPHER). Also for future visualization requirements, high through put expression/SNP arrays, education purposes, nuclear organization, epigenetic and molecular imaging this genomic 3D viewer can be the basis of many visual concepts.

Association of polymorphism of the liver X receptor gene with angina pectoris in the Japanese population. *M. Inoue[1], R. Uemura[1], T. Ikezaki[1], S. Kobayashi[1], S. Ikeda[2], S. Kohno[2], K. Tsukamoto[1]* 1) Dept of Pharmacotherapeutics, Nagasaki Univ Graduate Sch of Biomed Sci, Nagasaki, Japan; 2) 2nd Dept of Internal Med, Nagasaki Univ Sch of Med, Nagasaki, Japan.

Objective: Coronary artery disease (CAD) is a multifactorial disorder and consists of two major forms, angina pectoris (AP) and myocardial infarction (MI). The etiology of CAD contributes to atherosclerosis of coronary arteries. As a candidate gene susceptible to CAD, we focused on liver X receptor (LXR). LXR is a nuclear receptor that binds oxysterols. LXR has two isoforms, LXR and LXR, which play a role in decreasing cholesterol accumulation through inhibiting intestinal cholesterol absorption and transfer from peripheral tissues to the liver, while through stimulating uptake into liver, catabolism into bile acids, and biliary secretion, leading to protection against atherosclerosis and hypercholesterolemia. Thus, we have examined an association of *LXR* polymorphisms with CAD in the Japanese population. Methods: We studied 146 patients with AP, 97 patients with MI, and 165 gender- and age-matched control subjects with normal coronary artery after coronary angiography. Four single nucleotide polymorphisms (SNPs) in *LXR* were detected by PCR-restriction fragment length polymorphism and PCR-direct DNA sequencing analysis. Haplotypes composed of these 4 SNPs were estimated using SNP Alyze 6.1. The frequencies and distributions of haplotypes and diplotypes were compared between patients and controls by multivariate logistic regression analysis. Results: The frequencies of haplotype 2 (G at rs12221497, T at rs2279239, C at rs2279238, and T at rs7120118: G-T-C-T) and haplotype 3 (A-C-C-C) were significantly higher in AP patients than in controls (30.1% vs. 22.4%, odd ratio (OR) = 1.488, $P = 0.031$; and 10.8% vs. 6.4%, OR = 1.789, $P = 0.049$, respectively). Of a total of 143 patients with AP, 11 (7.7%) had a hap 2/hap 3 diplotype, the frequency being significantly higher than that in controls (4/165, 2.4%)(OR = 3.354, $P = 0.042$). Conclusion: The present study indicates that *LXR* may be one of the determinants of AP in the Japanese population.

Aggregation of lamin A/C or progerin in fibroblasts derived from Hutchinson-Gilford progeria syndrome (HGPS) is not resulted from interaction between progerin and the promoter of LMNA gene. *Y. Huang[1,2], H. Guo[1,2], N. Zhong[1,2,3]* 1) Peking University Center of Medical Genetics, Beijing, China; 2) Dept. Medical Genetics of Peking University Health Science Center; 3) New York State Institute for Basic Research in Developmental Disabilities, Staten Island, NY.

Hutchinson-Gilford progeria syndrome (HGPS) is a rare genetic disorder characterized by dramatic premature aging. Classic HGPS is caused by a de novo point mutation in exon 11 of the LMNA gene that encodes lamin A protein, activating a cryptic splice donor and resulting in a mutant lamin A protein, the progerin, that lacks the normal cleavage site to remove a C-terminal farnesyl group. Our previous study has shown that there is an aggregation in HGPS cells. We hypothesized that this aggregation is resulted from a pathological accumulation of uncleaved progerin. We proposed that the accumulated progerin might interact with the promoter of LMNA gene and interfere with the gene expression. To test our hypothesis, we have employed a dual-luciferase reporter assay to study the progerin, compared to a normal lamin A, effects on the promoter of LMNA gene. The dual-luciferase reporter system includes firefly Luciferase and Renilla Luciferase. The construct was transfected into 293T cells. Our pilot results present no evidence that progerin or lamin A would have a obvious interaction with the LMNA promoter, although alternative approaches are being under conducted to characterize the effects of progerin. Our studies have preliminarily excluded that mutant progerin may have pathological interaction on the gene expression of either normal lamin A/C or mutant progerin in HGPS.

A Novel Karyotype Involving a Pericentric X Chromosome Inversion and Mosaicism for Two Cell Lines with Different 5p Deletions, Presenting as Neonatal Hyperammonemia. *J. Gillis, A. George, M. Shago, D. Antinucci, A. Feigenbaum, M. Rohrbach* Division of Clinical and Metabolic Genetics, University of Toronto, Toronto, ON, Canada.

We present a case of a term female infant presenting on day 3 of life, with poor feeding, hypotonia, and lethargy. She subsequently developed seizures and vomiting and was found to have hyperammonemia and respiratory alkalosis, suggestive of a urea cycle defect. Low levels of plasma citrulline and arginine, as well as elevated levels of urine orotic acid were in keeping with a diagnosis of ornithine transcarbamylase (OTC) deficiency. OTC deficiency, an X-linked trait, is the most common inherited urea cycle disorder, with the most severe form usually restricted to males. Chromosome analysis revealed the karyotype; 46,X,inv(X)(p11.4q26.1),del(5)(p15.2)[16]/46,X,inv(X)(p11.4q26.1),del(5)(p14)[15] consistent with a mosaic female having 2 abnormal cell lines, each possessing one X chromosome with an apparently balanced pericentric inversion with estimated breakpoints at regions Xp11.4 and Xq26.1. Late replication studies demonstrated that the inverted X chromosome was active in the majority of cells. In addition, mosaicism was apparent for 2 different deletions on chromosome 5 resulting in monosomy 5p15.2 to 5pter in 52% and monosmomy 5p14 to 5pter in 48% of cells. FISH analysis of region 5p15.2 confirmed a deletion in all cells in keeping with Cri du Chat syndrome, which is known to be associated with severe psychomotor/mental retardation. Parental karyotypes were normal. Molecular analysis of the OTC gene did not identify a mutation, and assay for OTC enzyme activity in liver tissue is planned. In summary, we describe previously unreported de novo chromosomal rearrangements involving three chromosome abnormalities resulting in at least two clinically unrelated diseases, manifesting as a severe and complex phenotype in a female infant. We recommend that chromosome analysis be considered even in cases of apparent simple metabolic disease, in order to further elucidate the underlying molecular and cytogenetic mechanisms, as well as to provide appropriate genetic counseling and future prenatal testing.

Brain-Derived Neurotrophic Factor (BDNF) in autism. *C. Correia[1,2], A.M. Coutinho[1], M. Barreto[1,2], M. Martins[1,2], L. Lourenço[1,2], J. Almeida[3], C. Marques[3], T. S.Miguel[4], A. Ataide[4], G. Oliveira[3], A.M. Vicente[1,2]* 1) Instituto Gulbenkian Ciencia, Oeiras, Portugal; 2) Instituto Nacional de Saúde Dr. Ricardo Jorge, Lisbon, Portugal; 3) Hospital Pediátrico de Coimbra, Coimbra, Portugal; 4) Direcção Regional de Educação da Região Centro, Portugal.

Several lines of evidence implicate BDNF, a neurotrophin crucial for brain development and function, in autism. In this study, the role of BDNF in autism etiology was studied. We found that BDNF plasma levels in autistic children (N=146) were significantly increased compared with control children (H=51.69, $P<0.00001$) and positively correlated with serotonin levels ($r^2=0.289$; $P=0.004$), with an heritability of 30%. We therefore sought to identify genetic factors that might regulate BDNF distribution. Several candidate genes were assessed, including *BDNF* and its receptor *NTRK2* genes; the *HTR1A* gene region, since the HTR1A serotonin receptor regulates serotonin levels; and the *GAD1* gene, as it encodes a key regulator of glutamate which, neurotoxic when in excess, induces *BDNF* expression as a neuroprotective mechanism. We found an association of three markers in the *HTR1A* genomic region with BDNF levels ($^2=5.06$, df=1, $P=0.0245$; $^2=4.93$, df=1, $P=0.0264$; $^2=4.25$, df=1, $P=0.0392$). While only one marker in this region showed a strong association with autism in the overall population ($^2=30.13$, df=9, $P=0.0004$), the three markers associated with BDNF levels were also associated with autism in the subset of patients with high BDNF levels (Z=2.982, df=1, $P=0.0029$; Z=2.668, df=1, $P=0.0076$; Z=2.524, df=1, $P=0.012$). Unexpectedly these markers were located within *RNF180*, a recently identified gene mapping near *HTR1A*. *RNF180* encodes a protein belonging to the zinc ring finger family implicated in the ubiquitination signal pathway, which is important in maintaining protein homeostasis and in transcriptional regulation by histone ubiquitination. Our results corroborate previous reports, in smaller cohorts, of increased plasma BDNF in autistic patients. The results also suggest that *RNF180* may be involved in the regulation of BDNF levels through an as yet unexplained mechanism that may underlie autism etiology in a subset of patients.

Identification of Genes Involved in Neural Tube Defects and Neurogenesis. *A. katz[1], T. Hare[1], S. Khateeb[1], R. Ofir[1], V. Caspi[2], O.S. Birk[1]* 1) The Morris Kahn Laboratory of Human Genetics, the National Institute for Biotechnology in the Negev, Ben-Gurion University, Beer-Sheva, Israel; 2) the National Institute for Biotechnology in the Negev, Ben-Gurion University, Beer-Sheva, Israel.

Neural tube defects (NTDs) have an incidence of approximately 1 in 1,000 births worldwide. Numerous models of NTDs exist in the mouse. Studies of these models have led to the elucidation of specific molecular pathways critical to neural tube closure. The neural tube, formed from neuroephitheilum, closes at approximately the fourth week post-conception in the human foetus, and at E8.5 -E10 in the mouse. In an attempt to enhance and expand our understanding of the molecular mechanisms and pathways underlying neural tube closure, we undertook a high-throughput gene expression analysis (Affymetrix Mouse Genome 430 2.0 expression arrays) of open and closed sections of the mouse neural tube as it forms in the mouse embryo.
An array of known genes as well as novel genes (possibly associated with tube closure), were found to be over-expressed in the open sections of the neural tube as compared to the closed section. Other gene clusters were shown to be expressed more in the closed sections of the neural tube - suggesting a possible role in neurogenesis.
(TH, SK and AK contributed equally to this study).

Adiponectin gene *ADIPOQ* tagging SNP haplotype associations with serum adiponectin and modulation of gene expression by promoter SNPs. *T. Kyriakou[1], L.J. Collins[1], X. Wang[2], H. Snieder[2,3,4], R. Swaminathan[5], D.J. Hart[4], T.D. Spector[4], S.D. O'Dell[1]* 1) Nutritional Sciences Division, King's College London, United Kingdom; 2) Department of Pediatrics, Medical College of Georgia, Augusta, GA, USA; 3) Department of Epidemiology, University of Groningen, The Netherlands; 4) Twin Research and Genetic Epidemiology Unit, Kings College London, London, UK; 5) Department of Clinical Chemistry, Kings College London, London, UK.

Adiponectin is a potent insulin sensitizer in muscle and liver and low serum levels are associated with obesity and insulin resistance. We selected 8 tagging SNPs representing 12 common variants in the adiponectin gene (*ADIPOQ*) and tested their effect on serum adiponectin and measures of body fat in two independent samples of Caucasian females: the Chingford Study (n=808, mean age 62.85.9 years) and Twins UK (n=2718, mean age 47.412.6 years). In the Chingford cohort, tSNPs rs17300539 (-11391 G/A), rs182052 (-10068 G/A), rs16861209 (-7734 C/A), rs1501299 (+276 G/T) and rs1063537 (+3228 C/T) were significantly associated with fasting serum adiponectin levels (Ps=0.0001 to 0.014), explaining between 1.0% and 1.7% of the variance. Associations with all except rs1063537 were replicated in the Twins UK cohort (Ps=3.19 x 10^{-9} to 0.006), explaining between 0.93% and 1.88% of the variance. In addition rs16861209 was associated with BMI, weight, total fat mass, % fat, central fat mass and waist circumference (Ps=0.003 to 0.021). In order to investigate potential functional effects of SNP -11391 G/A, we cloned 1.2 kb of the *ADIPOQ* promoter region, which included SNPs -11391 G/A and -11377 C/G (rs266729), in a luciferase reporter plasmid. The four possible haplotype promoter constructs were transfected in differentiated 3T3-L1 adipocytes. Reporter gene assays showed that the -11391 G/A SNP had an effect on promoter activity only in the presence of the -11377 G-allele. The -11391G / -11377G promoter construct had approximately 2-fold higher promoter activity than the other three haplotypes tested. It therefore remains to be elucidated whether -11391 G/A or -11377 C/G is the causative SNP associated with serum adiponectin levels in the cohort studies.

The leukemogenic CALM/AF10 fusion protein alters the subcellular localization of the lymphoid regulator Ikaros. *P.A. Greif[1], B. Tizazu[1], A. Krause[1], E. Kremmer[2], S.K. Bohlander[1]* 1) Medicine III , Universität München / GSF, München, Germany; 2) Molecular Immunology , GSF , München , Germany.

The t(10;11)(p13;q14) translocation leads to the fusion of the CALM and AF10 genes. This translocation can be found as the sole cytogenetic abnormality in acute lymphoblastic leukemia, acute myeloid leukemia and also in malignant lymphomas. The expression of CALM/AF10 in primary murine bone marrow cells triggers the development of an aggressive myeloid leukemia in a murine bone marrow transplantation model. Interestingly, the leukemia propagating cell shows lymphoid characteristics including immunoglobulin rearrangements and B220 surface markers. Here we show that AF10 interacts with the lymphoid regulator Ikaros in yeast-two-hybrid assays. Ikaros is required for normal development of lymphocytes and aberrant expression of Ikaros has been found in leukemia. In a murine model, the expression of a dominant negative isoform of Ikaros causes leukemias and lymphomas. The Ikaros interaction domain of AF10 was mapped to the leucine zipper domain of AF10, which is required for malignant transformation by both the CALM/AF10 and the MLL/AF10 fusion protein. The interaction between AF10 and Ikaros was confirmed by GST-pulldown and co-immunoprecipitation. In contrast to AF10, CALM/AF10 alters the nuclear localization of Ikaros. The transcriptional repressor activity of Ikaros is reduced by CALM/AF10 but not by AF10. These results suggest that CALM/AF10 might have a dominant negative effect on Ikaros, and thereby block differentiation of the leukaemia propagating cell in CALM/AF10 positive leukemias.

FGF23 gene is associated with renal phosphate leak in calcium nephrolithiasis. *T. Esposito[1], G. Mossetti[2], D. Rendina[2], G. De Filippo[3], A. Ciccodicola[1], F. Gianfrancesco[1], P. Strazzullo[2]* 1) Institute of Genetics and Biophysics, Italian National Research Council, Naples, Italy; 2) Department of Clinical and Experimental Medicine, Federico II University Medical School, Naples, Italy; 3) Pediatric Endocrinology, Gaetano Rummo Hospital, Benevento, Italy.

Nephrolithiasis is a common disorder, affecting about 10% of the western population. Approximately 20% of patients with calcium nephrolithiasis and normal parathyroid function show reduced serum levels of phosphate associated to reduced renal phosphate reabsorption (i.e. renal phosphate leak). In this setting, we previously demonstrated that circulating levels of fibroblast growth factor 23 (FGF23), a hormone-regulating phosphate homeostasis, were significantly higher compared to stone formers without renal phosphate leak and to healthy controls. We collected 106 stone formers, 17 of them with renal phosphate leak, and 87 healthy controls and we sequenced the entire regulative and coding regions of FGF23 gene. We detected in 10 out of 17 stone formers with renal phosphate leak a non-synonymous change T239M in FGF23 gene. The T239M allele and genotype frequencies in stone formers with renal phosphate leak were significantly higher compared to controls [CvsT allele frequencies ($p=0.03$) and genotype frequencies ($p=0.007$)], and to stone formers without renal phosphate leak [CvsT allele frequencies ($p=0.024$) and genotype frequencies ($p=0.002$)]. No significant differences were found for T239M allele and genotype frequencies between stone formers without renal phosphate leak and controls The missense variation Thr239Met could significantly influence the structure as well as the biological properties of the FGF23 protein. In conclusion, our results indicate, for the first time, that there is a genetic link between T239M missense variant of the FGF23 gene and renal phosphate leak in patients with calcium nephrolithiasis.

Angiotensin converting enzyme gene polymorphism and diabetic nephropathy in Filipino type 2 diabetes mellitus patients. *E.M.C. Cutiongco[1], E. Paz-Pacheco[2], G.V. Jasul[2], M.C.A. Cruz[2]* 1) Institute of Human Genetics, National Institutes of Health Philippines, Manila, Philippines; 2) Department of Medicine, University of the Philippines - Philippine General Hospital, Philippines.

Objective: To determine the frequencies of angiotensin converting enzyme (ACE) gene insertion/deletion (I/D) polymorphism among Filipino type 2 diabetic patients and normal controls. Methods: We performed a preliminary analysis of the ACE gene polymorphism in diabetic patients with nephropathy, diabetic patients without nephropathy, and normal controls. Patients with established renal disease other than diabetic nephropathy were excluded from the study. The diabetic patients were evaluated by the following parameters: duration of diabetes, presence of comorbid conditions, body mass index (BMI), systolic blood pressure (BP), diastolic BP, glycosylated hemoglobin (A1c), and presence of nephropathy. We extracted DNA from peripheral blood and determined the type of polymorphism (II homozygote, DD homozygote or ID heterozygote) via polymerase chain reaction, restriction enzyme digestion, and gel electrophoresis techniques. We analyzed the data using independent T-tests and chi square tests to compare the clinical characteristics of the two groups of diabetic patients, and logistic regression analysis to determine odds ratio for development of nephropathy. Results: Among the patients with diabetic nephropathy (n=21), the ID polymorphism was more frequent (52.4%) compared to the homozygous II and DD polymorphisms. In those without diabetic nephropathy (n=21), the II genotype was more common (61.9%). The ID polymorphism was the more frequent genotype in the normal controls (n=24) (58.3%). The odds of developing diabetic nephropathy were increased by 4.8 times in those with ID polymorphism, and 2.9 times in those with DD polymorphism. Conclusion: We found that the D allele (ID and DD genotypes) was more common in patients with diabetic nephropathy, similar to the observation in South Indian patients. Genetic studies on larger diabetic populations are needed to establish the hypothesized role of the D allele in susceptibility to diabetic nephropathy.

Mitochondrial DNA instability and recessive POLG1 mutations in patients with isolated adult-onset sensory ataxic neuropathy. *S. Bannwarth[1, 2], K. Fragaki[1, 2], J. Pouget[3], D. Figarella-Branger[4], V. Paquis-Flucklinger[1, 2]* 1) Department of Medical Genetics, CHU Nice,; 2) UMR CNRS 6543, Medicine School, University of Nice-Sophia Antipolis; 3) Department of Neurology, CHU Timone, Marseille; 4) Department of Anatomopathology, CHU Timone, Marseille.

Nuclear gene defects affecting mtDNA stability include the mtDNA polymerase (POLG), the adenine nucleotide transporter (ANT1) and the Twinkle helicase. There is a considerable variability in the phenotype associated with POLG1 mutations which are responsible for autosomal dominant and recessive progressive external ophtalmoplegia (PEO), Alpers syndrome, a sensory ataxic neuropathy, dysarthria and ophtalmoparesis (SANDO) and a mitochondrial recessive ataxic syndrome. Nevertheless, patients with POLG1 mutations and sensory ataxic neuropathy always presented with associated muscular and/or central neurological system features. The aim of our study was to test whether POLG1 mutations can be responsible for isolated sensory ataxic neuropathy. We screened 15 patients by direct sequencing. Seven patients were men and the median age of the population was 57 years. The presenting and only feature was ataxia caused by axonal sensory neuropathy. A 50 year-old woman was found to be a compound heterozygous carrying the c.1391T>C mutation (M464T) in combination with the c.2302A>G substitution (K768E). No POLG1 mutation was found in other patients. Nevertheless, a muscle biopsy was performed in two cases. Ragged-red and COX negative fibers were found in one patient, with multiple mtDNA deletions by both long range PCR and Southern blot analysis. The patient was a 67 year-old man who developped ataxic symptoms at the age of 47. ENMG revealed normal motor potentials and absent sensory potentials in the four limbs. No mutations were detected in ANT1 or Twinkle. In conclusion, mitochondrial disease has to be considered as a cause of isolated adult-onset sensory ataxic neuropathy.

Combined Linkage and Association Mapping of Quantitative Trait Loci with Missing Genotype Data. *R. Fan[1], L. Liu[1], J. Jung[2], M. Zhong[1]* 1) Dept Statistics, Texas A&M Univ, College Station, TX; 2) Department of Medical and Molecular Genetics, Indiana University, School of Medicine, IN.

In genetics study, the genotypes or phenotypes can be missing due to various reasons. In this paper, the impact of missing genotypes is investigated for high resolution combined linkage and association mapping of quantitative trait loci (QTL). We assume that the genotype data are missing completely at random. Two regression models, ``genotype effect model'' and ``additive effect model'', are proposed to model the association between the markers and the trait locus. If the marker genotype is not missing, the model is exactly the same as those of our previous study, i.e., the number of genotypes or alleles is used as weight to model the effect of the genotypes or alleles in single marker case. If the marker genotype is missing, the expected number of genotypes or alleles is used as weight to model the effect of the genotypes or alleles. By analytical formulae, we show that the ``genotype effect model'' can be used to model the additive and dominance effects simultaneously; the ``additive effect model'' only takes care of additive effect. Based on the two models, F-test statistics are proposed to test association between the QTL and markers. The non-centrality parameter approximations of F-test statistics are derived to make power calculation and comparison, which show that the power of the F-tests is reduced due to the missingness. By simulation study, we show that the two models have reasonable type I error rates for a dataset of moderate sample size. The method is applied to analyze the angiotensin-1 converting enzyme (ACE) data.

***Odz4*: Understanding the role of highly conserved elements in gene expression.** *M.J. Cramer[1], M.J. Justice[2], A.C. Lossie[1]* 1) Animal Science, Purdue University, West Lafayette, IN; 2) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Odz4 is an important gene in mammalian development. Within the gene *Odz4*, there are six known embryonic lethal mouse mutants, which are characterized by abnormal mesoderm development, abnormal somite formation and defects in maternal blood flow to the embryo. Of these six mutants only one mutated allele has been found by conventional sequencing methods. The expression of *Odz4* is complicated and not well understood. In the embryo and adult mouse, there is a high incidence of alternatively spliced and tissue specific transcripts. These transcripts have the potential to generate at least 5 different protein isoforms. Recent studies have proven that non-coding RNAs can employ mRNAs to direct tissue and temporal gene expression. Our goal is to determine which of these alternatively spliced transcripts are important during development. We hypothesize that non-coding RNAs will play a major role in embryonic development and *Odz4* expression. We have identified 93 highly conserved non-coding elements (HCEs) in the 1.3Mb region surrounding *Odz4* that are 200bp in length and at least 75% identical between mouse and human. To date, the identity of these homologous regions has not been explored. Using reverse transcription (RT-PCR) we were able to identify that 73 of the 93 HCEs screened are expressed. RT-PCR between exon 1 and each HCE and each HCE and exon 6 was performed to identify which of these expressed HCEs are new exons of *Odz4*. The results indicate that there are many more exons in this gene than previous thought. Currently, 48 out of 93 HCEs are new exons of *Odz4*, while 20 out of 93 HCEs are not new exons. Our future research includes sequencing each of the newly identified exons to potentially identify the remaining mutations. We also intend to investigate the identity of the expressed HCEs that are not new exons of *Odz4*. It is very likely that they could be cis-regulatory elements, non-coding RNAs or they could play a role in the alternative splicing of *Odz4*.

Evaluation of the quality and quantity of DNA from buccal samples in the National Birth Defects Prevention Study. *M.M. Jenkins[1], M.L. Gallagher[1], S.A. Rasmussen[1], C. Sturchio[2], D.A. Koontz[1], P. Richter[1], S. Collier[1], M.A. Honein[1]* 1) Centers for Disease Control and Prevention, Atlanta, GA; 2) Battelle Contractor to CDC, Columbus, OH.

Analysis of polymorphisms in genes encoding proteins involved in metabolism of tobacco smoke is planned as part of a study to identify gene-environment interactions in the etiology of gastroschisis and anorectal atresia. The planned study will use data from a multisite, population-based case-control study of major birth defects that includes a maternal interview and self-collection of buccal cells using cytobrushes for each mother, father, and infant. Thus far, we have performed pilot studies to better understand the quality and quantity of DNA from buccal samples collected for the multisite study of major birth defects. An initial pilot study included 41 DNA samples from the Atlanta study site. Genotyping was completed in duplicate for 20 variants from 6 *CYP* and 2 *NAT* genes using Pyrosequencing technology. 11 of 41 samples (27%) had low DNA concentrations (<0.1ng/l), as determined by a real-time PCR assay specific for human gDNA. Among these samples, unsuccessful PCR amplification and evidence of allele drop-out (ADO) were observed. Three variants were selected for a subsequent pilot study completed on 65 Atlanta samples. The same methodology was used except that samples were tested in quadruplicate. 25 of 65 samples (38%) had low DNA concentrations. Unsuccessful amplification and discordance between replicate results, consistent with the occurrence of ADO, were again seen almost exclusively in the low DNA concentration samples. DNA quantitation is complete on all 1,721 parent and infant samples selected for the study of anorectal atresia and gastroschisis. 255 of the 1,721 samples (15%) had low DNA concentrations and will be excluded from further study to reduce genotyping errors. The preliminary studies have contributed to a better understanding of the quality and quantity of DNA obtained from buccal samples and the correlation between DNA concentration and ADO in NBDPS samples and may be of value to other genetic epidemiology studies.

Visual Analytics: A Novel Approach for Mining Inbred Population Pedigrees. *C. Fuchsberger, C. Pattaro, P.P. Pramstaller* Institute of Genetic Medicine, Bolzano, Italy.

To study inbred populations is a promising approach to identify disease susceptibility genes. In such populations, mining the very complex genealogies is a major challenge. Existing approaches keep statistical analysis and visualization step separate and, for computational issues, often focus only on sub-pedigrees. Visual Analytics (VA) is a technique combining Humans outstanding visual capabilities with the power of analytical methods to support the knowledge discovery process. We developed a novel, VA-based approach consisting of four steps: 1-ANALYSE FIRST. Application of pre-processing steps, such as, normalization and clustering. To preserve the hierarchical structure results of the clustering step were integrated into the pedigree drawing algorithm. 2-SHOW THE IMPORTANT. The inclusion of qualitative/quantitative information depends on the study goals. By using distortion techniques like Fish-Eyes, user focuses on details by preserving the global structure. 3-ZOOM, FILTER AND RE-ANALYSE. Since identifying family clustered diseases, risk factors and heritability patterns is an exploratory process (EP), dynamic queries were integrated. 4-DETAILS ON DEMAND. During the EP additional information is required: static data is retrieved from a data repository; dynamic information, such as the connection path between individuals, is calculated on the fly. We used the novel approach on 3 Italian population isolates (whole genealogy including 50,037 subjects; ~960 qualitative/quantitative traits available for 1175 subjects) to assess which disease combinations were common and tend to group in families. We discovered clusters at the population level. Identification of nuclear family disease clusters required deeper pedigree explorations. Several paths between different clusters were identified during the EP. Working with the whole genealogy missing and incomplete phenotypical and genealogical data could be partially inferred by human perception. VA does not quantify numerically the influence of the various factors; however, it allows the exploration of several hypotheses.

Population sub-structure revealed from genealogical and genetic data in two isolated populations in South Italy.

V. Colonna[1], T. Nutile[1], M. Aversano[1], G. Fardella[1], S. Bracco[1,3], L. Dionisi[1], M. Borra[4], M.F. Carfora[2], C. Angelini[2], M. Ciullo[1], M.G. Persico[1] 1) IGB-ABT, CNR, Naples, Italy; 2) IAC, CNR, Naples, Italy; 3) EURAC, Bolzano, Italy; 4) Stazione Zoologica Anton Dohrn , Naples, Italy.

We investigated the genealogical structure in the populations of two isolated villages, Gioi and Cardile in order to use them effectively in gene mapping studies. Study samples consist of individuals living in Gioi (N=882) and Cardile (N=474) of which 94% are in a single 5165-member pedigree. Despite the single pedigree and the fact that villages lie only 6 km apart, we suspected a potential sub-structure and thus we investigated this hypothesis, quantifying admixture between the villages according to genealogical data. For this purpose a sub-pedigree was reconstructed for each sample on the basis of genealogical records, going back 10 meiotic steps. Shared individuals between the sub-pedigrees per meiotic step were determined in a matrix described by an index. To asses the significance of this index, samples were mixed in a single data set and 10K more matrices with relative indexes were generated by randomly permuting the membership of this data set. We found that the index of the true matrix is significantly different from those obtained by resampling (p-value 10e-5). This indicates that, despite the fact that Gioi and Cardile have shared a number of ancestors, they could represent two sub-populations rather than a single population. In agreement with this finding, higher average kinship values (k) were found both in the sub-genealogies of Gioi (pedigree size= 4182; kG= 0.004) and Cardile (pedigree size = 2380; kC = 0.009) compared to that observed in the genealogy built from the whole study sample (pedigree size = 5255; kGC = 0.003). Haplotype analysis of the mtDNA Hypervariable Region II in Gioi and Cardile populations shows that very few haplotypes are shared between the populations while the majority are village-specific. This result gives further evidence of population substructure With this work we have shown for the first time, a powerful use of genealogical records to investigate population sub-structure.

The effect of DNA extraction method, source (blood vs. archival tissue) and concentration on allele call rate in a candidate-gene, association study using the Illumina Infinium platform. *M. de Andrade[1], J.M. Cunningham[2], T. Petterson[1], J. Larson[1], J.A. Heit[3]* 1) Biostatistics, Mayo Clinic College of Medicine, Rochester, MN; 2) Laboratory Medicine and Pathology, Mayo Clinic College of Medicine, Rochester, MN; 3) Cardiovascular Diseases, Mayo Clinic College of Medicine, Rochester, MN.

iSelect, the new custom Illumina Infinium application, allows genotyping of 7.6K-60K SNPs in a single BeadArray. This will be employed for a candidate gene association study for venous thromboembolism (VTE) at the Mayo Clinic, consisting of 1500 clinic-based, objectively diagnosed VTE cases and 1500 age, sex and residence area matched controls. We selected 16,700 SNPs for 780 genes in pathways relevant to the pathogenesis of VTE using a haplotype tagging algorithm that incorporated Illuminas design score for iSelect. Prior to running the entire set of DNA samples, we wished to evaluate the effect of DNA from different sources on the performance of the BeadArray, in part to guide us in selection of suitable samples to include in the study. We first genotyped recently isolated high-quality DNA to generate a cluster algorithm. These DNAs were 88 Olmsted County controls with no VTE at the time of blood collection, and with DNA concentration greater than 51 ng/L. The second used another 88 Olmsted County controls to investigate whether DNA extraction method, here PureGene (50%) and AGTC (50%), may affect the allele call. DNA extraction method was randomly assigned, using 6 of each per Illumina chip. The third was to investigate whether DNA concentration from lymphoblastoid cells and archive tissues may affect the allele call using 88 VTE cases that have either DNA extracted from archival tissue or lymphoblastoid cells. Controls include 2% samples replicates and a CEPH trio. These experiments are currently underway and we will report on the overall performance of this iSelect BeadArray and the effects of case status, age at blood draw, DNA extraction methods, type of DNA sample and DNA concentration on data quality.

BDNF gene polymorphisms are associated with stroke recovery at 3 months. *I. Albergaria[1], H. Manso[1,2], T. Krug[2], B. Nunes[1], G. Gaspar[1], L. Gouveia[3], I. Matos[4], M.V. Baptista[5], G. Lopes[6], R. Taipa[6], J.P. Gabriel[7], M.R. Silva[8], C. Dias[1], F. Gonçalves[9], M. Correia[6], J.M. Ferro[3], S. Oliveira[2], A.M. Vicente[1,2]* 1) Instituto Nacional Saúde Dr. Ricardo Jorge, Portugal; 2) Instituto Gulbenkian de Ciência, Portugal; 3) H. Sta. Maria, Portugal; 4) H.Distrital Mirandela; 5) H.Garcia de Orta; 6) H.Geral Sto. António, Portugal; 7) H. S. Pedro; 8) H.Fernando Fonseca; 9) H.Universidade de Coimbra, Portugal.

Stroke is a major cause for morbidity in developed countries. After a stroke episode 50-70% of patients regain functional independence, while 15-30% are permanently disabled and 20% require institutional care. Family history of stroke is associated with poor functional outcome but not stroke severity, age at onset or 90-day mortality. In spite of this evidence, few studies have investigated the impact of genetic factors in stroke outcome and recovery. In the present work, we analysed the role of a compelling candidate gene, Brain-derived Neurotrophic Factor (*BDNF*), in stroke functional outcome. BDNF is implicated in neuronal regeneration and proliferation, and has been shown to induce antiapoptotic mechanisms after stroke and to reduce infarct size and secondary neuronal cell death after induced stroke in animal models. Functional outcome in 403 stroke patients under 65 was assessed 3 months after a stroke episode using the modified Rankin Scale (mRS). 14 *tag* SNPs covering the *BDNF* coding and flanking sequences were tested for association with Rankin scores at 3 months using the Kruskal-Wallis non-parametric test. SNP rs10835210 was nominally associated with recovery (^{2}=6.75, 2 df, *P*=0.034). When only ischemic stroke patients were considered (N=304), three SNPs were significantly associated with mRS scores, rs10835210 (^{2}=9.873, 2 df, *P*=0.007), rs6265 (^{2}=6.398, 2 df,*P*=0.041), rs4923460 (^{2}=6.225, 2 df,*P*=0.044). A case/control association study in a population sample of 533 stroke patients and 507 controls in the same age range provided no evidence for the involvement of *BDNF* in stroke susceptibility. The results suggest a contribution of *BDNF* gene variants to the process of neuronal recovery after ischemic stroke that is independent of stroke susceptibility.

Dissection of apparently balanced translocations using high density SNP arrays. *J.M. Kogan, T.A. Smolarek, R.J. Hopkin, G.A. Grabowski* Division of Human Genetics, Cincinnati Children's Hospital, Cincinnati, OH.

Some individuals with de novo apparently balanced translocations and abnormal phenotypes have cryptic genomic imbalances that likely contribute to the phenotype. Methods such as fluorescence in situ hybridization and array comparative genomic hybridization have facilitated dissection of such rearrangements. These techniques can be time consuming and have limited resolution. In comparison, SNP-based microarray offers advantages for efficient detailed copy number analyses with high density and high throughput. This approach may be particularly applicable for defining deletions or duplications in complex chromosomal rearrangements.

Employing a protocol developed to assess the usefulness of the very high density Illumina and Affymetrix SNP-based microarray platforms, several submicroscopic chromosomal rearrangements have been identified, including two in individuals with complex apparently balanced translocations. SNP microarray analysis revealed one deletion in each patient at a translocation breakpoint that was not detected by standard cytogenetic analyses. A patient with microcephaly, developmental delay, severe hypotonia, and karyotype 46,XX,t(2;9;4)(p23;q12;p16) was found to have a 3 Mb deletion at 4p16.1-p16.2, just proximal to the Wolf-Hirschhorn critical region. Another patient with dysmorphic features, seizures, developmental delay, and karyotype 46,XX,der(8)t(8;11)(q13.3;q22.2),der(11)t(8;11)(q13.3;q13.5),ins(13;11)(q33.2;q13.5q22.2) was found to have a 5.5 Mb deletion at 13q33.2-q34. Several other complex rearrangements will be discussed.

Very high density chromosome analysis using SNP microarray provides resolution to the level of individual genes with a single test that has potential for automation and high throughput. The high resolution allows for consideration of the potential contributions of specific genes involved as well as possible therapeutic targets. Additionally, analysis focused on specific regions, such as known breakpoints of a de novo translocation, may reduce the chance of confusing polymorphic variants with disease-causing abnormalities.

GABA agonists rescue morphological, biochemical and behavioral phenotypes of the *Drosophila* model of fragile X syndrome. *S. Chang[1], S.M. Bray[1], D.C. Zarnescu[2], P. Jin[1], S.T. Warren[1]* 1) Department of Human Genetics, Emory University, Atlanta, GA; 2) Department of Molecular & Cellular Biology, University of Arizona, Tucson, AZ.

Fragile X syndrome (FXS) is caused by the functional loss of the fragile X mental retardation 1 (FMR1) gene. Deletion of the FMR1 ortholog in *Drosophila*, *dFmr1*, produce phenotypes useful as a FXS model system. We have discovered that dFmr1-deficient *Drosophila* die when reared on food containing increased levels of glutamate, consistent with the theory that loss of FMRP disrupts the regulation of glutamate signaling. Based on this observation, we have previously conducted a small molecule screen and identified several compounds that could rescue *dFmrp*-mediated lethality. In this study, we focused on three of them that have been implicated in the GABAergic inhibitory pathway. We found that treatments of GABA agonists, including GABA, could rescue *dFmrp*-deficiency lethality on glutamate supplemented food and that this rescue was blocked by a selective GABA(B) receptor antagonist. GABA agonists also rescued known *dFmr1*-deficient phenotypes such as mushroom bodies defects, excess Futsch translation and abnormal male courtship behavior. Our results show that GABA agonists, whether compensating for reduced GABA receptor expression or tempering excess excitatory glutamate stimulation, are capable of rescuing numerous *dFmrp*-deficient phenotypes *in vivo*. Since GABA agonists are already medically available, these data may accelerate pharmaceutical intervention in FXS.

Genetic interaction between the fragile X mental retardation protein and Brachyury during mammalian embryonic development. *R. Alisch, P. Jin, M. Epstein, T. Caspary, S. Warren* Dept Human Genetics, Emory Univ Sch Medicine, Atlanta, GA.

Fragile X syndrome is a common form of mental retardation, generally resulting from the absent expression of the *FMR1* gene. FMRP, the encoded protein, is an RNA-binding protein that associates with translating ribosomes and is believed to regulate translation of target mRNAs. We have previously demonstrated a genetic interaction between the *FMR1* ortholog in *Drosophila* and AGO1, a key component of the RNA-induced silencing complex (RISC) associated with the microRNA pathway. Since microRNAs also regulate translation, these data together suggest that FMRP may regulate translation in conjunction with the microRNA pathway. In order to more fully evaluate this possibility in mammals, we disrupted the AGO1 mammalian ortholog, *Argonaute2* (*Ago2*), in mice. The loss of *Ago2* results in gastrulation arrest, mesoderm expansion and ectopic expression of *Brachyury* (*T*). Previous work demonstrated two quantitative trait loci that modify the classic shortened tail phenotype in heterozygous *T* (T+) mice that map within 2 cM of both *Ago2* and *Fmr1*. We have demonstrated that heterozygosity for the *Ago2* knockout modifies the *T*/+ tail phenotype, suggesting *Ago2* is indeed a modifier of *T*. Here we show similar evidence that *Fmr1* may be the other *T* modifier. *Fmr1* knockout (ko) mice were crossed with *T*/+ mice, and *T*/+ *Fmr1* ko offspring were analyzed for tail length. While the tail to body length ratio (TBR) in wild-type and *Fmr1* ko mice is ~0.8 and the TBR in *T*/+ is ~0.23, the TBR in *T*/+ *Fmr1* ko mice is ~0.4. This partial rescue of the shortened tail phenotype in the *T*/+ *Fmr1* ko mice (P value <0.03) reveals a genetic interaction between *Fmr1* and *T*. These studies are the first to suggest a role for FMRP during embryonic development in mammals. Since mammals have three *Fmr1* paralogs, a role for FMRP in early development may have been missed in *Fmr1* ko mice due to partial complementation by the *Fmr1* paralogs *FXR1* and *FXR2*. The elucidation of these interactions may provide new insight into the molecular pathogenesis of fragile X syndrome.

Mutations in the noncoding regions of *ACVRL1* and *ENG* in Hereditary Hemorrhagic Telangiectasia. *K. Damjanovich[1], H. Escobar[2], J. McDonald[1,3], F. Gedge[1], L.-S. Chou[1], P. Bayrak-Toydemir[1,4]* 1) ARUP Institute for Clinical and Experimental Pathology, Salt Lake City, UT; 2) DNA Sequencing and Genomics Core Facility, University of Utah, Salt Lake City, UT; 3) Dept. of Radiology, University of Utah, Salt Lake City, UT; 4) Dept. of Pathology, University of Utah, Salt Lake City, UT.

Hereditary Hemorrhagic Telangiectasia (HHT) is a vascular dysplasia characterized by arteriovenous malformations and telangiectasia. The majority of the HHT cases are caused by mutations in the coding regions of activin A receptor type II-like (*ACVRL1*) and endoglin (*ENG*) genes. However, approximately 20% of the HHT cases do not have mutations in the coding regions of either gene that can be detected by sequencing or deletion/duplication testing by multiplex ligation probe amplification (MLPA). We had 28 HHT patients whom we were unable to find the causative mutations in the coding regions of *ACVRL1* and *ENG*. Locus specific linkage analysis with the families of two of these patients suggested linkage to *ACVRL1* locus and one family had linkage to the *ENG* locus. This prompted us to screen for the noncoding regions of the HHT genes in our cohort. We sequenced the 5 and 3 untranslated regions (UTRs) and introns of *ACVRL1* and *ENG*. Based on studies in mice we selected critical regions of the 5 UTR of both genes. We sequenced about 9kb from the 5UTR region, two 600 bp segments, up to 8 kb upstream of the *ENG*, and the entire 3 UTR of both genes. We sequenced all the introns of both genes. For the 4 large introns in *ENG*, we used a mutation screening protocol based on heteroduplex formation followed by targeted sequencing. For unreported sequence variants found, we sequenced the available family members to determine the segregation with the disease or 100 chromosomes from healthy individuals. We will report our findings and discuss the role of noncoding region mutations of *ENG* and *ACVRL1* genes in HHT. Some of these mutations are candidates for future studies to explore their disease causing potential. In addition, by determining the sequences of critical importance, our results will enhance our knowledge of the normal *ACVRL1* and *ENG* function.

Polar Body Preimplantation Genetic Diagnosis (PGD) for a de novo mutation in the Duchenne Muscular Dystrophy (DMD) gene: Use of reverse linkage on polar bodies 1 and 2 for confirmation of mutation status in embryos. *G. Altarescu[1], B. Brooks[2], T. Eldar-Geva[2], E. Hadar[2], E.J. Margalioth[2], E. Levy-Lahad[1], P. Renbaum[1]* 1) Medical Genetics Unit, Zohar PGD Lab Shaare Zedek Medical Center, Jerusalem, Israel; 2) IVF Unit, Shaare Zedek Medical Center, Jerusalem, Israel.

We constructed a haplotype based on linked polymorphic markers in a family in which the female proband is a carrier of a new missense mutation in the DMD gene for use in PGD analysis. Single cell diagnosis for PGD requires simultaneous analysis of multiple linked polymorphic markers in addition to mutation analysis in order to reduce misdiagnosis due to allele drop out (ADO). Linkage analysis requires building a family haplotype spanning at least two generations. We present a couple, in which the female was a symptomatic carrier of a new mutation in the DMD gene (T1055G), precluding linkage prior to the PGD cycle. 24 polymorphic markers were identified flanking the DMD gene in a region of less than 2 Mb. Of these, 14 markers (7 intragenic) were found to be informative in this couple, and the maternal and paternal alleles of the proband were identified. Polar bodies 1 (PB1) and 2 (PB2) were biopsied and eight markers together with the familial mutation (mapping in the order DMD-TTTC, DMD-CT, DXS1214, DXS1036, DXS1219, T1055G, DXS1238, DMD-AT, DMD-GAAA) were amplified in a multiplex PCR reaction, followed by hemi-nested fluorescent PCR analysis. The T1055G familial mutation was detected by sequencing and restriction enzyme digestion, and both PB1 and PB2 results were used to link the mutation to the affected maternal allele. Of 7 retrieved oocytes, 4 extruded PB1. Two PB1s were homozygous for all 8 markers and the mutation, each for a different maternal allele, one carried the wild type 1055T sequence, while the other carried the 1055G mutation. 2 of the 4 oocytes fertilized, and analysis of the hemizygous PB2s confirmed the mutation linkage observed in the 2 homozygous PB1s. Both embryos were mutation carriers, and therefore neither was transferable. Concomitant analysis of PB1 and PB2 is a powerful tool for reverse linkage analysis in cases of de novo mutations for maternal autosomal dominant and X-linked disorders.

What's the best statistic for a simple test of genetic association in a case-control study? *C.L. Kuo*[1], *E. Feingold*[1, 2]
1) Dept Biostatistics, Univ Pittsburgh, Pittsburgh, PA; 2) Dept Human Genetics, Univ Pittsburgh, Pittsburgh, PA.

Large-scale genetic association studies genotype as many as 500,000 SNPs at a time, but analysis typically starts with univariate statistical tests (e.g. chi-squared tests, regression) of each marker individually. For example, for a case control study most people perform chi-squared tests in the initial association scan, but this can be an allele-based test or a genotype-based test. For a genotype-based test, one can use a 2 df test on the 2 x 3 table (3 genotypes), a 1 df trend test, or a 1 df test that combines the heterozygote class with the rarer homozygote class. Some studies use logistic regression instead of chi-squared tests so that covariates can be incorporated into the initial scan. This presents essentially the same options as the chi-squared test for modeling the genotype using 1 or 2 degrees of freedom, but in addition the model can involve gene-environment interactions if desired. Surprisingly little literature has compared the power of these different statistical procedures, and we have observed a huge variety of procedures used in real applications. The seminal paper by Sasieni (1997) compares the allele-based test with the genotype-based trend test, and concludes that the allele-based test is generally not recommended. However, Sasieni was for the most part considering an estimation question rather than the hypothesis-testing question that is probably more relevant to genome scans. In addition, newer ideas about what kinds of population genetic models are expected under both the null and the alternative may mean that Sasieni's conclusions should be reconsidered. In our work we review the options for a simple genetic association test in a case-control study and take a rigorous statistical approach to discovering which tests are most powerful for initial scans in genetic association studies. We consider the problem primarily in terms of which test has the highest power for a single test of association under different genetic models, but we also comment briefly on the issue of how the tests/procedures might be expected to perform when an entire genome is scanned.

Association analysis of growth factor genes FGF2 and VEGF with stroke susceptibility. *B.V. Fonseca[1], H. Manso[1,2], T. Krug[1], B. Nunes[2], I. Albergaria[2], G. Gaspar[2], L. Gouveia[3], I. Matos[4], M.V. Baptista[5], G. Lopes[6], R. Taipa[6], J.P. Gabriel[7], M.R. Silva[8], C. Dias[2], F. Gonçalves[9], M. Correia[6], J.M. Ferro[3], S.A. Oliveira[1], A.M. Vicente[1,2]*
1) Inst. Gulbenkian de Ciencia, Portugal; 2) Inst. Nacional Saúde Dr. Ricardo Jorge, Portugal; 3) H. Sta. Maria, Portugal; 4) H. Distrital Mirandela, Portugal; 5) H. Garcia de Orta, Portugal; 6) H. Geral Sto. António, Portugal; 7) H.S. Pedro, Portugal; 8) H. Fernando Fonseca, Portugal; 9) H.Universidade Coimbra, Portugal.

Growth factors like basic fibroblast growth factor (FGF2) and vascular endothelial growth factor (VEGF) are key regulators of neuronal regeneration and proliferation previously implicated in stroke pathophysiology and functional outcome. FGF2 is known to protect against ischemic injury in rat brain, while improving sensorimotor function and reducing infarct size after focal ischemia. VEGF is a secreted mitogen associated with angiogenesis enhancement in the ischemic brain and with reduced neurological deficits during stroke recovery. We therefore evaluated the role of the genes encoding FGF2 and VEGF in stroke susceptibility and recovery. We tested 14 tag SNPs in the FGF2 gene and 8 tag SNPs in the VEGF gene for association with stroke risk in a population of 533 stroke patients and 507 unrelated controls. A weak association of one FGF2 SNP (rs1960669: 2=4.342, 2df, P=.037) with stroke susceptibility was found. One specific haplotype was associated with increased stroke risk (rs6899540-rs6900017-rs6905288, 2=7.564, P=.006). Two VEGF SNPs were associated with stroke risk (rs3025010, 2=8.139, 2df, P=.017; rs3025033, 2=6.916, 2df, P=.032). Haplotype analysis further showed an association of one specific haplotype with stroke protection (rs11938826-rs308441-rs308442, 2=4.625, P=.0315). The impact of these genes in functional outcome was tested in 403 stroke patients, assessed 3 months after a stroke episode using the modified Rankin Scale, but no evidence for association was found for any of the tested markers. Overall these results indicate that FGF2 and VEGF are not major stroke risk factors and do not contribute to variation in stroke recovery in this population.

Translation of *SOX10* 3 untranslated region causes a complex severe neurocristopathy by generation of a deleterious functional domain. *K. Inoue[1], T. Ohyama[2], Y. Sakuragi[1], Y. Lihua[1], R. Yamamoto[1], Y. Goto[1], M. Wegner[3], J.R. Lupski[2]* 1) Dept MR & BD Res, Natl Inst Neurosci, NCNP, Tokyo, Japan; 2) Dept Mol Hum Genet, Baylor Coll Med, Houston, TX; 3) Institut für Biochemie, Emil-Fischer-Zentrum, Universität Erlangen, Erlangen, Germany.

Peripheral demyelinating neuropathy, central dysmyelinating leukodystrophy, Waardenburg syndrome and Hirschsprung disease (PCWH) is a complex neurocristopathy caused by *SOX10* mutations. Most PCWH-associated *SOX10* mutations result in premature termination codons (PTCs), for which the molecular mechanism has recently been delineated. However the first mutation reported to cause PCWH was not a PTC. It was a disruption of the native stop codon that by conceptual translation extends the protein into the 3 untranslated region (3UTR) for an additional 82 residues. Molecular pathoetiology for this extension mutation remains largely unknown. In this study, we sought to determine the functional properties of the SOX10 extension mutation using in vitro functional assays. Despite the wild type SOX10 coding sequence remaining intact, the extension mutation led to severely diminished transcription and DNA binding activities. Nevertheless, it showed no dominant-negative interference with wild type SOX10. Within the 82-amino acid tail, an 11 amino acid region (termed the WR domain) was responsible primarily for the deleterious properties of the extension. The WR domain, presumably forming an a-helix structure, dramatically inhibited SOX10 transcription activities from different positions within the SOX10 protein. The WR domain can also affect the other transcription factors in cis with graded effect, suggesting that it probably elicits a toxic functional activity by itself. Together, molecular pathology for the SOX10 extension mutation is distinct from that of more common PTC mutations. Failure to properly terminate SOX10 translation causes the generation of a deleterious functional domain within the 3UTR that causes a severe neurological disease.

ARC syndrome in three male siblings with classic and new findings. *K. Goodin[1], P. Gissen[7], A.S. Knisely[8], N. Ambalavanan[2], A. Theos[4], D. Kelly[5,6], S.L. Rutledge[1,2,3]* 1) Genetics, University of Alabama at Birmingham, Birmingham, AL; 2) Pediatrics, University of Alabama at Birmingham, Birmingham, AL; 3) Neurology, University of Alabama at Birmingham, Birmingham, AL; 4) Dermatology, University of Alabama at Birmingham, Birmingham, AL; 5) Pathology, University of Alabama at Birmingham, Birmingham, AL; 6) Department of Pathology and Laboratory Services, The Children's Hospital of Alabama, Birmingham, AL; 7) Section of Medical and Molecular Genetics, University of Birmingham, Birmingham, UK; 8) Institute of Liver Studies, King's College Hospital, London, UK.

Arthrogryposis-Renal tubular dysfunction-Cholestasis (ARC) syndrome presents with the findings noted in the syndrome title. ARC is also associated with failure to thrive, recurrent infections, and ichthyosis. Dysmorphic features include low set ears, sloping forehead, and hirsutism. ARC is an autosomal recessive disorder associated with germline *VPS33B* mutations which may alter vesicular transport. We report three Guatemalan male siblings who presented in the neonatal period with cholestatic jaundice, failure to thrive, recurrent infections, and dysmorphic features previously associated with ARC. The second child had ichthyosis on skin biopsy. In addition, the children had wide-spaced nipples and elevated cerebrospinal fluid (CSF) protein levels; neither feature has so far been reported in ARC. CSF protein concentrations were prominently elevated, (~200-600 [mg/dL, expected 15-45 mg/dL]). The first two infants died before definitive diagnosis. The third child was homozygous for a *VPS33B* mutation previously associated with ARC. Liver biopsy demonstrated findings associated with ARC and consistent with abnormal intracellular protein transport. Due to the clinical similarity, it is presumed that all three siblings had ARC. Our observations further support the association of ARC with findings previously reported. They also identify a novel association of ARC syndrome with wide-spaced nipples and elevated CSF protein levels; the latter could be secondary to a protein trafficking defect in neural tissues. These observations require confirmation in a larger set of patients.

Early interstitial lung disease in familial pulmonary fibrosis. *B.R. Gochuico[1,6], P. Ren[1], N.A. Avila[2], C.K. Chow[2], T.J. Franks[3], W.D. Travis[3], J.P. McCoy, Jr.[4], R.M. May[1], H.P. Wu[1], D.M. Nguyen[5], M. Arcos-Burgos[6], S.D. MacDonald[1], I.O. Rosas[1]* 1) Pulmonary-Critical Care Medicine Branch, NHLBI, NIH, Bethesda, MD; 2) Diagnostic Radiology Department, CC, NIH; 3) Department of Pulmonary and Mediastinal Pathology, AFIP, Washington, DC; 4) Flow Cytometry Core Facility, NHLBI, NIH; 5) Surgery Branch, NCI, NIH; 6) Medical Genetics Branch, NHGRI, NIH.

Purpose: Familial pulmonary fibrosis (FPF) is a rare, autosomal dominant disease with variable penetrance. Identification of early, asymptomatic interstitial lung disease (ILD) in populations at risk of developing FPF may improve the understanding of the natural history of idiopathic pulmonary fibrosis (IPF), a progressive ILD of unknown etiology with a poor prognosis. Methods: To characterize features of early, asymptomatic ILD in family members of patients with FPF, 164 subjects from 18 kindreds affected with FPF were evaluated for ILD at the NIH Clinical Center. Bronchoalveolar lavage (BAL) cells were analyzed using flow cytometry. Lung biopsies were performed in six subjects with early ILD. Results: High-resolution computed tomography (HRCT) findings of early ILD were identified in 31 (22%) of 143 asymptomatic subjects. Subjects with early ILD were significantly younger than subjects with known FPF ($p<0.001$) and significantly older than related control subjects without lung disease ($p<0.001$). A history of smoking was identified in 45% of subjects with early ILD and in 67% of subjects with FPF; these percentages were significantly higher than that of related control subjects (23%) ($p=0.02$ and $p<0.001$, respectively). Percentages of activated CD4+ lymphocytes were significantly higher in BAL cells from subjects with early ILD compared to related control subjects ($p<0.001$). Lung biopsies performed in subjects with early ILD revealed various histologic subtypes. Conclusions: Early, asymptomatic ILD in individuals at risk of developing FPF can be identified using HRCT scan of the chest, especially in active or former smokers. In this cohort with early lung disease, CD4+ BAL cells are activated, and lung biopsies demonstrate different histologic subtypes of ILD.

Cloning of chromosome 3 inversion breakpoints in a 3-generation family with short stature reveal multiple repetitive elements. *U. Dutta, F. Matthes, I. Hansmann, D. Schlote* Inst Human Gen & Med Biol, Halle/Saale, Germany.

Chromosomal rearrangements are often associated with a specific phenotype and they are a significant cause of human disorders. Mapping of breakpoints is a powerful tool for identification of such disease genes. Here we report a case of short stature in a girl with a karyotype of 46, XX,inv(3)(p24.1q26.1). Cytogenetic analysis had revealed a familial pericentric inversion 3, being heterozygous in the proband, her mother and grand mother, both of them also with short stature. In order to characterize the breakpoint physically, FISH analysis with large YAC and BAC clones were performed. Four p specific YACs and six BAC clones were used as probes for FISH. YAC clone CEPHy904H0787 (1090 kb) gave a split signal on the metaphase chromosomes of the proband. The split signal indicates that the target sequence carries the inversion breakpoint. Two BAC clones RP11666G20 and CTD2007B5 were identified spanning the breakpoint region, assigning the breakpoint to 3p24.1 and thus narrowed down the breakpoint region to 97.5 kb. Out of the 15 YACs and 10 BACs selected on the q arm, YAC CEPHy904G07889 (1610 kb) and BAC clone RP11-12N13 showed a split signal assigning the breakpoint to chromosomal band 3q26.1. Using sub cloned fragments of these BACs as well as Long range PCR products as probes the breakpoints were now located within a region of 3 kb and 5.3 kb on p and q respectively. Analysis of the genomic sequence surrounding the inversion breakpoints revealed 30% repetitive nature of the DNA containing LTR33A, MER67C, L2 and MER67D elements on p region and LTR16C, MER20, MLT2B1, LTR1B ,simple repeats and low copy repeats on q region. We determine that the breakpoints occurred between these repetitive regions. The presence of these repetitive elements, especially MER and LTR elements at the junction of the breakpoints suggest that the inversion may be the result of these repetitive elements. Our findings will help to provide a better understanding of the molecular mechanism underlining the spontaneous chromosome rearrangements in the human genome.

Effect of chloroquine on human lymphocytes, *in vitro*: Micronucleus assay. *I.P. Aranha[1], C.L.R. Chagas[1], I.C.D. Silva[2], M.Q. Monteiro[2], E.C.M. Passos[2]* 1) Inst. de Biologia, Univ. do Estado do Rio de Janeiro, Rio de Janeiro, Brazil; 2) Fac. de Ciências Médicas, Univ. do Estado do Rio de Janeiro, Rio de Janeiro, Brazil.

Chloroquine was initially used for the treatment of malaria but due to its antiinflamatory characteristics, it has also been successfully used in the treatment of reumathoid arthritis, of cutaneous porphyria and of lupus erithematosus. In this work, the micronucleus assay in human lymphocytes was used to observe the effect of chloroquine on these cells. Micronuclei appear during cell division as a result of acentric chromosome fragments or whole chromosome, outside the nucleus. Peripheral whole blood cells were collected from healthy donors 18 to 30 years old. Cells were incubated at 37^{o}C for 72 hours in enriched RPMI 1640 medium in the presence of chloroquine (15ng/ml). Cells not exposed to the drug served as control for the experiment. Lymphocytes were exposed to cytochalasin B (4g/ml) 44 h postinitiation. Following fixation, cells were stained with Gurr's Giemsa (2%) and were analyzed under the optical microscope. In the test group, from 11742 binucleated cells observed, 57 micronuclei were found while in the control group from 11001 cells analyzed, 4 micronuclei were observed. The chi-square test with Yates correction showed that our results were extremely significant (p0.0001) indicating an association of chloroquine and the occurrence of micronuclei.

Body mass index (BMI) and height velocity by age and gender in children with achondroplasia. *J.E. Hoover-Fong[1], K.J. Schulze[2], J. McGready[2], C.I. Scott[3]* 1) Inst Genetic Medicine, Johns Hopkins Univ, Baltimore, MD; 2) Bloomberg School of Public Health, Johns Hopkins Univ, Baltimore, MD; 3) AI DuPont Hospital for Children, Wilmington, DE.

OBJECTIVE: To examine BMI in relation to indices of height (e.g. body segments, height velocity) and develop age-appropriate BMI charts for clinical use in children with achondroplasia. METHODS: An anthropometry database was created from single observer data extracted from clinical records of 334 individuals with achondroplasia. BMI (weight, kg/height, m2) percentiles (5, 50, 95th) were estimated from birth to 16 years of age by gender, using a one month window (+ 0.5 months) around each time point and smoothed by a quadratic smoothing algorithm. Growth velocity (cm/year) was calculated at the mid-point between every two consecutive height values if the interval was 2-18 months. Upper and lower segment ratios were also examined by age. RESULTS: Data from 241 and 236 subjects contributed 1935 BMI and 1846 height velocity datapoints, respectively. A BMI peak in infancy and nadir in childhood is not observed in achondroplasia as in average stature children. From 2-6 years of age, the entire achondroplasia BMI distribution (5th-95th percentile) is above the 95th percentile of average-stature peers. Thereafter to 16 years, the lower half of the achondroplasia BMI distribution overlaps the upper half of the average stature BMI distribution. Although birth length is comparable between achondroplasia and average stature, peak height velocity during infancy in achondroplasia is nearly half that of average stature infants. There is also no evidence of a pubertal growth spurt in achondroplasia. Upper segment measurements, but not lower, were associated with BMI ($p=0.05$) by regression analysis. CONCLUSIONS: BMI-for-age is higher in children with achondroplasia than average stature peers, necessitating specific BMI curves for clinical use in this population. In achondroplasia, overall height is compromised due to limb shortening, therefore body mass is centered about the trunk. Health consequences associated with BMI have yet to be determined in this population.

Direct testing of untyped SNPs using multimarker tags. *S. Griffiths, F. Dudbridge* MRC Biostatistics Unit, Cambridge, United Kingdom.

In association studies it is generally too expensive to genotype all variants in all subjects. We can exploit linkage disequilibrium between SNPs to select a subset that captures the variation in a training data set obtained either through direct resequencing or a public resource such as the HapMap. These tag SNPs are then genotyped in the whole sample. Multimarker tagging is a more aggressive adaptation of pairwise tagging that allows for combinations of tag SNPs to predict an untyped SNP. Here we describe a new method for directly testing the association of an untyped SNP using a multimarker tag.

Previously, other investigators have suggested testing a specific tag haplotype, or performing a weighted analysis using weights derived from the training data. However these approaches do not properly account for the imperfect correlation between the tag haplotype and the untyped SNP. Here we describe a straightforward approach to testing untyped SNPs using a missing-data likelihood analysis, including the tag markers as nuisance parameters. The training data is stacked on top of the main body of genotype data so there is information on how the tag markers predict the genotype of the untyped SNP. The uncertainty in this prediction is automatically taken into account in the likelihood analysis.

We compare our approach with testing specific tag haplotypes and separately with WHAP, a method described recently by Zaitlen et al. We show that our approach yields more power than single haplotype imputation and similar power to WHAP, yet it has the advantages that it takes into account training set phenotypes and we may obtain an estimate of the odds ratio.

.

VEGF polymorphisms associate with Kawasaki Disease: replication of a susceptibility locus for pediatric coronary vasculitis. *W. Breunis[1], S. Davila[2], V. Wright[3], M. Hibberd[2], M. Levin[3], J. Burns and the US KD Genetic consortium[4], D. Burgner[5], T. Kuijpers[1]* 1) Emma Children's Hospital, Netherlands; 2) Genome Institute of Singapore, Sinagapore; 3) Imperial College London, England; 4) UCSD School of Medicine, USA; 5) School of Paediatrics and Child Health, Australia.

Background: Kawasaki Disease (KD) is an acute systemic vasculitis that occurs in young children. Based on clinical and epidemiologic parameters an infectious cause is assumed, however the etiology still remains unknown. A genetic influence is suggested by differences in annual incidence between different ethnicities. **Objective**: In a previous study we have shown that the *VEGF* haplotype CGCC (based on rs699947, rs2010963, rs25648 and rs3025039) was significantly associated with the development of KD (hap score 3.8; p = 0.0002) in a Dutch Caucasian KD cohort of 170 patients and 300 controls. To test this association we conducted a large family-based association study. **Methods**: 14 SNPs in the *VEGF* gene, selected as tagging SNPs to cover common genetic variants, were analyzed as a part of a larger Illumina GoldenGate assay investigating 1,903 members of 583 KD families, including 498 trios, from Australia, UK and US. Genotyping of the families was performed with a Beadstation 500G Genotyping system and genotypes were analyzed with Beadstudio software from Illumina. Allelic association was tested using PBAT. **Results**: Of the 14 analyzed SNPs in the *VEGF* gene 3 SNPs were associated with susceptibility for KD (rs833068, rs3025033 and rs3025039). The SNP C>T at position 236 bp 3' of STP (rs3025039) was seen with a frequency of 14% in the parents which is similar to the frequency in our Dutch control population in our previous study. Asymmetric transmission was observed from heterozygous parents to their affected offspring (p = 0.005, transmitted : untransmitted ratio 141:98). **Conclusion**: Our results confirm our previously observed association of KD susceptibility and polymorphisms in the *VEGF* gene in an independent cohort of KD patients. As VEGF is a multifunctional cytokine the exact role of VEGF remains unclear and further functional studies are warranted.

Introduction of QF-PCR as a rapid aneuploidy screen for all women undergoing amniocentesis: A pilot project.

D. Allingham-Hawkins[1], E. Winsor[2], D. Chitayat[2], V. Cirigliano[3], A. Summers[1], K. Chun[1] 1) Genetics Program, North York General Hosp, Toronto, ON, Canada; 2) Mount Sinai Hosp, Toronto, ON, Canada; 3) General Lab, Barcelona, Spain.

Aneuploidies of chromosomes 13, 18, 21, X and Y are the most common abnormalities detected in prenatal specimens, representing ~70% of all chromosome abnormalities detected and ~77% of unbalanced abnormalities. Given that conventional chromosome analysis typically takes 10-14 days due to the need for cell culture, it is desirable to have a rapid, cost effective method of ruling out these common abnormalities thereby reducing patient anxiety. Quantitative fluorescent PCR (QF-PCR) uses multiple short tandem repeats (STRs) on each of the chromosomes of interest analysed on an automated DNA sequencer to detect numerical changes. To investigate the feasibility of introducing QF-PCR as a routine rapid aneuploidy screen, we are conducting a pilot study comprised of 200 blind validation specimens followed by 1000 prospective amniotic fluid specimens from two large prenatal diagnostic centres in Toronto, Canada. The Aneufast^{TM} (Genomed, UK) kit is being used for all analyses. This kit uses two initial multiplex reactions with 4 STRs on each of chromosmes 13, 18 and 21, two polymorphic X/Y markers and HPRT, SRY and amelogenin for sexing. Reflex reactions with additional markers are available for each chromosome to confirm abnormals or clarify ambiguous results. Among the validation specimens, 194/195 were identified correctly while 5 (failure rate = 2.5%) failed to amplify. The one incorrect result was a XX/XO mosaic interpreted as a normal female. The first 644 study specimens have shown a positive predictive value of 100% (27/27 predicted to be abnormal were true positives) and a negative predictive value of 99.8% (607/608 predicted to be negative for aneuploidy were true negatives). One XX/XXX specimen was interpreted as normal. The failure rate was 1.4%. The other major outcome measure being studied is the turnaround time in hours from receipt of the specimen and issuing of the report. The results for all 1000 specimens will be presented and next steps in delivery of this service discussed.

Mitotic reduction divisions in adult murine hepatocytes. *A.W. Duncan[1], N.K. Paulk[1], M.J. Finegold[2], M. Grompe[1]*
1) Oregon Stem Cell Center, Oregon Health and Science University, Portland, OR; 2) Texas Children's Hospital, Dept. of Pathology, Houston, TX.

Hepatocytes are unique among cell types as they are frequently polyploid. We propose that hepatocyte polyploidization is a dynamic and reversible process that promotes liver adaptation. We previously showed that mouse hepatocytes derived by cell fusion of transplanted bone marrow cells may proliferate and restore normal liver function in an animal model of metabolic liver disease, the fumarylacetoacetate hydrolase (*Fah*) knockout mouse. Chromosomal analysis revealed the presence of fusion-derived hepatocytes containing half of the expected DNA content. We hypothesized that a fraction of fusion-derived hepatocytes underwent a mitotic reduction division, yielding daughter cells with half the chromosomes of parental cells.

To determine whether mitotic reduction divisions play a role in normal liver regeneration, transplantation studies were performed. Highly pure FACS-sorted octaploid hepatocytes from wild-type mice were transplanted into congenic *Fah* knockout mice. Livers from transplanted animals showed extensive repopulation. Consistent with the idea that polyploid hepatocytes undergo reduction division during regeneration, immunohistochemical analysis of donor-derived nodules revealed the loss of one or more donor markers. Moreover, FACS and cytogenetic analysis of repopulated livers revealed donor-derived diploid, tetraploid and octaploid hepatocytes. Together these data showed that octaploid hepatocytes give rise to diploid cells during liver regeneration, demonstrating that hepatocyte polyploidization is reversible by mitotic reduction divisions. During reduction divisions independent markers segregate randomly, and we therefore propose that such divisions promote adaptation to hepatotoxic stress. The independent segregation of chromosomes from polyploid cells results in genetically heterogeneous diploid daughter hepatocytes. Daughter cells may inherit a selective advantage, yielding either a subset of normal cells more resistant to hepatotoxins or transformed hepatocytes with tumorigenic properties.

Genomic Initiative at the Javeriana University: Human genetics and biological diversity, the necessity of Metagenomics. *J. Bernal, F. Suarez, A. Ordoñez, I. Zarante* Inst Genetica Humana, Univ Javeriana, Bogota, Colombia.

The Colombian Genomics Platform project integrates the strengths of six Colombian well-known research groups with experience in Environmental Metagenomics and Human Genomics of Mendelian and multifactorial diseases. Colombia is considered to be the second country in diversity in the planet. Its area, which is less than 1% of the planet, includes 10% of the world biological diversity of the world and 50% of the existing plants. Colombia is actually in a full process of epidemiological transition and the birth defects are becoming the principal cause of mortality in early childhood, at the same time multifactorial diseases like cancer or cardiovascular diseases are increasing its prevalence. Objectives: To establish a Genomic platform in Colombia in order to promote and make easier the development of projects in different research groups that aim to describe and use biodiversity and genetic resources of our country. To determine the interaction, between genes and environment, in the clinical and non-clinical aspects. To develop clear policies related to the use of genetic resources in legal and economic aspects and develop a group of bioethical aspects related to Metagenomics in a biodiverse country. Methods: integration of research groups under a unique genomics work platform under the direction of the Instituto de Genética Humana at the Pontificia Universidad Javeriana. Results: the different research projects of Human Genomics, e.g. SNPs Mapping: The codifying regions of the following genes will be sequenced and regulated: L1CAM for hydrocephaly, CRELD1, GATA4, ACVR2B, GJA1 and JAG1 for heart congenial malformations, MTR, y MTRR for neural tube disorders and IRF6 for cleft lip and palate; Environmental Genomics e.g. analysis of Metagenomics in a highly intensive shrimp farming system and characterize the bacterial populations by means of 16S rRNA analysis, bioinformatics and bioethics are further described and discussed.

SIX1 Mutation Screening in 247 Branchio-Oto-Renal Syndrome Families: A Recurrent Missense Mutation Associated With BOR. *A. Kochhar[1, 2], D.J. Orten[3], J.L. Sorensen[2], S.M. Fischer[2], C.W.R.J. Cremers[4], W.J. Kimberling[3], R.J.H. Smith[2]* 1) Doris Duke Charitable Foundation; 2) Department of Otolaryngology, Head and Neck Surgery, University of Iowa, Iowa City, IA; 3) Department of Genetics, Boys Town National Research Hospital, Omaha, NE; 4) Department of Otorhinolaryngology, University Hospital Nijmegen, Nijmegen, The Netherlands.

Branchio-oto-renal syndrome (BOR; MIM# 113650) is a clinically heterogeneous autosomal dominant form of syndromic hearing loss characterized by variable hearing impairment, malformations of the pinnae, the presence of branchial arch remnants, and various renal abnormalities. Both *EYA1* and *SIX1* are expressed in developing otic, branchial and renal tissue. Consistent with this expression pattern, mutations in both genes cause BOR syndrome. Mutations in *EYA1* are found in approximately 40% of patients with the BOR phenotype, however, the role of *SIX1* is much lower. To date only three different *SIX1* mutations have been described in BOR patients. The current screen of 247 BOR families detected five novel *SIX1* mutations (c.50T>A, c.218A>C, c.317T>G, c.329G>A, c.334C>T) and one previously reported mutation (c.328C>T), all of which are within the protein-binding Six domain. Phenotypic variability was high in these BOR families. Seven of the eight known *SIX1* mutations are missense and the one in frame deletion is predicted to be functionally similar. The wide phenotypic variability precludes making genotype-phenotype correlations at this time.

Candidate regions for susceptibility genes linked to synaesthesia: results of a whole-genome scan. *J.E. Asher[1, 2], J.A. Lamb[3], S. Baron-Cohen[2], D. Brocklebank[1], E. Maestrini[4], L. Addis[1], M. Sen[1], P. Bolton[5], S. Rahman[6], H. Waine[2], A.P. Monaco[1]* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK; 2) Department of Psychiatry, University of Cambridge, Cambridge, UK; 3) Centre for Integrated Genomic Medical Research, University of Manchester, Manchester, UK; 4) Dipartimento di Biologia, Universita di Bologna, Bologna, Italy; 5) Department of Child and Adolescent Psychiatry, Institute of Psychiatry, London, UK; 6) Institute of Neurology, University College London, London, UK.

Synaesthesia is a neurodevelopmental condition affecting 0.05 - 1% of the population in which a stimulus in one sensory modality triggers an automatic, consistent response in another modality (e.g. sound triggers the perception of colour) or a different facet of the same modality (e.g. black text triggers the perception of colour). Previous familiality studies indicate a strong genetic component and several pedigree analyses support a single-gene X-linked dominant mode of inheritance. Here we report the results of the first genome scan for susceptibility genes linked to synaesthesia. A whole-genome linkage scan using 410 microsatellite markers (mean inter-marker distance = 9.05cM) was performed in 43 families (n = 196). NPL analysis using Merlin 1.1a detected 14 potential candidate regions on 11 chromosomes with LOD scores > 1. Fine-mapping with additional microsatellites (mean inter-marker distance = 5.00cM) provided additional evidence for 12 candidate regions on 10 chromosomes, with 4 regions showing LOD scores > 2 and 2 regions showing LOD scores > 2.3 (maximum LOD = 2.37, p = 0.0005). We are performing a family-based analysis to investigate the presence of locus heterogeneity. Preliminary results from an HLOD analysis using Merlin indicate strong evidence for linkage to chromosome 2. No support was found for linkage to the X-chromosome; in addition, we have identified the first confirmed cases of male-to-male transmission of synaesthesia. Together with existing data, these results indicate that synaesthesia is most likely a complex disorder with substantial locus heterogeneity.

Choosing relatives for missing person identification by DNA typing. *J. Ge[1,2], R. Chakraborty[1]* 1) Dept Biomed Eng, Univ Cincinnati, Cincinnati, OH; 2) Ctr Genome Information, Dept Environmental Hlth, Univ Cincinnati, Cincinnati, OH.

Over the past two decades use of DNA forensics in criminal and civil investigations established it as a reliable tool for personal identification. Concerns have recently shifted on developing an infrastructure of DNA-based identification of war victims in mass graves, missing soldiers or military personnel from past wars, missing person from mass disasters caused natural catastrophes or terrorism acts, etc. When direct reference samples (i.e., antemortem samples) from missing individuals are not available, identifications are based on ranking of likelihood ratios constructed from comparison of DNA profiles of remains of presumed missing person with reference sample of family members, one or multiple of them at a time. A novel method based on the classical Elston-Stewart algorithm is developed for personal identification with autosomal markers. This method jointly considers DNA profiles from all available family members and missing persons are identified by ranking the pedigree likelihood ratios with alternative hypotheses (e.g., the missing person is unrelated to the family members of the pedigree) for all putative pedigrees. In general, the more relatives are typed, the better precision is obtained in identification. However, to reduce cost and increase efficiency, it is more economical to sample and type the most informative relatives. To determine which and how many relatives should be typed, we selected the most informative relatives (e.g. parent, child, full sib, etc.), and ranked the information content of different combinations of relatives (e.g. both parents, two children, two full sibs, etc.) to make recommendations on the type and number of relatives for identification. Simulation study shows that, with single reference sample, informativeness of relationship increase with coefficient of kinship; but single second-degree relative reference sample (e.g. half sib and grandchild) is not reliable for identification. If two reference samples were to be chosen, with both parents typed the likelihood ratio generally ranks the highest. References with at least one parent or child typed are recommended. (Research supported by grant NIH-GM-41399 (to RC).

An E3 Ubiquitin Ligase, Rnf41, is associated with anxiety-like behavior, major depression, and b-carboline-induced seizure. *H.K. Gershenfeld[1], S. Kim[1], S. Zhang[2], K. Choi[3], R.L. Reister[1], A.F. Baykiz[4]* 1) Dept. of Psychiatry and Integrative Biology, UT Southwestern, Dallas, Tx; 2) Dept. of Psychiatry, Univ. of Conn., Farmington CT; 3) Stanley Laboratory of Brain Research, Rockville, MD; 4) Elazyg Asker Hastanesi Psikiyatri Klinigi, 23300 Elazig, Turkey.

Using an unbiased genetic approach, Quantitative Trait Loci (QTL) influencing anxiety-like behaviors and b-carboline-induced seizure have been mapped to the distal portion of mouse chromosome 10. An interval specific congenic mouse line containing the telomeric region of the C57BL6/J chromosome 10 on the A/J background narrowed down the chromosomal region of interest (66 cM to telomere), defined the behavioral influences of this region, and permitted gene expression profiling to identify a candidate gene. Ring Finger 41, (Rnf41 / Neuregulin Degrading Protein; Nrdp), an E3 Ubiquitin Ligase, was the only gene differentially expressed comparing the hippocampi of A/J vs C10 congenic mice as well as A/J vs B6 mice by microarray studies. RNF41 expression levels were significantly reduced in the hippocampi of A/J mice compared to C57BL6/J and the congenic mice. In addition, expression levels of Rnf41 mRNA and proteins were reduced in A/J mice compared to B6 mice across postnatal development. Rnf41 hippocampal mRNA expression levels were significantly correlated with open field behavior in the LxS recombinant inbred panel of mice, providing an independent replication. As anxiety and depressive disorders share a genetic predisposition, RNF41 was a potential candidate gene for psychiatric illness. Using human, post-mortem prefrontal cortex (Brodmanns Area 46/10) tissue of patients and controls, RNF41 mRNA expression levels were reduced significantly in patients with major depression and bipolar disorder compared to unaffected controls. Overall, RNF41 is a pleiotropic candidate gene for anxiety-like behaviors and beta-carboline induced seizure response. This RNF41 E3 Ubiquitin ligase and its physiologic binding partners are discussed as potentially novel mechanisms for influencing behavior variation relevant to psychiatric illness.

Search for Genomic Alterations in Monozygotic Twins Discordant for Cleft lip and Palate. *J.W. Kimani[1], K. Yoshiura[2], J.C. Murray[1]* 1) Department of Pediatrics, University of Iowa, Iowa City, IA; 2) Department of Human Genetics, Nagasaki University Graduate School of Biomedical sciences, Nagasaki, Japan.

Postzygotically occurring genomic alterations that result from mitotic recombination and other somatic events have been proposed to underlie monozygotic (MZ) twin discordance. We scanned for such alterations in a cohort of MZ twins discordant for isolated cleft lip and/or palate (CLP) with the aim of detecting any chromosomal abnormalities that can reveal candidate genes within altered genomic fragments. Our analyses consisted of an array comparative genomic hybridization (aCGH) target containing 2,173 genomic BAC clones (n=6 pairs), an Illumina custom genotyping array covering 1,536 SNPs derived from 350 candidate genes (n=20 pairs) and the Affymetrix GeneChip Human Mapping 50K Xba I (n=2 pairs) and the 250K Nsp I (n=10 pairs) arrays. The aCGH provided an average resolution of 1 BAC clone every 1Mb, but no copy number changes were detected. Average twin genotype concordance for both Illumina and Affymetrix assays was >99%, and paired analyses were carried out for both platforms using the Beadstudio software and the Copy Number Analysis Tool respectively. However, we did not detect any allelic imbalances through loss of heterozygosity or copy number changes within the resolution of the respective assays. Sequencing of a subset of SNPs with discordant genotype calls in both twins and the parents verified genotype concordance and showed consistency with Mendelian inheritance. Our results demonstrate that postzygotic genomic alterations are not a probable cause of MZ twin discordance for isolated CLP. However, balanced genomic alterations, tissue-specific events and small aberrations beyond the detection level of our experimental approach cannot be ruled out.

Polymorphism in the CYSLTR1 gene is associated with asthma in a Chinese population. *X. Hong[1], H. Zhou[2], H.J. Tsai[3], X. Xu[2], X. Wang[3], X. Xu[1]* 1) Center for Population Genetics, School of Public Health, University of Illinois at Chicago, chicago, IL; 2) Program for Population Genetics, Harvard School of Public Health, Boston, MA; 3) Mary Ann and J. Milburn Smith Child Health Research Program, Childrens Memorial Hospital and Children's Memorial Research Center; Department of Pediatrics, Feinberg School of Medicine, Northwestern University, Chicago, IL.

Asthma is a heterogeneous respiratory disease characterized by chronic inflammation of the airways, reversible brochoconstriction, airway hyperreactivity, eosinophilia, and musus hypertecretion. We conducted a genetic study among 174 asthmatic cases and 347 matched controls using a candidate-gene association approach in a Chinese population. A total of 129 SNPs of 113 asthma-related candidate genes, which are either located in the coding regions or in the exon-intron junction regions, were genotyped using Sequenom MassArray technology. A significant association was found between SNP rs320995 in the CYSLTR1 gene and physician-diagnosed asthma after adjusting age, age squared, height, height squared, weight, smoking status and gender. Under the recessive model, subjects with GG genotype in SNP rs320995 had 2.8 times higher risk of developing asthma than those with AA or AG genotype (OR=2.8; 95% CI=1.7-4.6; p = 0.00007). We also observed significant associations of SNP rs320995 with baseline FEV1/FVC (p =0.00001), and eosinophil counts (p = 0.00002). Of note, all the associations remained statistically significant after Bonferroni correction for multiple tests. Since this SNP is located on X chromosome, we performed association tests stratified by gender. But no gender effect was found on the association between rs320995 and asthma-related phenotypes. The CYSLTR1 receptor, when activated by cysteinyl leukotrienes, can mediate proliferation and contraction of smooth muscle and eosinophil migration to the lung. Our results provided strong evidence that genetic predisposition of rs320995 in the CYSLTR1 gene may play a role in the development of asthma. Further replication in an independent population is needed to validate these results.

Are we missing low level chromosomal mosaicism? Mosaic Trisomy 9 identified via Comparative Genomic Hybridization. *K.A. Chapman[1], D.M. McDonald-McGinn[1], R. Jethva[1], L. Campbell[1], M. Falk[1], S. Spinner[1], L. Shaffer[2], E.H. Zackai[1]* 1) Clinical Genetics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Signature Genomic Laboratories, LLC, Spokane, WA.

Standard cytogenetic studies routinely include a 20 cell count which excludes 14% mosaicism with 95% confidence. We report three patients with mosaic trisomy 9 identified using commercially available comparative genome hybridization (CGH) and confirmed by interphase FISH following normal chromosomal analysis. All three patients have features consistent with mosaic trisomy 9: Patient 1 presented at 2 months of age with upslanting palpebral fissures, overfolded helices, a cleft palate, micrognathia and significant failure to thrive; Patient 2 was evaluated at birth with overfolded helices, micrognathia and hydronephrosis and again at 14 months with failure to thrive, recurrent URIs and developmental delay; and Patient 3 was seen at 21-months of age due to recurrent URIs, dysphagia, kyphoscoliosis, low-set ears with overfolded helices and developmental delay. Standard karyotypes, counting 20 cells, were reportedly normal in all three patients. However, CGH identified mosaic trisomy 9, confirmed via interphase FISH in 13%, 18% and 8% of cells respectively. Subsequently, the original cytogenetic metaphase slides for patient 2 were re-reviewed and found to have 3/30 cells with trisomy 9 mosaicism therefore independently corroborating the CGH results. Thus, these findings suggest that we may in fact have been missing low-level cytogenetic mosaicism in metaphase cells and highlights the utility of CGH for identifying such abnormalities followed by confirmatory interphase FISH .

Living in a box: Three cosegregating genes as determinants of heart failure. *F. Friedrichs[1, 2], C. Zugck[2], G.-J. Rauch[2], B. Ivandic[2], D. Weichenhan[2], M. Mueller-Bardorff[3], N.E. El Mokhtari[4], V. Regitz-Zagrosek[5], R. Hetzer[5], A. Schaefer[4], S. Schreiber[4], J. Chen[6], I. Neuhaus[6], R. Ji[6], N.O. Siemers[6], N. Frey[2], W. Rottbauer[2], H. Katus[2], M. Stoll[1]* 1) Leibniz-Institute for Arteriosclerosis Research, Münster, Germany; 2) University Hospital Heidelberg, Heidelberg, Germany; 3) University Clinics Schleswig-Holstein Lübeck, Lübeck, Germany; 4) University Clinics Schleswig-Holstein Kiel, Kiel, Germany; 5) Deutsches Herzzentrum Berlin, Berlin, Germany; 6) Bristol-Myers Squibb Research and Development, USA.

The finding of multiple cosegregating susceptibility genes is considered a limitation for identification of the underlying disease gene. We performed a comprehensive linkage disequilibrium (LD) mapping study for human cardiomyopathy in three independent Caucasian study samples and show replicated association of a 600 kilobases LD block on 5q31.2-3 with heart failure. We analyzed evolutionary relationships of the haplotypes using a median joining network to identify SNPs representing groups of related haplotypes (e.g. a group of risk related haplotypes tagged by rs2569193; first sample: odds ratio (OR)=0.73, 95% CI=0.55-0.96, p=0.024; second sample: OR=0.81, 95% CI=0.66-0.99, p=0.039; third sample: OR=0.64, 95% CI=0.45-0.91, p=0.012). The associated cluster harbors several co-expressed genes and is conserved in syntenic blocks in other mammalian genomes. Estimates of Ka/Ks evolutionary characteristics comparing human, rodent, chicken, and frog are consistent with high functional conservation of the loci within the region. Synteny is largely intact in birds, detectable in amphibians, but not present in fish. To elucidate the individual contribution of the clustered genes the human genetic studies were complemented by functional studies using antisense oligonucleotide mediated knock-down in zebrafish. We show that three of the clustered genes, HBEGF, IK and SRA1, independently result in a myocardial phenotype of contractile dysfunction. We hypothesize that the emergence and conservation of LD in the genome reflects clusters of functionally cooperating genes that synergize to determine a complex trait.

Association of IGF2 gene mutation with Type 2 diabetes mellitus and Diabetic Nephropathy. *Q. Hasan[1,2,3], S. Movva[2], S. Saharia[2], Y.R. Ahuja[3]* 1) Department of Genetics and Molecular medicine, Kamineni Hospital, Hyderabad, Andhra Pradesh, India; 2) Department of Genetics, Bhagwan Mahavir Hospital and Research Centre, A.C.Guards, Hyderabad- 500004, India; 3) Department of Genetics, Vasavi Hospital and Research Centre, Lakdi ka-pool, Hyderabad-500004, India.

Numerous metabolic pathways and associated groups of genes have been proposed as candidates having a role in the genetic susceptibility to type 2 diabetes mellitus (DM) and its devastating complication diabetic nephropathy (DN). Products of a wide range of genes might mediate the onset of DM and the renal changes resulting in DN. IGF2 is a widely expressed peptide that is essential for normal development. It is a growth promoting polypeptide that shares a high degree of structural homology with insulin. IGF2 is synthesized primarily by the liver, but it is also produced locally by many tissues, where it acts in an autocrine or paracrine manner. It is a 67 amino acid neutral polypeptide and is the major IGF present in human plasma. Animal studies have suggested that activation of a number of growth factor systems, including the insulin-like growth factors, may be involved in the development of DN. However, to date there are no studies of this gene in relation to DM or DN. Hence a 100bp region in exon 7 was PCR amplified and screened by SSCP in 336 individuals, which included DN, DM and controls. 11 percent of DN cases and 5 percent of diabetics showed a mobility shift compared to none of the controls. Sequence analysis identified a novel mutation which causes a deletion of A at 827 bp position, resulting in a frame shift mutation, which affects the entire sequence and may be affecting the structure or the activity of IGF2. This newly identified mutation in the exon 7 of IGF2 gene could be associated with early onset of DM symptoms and early development of DN in diabetics, who carried this mutation. More studies in different ethnic groups and larger sample size are warranted with this IGF2 mutation to establish it's association with diabetes and its complications and also to establish it as a diagnostic or prognostic marker.

Towards a zebrafish model of Spinocerebellar Ataxia Type 1: Cloning of the zebrafish Ataxin-1 and Ataxin-1 Like Homologs. *K.M. Carlson[1], S.C. Ekker[2], H.Y. Zoghbi[3], H.T. Orr[1]* 1) Lab Medicine & Pathology; 2) Genetics, Cell Biology & Deveopment, Univ of Minnesota, Minneapolis, MN; 3) Mol & Human Genetics, Pediatrics, Howard Hughes Medical Institute Baylor Col of Medicine, Houston, TX.

Spinocerebellar Ataxia-Type 1 (SCA1) is an autosomal dominant neurodegenerative disease resulting in a glutamine repeat expansion in ataxin-1 (ATXN1). Recently, an ATXN1 paralog, Ataxin-1 Like (ATXN1L), was described and shown to play a role in mediating SCA1 pathology. To further characterize the function of the ATXN1 gene family in both Purkinje cell development and SCA1 pathology, we have initiated the steps towards developing a SCA1 zebrafish model. To begin, we cloned the zebrafish homologs of both proteins. ATXN1 and ATXN1L contain a highly conserved AXH domain that is involved in protein/protein interactions. A search of the zebrafish genome using the hATXN1 AXH domain identified three putative zebrafish AXH domains that are greater than 60% identical to hATXN1 (Chr. 7, 16 and 19). The chr.19 and 16 domains are most similar to ATXN1 (82% and 78% identical respectively) while the chr. 7 domain is most similar to ATXN1L (83% identical). Following further sequence analysis, we isolated RNA from 24-hour zebrafish embryos and used RT-PCR to clone the complete coding sequence of the three zebrafish ATXN1 genes. Protein conservation and whole genome sequence alignment suggest that there are two hATXN1 homologs on chr. 19 and 16 in the zebrafish genome (zATXN1 and zATXN1 respectively) and one hATXN1L homolog on chr. 7 (zATXN1L). Overall, zATXN1 and zATXN1 are 46% and 35% identical to hATXN1, while zATXN1L is 40% identical to hATXN1L. A closer look at the ATXN1 homologs show that although they do not include a polyglutamine tract, other key protein features involved in SCA1 pathogenesis, including a nuclear localization sequence and phosphorylation site at S776, are conserved. We are currently characterizing the expression pattern of the ATXN1 gene family in the developing zebrafish embryo. Our data suggests that the zebrafish will be a useful model system for studying the developmental role of ATXN1 as well as further studying ATXN1-induced pathogenesis.

Evaluation of the Klotho and GAS6 positional candidate genes on chromosome 13 for association with non-diabetic end-stage renal disease in African Americans. *M.A. Bostrom[1], P.J. Hicks[1], D.W. Bowden[1,2], B.I. Freedman[3]*
1) Department of Biochemistry, Wake Forest University, Winston-Salem, NC; 2) Center for Human Genomics,Wake Forest University, Winston-Salem, NC; 3) Department of Internal Medicine, Wake Forest University, Winston-Salem, NC.

African Americans have increased susceptibility to hypertensive (non-diabetic) end-stage renal disease (H-ESRD) compared to Caucasians and extensive evidence supports a genetic contribution. A genome-wide scan in African American families with H-ESRD revealed evidence for linkage in two regions on chromosome 13, 13q13.1 (LOD = 3.90) and 13q33.3 (LOD = 5.20). We evaluated 310 non-diabetic African Americans with H-ESRD and 353 African American healthy controls to investigate positional candidate genes in these regions. Using a case control design, we tested polymorphisms in the candidate genes: Growth Arrest Specific factor 6 (GAS 6) at 13q34 (a vitamin K-dependent growth potentiating factor upregulated in mice with glomerulonephritis) and Klotho on 13q13.3 (a type I membrane -glucuronidase-like protein highly expressed in the kidney and which has reduced mRNA expression in chronic renal failure). A total of 13 tagging SNPs in GAS6 were genotyped in the African American H-ESRD case control collection, 3 of which, (rs7333857, rs9577924, rs11842990), did not conform to Hardy Weinberg expectations. Genotypic association analyses demonstrated minor evidence for association at one SNP, rs11842990, ($p = 0.023$). Of the 24 tagging SNPs genotyped in the Klotho gene, one SNP (rs564481) did not conform to Hardy Weinberg expectations. Evidence for association was observed at 2 SNPs, rs564481 and rs650439, ($p = 0.0003$ and $p = 0.01$, respectively). The rs564481 SNP is located in an exon that is not translated in the truncated Klotho isoform b and further molecular genetic analysis is underway. These data suggest that at least one gene on chromosome 13 is associated with susceptibility to H-ESRD in African Americans.

Molecular pathology of deafness due to mutation in *PMP22*. *M.J. Kovach[1], V.E. Kimonis[2], T.A. Carver[1], B. Andrews[1]* 1) Biological & Environmental Sciences, University of Tennessee, Chattanooga, TN; 2) Division of Genetics and Metabolism, University of California Irvine Medical Center, Irvine, CA.

Charcot-Marie-Tooth disease (CMT) is an autosomal dominant disorder characterized by progressive peripheral neuropathy caused primarily by a duplication of the PMP22 gene. A clinical and genetic variant of CMT associated with profound and progressive sensorineural deafness was described in a large family from Illinois. Molecular analysis identified a unique point mutation in the gene instead of the common duplication. PMP22 is a member of the family of Growth arrest specific (Gas) genes, which have been shown to regulate gene expression, cell death and cell division. Although expression of PMP22 is highest in myelin-forming Schwann cells, the transcript is also detected in non-neural tissues, particularly at critical developmental time-points. Thus, PMP22 expression has been proposed to have two functions: a role in peripheral nerve myelination and a role in cell growth regulation in non-neural tissues. It is hypothesized that a similar dual expression of PMP22 is necessary for normal hearing.

The purpose of this study is to dissect the molecular pathology of deafness using the Trembler-J mouse as a model of PMP22-associated auditory dysfunction. Expression patterns of the murine PMP22 protein in the cochlear duct were evaluated in normal mice and mice with a mutant PMP22. Non-neural staining of PMP22 protein was observed primarily in the marginal and intermediary cells of the stria vascularis with weak, occasional localization of PMP22 protein in cells of spiral ligament and basilar membrane. A potential role for deafness genes expressed in the stria vascularis and spiral ligament may be in maintenance of the electrochemical potential through recycling of potassium ions. Concomitantly, differential display identified 74 transcripts differentially expressed relative to functional levels of PMP22, 85% of which are down-regulated in the Tr-J mouse. This study will provide insight to cellular functions and protein:protein interactions that involve PMP22 and help define the role of PMP22 in normal hearing.

***FMR4*: A Novel Primate-Specific Transcript Silenced in Fragile X Syndrome.** *A. Khalil, M. Faghihi, F. Modarresi, C. Wahlestedt* Biochemistry, The Scripps Research Institute, Jupiter, FL.

Fragile X syndrome (FXS) is the most common cause of inherited mental retardation. It is caused by a CGG expansion in the 5 UTR of *FMR1* which leads to the absence of the fragile X mental retardation protein (FMRP). However, *Fmr1* knockout and CGG repeat expansion knock-in mouse models for FXS did not fully recapitulate all of the phenotypes observed in human patients. Furthermore, longitudinal clinical observations of fragile X patients have shown that the severity of the cognitive, behavioral and morphological symptoms of FXS is highly variable. Therefore we postulated that there could be other genetic elements in addition to *FMR1* that could be responsible for the fragile X syndrome phenotype.

Using genomic approaches we discovered a new transcript upstream of *FMR1* which we refer to as *FMR4*. We found *FMR4*, similar to *FMR1*, to be silenced in fragile X patients and up-regulated in pre-mutation carriers in untransformed leukocytes. Northern blot analysis shows that *FMR4* is expressed in several human tissues including brain, liver, placenta, small intestine, colon and spleen. Knockdown of *FMR1* by several siRNAs did not affect *FMR4* and vice versa suggesting that *FMR4* is not a regulatory transcript for *FMR1*. Interestingly, however, the knockdown of *FMR4*, but not *FMR1*, is important for human cell viability *in vitro*; knockdown of *FMR4* resulted in cell cycle defects and apoptosis. These findings are potentially significant since: 1) like *FMR1*, the newly discovered *FMR4* transcript is silenced in fragile X patients and could therefore relate directly to fragile X syndrome symptomatology; 2) *FMR4* is a primate-specific transcript which could help explain the failure of animal models to fully recapitulate all of the human phenotypes in fragile X syndrome; and 3) our results also demonstrate a potential role for a non-coding RNA transcript in an inherited human disorder.

Genes showing accelerated evolutionary properties associate with communication abilities in humans. *K.J. Kelsey[1], J.B. Tomblin[2], J.B. Bjork[1], S.K. Iyengar[3], L.E. Sucheston[4], B.K. Samelson[1], J.C. Murray[1]* 1) Dept Pediatrics, The University of Iowa, Iowa City, IA; 2) Dept Speech Pathology and Audiology, U of Iowa, Iowa City, IA; 3) Dept Epidemiology and Biostatistics, Case Western Reserve, Cleveland, OH; 4) Dept Biostatistics, SUNY-Buffalo, Buffalo, NY.

Evolutionary acceleration is a property ascribed to complex human traits such as speech, language, and reading. We examined two positively selected regions, the gene ASPM and the human accelerated region (HAR) HAR1, for association with language. HARs are segments of the genome considered to have undergone strong, recent, positive selection, suitable for the detection of human-specific traits. HAR1 is a composite of two RNA genes, HAR1F and HAR1R, with HAR1F showing strong expression in the human developing neocortex. ASPM is a gene involved in the regulation of brain size, with mutants causing microcephaly. We conducted association studies of 581 second-grade children in nuclear families with a wide range of speaking and reading abilities. Five SNPs were genotyped in ASPM and seven around HAR1. Single SNP association was performed via linear regression, accounting for sibling and family effects by ASSOC in the S.A.G.E. software. Haplotype analyses were performed for the binary trait SLI using the Pedigree Disequilibrium Test (PDT) using Unphased. Single word reading showed the strongest single association with ASPM (rs107377686, p=.008). This SNP, along with rs6700180, are part of a significant two SNP haplotype (p=.03). Other traits that also showed association were: speech sound production proficiency, reading comprehension, and nonverbal IQ. For HAR1, multiple SNPs were associated with reading comprehension, nonverbal IQ, single word reading, speech sound proficiency, phonological awareness, reading decoding, and phonological memory. Of these, rs6011605 and rs6089838 showed the best signals (p=.008 for three measures). Combined into a two SNP haplotype, a significant association with spoken language was found (p=.00003). The association of ASPM and HAR1, two evolutionarily accelerated regions, with cognitive linguistic measures provides an impetus to additional studies of their roles in neurodevelopment.

Enzyme Replacement Therapy (ERT) in females with Fabry disease: an update from FOS - the Fabry Outcome Survey. *D.A. Hughes[1], M.A. Barba-Romero[2], P.B. Deegan[3], A. Linhart[4] on behalf of the FOS Research Group* 1) Royal Free and University College Medical School, London, UK; 2) Albacete University Hospital, Albacete, Spain; 3) Addenbrookes Hospital, Cambridge, UK; 4) Charles University, Prague, Czech Republic.

Fabry disease is an X-linked lysosomal storage disorder characterized by deficient activity of the enzyme -galactosidase A. Signs and symptoms of Fabry disease are observed in both hemizygous males and heterozygous females and include neuropathic pain, cardiac symptoms, disturbances in renal function and stroke. Data from FOS, an international database of patients with Fabry disease, were analyzed to examine the effect of long-term ERT in heterozygous females with Fabry disease. In March 2007, 1356 patients were registered with FOS, comprising 558 adult males, 572 adult females and 226 children. The mean age at FOS entry for adult females was 43.7 years and the mean age at which ERT was started was 45.3 years in these patients.

Following 3 years of ERT, neuropathic pain - assessed using the brief pain inventory (BPI) - was improved (BPI pain at its worst, 4.15 [2.34-5.96] versus 4.92 [3.68-6.17] at baseline, mean [95% CI], n = 13, p = n.s.). Similarly, QoL - assessed using the EQ-5D questionnaire - was improved after 3 years of ERT (EQ-5D score, 60.7 [50.5-69.9] versus 58.1 [46.4-69.8] at baseline, mean [95% CI], n = 12, p = n.s.). A decrease in left ventricular mass (LVM) was observed after 3 years of ERT (LVM indexed for height, 46.3 [34.4-52.3] $g/m^{2.7}$ versus 50.9 [41.0-61.0] $g/m^{2.7}$ at baseline, mean [95% CI], n =16, p = n.s.). Renal function - assessed by measuring glomerular filtration rate (GFR) - remained stable over 3 years of ERT (GFR, 65.2[61.2-70.3] ml/min/1.73 m^2 versus 67.5 [63.5-71.4] ml/min/1.73 m^2 at baseline, mean [95% CI], n = 30, p = n.s.).

These data suggest the beneficial effects of long-term ERT on clinically significant aspects of Fabry disease in heterozygous females. Early diagnosis and prompt therapeutic intervention may lead to further clinical benefit in female patients with Fabry disease.

Chromosomal rearrangement mechanisms underlying six terminal deletions of 1p36 detected by MLPA analyis for a panel of probes in the 1p36 region. *C. D'Angelo[1], J. da Paz[2], C. Kim[3], D. Bertola[3], C. Lourenço[4], C. Koiffmann[1]*
1) Depto Genética, USP, São Paulo, Brazil; 2) Depto Neurologia, HC-FMUSP, São Paulo, Brazil; 3) Unidade de Genética Clínica, ICr/HC-FMUSP, São Paulo, Brazil; 4) Depto Genética, HC-FMUSP, Ribeirão Preto, Brazil.

Monosomy 1p36 syndrome results from a variety of chromosomal rearrangements with scattered breakpoints on the most distal 10.5 Mb of 1p. Sequence analysis of breakpoint junctions of terminal 1p36 deletions have revealed diverse mechanisms underlying formation and/or stabilization that favors a variety of double-strand-break repair pathways competing to repair a terminally deleted chromosome. We have found evidences for telomere healing, breakage-fusion-bridge (BFB) cycles and telomere capture by performing MLPA and FISH on six patients with 1p36 monosomy. MLPA analyses with SALSA P147 and P036/B disclosed four <3 Mb simple terminal truncations and one additional 2.2-2.4 Mb terminal deletion with proximal 1p36 segments triplicated and duplicated. A sixth larger deletion (~6-7 Mb) showed duplication of sequences at 1qter, subsequently confirmed by Multiprobe FISH to be translocated onto the 1pter. Subtelomeric FISH with the 1p probe confirmed all the deletions as terminal with de novo origin. Four patients with informative results from microsatellite analyses showed maternal inheritance. All the patients had in common the deletion of the GABRD and SKI genes. Four out of six patients presented in some period of their life obesity and/or hyperphagia, and three were initially referred for PWS testing. Our preliminary data suggests that four seemingly pure terminal deletions represent terminally deleted chromosomes repaired by telomere healing. The finding of a complex terminal deletion with a more proximal duplication and triplication is indicative of BFB cycles. We propose three BFB cycles for the formation of this chromosome before becoming structurally stable. Similarly, the observed der(1)t(1;1)(p36;q44) that resembles other three previously described rearrangements may represent a terminal deletion stabilized as a derivative chromosome by a telomere capture event. Supported by FAPESP, CEPID/FAPESP, CAPES, CNPq.

Multi-ethnic Comparisons of Genome-wide Alterations in Breast Cancer Using Paraffin Embedded Samples. *L. Baumbach[1], M.E. Ahearn[1], M. Jorda[1], C. Gomez[1], T.A. Halsey[2], K. Ellison[2], S.M. Farragher[2], G.L. Jellema[2], S. Gluck[1]*
1) Miller School of Medicine, University of Miami, Miami, FL; 2) Almac Diagnostics, Durham, North Carolina.

Approximately 178,000 US women will be identified with invasive breast cancer (BC) this year; about 41,000 will die from the disease. It is recognized that ethnic-specific disparities in stage of presentation/survival rates exist in BC patients. **These disparities remain an enigma**. To investigate a possible genetic basis, we are extending our study of genomic changes in BC samples from African-American (AA) women to a multi-ethnic cohort consisting of 20 each AA, Hispanic white and non-Hispanic white (Caucasian) women matched for age of diagnosis, cancer stage, and hormone receptor status. Tissue samples are evaluated for gene expression differences, as well as DNA copy number (CNV)/chromosome alterations by CGH arrays. We completed a feasibility study using paraffin embedded tissue samples. Gene expression differences in tumor vs. normal breast tissue were analyzed in sections from three AA and three Caucasian BC pathology specimens matched for age and receptor status (ER+/PR+/Her2-). Slides were macro-dissected for tumor vs. normal tissue. RNA was isolated, labeled cDNA generated, and hybridization of tumor and normal cDNA performed using Almac Diagnostics proprietary Breast Cancer DSA Research Tool. Approximately 18,000 transcripts were analyzed for expression differences in normal vs. tumor tissue. Distribution analysis, hierarchical clustering and principal component analysis were used to analyze the data within and across ethnic groups. There were 1735 unique differentially expressed genes in the AA tumor samples, 787 unique differentially expressed genes in the Caucasian tumor samples, and only 194 differentially expressed genes in common. We now are extending the study to additional samples, as well as assessing CNV by CGH arrays. It is likely that the completed study will result in an increased understanding of the biological basis of ethnic-specific BC disparities, which may ultimately lead to individualized, ethnic-specific diagnostic and therapeutic approaches.

The first genome-wide inter-population linkage study of migraine families points to a locus on chromosome 10q22-q23. *V. Anttila[1,2,3], D.R. Nyholt[4], M. Kallela[3,5], V. Artto[3,5], S. Vepsäläinen[3,5], A. Sarahonka[1,2,3], P. Tikka-Kleemola[1,2,3], E. Hämäläinen[2,3], J. Terwilliger[2,3], L. Peltonen[2,3,6,7], M. Färkkilä[3,5], N.G. Martin[4], M. Wessman[2,3], A. Palotie[1,2,3,7]* 1) Finnish Genome Center, University of Helsinki, Helsinki, Finland; 2) Biomedicum Helsinki, Research Program in Molecular Medicine, University of Helsinki, Helsinki, Finland; 3) Center of Excellence in Complex Disease Genetics, University of Helsinki, Helsinki, Finland; 4) Genetic Epidemiology Laboratory, Queensland Institute of Medical Research, Brisbane, Australia; 5) Department of Neurology, Helsinki University Central Hospital, Helsinki, Finland; 6) Department of Molecular Medicine, National Public Health Institute, Helsinki, Finland; 7) The Broad Institute of MIT and Harvard, Cambridge, Massachusetts, USA.

To date, several genetic loci have been linked to common forms of migraine, though consistency between studies remains a problem. We performed a joint analysis of two new, large, well-characterized study samples from Finland and Australia. Some 400 microsatellite markers were genotyped in 1675 subjects, from 77 large independent Finnish multigenerational and 125 independent Australian nuclear migraine with aura families. Parametric and non-parametric qualitative two-point and multipoint linkage analyses, as well as QTL analyses, were performed using the migraine end-point diagnosis as well as phenotypes from trait component analysis and latent class analysis. We found significant evidence of linkage to a locus on chromosome 10q22-q23 in both samples separately, as well as in a joint analysis. In the Finnish study sample, the highest two-point HLOD of 4.37 was reached at marker D10S2470, and the highest multipoint LOD 5.52 was reached at 104.5 cM. In the Australian study sample, QTL analysis positions the peak at 102 cM, with a multipoint LOD of 3.68. This locus has now been detected in five separate genome-wide scans (including those reported here), providing by far the best consistency for any locus reported in common forms of migraine. In addition, our results also confirm six previously detected loci on 4q31, 5q21, 13q21, 15q11-q13, 17p13, and 18q12.

Characterization of a balanced translocation breakpoint to within the FOXP2 gene in a two-generation family with language impairment. *J.B. Bjork[1], J.B. Tomblin[2], C.A. Williams[3], S.R. Patil[1], M.R. O'Brien[2], J.C. Murray[1]* 1) Dept Pediatrics, U of Iowa, Iowa City, IA; 2) Dept Speech Pathology and Audiology, U of Iowa, Iowa City, IA; 3) Dept Pediatrics, U of Florida, Gainesville, FL.

We have previously reported on a balanced 7;13 chromosomal translocation within the forkhead transcription factor gene, FOXP2, in a mother-daughter pair. Both individuals present with a developmental language disorder that persists despite adequate intelligence and opportunity for language learning. BAC and fosmid clones were utilized in fluorescent in-situ hybridization (FISH) analysis on G-banded metaphase chromosome spreads to map the breakpoint. Long-range PCR was used to amplify a segment of DNA across the breakpoint on the der(7) and der(13) chromosomes. Sequence analysis revealed the translocation breakpoint to be within intron 9-10 of FOXP2 on chromosome 7, and within intron 7-8 of RFC3 on chromosome 13. A frameshift mutation is anticipated for each fusion protein transcribed from the FOXP2 gene variants, FOXP2-RFC3 and RFC3-FOXP2, resulting in the premature truncation of gene transcripts. It is hypothesized that this truncation yields an unstable cytoplasmic protein product, similar to that described in a family with a R328X mutation in FOXP2 (MacDermot et al., 2005; Vernes et al., 2006). It is not yet known whether these products are in fact present in this affected mother and daughter. However, it is probable that haploinsufficiency of the FOXP2 protein cosegregates with language difficulties. In addition, it is hypothesized that the proximity of the RFC3 gene to NBEA, a gene implicated in autism, may further influence the phenotype of this family.

Confirmation study of prostate cancer risk variants at 8q24 in African Americans identifies a novel risk locus. *R. Kittles[1], C. Robbins[2], J. Benn Torres[1], S. Hooker[1], C. Bonilla[3], W. Hernandez[1], A. Candereva[2], C. Ahaghotu[4], J. Carpten[2]* 1) Dept Medicine, MC 6091, Univ Chicago, Chicago, IL; 2) Division of Integrated Cancer Genomics, Translational Genomics Research Institute, Phoenix, AZ; 3) Department of Clinical Pharmacology, University of Oxford, Oxford, UK; 4) Division of Urology, Howard University Hospital, Washington, DC.

Prostate cancer (Pca) is a common complex disease that disproportionately affects men of African descent. Recently, several different common variants on chromosome 8q24 have been shown to be associated with Pca in multiple studies and ethnic groups. The objective of this study was to confirm the association of 8q24 markers with Pca in African Americans. We genotyped 24 markers along 8q24 and 80 unlinked ancestry informative markers in a hospital-based case-control sample of 1,057 African American men (490 Pca cases and 567 healthy controls). Association analyses of 8q24 markers with prostate cancer risk were adjusted for both global and local 8q24 admixture stratification using estimates from ancestry informative markers. We report that rs7008482, which maps to the 8q24.13 region, is an additional independent prostate cancer risk variant (P= 5 x 10-4) and we also replicate the association of rs16901979 with prostate cancer (P=0.002). Other published risk variants in the region such as rs1447295 and rs6983267 did not replicate in our population. Both rs7008482 and rs16901979 independently predicted risk and remained significant (P<0.001) after controlling for each other. Our most significantly associated SNP, rs7008482 mapped to 8q24.13, approximately 2.2Mb proximal to the DG8S737/ rs1447295 region at 8q24.21. These findings are intriguing since SNP rs7008482 lies within an area on 126.2Mb surrounded by several interesting candidate genes which are amplified and overpressed in Pca. Further additional genotyping within this region and functional analyses are underway. Taken together, multiple studies, including ours strongly support the existence of several independent susceptibility loci within the 8q24 region of the genome.

***PON2* Polymorphisms, PON Activity, and Systemic Lupus Erythematosus (SLE).** *S. Dasgupta[1], F.Y. Demirci[1], A.H. Kao[2], E.Y. Rhew[3], F. Bontempo[4], C. Kammerer[1], R. Ramsey-Goldman[3], S. Manzi[2], M.I. Kamboh[1]* 1) Dept. of Human Genetics, Univ Pittsburgh, GSPH, Pittsburgh, PA; 2) Lupus Center of Excellence, Univ. of Pittsburgh, Pittsburgh, PA; 3) Div. of Rheumatology, Northwestern Univ., Chicago, IL; 4) Dept. of Medicine, Univ. of Pittsburgh, Pittsburgh, PA.

SLE is a multisystem autoimmune disease that predominantly affects the women at child-bearing age. The risk of coronary heart disease (CHD) in SLE women is up to 50 times higher than in the general population. Several studies have implicated the association of low paraoxonase (PON) activity with CHD and our studies have demonstrated that low PON activity is independently associated with SLE. Two SNPs in the PON1 gene (codon 55 and codon 192) are known to be major regulators of serum PON activity, though the extent of contribution from subsequently characterized PON2 and PON3 genes remain to be determined. The purpose of this study was to determine the impact of *PON2* polymorphisms on PON activity and risk for SLE. Eleven *PON2* Tag SNPs, including two non-synonymous SNPs, were genotyped in 350 Caucasian SLE patients and 454 Caucasian healthy control women using RFLP, Pyrosequencing, or TaqMan allelic discrimination methods. Haploview analysis using our data revealed pairwise LD (D> 0.8) for several SNP pairs, however, strong correlation (r^2 > 0.8) were observed only for two SNP pairs (rs9641164 & rs1639 and rs3735586 & rs6954345) therefore one SNP from each SNP pair (rs9641164 and rs3735586) were excluded from haplotype analysis. Haplotype analysis revealed significant association with SLE risk (P < 0.001). Five SNPs revealed significant association (P < 0.05) with age, BMI, and smoking-adjusted serum PON activity in single-site analyses in both cases and controls. The effects of 2 SNPs (rs6954345 and rs11545491) remained significant in a multiple linear regression model that also included the two *PON1* SNPs (codon 55 and codon 192). We identified specific haplotypes significantly associated (P < 0.05) with either low or high serum PON activity. These results indicate that in addition to the known effect of *PON1* on PON activity, *PON2* genetic variation also contributes towards PON activity and SLE risk.

A Support Vector Machine Approach for Detecting Gene-Gene Interaction. *S.H. Chen[1], J. Sun[2], L. Dimitrov[2], A.R. Turner[2], T.S. Adams[2], S.L. Zheng[2], H. Grönberg[3], J. Xu[2], F.C. Hsu[4]* 1) Department of Industrial Management, National Yunlin University of Science and Technology, Yunlin, Taiwan; 2) Center for Human Genomics, Wake Forest University School of Medicine, Winston-Salem, NC; 3) Department of Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden; 4) Department of Biostatistical Sciences, Wake Forest University School of Medicine, Winston-Salem, NC.

Although genetic factors play an important role in most human diseases, multiple genes or genes and environmental factors may influence individual risk. In order to understand the underlying biological mechanisms of complex diseases, it is important to understand the complex relationships that control the process. In this paper, we consider different perspectives, from each optimization, complexity analysis, and algorithmic design, which allows us to describe a reasonable and applicable computational framework for detecting gene-gene interactions. Accordingly, support vector machine and combinatorial optimization techniques (local search and genetic algorithm) were tailored to fit within this framework. Although the proposed approach is computationally expensive, our results indicate this is a promising tool for the identification and characterization of high order gene-gene and gene-environment interactions. We have demonstrated several advantages of this method, including the strong power for classification, less concern for over-fitting, and the ability to handle unbalanced data and achieve more stable models. We would like to make the support vector machine and combinatorial optimization techniques more accessible to genetic epidemiologists, and to promote the use and extension of these powerful approaches.

Genetic evidence that insulin secretion plays a role in the development of polycystic ovary syndrome: the *FEM1B* gene. *M.O. Goodarzi[1], J.F. Maher[2], H.J. Antoine[1], J. Cui[1], Y-D.I. Chen[1], W.A. Hsueh[3], X. Guo[1], J.I. Rotter[1], R. Azziz[1]*
1) Cedars-Sinai Med Ctr, Los Angeles, CA; 2) UT Southwestern Med Ctr, Dallas, TX; 3) UCLA Med Ctr, Los Angeles, CA.

Polycystic ovary syndrome (PCOS), the most common endocrine disorder of reproductive age women, is characterized by infertility, hyperandrogenism, and hyperinsulinemia. The human *FEM1B* gene is a homolog of *fem-1*, a sex-determination gene of *C. elegans* that controls masculinization. Herein, we consider *FEM1B* as a candidate gene for PCOS, a disorder of masculinization. Mice with knockout of the *fem1b* gene displayed abnormal glucose tolerance and impaired acute phase insulin secretion. To first confirm a role of *FEM1B* in human insulin secretion, we studied 804 individuals from 191 families (Mexican-Americans from Los Angeles, CA). Insulin secretion (insulinogenic index at 30 minutes, IGI30) was quantified by oral glucose tolerance test in 518 subjects. We genotyped 3 single nucleotide polymorphisms (SNPs) in *FEM1B*; all were in the same haplotype block. Generalized estimating equation methods were used in the association analysis. Haplotype GGA (frequency 22%), which is identified by the minor allele of SNP rs10152450, was associated with decreased insulin secretion (P=0.02). We then evaluated the role of *FEM1B* in PCOS. We genotyped 287 women with PCOS and 187 controls (all non-Hispanic Whites from Birmingham, AL). Association with PCOS was evaluated with logistic regression; association with quantitative traits was tested using ANCOVA. Carriers of the minor allele of rs10152450 had a reduced frequency of PCOS (odds ratio 0.52, P=0.01). Minor allele carriers of this SNP also had lower insulin secretion (P=0.01) calculated as HOMA-%B (index based on fasting glucose and insulin). Haplotype GGA exhibited the same associations. This haplotype occurred with a 28% frequency in PCOS and 37% in controls (^{2}=7.2, P=0.007). These results implicate *FEM1B* in insulin secretion in two distinct populations, consistent with the mouse data, and suggest that inherited reduction in insulin secretion can protect against PCOS. The latter is consistent with *in vitro* data that insulin promotes ovarian androgen secretion.

Impact of data synthesis on the power and stability of association analysis: joint analysis of family and case-control data with a moving window approach. *C. Gray-McGuire, R.C. Elston, Q. Lu* Dept Genetic Epidemiology, Case Western Reserve Univ, Cleveland, OH.

As more and more genome-wide and candidate gene association studies are conducted, two primary challenges to the analysis and interpretation of such data have emerged: 1) how can we obtain the large sample sizes vital to the detection of the small effects likely to characterize complex disease and 2) will the analysis of a large number of single nucleotide polymorphisms (SNPs) individually be sufficient to detect these effects? Attempts to overcome the first challenge have focused primarily on the assembly of large case-control samples without making use of the many large collections of family data already available from previously conducted linkage studies. Strategies to address the second challenge often include estimation of haplotypes - which may lose power, particularly when evaluating genome scan data, because of the increase in degrees of freedom involved.

We present here an approach for the joint analysis of family samples, extended pedigrees and case-control data, offering a means by which to dramatically increase sample sizes, together with moving window approach to increase the power of high density SNP data. Within the context of a candidate region analysis, we demonstrate that by combining information from a family sample and population based controls, as well as by combining information from adjacent SNPs, we can obtain results that are both less significant in regions of spurious association (from p= 7.5 x 10-8 to p=0.5) and more significant in a region containing an independently identified disease susceptibility haplotype (from p=0.09 to p= 8 x 10-6). Further, we show that, even for a relatively small sample size, the Wald and likelihood ratio test (LRT) statistics are far more stable using a multilocus (Wald/LRT ratios ranging from 0.99 to 18) rather than a single locus (Wald/LRT ratios ranging from 0.95 to 56) model. Finally, we offer suggestions, based on our results, for finding the optimal window size.

Common variant of SOSTDC1 is associated with increased risks of fractures and osteoporosis--A novel candidate gene revealed by fine mapping from Anhui genome-wide scan. *Y. Hsu[1,2], T. Niu[1], H. Terwedow[1], C. Rosen[3], J. Brain[1], X. Xu[4]* 1) Mol & Integ Physiol Sci Pgm, Harvard Sch Public Health, Boston, MA; 2) Hebrew SeniorLife and Harvard Medical Sch, Boston, MA; 3) Maine Center for Osteoporosis Research and Education, St. Joseph Hospital, Bangor, ME; 4) Sch Public Health, UIC, Chicago, IL.

Previously, we have revealed 3 novel QTLs (LODs >3.65) on Chr7p21, Chr2q24 and Chr5q21 for bone mineral density (BMDs) in a genome-wide scan of 3093 adult Chinese siblings selected based on their extreme hip BMD. To narrow down the QTL region, we first genotyped 10-20 microsatellite markers in each of the QTLs in the same 3093 siblings. Fine mapping of the Chr7p21 QTL narrowed to a 8 cM region (LOD=3.72). Among 23 known genes in this region, twist homolog 1 (TWIST1) and sclerostin domain-containing protein 1 (SOSTDC1) have been known functionally relevant to bone metabolism. To test whether polymorphisms in the TWIST1 and SOSTDC1 are associated with osteoporosis, we genotyped tag SNPs in an independent set of 2392 extreme low FN BMD cases (T-score <-1) and extreme high FN BMD controls matched by age and sex, selected from a study of 23,327 Chinese. Multiple logistic regression with additive genetic model was used. First, the adjusted ORs for extreme low FN BMD was associated with 3 adjacent SNPs located in exon1 and intron1 of SOSTDC1 (ORs 1.4-1.6, $p<0.00004$, permutation test $p<0.0005$) in men. A weak association was found in women for the SNP located in exon1 ($p=0.017$). No association was found for TWIST1 SNPs. Second, the ORs(95%CI) for men carrying the polymorphic allele A for the strongest associated SNP (rs16878762, MAF=0.29) of SOSTDC1 were 1.7(1.3-2.4) for osteoporosis, and 2.0(1.1-3.7) for osteoporotic fractures. Third, SNP rs16878762 was associated with SOSTDC1 gene expression in men($p=0.004$) and women($p=0.049$). Notable, despite the close homologue to sclerostin (SOST), no association was found for SOST polymorphism (SRP9) in our study population. In sum, results from linkage, population-based association, and gene expression studies all suggest SOSTDC1 variants may causally reduce BMDs and increase risks of osteoporotic fractures.

Familial idiopathic scoliosis and the IRX gene family. *C. Justice[1], N.H. Miller[2], B. Marosy[3], D. Behneman[1], A.F. Wilson[1]* 1) Genometrics Section, IDRB, National Human Genome Research Institute, National Institutes of Health, Baltimore, Maryland; 2) University of Colorado, The Childrens Hospital, Denver, Colorado; 3) Institue of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, Maryland.

Familial idiopathic scoliosis (FIS) is characterized by a lateral curvature of the spine present in otherwise normal individuals that affects 2 to 3% of the population. The original sample was comprised of 202 families with at least two individuals with scoliosis. Prior to analysis, three subgroups were determined including: most likely mode of inheritance (XLD vs. AD), families with at least two members with kyphoscoliosis, and families with at least two members with triple curves. Linkage analysis was performed in each subgroup with 391 STRP markers. Linkage analysis of the kyphoscoliosis subgroup (7 families, 53 individuals) identified candidate regions on chromosomes 5 and 13. The region on 5p13 (~3 Mb) contained only three genes, all belonging to the Iroquois homeobox (IRX) gene family. Three other IRX genes were located on 16q, in a region also linked to FIS in our AD subgroup.

To compare the distribution of other gene families in linked vs. non-linked regions, FIS-linked regions were defined as being 5 Mb from two consecutive p-values < 0.025 (26 regions ,15% of the genome). A BLAT search was performed with the IRX1 mRNA sequence, and 65% of homologous loci were in regions linked to FIS. Four other genes, three on chromosome 5 and one on chromosome 12, of similar size to IRX1, also underwent a BLAT mRNA homology search. The number or regions linked to FIS ranged from 17% to 36%, substantially less that for the IRX gene family.

Myeloperoxidase gene variations are associated with low-density-lipoprotein characteristics. *G. Dolley[1,2,3], B. Lamarche[3], J.P. Després[4,5], C. Bouchard[6], L. Pérusse[1,5], M.C. Vohl[1,2,3]* 1) CRML, CHUL Research Centre, Quebec, Canada; 2) Department of Food Science and Nutrition, Laval University, Quebec, Canada; 3) Nutraceuticals and Functional Foods Institute (INAF), Quebec, Canada; 4) Quebec Heart Institute, Quebec, Canada; 5) Department of Social and Preventive Medicine, Laval University, Quebec, Canada; 6) Pennington Biomedical Research Center, Baton Rouge, Louisiana, USA.

Background: The small, dense LDL phenotype is associated with an increased cardiovascular disease risk. A genome-wide scan performed on 236 nuclear families of the Quebec Family Study (QFS) revealed a QTL for LDL peak particle size (LDL-PPD) on the 17q21 region. This region contains the myeloperoxidase gene (MPO). MPO is thought to be part of an important pathway for LDL oxidation and atherosclerosis progression. MPO is able to oxidize LDL, and MPO-modified LDL particles have been detected in atherosclerotic plaques. **Objectives**: To test the association between MPO gene polymorphisms and LDL-PPD as well as plasma lipid levels. **Methods**: Analyses were performed on 680 subjects of QFS. LDL-PPD was measured by gradient gel electrophoresis on non-denaturating 2-16% polyacrylamide gradient gels. Direct sequencing of the coding regions, exon-intron splicing boundaries and the regulatory regions was performed on 25 subjects. Genotyping was performed either by taqman or direct sequencing. **Results**: MPO gene sequencing revealed 16 polymorphisms. Three SNPs not in LD (r2 0.73) were retained for genotyping on the whole cohort (c.-653G>A, c.157G>T and c.2149A>G). No significant association was found with LDL-PPD. However, the c.-653G>A MPO polymorphism was associated with lower plasma total cholesterol, LDL-cholesterol and LDL-apolipoprotein B (apoB) levels (p=0.036, p=0.049 and p=0.016, respectively). These associations were observed when the phenotypes were adjusted for the effects of age and sex, and remained significant with further adjustment for body mass index. **Conclusion**: The MPO gene variants are not associated with LDL-PPD. However, the c.-653G>A is associated with significant variation in LDL-cholesterol and LDL-apoB concentrations.

Replication of DCDC2 and KIAA0319 in a single population with language disorder. *S.K. Iyengar[1], J.B. Tomblin[2], K.J. Kelsey[3], J.B. Bjork[3], L.E. Sucheston[4], B.K. Samelson[3], J.C. Murray[3]* 1) Dept Epid/Biostat, Case Western Reserve Univ, Cleveland, OH; 2) Dept Speech Pathology and Audiology, U of Iowa, Iowa City, IA; 3) Dept Pediatrics, U of Iowa, Iowa City, IA; 4) Dept Biostatistics, SUNY-Buffalo, Buffalo, NY.

DCDC2 and KIAA0319 have been repeatedly linked to dyslexia, a reading disorder (RD) characterized by poor phonological and word decoding abilities. Both genes are expressed in the brain and implicated in neuronal migration. Previously, each has been linked independently to RD in different populations. We conducted an association study of 581 second-grade children in nuclear families, with and without language-learning disabilities. Linkage disequilibrium was analyzed by genotyping five SNPs in DCDC2 and five SNPs in KIAA0319. Single SNP association analysis was performed via linear regression, accounting for sibling and family effects by the program ASSOC in the S.A.G.E. software package. All p-values presented are likelihood ratio p-values, although a Wald test was also conducted with similar effects. All SNPs in DCDC2 showed association with measures of nonword decoding in kindergarten (p-values 0.001 to 0.05). The SNP, rs807701, which showed the most significant p-value for nonword decoding, was also significantly associated with single word reading (p=.003). For KIAA0319, two SNPs were significantly associated with performance or non-verbal IQ (rs12193738, p=.002; rs9393572, p=.02). The SNP rs12193738 was also associated with reading comprehension (p=.003), phonological memory (p=.003), with marginal association for spoken language, phonological awareness, and nonword decoding. Phenotypes associated with DCDC2 are closely related to phonological abilities and consistent with core features of dyslexia. Phenotypes associated with KIAA0319 are more diverse, but include aspects of language associated with meaning. It is hypothesized that these reading-related loci may affect slightly different neurodevelopmental pathways and contribute to different profiles of reading impairment. This is the first time both DCDC2 and KIAA0319 have been associated with reading and other cognitive linguistic measures in the same sample.

Mediating and moderating types of gene-environment interaction effects in genetic epidemiology. *B.M. Chakraborty[1], M.B. Rao[1,2], R. Chakraborty[1,2]* 1) Dept. Environmental Hlth; 2) Ctr. Genome Information, Univ. Cincinnati, Cincinnati, OH.

Gene-environment interaction (GxE) is inferred from heterogeneity of environmental (E) effects across different genotypes or by showing that the genotypes (G) have different effects under varying environment. GxE effects may be significant in the absence of main effects of G and/or E. Distinctions of different forms of GxE effects are made by using concepts of mediators and moderators, analyzed by structural equation models and path diagrams. The hypothesis that the joint effects of genes, exercise habit, and diet on obesity are explained by their mediating type of interaction effects has a mechanistic support. More commonly, GxE interactions may be of moderating type, examples of which are provided here. Such situations arise when effects of each individual gene on the phenotype are modest, and/or there is no association of genotype and environmental exposures. In contrast with the case where some obesity-related genes involved in central nervous systems and energy expenditure and adipocyte differentiation may regulate food intake and energy expenditure, the moderator type of GxE effects may be involved in pediatric asthma, Parkinsons disease (PD), and impairment of neuromotor function. For childhood asthma, genotypes at certain loci (e.g., CD14) may interact with diesel exposure, without any association of genes with diesel exposure. Likewise, for PD, CYP2D6 poor metabolizers are not at increased risk of PD in absence of pesticide exposures, but pesticides effect on PD is increased by about twofold in poor metabolizers. Without any correlation of pesticide exposure with CYP2D6 genotypes, this becomes a moderating type of pesticide x CYP2D genotype interaction effect on PD. Similarly, childhood lead exposure is associated with impairment of neuromotor function, the strength of which varies by genotypes of at 4 polymorphic sites (DRD2-A, DRD2-B, VDR, and NAT2-Taq1). Association of genotypes with lead exposure is modest (only the VDR locus mildly shows this). We provide a theoretical framework for distinguishing such GxE interaction effects with relevant power computations.

Somatic instability in Friedreich ataxia progresses throughout life, and includes large, age-dependent expansions in dorsal root ganglia. *I. De Biase[1], R. Clark[1], A. Rasmussen[1, 2], S. Al-Mahdawi[3], A. Monticelli[4], S. Cocozza[4], M. Pook[3], S.I. Bidichandani[1]* 1) Dept Biochemistry, Univ Oklahoma HSC, Oklahoma City, OK; 2) Instituto Nacional de Neurología y Neurocirugía, Mexico City, Mexico; 3) Brunel University, Uxbridge, UK; 4) Univ Federico II, Naples, Italy.

Friedreich ataxia (FRDA) patients are homozygous for large expansions of a GAA triplet-repeat (GAA-TR) sequence in the FXN gene. The neurodegeneration involving primarily the dorsal root ganglia (DRG) results in the progressive ataxia. The high sensitivity of DRG to frataxin deficiency is the likely cause of this selective degeneration, but the progressive nature remains unexplained. The expanded GAA-TR is highly unstable in somatic and germ cells. To test whether somatic instability contributes to the tissue-specific and progressive nature of FRDA, we analyzed GAA-TR instability in multiple tissues from six autopsies of FRDA patients. Small-pool PCR analysis showed that DRG had a significantly higher frequency of large expansions compared with all other tissues ($P<0.001$). There was a significant age-dependent increase in the DRG large expansions frequency, which ranged from 0.5% at 17y to 13.9% at 47y ($R=0.78$; $P=0.028$). A transgenic mouse carrying the entire human FXN locus with an expanded tract showed the same age-dependent, DRG-specific increase in large expansions indicating that the DRG-specific somatic instability is not secondary to the disease process. Progressive pathology involving the DRG is therefore likely due to age-dependent accumulation of GAA-TR large expansions. Compared with adult-derived tissues, SP-PCR analysis of multiple tissues of an 18-week fetus homozygous for large expansions revealed a remarkably low level of instability (4.2% vs 30.6%, $P<0.0001$). The overall mutation load in vivo, measured in blood samples, increased with patient age, ranging from 7.5% at 18-weeks gestation to 78.7% at 49 years of age ($R=0.91$; $P=0.0001$). FRDA somatic instability occurs mostly after early embryonic development, progresses throughout life, and possibly contributes to disease pathogenesis and progression. Postnatal repeat expansion in specific tissues is a common theme in triplet-repeat diseases pathogenesis.

Novel SOX3 mutations in patients with various forms of syndromic pituitary defects. *I. Giurgea[1, 3], K. Machinis[1], M.-P. Vié-Luton[1], G. Pinto[4], B. Mignot[5], A.-M. Bertrand[5], C. Naud-Saureau[6], S. Rose[1], F. Kurtz[7], M. Legendre[1, 2], M.-L. Sobrier[1], J. Léger[8], P. Czernichow[8], S. Amselem[1, 2]* 1) INSERM U654, Hôpital Armand Trousseau, Paris, France; 2) AP-HP, Hôpital Armand Trousseau, Service de Génétique et d'Embryologie médicales, Paris, France; 3) AP-HP, Groupe Henri Mondor-Albert Chenevier, Service de Biochimie et Génétique, Créteil, France; 4) AP-HP, Hôpital Necker Enfants Malades, Service d'Endocrinologie, Paris, France; 5) Hôpital Saint Jacques, Service d'Endocrinologie, Besançon, France; 6) Hôpital de Lorient, Service de Pédiatrie, Lorient, France; 7) Hôpital de Saint-Avold, Service de Pédiatrie, Saint-Avold, France; 8) AP-HP, Hôpital Robert Debré, Service d'Endocrinologie, Paris, France.

SOX3 is a transcription factor involved in the control of pituitary function and development. So far, few mutations have been identified in this X-linked gene. To assess SOX3 involvement in human pathology, we investigated 50 unrelated boys with pituitary dysfunction and midline central nervous system (CNS) defects. Mutations were identified in 8 patients from 6 unrelated families. Expansions of the polyalanine tract (+8 and +11 Ala) were found in 4 boys from 2 families with isolated growth hormone deficiency (IGHD) and strabismus. A contraction of the polyalanine tract (-9 Ala) was found in a patient with a combined pituitary hormone deficiency (CPHD) and callosal anomalies. Missense mutations were observed in 3 patients: p.Ala102Ser in a patient with blindness related to septo-optic dysplasia and severe midline CNS anomalies, p.Ala5Pro in one with IGHD and behaviour problems, p.Pro3Ser in a patient with CPHD. All patients had morphological pituitary anomalies: anterior pituitary hypoplasia (7/8), abnormal pituitary stalk (5/7), and ectopic posterior pituitary (4/8). This report broadens the clinical spectrum of SOX3 related disorders.

Changes in an Inherited Ring (22) as a Result of Meiotic Recombination; Implications for Counseling. *V. Jobanputra, E. Ash, K. Anyane-Yeboa, A. Sobrino, O. Nahum, B. Levy, D. Warburton* Columbia University Medical Center, New York, NY.

We describe a case of a 21 month old child with developmental delay, microcephaly (<3rd %), coarse hair, epicanthic folds & hypotonia. Language & any intentional sounds were absent & there was lack of eye contact. Walking was unsteady with a wide-based gait. Brain MRI showed enlarged ventricles without hydrocephalus. Chromosome analysis revealed a maternally inherited ring(22). Cytogenetic studies on the mother showed the r(22) to be present in about 10% of her lymphocytes. FISH on the mother indicated that the 22qter probe was adjacent to the centromere in the r(22). Her ring was also ARSA+ & D22S75+. Thus, no long arm material appeared to be missing & the maternal karyotype describing the ring could be written as 46,XX,r(22)(p11.2q13.3).ish r(22)(D22S75+, ARSA+, qter+). Cytogenetic analysis of the child revealed a non-mosaic ring chromosome that was larger & had a different morphology than that observed in the mother. There was a non-staining gap next to the centromere that was acro-p positive by FISH analysis. The r(22) was also positive for D22S75 but negative for ARSA and 22qter. While the child appeared to have inherited the same ring from the mother, it was in fact different having gained (short arm including the 2ndary constriction) and lost (distal 22q) material. SNP Oligonucleotide Microarray Analysis (SOMA) confirmed the childs deletion and showed it was 3.6 Mb in size. The patients karyotype was thus 46,XX,r(22)(p13q13.31).ish r(22)(acrop+, D22S75+, ARSA-, qter-), oligo arr q13.31qter(45,979,243-49,580,000)x1. These changes are not consistent with the rearrangements expected to occur in mitosis within the inherited ring. Rather they suggest that meiotic exchange occurred between the ring and the normal 22 in the mother, thus introducing the short arm material. To our knowledge this is the first case suggesting that such exchanges can occur. For counseling purposes it is important to note that an apparently benign ring in a parent can undergo rearrangements in meiosis to produce an unbalanced chromosome associated with developmental abnormalities.

Mutation analysis of VLCAD gene in neonates -a sensitive and cost effective tiered approach. *M. Koul[1], J. Stoddard[1], J. Hempel[1], S. Edstrom[1], B. Cohen[2]* 1) Clinical Diagnostics,Transgenomic Labs, Transgenomic, Omaha, NE; 2) Cleveland Clinic, Cleveland.

Very-long-chain acyl-CoA dehydrogenase- VLCAD deficiency is an autosomal recessive disorder resulting from an inborn error of fatty acid oxidation. Fatty acid oxidation defects, including VLCAD deficiency, may account for as many as 5% of sudden infant death patients. VLCAD protein is loosely bound to inner mitochondrial membrane unlike the other acyl-CoA dehydrogenases-short, medium and the long. Over 150 mutations have been identified in the VLCAD gene. 40% of mutations seen in VLCAD gene are accounted by 779C>T, 830_832del and 848 T>C mutations, it is imperative to screen the entire gene following an initial screen of three common mutations routinely for asymptomatic neonates. This tier screening approach would avoid false-negative diagnoses of VLCAD deficiency in newborns. Genomic DNA isolated from samples have been analyzed with our tiered approach in which a total of 13 amplicons covering the entire VLCAD gene including coding regions and splice junctions are PCR-amplified with a high-fidelity DNA polymerase and analyzed by DNA double strand sequencing under fully optimized conditions for mutation screening. A initial single amplicon screen identifies the three most common mutations while the rest 12 amplicon screen identify any other mutation in the gene thus a cost-effective and sensitive screen. Advent of genotype-phenotype correlation in this disorder, the information derived from mutational analysis is essential in designing the appropriate follow-up and therapeutic regime for these patients. This screening process would also provide carrier frequencies of the most common VLCAD mutations in the population.

Genome-wide scan of copy number variation in Attention deficit hyperactivity disorder (ADHD). *B. Franke[1,2], J. Hehir-Kwa[1], S. Vermeulen[1], J. Veltman[1], J. Lasky-Su[3], P. Asherson[4], M. Gill[5], J. Sergeant[6], R. Ebstein[7], A. Rothenberger[8], HC. Steinhausen[9], T. Banaschewski[10], R. Oades[11], E. Sonuga-Barke[12], A. Miranda[13], H. Royers[14], J. Buitelaar[2], S.V. Faraone[15] for the IMAGE consortium* 1) Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands; 2) Psychiatry, Nijmegen, NL; 3) Boston, MA, USA; 4) London, UK; 5) Dublin, Ireland; 6) Amsterdam, NL; 7) Jerusalem, Israel; 8) Göttingen, Germany; 9) Zurich, Switzerland; 10) Mannheim, Germany; 11) Essen, Germany; 12) Southampton, UK; 13) Valencia, Spain; 14) Ghent, Belgium; 15) SUNY Upstate Medical University, Syracuse, NY, USA.

Recent data suggest that copy number variants (CNVs) can contribute to complex disease susceptibility. The relative impact of CNVs compared to single nucleotide polymorphisms (SNPs) on one of the processes underlying disease vulnerability, variable gene expression, has been estimated to range around 18% (Stranger et al, Science 315:848-53). The involvement of CNVs in ADHD etiology has not been investigated. Within the International Multi-site ADHD Genetics Study (IMAGE), sponsored by the Genetic Association Information Network (GAIN), a whole genome association study investigating over 500.000 SNPs is currently carried out on 958 European Caucasian parent-child trios with offspring meeting the DSM-IV combined-type criteria for ADHD. Families were collected in the Netherlands, Ireland, the UK, Germany, Belgium, Switzerland, Spain and Israel. Using the intensity data from the SNP analysis carried out at Perlegen Sciences, copy number information will be extracted for each individual. In an overall analysis, we will identify known and new CNVs in the patients and their parents. By comparing parents with offspring we will investigate which CNVs are inherited, which are de novo. For inherited CNVs a TDT-based association study will be carried out. For those that occur de novo in the patients, we will investigate the gene content to find out if the CNV carries genes that can explain the presence of ADHD in the particular patient. In conclusion: CNV analysis in ADHD can potentially identify new candidate genes for this disorder.

Improved detection of 22q11 rearrangements with a high density MLPA probe set. *G. Jalali[1], J.A.S Vorstman[1], A. Errami[2], R. Vijzelaar[2], J. Biegel[1], T. Shaikh[1], B.S. Emanuel[1]* 1) Dept Genetics, CHOP, Philadelphia, PA; 2) MRC-Holland, Netherlands.

Chromosome-specific low copy repeats or segmental duplications predisposes chromosome 22 to deletions and duplications. The current diagnostic procedure for detection of deletions and duplications at 22q11.2 is chromosomal analysis coupled with fluorescence in situ hybridization (FISH). Recently, a PCR based multiplex ligation dependent probe amplification (MLPA) method has been used for this purpose. However, there are copy number variations in 22q11.2 that are only detected by high throughput platforms such as array CGH and not the current FISH probes or MLPA kit. Here we report on development of a high density MLPA (MLPA-HD) kit capable of detecting aberrations of chromosome 22. The MLPA-HD probe set detects copy number changes at 37 loci on the long arm of chromosome 22. These include the 3Mb region commonly deleted in DiGeorge/Velocardiofacial Syndrome (DGS/VCFS), the Cat Eye Syndrome (CES) region and more distal regions in 22q11 recently shown to be deleted in patient samples. We have used this HDMLPA probe set to analyze 363 previously well-characterized samples with a variety of different rearrangements at 22q11. We demonstrate that the HDMLPA kit can detect copy number alterations with excellent sensitivity and specificity. In addition to detection of the common recurrent deletions associated with DGS/VCFS, variant chromosome 22 aberrations that are distal to this region and duplications within this region have been detected. Further, the HDMLPA detects deletion endpoint differences between patients with the common 3 Mb deletion. Thus, the HDMLPA set allows for detection of aberrations that would not have been disclosed by either diagnosticFISH probes or the currently available MLPA kit. Based on these findings, the HDMLPA kit is proposed as a cost effective alternative to the currently available detection methods for individuals with features of the 22q11.aberrations. The HDMLPA probe set could replace FISH with N25 or TUPLE1 probes for the clinical diagnosis of 22q11.2 deletions and duplications in patients with the relevant phenotypic characteristics.

Genome-wide association analysis identifies risk loci for obesity in the Old Order Amish. *M. Fu, E. Rampersaud, H. Shen, X. Shi, L. Zhang, J. Shelton, J. Yin, J. OConnell, B.D. Mitchell, A.R. Shuldiner* Dept Med, Div Endocrinology, Univ Maryland, Baltimore, MD.

Obesity is associated with an increased risk of type 2 diabetes, metabolic syndrome, cardiovascular disease, and some forms of cancer. Genetic susceptibility to obesity is well recognized, with estimates of the heritability of body mass indix (BMI) ranging from 30 to 70%. We performed a genome-wide association scan (GWAS) for obesity susceptibility genes in the Old Order Amish. We genotyped 382,935 single-nucleotide polymorphisms (SNPs) in 861 subjects from the HAPI Heart Study and prioritized 32 loci showing significant association with age-, age2- and sex-adjusted BMI (P 10-4). To distinguish true associations from false positives, we compared these results to GWAS results from the nondiabetic control group of the Diabetes Genetics Initiative (DGI) and the Amish Family Diabetes Study (AFDS). We confirmed the previously reported association between BMI and SNPs in FTO (P = 4.6×10-5). SNP rs9939609 in FTO was also significantly associated with type 2 diabetes (P = 0.007) in the Amish; this association was abolished by adjustment for BMI (P = 0.532) suggesting that variation in FTO increases diabetes risk through its effect on obesity. There was no evidence for association between BMI with variants in the INSIG2 gene. We identified four novel obesity susceptibility loci in and around the genes ALK, ANK2, SLC24A3, and PRKG1. PRKG1 is a cyclic GMP-dependent protein kinase (PKG) that is a major receptor for cGMP in a variety of cells and has an evolutionary conserved structure. Allelic variation in the PRKG1 homolog in Drosophila or alterations in expression in the honey bee Apis mellifera and the nematode C. elegans result in differences in food-related behaviors. Furthermore, PRKG1 is located on 10q11, under our previously reported linkage peak (lod = 2.73, P = 0.0002) for BMI-adjusted leptin. In summary, the results of our GWAS of BMI in the Amish identified a tractable number of novel candidate genes that warrant further investigation.

The UGT2B17 gene deletion polymorphism and risk of prostate cancer: A case-control study in Caucasians. *C.J. Gallagher[1], F.F. Kadlubar[3,4], J.E. Muscat[1], C.B. Ambrosone[2], N.P. Lang[3,5], P. Lazarus[1]* 1) Health Evaluation Sciences, Pharmacology, and the Penn State Cancer Institute, Penn State College Medicine, Hershey, PA; 2) Epidemiology, Roswell Park Cancer Institute, Buffalo, NY; 3) Surgery and Epidemiology, University of Arkansas for Medical Sciences, Little Rock, AR; 4) Pharmacogenomics and Molecular Epidemiology, National Center for Toxicological Research, Jefferson, AR; 5) Central Arkansas Veterans Healthcare System, Little Rock, AR.

UDP-glucuronosyltransferase (UGT) 2B17 is a phase II metabolizing enzyme that mediates the glucuronidation of androgens and is expressed in the prostate. Variations in androgen levels have been suggested as a risk factor for prostate cancer, but results are inconsistent. Polymorphic variants in androgen metabolizing enzymes may alter androgen levels and therefore affect risk for prostate cancer. A deletion polymorphism in the UGT2B17 gene is associated with a substantial reduction in glucuronidation activity in vitro. We examined the association between the UGT2B17 deletion and the risk of incident prostate cancer in a population-based study from central Arkansas that included 411 Caucasian cases and 397 Caucasian controls. We developed a high-throughput procedure that uses real-time PCR and allelic discrimination for genotyping analysis. There was no significant difference in the prevalence of the UGT2B17 deletion genotype between prostate cancer cases (10%) and controls (12%). The odds ratio (OR), adjusted for age, smoking, and family history of prostate cancer, was not significant when comparing deletion homozygote subjects (0/0) (OR=0.89, 95% CI 0.55-1.45) or heterozygote subjects (+/0) (OR=0.99, 95% CI 0.73-1.35) to wild type subjects (+/+). There was also no association with prostate cancer risk when collapsing genotypes. These findings suggest that the UGT2B17 deletion is not associated with prostate cancer risk in Caucasians.

Perceptions from Undergraduate Nursing Students Regarding Nurses' Competencies in Genetics and Genomics.

M. Floria-Santos[1], E.M.M. Santos[2], L.C. Nascimento[1], L.M. Alvarenga[1], M.F. Prearo[1], C.M. Cenzi[1], K.A. Calzone[3] 1) University of São Paulo at Ribeirão Preto College of Nursing, Department of Maternal-Child Nursing and Public Health, SP, Brazil; 2) Cancer Hospital A.C. Camargo, SP, Brazil; 3) National Institutes of Health, National Cancer Institute, Center for Cancer, Bethesda, MD, USA.

Introduction: International health organizations have emphasized the importance of integrating genetics/genomics content into nursing curricula to prepare the nursing workforce now and for the future. This research aimed to increase Brazilian undergraduate nursing students awareness about that importance, and to assess their perceptions regarding Essential Nursing Competencies and Curricula Guidelines for Genetics and Genomics. Methods: This is a descriptive exploratory study with a quantitative approach. Competencies were translated into Portuguese, and a 6 point Likert scale was applied to each. Data were collected between March-October/2006. Students answered sociodemographic questions and scored each competence. Results: 221 responded, 33.7% first year students, 36.7% second; and 30.3% fourth; mean age was 21.38 yo; 94.1% women; 97.3% single, and 87.8% Caucasian. The 62% students who knew the meaning of genomics showed highest levels of concordance with the competencies. First year students reported more agreement with the competencies compared with fourth year, (25/28 competencies showed statistical differences). The most scored competencies related to knowledge and technology incorporation into nurse practice, and last was insurance providers/payers. Discussion: Differences among years can be attributed to nursing curriculum changes. Concordance level probably has cultural influences. Future research is needed to compare perceptions and identify needs among nurses worldwide.

Serotonin Related Genes in Autism. *B.M. Anderson[1], N. Schnetz-Boutaud[1], M.L. Summar[1], J. Bartlett[1], M. Cuccaro[2], J.R. Gilbert[2], M.A. Pericak-Vance[2], J.L. Haines[1]* 1) Center for Human Genetics Research, Vanderbilt Univ, Nashville, TN; 2) Miami Institute for Human Genomics, Miami, FL.

Introduction: Autism is a severe neurodevelopmental disorder with a strong genetic component. Despite numerous genome screens and individual candidate gene studies, the underlying genetic etiology remains largely unknown. Increasing evidence suggests that autism is more genetically complex than previously thought, and that single gene approaches toward dissecting autism genetics may not be informative. We are taking the alternative approach of testing for interactive effects of multiple genes within the serotonin pathway. Methods: We tested 75 SNPs within 13 different genes related to serotonin including TPH1, TPH2, HTR1A, HTR2A, HTR3A, SLC6A4, SLC7A5, YWHAZ, and DDC. SNPs were chosen to represent the linkage disequilibrium patterns across each gene, and included when possible common coding variants. The dataset consists of over 345 multiplex families and 292 parent-child trios collected at two centers in the southeast United States. Initial analyses included single locus family-based association tests, considering both parental and proband gender. Subsequent analyses examined explicitly for gene-gene interactions using multifactor dimensionality reduction (MDR). Results: Single locus analyses generated marginally significant results for YWHAZ and HTR3A, however, these did not survive correction for multiple comparisons. Preliminary two-way interaction analysis with MDR did not identify any significant interactive effects; higher-order interaction analyses are ongoing. Conclusions: As expected, none of the tested genes generated significant results when considered individually. The lack of a strong two-locus interactive effect suggests that either interactions among these genes do not exert a strong effect on autism, or the effect requires a higher order interaction.

The Use of Preferential Imbalance to Identify Skin Cancer Susceptibility Loci. *A.M. Dworkin[1], D. Bautista[6], K. Ridd[2], D. Pinkel[2], B. Bastian[2, 3], A.E. Toland[4, 5]* 1) OSU IBGP; 2) UCSF Cancer Research Institute; 3) UCSF Dept. of Dermatology; 4) OSU MVIMG; 5) OSU CCC; 6) OSU Coll. Math & Physical Sci.

Cutaneous squamous cell carcinoma (SCC) is the second most common type of nonmelanoma skin cancer. Organ transplant recipients (OTR) have an increased incidence and aggressiveness of SCC. The mechanisms underlying this phenomenon are unknown, but effective treatments or prevention methods for these skin tumors would have a significant impact upon morbidity in this group of patients. This project is assessing the genetic components of SCC susceptibility by comparing multiple tumors from organ transplant recipients (OTR) to look at repeated aberrations within an individual in which allelic imbalance occurs. Preferential imbalance (gain or loss) of an allele may indicate the presence of a polymorphism that is driving the imbalance which could then be considered a candidate for SCC susceptibility. Studies using array comparative genomic hybridization in 133 tumors from OTRs led to the identification of regions of frequent copy number changes in multiple tumors from OTR. We used microsatellite markers from these regions to determine if there were alleles showing preferential imbalance in individuals with multiple SCCs. Forty-five patients with at least 4 tumors each were genotyped for 28 microsatellite markers mapping to regions of frequent copy number aberrations. To test whether the observed imbalances were random or preferential, we developed a method based on a hybrid of Bayesian and frequentist approaches. For this, each marker was analyzed separately in each individual, and individual data were subsequently combined for each marker. We then computed the ratio of the odds that imbalances occurred randomly rather than preferentially and then tested for significant departures from unity. We identified statistically significant allelic imbalance for 7 markers. Four of these 7 markers are located on chromosome 3. Our data suggest that a polymorphism is driving somatic copy number changes in tumors at this locus. The use of allele specific somatic alterations in tumors may provide a new means of identification of cancer susceptibility genes.

Genome-wide Linkage Analysis of Utah high-risk Melanoma Pedigrees using a high-density SNP genotyping set.

L.A. Cannon-Albright[1], J.M. Farnham[1], S.A. Leachman[1,2] 1) Univ Utah Sch Medicine, Salt Lake City, UT; 2) Huntsman Cancer Institute, Salt Lake City, UT.

We ascertained and sampled 21 high-risk melanoma pedigrees from the Utah Population Data Base resource, which is linked to Utah Cancer Registry records. Each pedigree had 3 or more melanoma cases (one of whom, aged 50 years or less, screened negatively for p16 CDK4, and ARF) and each had a significant excess of melanoma among the descendants of the pedigree founder. Melanoma cases were genotyped with the Illumina 550k SNP set. We performed genome-wide (GW) linkage analysis of different sets of markers, attempting to reduce bias due to LD between SNPs. We selected markers based on genetic distance (0.2 - 0.4cM) to reduce the possibility of LD; we also selected a subset of markers with no evidence for LD using published HAPMAP data. We excluded SNPs in LD based on pairwise r2, and selected maximally informative SNPs at a density determined to extract full information for linkage analysis. The SNP sets analyzed varied from n = 5,000 to n=27,000 markers. The set of SNPs selected for no evidence of LD had minimum heterozygosity = 0.30, with maximum r2 = 0.16. MCLINK, a Monte Carlo, Markov Chain linkage analysis tool, was used to perform multipoint linkage analysis using the TLOD statistic, and using an affecteds only model for melanoma with disease allele frequency = 0.003 and a low sporadic rate. GW analysis of the SNPs selected for average distance between markers = 0.2 showed significant evidence of linkage (het TLOD > 3.0) for chromosomes 8 and 22; analysis at greater average distances suggests these results are biased due to the presence of some LD. GW analysis of the SNPs selected to have no LD showed no regions with significant evidence for linkage, but identified 2 suggestive regions on chromosome arms 6p and 21q (heterogeneity TLODs 2.05 and 2.15, respectively). Several linked pedigrees were identified for 6p and for 21q that had at least nominal linkage evidence (Lod>0.59). For chromosome 6p there were 8 linked pedigrees with a range of TLOD from 0.78 - 2.00; for chromosome 21q there were 5 linked pedigrees with a range of TLOD from 0.71 - 2.05).

PhenCode: Linking Human Mutations and Phenotype. *B. Giardine[1], C. Riemer[1], W.J. Kent[2], W. Miller[1], R.C. Hardison[1]* 1) Center for Comparative Genomics and Bioinformatics, Pennsylvania State Univ, University Park, PA; 2) Center for Biomolecular Science and Engineering, University of California, Santa Cruz, CA.

PhenCode is a collaborative project to connect phenotype and clinical data with information on genome sequences, evolutionary history, and function. The phenotype data are located in various locus-specific databases (LSDBs) and centralized repositories, whereas genome data are located in browsers such as the one at UCSC. The project currently incorporates data from 119 LSDBs and SwissProt, including mutations associated with cystic fibrosis, phenylketonuria, immune disorders, muscular dystrophy, anemia, and cancer. The Locus Variants track at the UCSC Genome Browser displays genomic positions of the variants. By viewing Locus Variants in register with other tracks, users can integrate information from multiple data types. The detail page, accessed by clicking on a mutation in the display, presents summary information about the genotype and phenotype of the variant, along with links back to the data source for greater detail. One example shows different phenotypic severities of deletions that do or do not remove distal enhancers. The UCSC Table Browser provides the ability to query across the summary data from the LSDB's as well as queries comparing data across tracks. An example of this would be getting the substitutions from the Locus Variants track that are not in dbSNP but are in conserved regions. Websites:

Documentation for the PhenCode project: http://www.bx.psu.edu/

Locus Variants track (hg17, hg18): http://genome.ucsc.edu/.

Apparently balanced translocations are molecularly distinct in clinically affected patients by comparison with unaffected controls. *J. Baptista[1], S. Gribble[2], E. Prigmore[2], N. Carter[2], P. Jacobs[1], J. Crolla[1]* 1) Wessex Regional Genetics Laboratory, Salisbury, UK; 2) The Wellcome Trust Sanger Institute, Cambridge, UK.

De novo apparently balanced translocations (ABTs) can be present in both clinically affected and unaffected individuals. Molecular studies of ABTs have shown that an abnormal phenotype might be due to cryptic imbalances and/or gene disruption. To test the hypothesis that these features would be found in ABTs of affected patients, but not in those of unaffected individuals, we have analysed 14 affected and 18 unaffected cases all of whom have been examined by a Clinical Geneticist. For affected patients, breakpoint mapping was done by array painting and FISH, and a whole genome scan was conducted using array CGH on the Sanger 30K WGTP array. Molecular characterisations in unaffected individuals were done by FISH and array CGH on the Sanger 1 Mb array.
Array CGH imbalances were detected in 6/14 affected patients, but in none of the unaffected individuals. All of the imbalances were deletions from 200 Kb to 2.5 Mb in size and these were present at/near the breakpoints in 3 cases and in chromosomes unrelated to the translocations in 3 other cases. In 5 affected patients, one breakpoint disrupted a specific gene and in a further 7 gene disruption is likely. Surprisingly, gene disruption by a breakpoint was seen in 8/18 unaffected individuals and in a further 7 gene disruption was likely. As hypothesized, an abnormal phenotype might be explained by genomic imbalances in 40% of patients and by breakpoint-mediated pathogenic gene disruption in a minimum of 35%. The analysis of unaffected individuals showed none to have an imbalance, but a minimum of 44% to have a breakpoint disrupting a gene. In view of the fact that only about 5% of the genome is comprised of genes, this finding in the unaffected individuals suggests that some feature of the chromatin of genes makes them susceptible to breakage. The genes disrupted in this group are presumably not dosage sensitive and thus provide a platform of comparison that might help to establish genotype-phenotype correlations.

Molecular mapping of the 12q13-15 amplicon and identification of new target oncogenes in well-differentiated liposarcomas. *L. Bianchini, A. Italiano, F. Keslair, F. Pedeutour* Lab. of Tumor Genetics, Univ. Hospital Nice and CNRS UMR 6543, Nice, France.

The characteristic supernumerary rings and giant chromosomes of well-differentiated and dedifferentiated liposarcomas (WDLPS/DDLPS) are composed of amplified material from chromosome 12q13-15. The MDM2 and CDK4 genes are usually considered as the targets of the 12q amplicons. However, most data were obtained before the availability of precise and complete maps and were based on small series of WDLPS/DDLPS. Our goal was to precisely define the structure of the 12q13-15 amplicon and to identify new potential target genes of amplification. We investigated a series of 38 WDLPS/DDLPS using fluorescence in situ hybridization (FISH) analysis with a panel of BAC probes encompassing the CDK4-MDM2 region. We studied MDM2, CDK4, CHOP/DDIT3, HMGA2 and GAS41 expression in 11 of 38 cases, using real time quantitative RT-PCR (Q-RT-PCR). We showed the presence of two discrete amplicons centred around MDM2 and CDK4, respectively. In all cases, the centromeric border of the CDK4 amplicon was located precisely downstream to the 5 end of CHOP at 12q13 suggesting that CHOP might be deregulated by the close proximity of the amplicon. Moreover, CHOP is already known for being the seat of the translocation breakpoint in myxoid/round cell liposarcoma. We found that CHOP was overexpressed in 9 of 11 cases demonstrating that CHOP is involved in the development of WDLPS/DDLPS. We found that HMGA2, located between CDK4 and MDM2, was amplified and structurally rearranged in all cases. HMGA2 is known to be the seat of structural rearrangements in lipoma. Our results suggest that the HMGA2 region might be a fragile zone; its disruption would be a major event in the pathogenesis of both benign and malignant adipose tissue tumors. We finally found that GAS41, originally described to be frequently amplified in gliomas, was co-amplified with MDM2 in 83% of cases. Overexpression of GAS41 was detected in 91% of cases. Our results suggest that GAS41 may play an important role in the tumorigenesis of WDLPS/DDLPS and provide evidence for several oncogenes besides MDM2 and CDK4 in the pathogenesis of WDLPS/DDLPS.

Role of WD repeat proteins DMXL1 and DMXL2 in health and disease. *M.R. Hegde, L.H. Chin* Dept Human Genetics, Emory Univ Sch Medicine, Atlanta, GA.

Prader-Willi syndrome (PWS) is a developmental disorder characterized by mental retardation (MR), infantile, hypotonia, poor suck reflex, growth retardation, and childhood onset of pronounced hyperphagia resulting in morbid obesity. PWS is a classic imprinting disorder with most cases resulting from paternal deletions of 15q11-q13 or maternal uniparental disomy 15. However, not all patients who present with PWS-like phenotype have chromosome 15 involvement, suggesting genetic heterogeneity. We have recently identified 6 novel missense mutations in the DMXL1 gene on chromosome 5 in 12% (6/52) of patients with a PWS-like phenotype who previously tested negative for known chromosome 15 etiologies. While the function of DMXL1 is unclear, it is a member of the highly conserved WD repeat protein family, found in all major eukaryotic taxa. Indeed, all six mutations replace an amino acid conserved in DXML1 from human to yeast. A highly similar gene, DMXL2, maps to chromosome 15q21 and a microdeletion of the region including the DMXL2 gene has been reported in a small number of patients with MR, hypotonia, growth retardation and obesity. We therefore hypothesize that mutations in either DMXL1 or DMXL2 may present with a PWS-like phenotype and may account for a sizable fraction of the genetic heterogeneity. We are currently conducting extensive mutation and functional analysis of the mutations in DMXL1 and DMXL2 genes and their proteins. It is hoped that this study will define a novel genetic disorder resembling PWS and provide initial clues to the mechanism of the disorder by biochemical and model system studies.

Comparison of X Chromosome Inactivation Patterns in Multiple Tissues from Human Females. *D.C. Bittel, N. Kibiryeva, Z. Talebizadeh, M.G. Butler* Section of Medical Genetics, Children's Mercy Hospital and Clinics and University of Missouri-Kansas City, MO.

X-chromosome inactivation (XCI) is the mechanism by which gene dosage uniformity is achieved between female mammals with two X chromosomes and male mammals with a single X chromosome. XCI occurs early in embryonic development of somatic cells in human females and is subsequently stable in all daughter cells. Therefore, each tissue of a female is composed of cells which actively transcribe genes from either the maternal or the paternal X chromosome. X chromosome silencing is thought to occur at random in the general female population; therefore the ratio of the maternal to paternal XCI should have a normal distribution with an average ratio of maternal to paternal XCI of approximately 50:50. However, females have been reported with X-linked disorders (e.g., Rett syndrome) and XCI skewness (e.g., > 80:20). For genetic testing, tissues of convenience (e.g., blood) are commonly used; however, the relationship with inaccessible tissues (e.g., brain) is poorly understood. For accessible tissues to be informative for genetic analysis, a high degree of concordance of genetic findings among tissue types would be required. We analyzed XCI patterns in multiple tissues from human females to determine the relationship of XCI among several tissues within individuals at different ages. We analyzed 278 autopsy tissues from 26 females grouped by age as follows: fetus (N=4); 0 - 2 yrs (N=5); 5 - 8 yrs (N=3); 15 - 20 yrs (N=4); 21 - 40 yrs (N=4); 41 - 60 yrs (N=3) and > 60 yrs (N=3). Thirty six different tissues were collected from the three embryonic germ layers with an average of 4 tissues from endoderm (e.g., liver, pancreas, lung, colon), 6 tissues from mesoderm (e.g., blood, spleen, heart, kidney, psoas, adrenal) and 2 from ectoderm (e.g., skin, cerebrum). There was a trend for increasing XCI skewness in blood DNA with age. However, the variation in XCI pattern was reasonably consistent within a subject (< 17% variation) particularly in younger females suggesting it may be reasonable to extrapolate between accessible and inaccessible tissues of interest for study.

Atypical Presentations of Noonan Syndrome with Hematologic Disease. *R. Jethva[1, 2], J. Ganesh[2], I. Krantz[1], S. Saitta[1], L. Campbell[1], P. Kaplan[2]* 1) Division of Human Genetics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Section of Metabolic Disease, Children's Hospital of Philadelphia, Philadelphia, PA.

Noonan syndrome (NS) is an autosomal dominant disorder characterized by typical facial features, skeletal anomalies, cardiac defects, and developmental delay. It is genetically heterogenous and has variable clinical expression. The classic physical features include short stature, triangular facies, curly and coarse hair, low-set ears with thickened pinnae, ptosis, epicanthal folds, down-slanting palpebral fissures, webbed or short neck, low posterior hairline, excess nuchal tissue, and skeletal anomalies. In newborn infants, however, facial features may be subtle. These infants often have normal birth growth parameters and the phenotype may be limited to generalized edema and excess nuchal tissue. Approximately 80% of affected individuals have a cardiac anomaly, including pulmonic stenosis and hypertrophic cardiomyopathy. Patients with NS may have many other systemic complications. Specifically, hematologic findings can include hepatosplenomegaly, thrombocytopenia, coagulopathy, and leukemia. We report three cases of NS that presented with hematologic features diagnosed as juvenile myelomonocytic leukemia (JMML). Each infant had an atypical physical phenotype, which led to delays in diagnosis. Although each individual lacked the classic features, there were other findings suggestive of NS. In addition to having JMML, all three cases had severe failure to thrive, developmental delay, and at least one other common feature of NS, including pulmonic stenosis and wide-spaced nipples. We illustrate that patients with NS and JMML may not present with classic phenotypic features, thus making the diagnosis of NS more difficult. These cases highlight the importance of considering NS in infants with postnatal growth failure, developmental delay, hematologic disease, and usually at least one other common feature of NS. Making the diagnosis is particularly important because the prognosis of JMML in patients with NS is reported to be significantly better than in non-NS patients with JMML.

Significance of submicroscopic genomic imbalances in mental retardation. *A.C.V. Krepischi-Santos[1], A.M. Vianna-Morgante[1], F. Kok[2], C.A. Kim[3], P.A. Otto[1], C. Rosenberg[1]* 1) Genetics and Evolutionary Biology, Institute of Biosciences - University of São Paulo, Brazil; 2) Department of Neurology, Hospital das Clínicas, University of São Paulo, Brazil; 3) Genetics Unit, Department of Pediatrics, Instituto da Criança - University of São Paulo, Brazil.

Cognitive impairment is the most common effect of a chromosome abnormality, frequently associated to dysmorphic features and malformations. Molecular cytogenetics is a powerful tool to identify chromosome abnormalities and the resolution was greatly improved by the use of genomic micro-arrays. We applied 1 Mb whole-genome array-CGH (comparative genomic hybridization to arrays) screening to the study of 100 mentally impaired syndromic subjects. Extensive clinical and genetic investigations could not determine the cause of their abnormal phenotypes. They all had normal G-banded karyotypes. The objective of the study was to disclose submicroscopic genomic imbalances (and genes) causally related to mental retardation. Imbalances detected by array-CGH were confirmed by other methods (FISH or MLPA). Our data indicate that 33% of the group present alterations below the level of resolution of standard clinical cytogenetics. The imbalances that were either de novo or inherited from carriers of balanced rearrangements have been considered causative (22%). The imbalanced chromosome regions are strong candidates to harbor genes related to the specific phenotypes. On the other hand, imbalances not previously found in normal controls have been detected both in the affected patients and their phenotypically normal parents (11%). The significance of this DNA copy number variation is unclear. Our inability to distinguished between copy number changes that represent rare variants from those that are related to the phenotype is due to the lack of knowledge about the copy-number variability at the population level. Our results clearly indicate that array-CGH analysis greatly contributes to elucidate the causes of mental retardation of unknown etiology. The identification of imbalances in such families can lead to detection of carriers and has clear implications for genetic counseling.

CEBP is a candidate regulator of brain disease in prosaposin deficiency mice. *L. Jia[1], Y. Sun[1], M.T. Williams[2], M. Zamzow[1], H. Ran[1], B. Quinn[1], B.J. Aronow[3], C.V. Vorhees[2], D.P. Witte[4], G.A. Grabowski[1]* 1) Div Human Genetics,; 2) Div Neurology,; 3) Div Biomedical Informatics,; 4) Div Pediatric Pathology, Cincinnati Children's Hosp, Cincinnati, OH.

The physiological importance of prosaposin has been demonstrated by the genetic deficiencies of individual saposins or prosaposin that leads to various glycosphingolipid (GSL) storage diseases. Our hypomorphic prosaposin deficient mouse model, PS-NA, exhibits 45% of WT levels of saposins in the brain and showed neurological pathology that included GSL storage in neurons and loss of Purkinje cells. Deterioration of neuronal function was observed by 6 wks using narrow bridge test. To explore the molecular mechanism(s) responsible for disease progression, temporal transcriptome microarray analyses of mouse brain tissues were conducted using mRNA from three prosaposin deficiency models: PS-NA, prosaposin null (PS-/-) and 4L/PS-NA (a V394L/V394L glucocerebrosidase mutation and PS-NA). Central nervous system gene expression alterations were detectable at birth and were of a greater magnitude in cerebellum than cerebrum. Differentially regulated genes encompassed a broad spectrum of cellular functions. Down-regulated genes did not change with age, but up-regulated genes (75%) did tend to increase in number and magnitude suggesting that cellular coping and disease propagation mechanisms were operative. A common transcription factor, CEBP, was up-regulated in all three models at all time points. Network analysis revealed that CEBP has functional relationships with genes in transcription, proinflammation, death, binding, myelin and transport and represented the regionally specific gene expression abnormalities preceded the histological and behavioral changes. Our results indicate that temporal gene expression profile changes have provided novel insight into the molecular mechanism responsible for GSL storage disease progression. CEBP is a candidate regulator of brain disease in prosaposin deficiency and may represent a novel therapeutic target to modulate disease progression. It remains to be determined if CEBP signaling is playing an accelerating or progression suppressive role.

Preimplantation genetic screening (PGS) for aneuploidy in couples undergoing donor egg *in vitro* fertilization cycles. *A. Benner[1], R. Pen[1], P. Kearns[1], P. Browne[2], W.G. Kearns[1]* 1) Shady Grove Center for Preimplantation Genetics, Rockville, MD; 2) Shady Grove Fertility Reproductive Science Center, Rockville, MD.

Purpose: Preimplantation genetic screening (PGS) is used in an effort to decrease spontaneous miscarriage, prevent the birth of aneuploid offspring and to increase the delivery rate by removing genetically abnormal embryos from the pool of embryos to be transferred. Most currently available information regarding aneuploidy rates among human preimplantation embryos comes from PGS of embryos from patients with impaired fertility. PGS for aneuploidy is not a common recommendation for the donor egg patient group, but we and others have demonstrated preliminary evidence that aneuploidy rates in this patient group exceeds 40% of the embryos analyzed. Therefore, we determined aneuploidy rates in 61 couples undergoing donor egg IVF cycles.

Methods: Sixty-one couples underwent donor egg IVF-PGS due to poor outcomes from prior fertility therapy. Laser-assisted embryo biopsy was performed on day-3 and PGS was done on 797 cleaving embryos from 61 initiated cycles. The mean donor age was 26.5 years (range of 21 to 31). Multi-color fluorescence *in situ* hybridization (FISH) was used to determine aneuploidy for chromosomes 13, 14, 15, 16, 17, 18, 21, 22, X and Y. Hybridization, stringency washes and fluorescent microscopy was performed according to routine laboratory protocols. Clinical outcomes of these cycles were determined.

Results: All 61 women had an embryo transfer. Five percent (40/797) of the embryos were not diagnosed due to poor blastomere quality. Fifty-one percent (386/757) of the analyzed embryos were abnormal for at least one of the 10 chromosomes tested. The clinical pregnancy rate was 77% (47/61) per patient and per embryo transfer. There were no miscarriages, misdiagnosis, or mosaic embryos.

Conclusions: This study from donor egg cycles provides insight into the presence of aneuploidy in a low risk population. Pregnancy rates were similar in these patients to those undergoing donor egg IVF without PGS.

Deletion of *Mecp2* in hypothalamic neurons results in obese, anxious and aggressive mice. *S.L. Fyffe[1], J.L. Neul[1], R.C. Samaco[1], H.T. Chao[1], S. Ben-Shachar[1], E.H. Goulding[3], E. Sullivan[3], L.H. Tecott[3], H.Y. Zoghbi[1,2]* 1) Baylor College of Medicine, Houston, TX; 2) Howard Hughes Medical Institute; 3) University of California San Francisco, San Francisco, CA.

Rett syndrome (RTT) is an X-linked neurodevelopmental disorder caused by mutations in the gene encoding methyl-CpG-binding protein 2 (MeCP2). *Mecp2* null mice are hypoactive, tremulous, have weight abnormalities and die by 10 weeks of age. Mice bearing a truncated *Mecp2* allele ($Mecp2^{308}$) survive up to 15 months and display many neurological features of RTT including weight abnormalities, increased anxiety-like behavior and an abnormal stress response. Furthermore, $Mecp2^{308}$ mice have increased levels of the MeCP2 target gene, corticotropin-releasing hormone, in the paraventricular nucleus. This led us to propose that MeCP2 regulates the expression of neuron-specific genes and that dysfunction of specific neurons causes a subset of RTT features. To test this hypothesis, we removed *Mecp2* from the hypothalamic neurons of the paraventricular and supraoptic nuclei by crossing mice carrying a conditional *Mecp2* allele ($Mecp2^{flox}$) to mice that carry a *Sim1*-cre recombinase transgene. Eight neurobehavioral tests were performed on 16 mice from each of the 4 possible genotypes. Open field analysis revealed that the conditional knockout mice (CKO) have a lower center to total distance ratio than control littermates (p0.01) suggesting that they experience elevated levels of anxiety. Resident intruder analysis demonstrated that CKO mice engage in more aggressive behaviors such as tail rattling and attacking (p0.01) than their control littermates. Finally, CKO mice are heavier than wild type littermates (p0.001) beginning at 7 weeks of age. We investigated the cause of this weight gain and found that CKO mice exhibit an increase in daily food intake (p0.0001) without significant changes in activity level or resting metabolic rate. These findings suggest that MeCP2 is critical for the regulation of pathways involved in food intake, stress response and social behavior. Furthermore, they suggest that the loss of MeCP2 in specific hypothalamic neurons is sufficient to reproduce a subset of the features seen in RTT.

High-throughput genotyping of the duplicated gene encoding dopamine receptor 5. *D.J.E. Housley[1], M. Nikolas[2], K.A. Jernigan[1], P.J. Venta[1], J.T. Nigg[2], K.H. Friderici[1]* 1) Dept of Microbiology and Molecular Genetics, Michigan State University; 2) Dept of Psychology, Michigan State University, East Lansing, MI.

Several independent association-based studies have implicated the *DRD5* locus in contributing to attention deficit hyperactivity disorder (ADHD). However, as promising as this locus is, its coding region has not been fully evaluated in most study populations, most likely due to the presence of two highly similar pseudogenes. Our goal was to develop a high-throughput approach to evaluate the entire *DRD5* coding region for new variants and to make accurate genotyping calls for common SNPs. A restriction enzyme site present in both pseudogenes, but absent in *DRD5*, presented an opportunity to use an enzyme treatment prior to amplification to eliminate co-amplification of the duplicated loci. Sequencing of PCR products from 31 trios of an ADHD affected child and both parents confirmed the purity of the amplicons, allowed for discovery of new variants, and enabled confident genotyping calls. Two common variants were genotyped in the trios, which enabled haplotype construction and determination of frequencies in the population. In addition, two previously described rare variants were found: one non-synonymous substitution and one nonsense mutation. We also compared the recorded SNPs in the UCSC browser and HapMap to mismatches between gene and pseudogenes and found that many SNPs from the databases in this region most likely represent gene/pseudogene mismatches. A bioinformatics approach, used to evaluate the extent of the duplicated region, revealed that two separate chromosomal segments, near and including *DRD5*, were duplicated onto HSA1 and 2. The promoter region of *DRD5* was part of a separate duplication event involving 16.6 kb of sequence upstream from the transcription start site, which includes a microsatellite commonly used for association-based studies. This analysis illustrates the importance of using caution when choosing SNPs from databases in regions of suspected duplications. Additionally, we provide a simple and relatively inexpensive method to analyze sequence variation using a high-throughput approach, which can be easily adapted to other duplicated genomic regions.

The Database of Genomic Variants - annotating structural variation in the human genome. *L. Feuk[1, 2], J. Zhang[2], B. Thiruv[2], J.R. McDonald[2], S. W. Scherer[1, 2]* 1) Program in Genetics & Genome Biology, The Hospital for Sick Children, Toronto, ON, Canada; 2) The Centre for Applied Genomics, The Hospital for Sick Children, Toronto, ON, Canada.

The Database of Genomic Variants (http://projects.tcag.ca/variation/) is a comprehensive and curated catalogue of structural variation in the human genome. Copy number variants (CNVs) and inversions larger than 1kb in size are included. Its current content is based on 40 publications, with 6,4820 CNVs and 77 inversions represented. Merging entries for structural variants that overlap yields 3,643 variable loci or regions. In the clinical diagnostic setting, comparative genome hybridization (CGH) has been introduced as a means to search for submicroscopic CNVs in the investigation of certain clinical phenotypes, and potential applications are expanding rapidly. In the research laboratory, screening of large human cohorts for CNVs is now common. Currently, one of the major problems lies in the interpretation of the resulting data. The cost of genome-wide screening still prohibits many researchers from running large groups of control samples. It is therefore important to have access to a comprehensive list of regions already identified as CNVs in previous studies. The Database of Genomic Variants facilitates the interpretation of studies screening for CNVs, in relation to previously published work. The data are represented in table format, genome browser format, and text files available for download. The genome browser is ideal for viewing structural variation in relation to other genomic features, such as genes, clones and segmental duplications. The database has been designed to be easily navigated and suitable for all users, independent of bioinformatics experience. Here we present an overview of the database along with our future plans for its expanded content and enhanced presentation.

Macrocephaly in autism is not a homogeneous marker phenotype. *M.M. Keegan, T.N. Takahashi, J.H. Miles*
Thompson Center for Autism, University of Missouri Hospital, Columbia, MO.

Autism spectrum disorders (ASD) are a broad category of neurodevelopmental disorders which can originate from a variety of genetic and environmental causes. To delineate this heterogeneity we have looked for biologically based phenotypes occurring in a significant proportion of individuals with ASD. One informative phenotype is macrocephaly defined as head circumference (HC) 97% which occurs in 25-35% of individuals with autism and in 37-47% of parents of ASD children (Miles et al. 2002). Longitudinal data, however, are conflicting; some studies report normal or low head size at birth with accelerated head growth in the first few months or between 2 and 3 years, hypothesizing that sudden increase in growth velocity is the correct autism associated phenotype. We examined longitudinal HC curves of 55 children (49 males, 6 females) with classical autistic disorder (AD) with an essential phenotype, who attend a large research based autism center, had birth HC and at least 3 more measurements. Our results indicate that the majority of AD children (62%) have normal HC at birth (Z= -1.0 to 0.5) and continue to have head growth consistently within the normal range with no period of excessive growth. The remaining 38% have normal HC at birth (Z= -1.3 to 1.4) but become macrocephalic. This group is also heterogeneous with 31% having surpassed 97% by age three, 31% in mid-childhood (ages 3-7), and 37.5% after age 8 years. Parents of both groups were considerably more apt to be macrocephalic than expected (60% fathers, 12% mothers in macrocephalic group, 54% fathers, 10% mothers in normocephalic group). These results indicate that macrocephaly is clearly an ASD risk factor, but is a heterogeneous phenotype which undoubtedly has a variety of developmental origins. Previous conflicting reports can usually be attributed to known pitfalls in the study of pediatric head growth including unreliability of birth HC due to molding during delivery, lack of consistent measurement techniques, the dearth of longitudinal studies in typically developing populations and the lingering misperception that ASDs are one homogeneous disorder where averaging measurements is valid.

Relative Warfarin Resistance in Two Patients with VKORC1 g5417t (D36Y). *C. King[1], C. Eby[1,2], R. Porche-Sorbet[2], P. Ridker[3], V. Luzzi[1,2], B. Gage[1]* 1) Department of Internal Medicine, Washington University School of Medicine, Saint Louis, Missouri; 2) Department of Pathology & Immunology, Washington University School of Medicine, Saint Louis Missouri; 3) Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts.

Common polymorphisms in genes for vitamin K epoxide reductase (*VKORC1*) and cytochrome P450 2C9 (*CYP2C9*) affect warfarin requirements. However, they do not explain warfarin resistance, which runs in some families. Recently, investigators identified a new *VKORC1* Asp36Tyr (g5417t) polymorphism that predisposed to relative warfarin resistance in 15 Israeli patients and 2 German patients taking warfarin. Our goal was to quantify the prevalence and relevance of this polymorphism in a diverse American population. We identified outliers whose ratio of therapeutic to predicted warfarin dose (based on *CYP2C9* & *VKORC1*-1639 genotype, body surface area, race, smoking, and medications) was either above the 90th (high-dose) or below the 10th (low-dose) percentiles. From a parent cohort of 900 patients taking warfarin, 39 outliers were African-American, 70 were Caucasian, and 3 identified as Hispanic. After primers were designed, PCR and Pyrosequencing were used to examine Asp36Tyr. None of the 54 low-dose outliers had this *VKORC1* variant. Two of 58 high-dose outliers carried the variant. The first was a homozygous (TT) patient with a therapeutic warfarin dose of 10 mg/day, 200% of what was predicted by the pharmacogenetic-based dosing algorithm at www.WarfarinDosing.org. The second patient was heterozygous (GT) with a therapeutic dose of 3.6, 170% of what was predicted in this elderly patient. Both patients were Caucasian. Larger studies of this polymorphism in patients taking warfarin are indicated.

Turner syndrome and trisomy 14 chromosomal mosaicism in a patient: First reported case. *M. Díaz-Rodríguez[1,2], L.E. Becerra-Solano[1,2], L.l. Arnaud-López[1,2], J.M. Mantilla-Capacho[1,2], M. Ortíz-Aranda[1,2], A.I. Vasquez[1], J.A. Nastasi-Catanese[1,2,3], L.E. Figuera[1]* 1) Division de Genética, CIBO-IMSS, Guadalajara, Jalisco, México; 2) Doctorado en Genética Humana, Centro Universitario de Ciencias de la Salud, Universidad de Guadalajara, Guadalajara, Jalisco, México; 3) Universidad de Oriente, Núcleo Bolívar, Unidad de Genética, Ciudad Bolívar, Bolívar, Venezuela.

Turner syndrome (TS) has an occurrence about 1:2500 to 1:3000 in live-born girls. Around 50% of them have a X monosomy (45,X), and one third have a mosaicism for 45,X. On the other hand, Trisomy 14 is a rare aneuploidy characterized by growth and psychomotor retardation, microphthalmia, broad nasal bridge, wide mouth, asymmetries in face and limbs, and cutaneous pigmentary abnormalities. It has been proposed, for both aneuploidies, that pure lines are lethal. We present a 26 year-old female with a karyotype mos45,X[45]/47XX,+14[5]. Her clinical features were: short stature, small and deep eyes with convergent strabismus, short downward slanting palpebral fissures, broad nasal bridge, mouth with turned down corners, short and wide neck, multiple nevi, swirly hyperpigmentation of the skin, wide thorax, mammary tanner stage II-III, cubitus valgus, limitation on elbows movements, hypertrichosis on forearms, bilateral short fifth metacarpal, shortening in the fourth metatarsus, edema in feet, and body asymmetry (right hemihyperplasia). The patient showed spontaneous menarche at 15 year-old and secondary sexual development. X-ray studies: diminished bone density, lumbar-sacral scoliosis and lordosis, asymmetry and shortness in the lateral segment of vertebral body in vertebras T5, T7 and L2, asymmetric hip, dysplasic right femoral head, dislocation of patella and lateral deviation in the fourth metatarsal. Hormonal profiles (FSH, LH, prolactin and thyroid hormones) were normal. Because there was a overlapping in clinical manifestations of TS and trisomy 14, the determination of the cell line that had the most influence on the phenotype was not possible. We propose for this mosaicism, resulting from a double event, each cell line is rescuing the other one.

Examination of the IL-4R gene in families with Multiple Sclerosis. *Y. Bradford[1], R.L. Zuvich[1], J.L. McCauley[1], B.M. Anderson[1], N. Schnetz-Boutaud[1], J.R. Oksenberg[2], L.F. Barcellos[3], S.L. Hauser[2], M.A. Pericak-Vance[4], J.L. Haines[1]* 1) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN, USA; 2) University of California at San Francisco, San Francisco, CA, USA; 3) University of California at Berkeley, Berkeley, CA, USA; 4) University of Miami School of Medicine, Miami, FL, USA.

Multiple sclerosis (MS) is a chronic inflammatory disorder of the central nervous system with a complex etiology. While the contribution of the Major Histocompatibility Complex (MHC) to genetic susceptibility for MS has been long established with strong associations to the HLA-DRB locus (primarily to the HLA-DRB1*1501 allele), identifying other risk genes has been problematic. However, we recently identified and confirmed a strong association with a coding SNP within the IL-7R gene. Given these strong findings along with the nature and interplay of cytokines and their central involvement within the bodys immune response, we hypothesized that additional cytokines or other immunity-mediated mechanics may play a substantial role in MS susceptibility. One such putative candidate gene, interleukin-4-receptor (IL-4R), is known to stimulate B-cell and T-cell development and differentiation. Additionally, IL-4R has been associated with other autoimmune diseases such as asthma and type-1 diabetes, and we had previously identified an association of IL-4R with MS in African-Americans. To investigate the possible association of the IL-4R gene with MS in a Caucasian population, we have initially genotyped 8 SNPs across an approximately 44kb region in 170 Caucasian multiplex families with 186 affected sib-pairs and 101 other affected relative pairs. However, our initial analysis shows no strong evidence of association between MS and IL-4R, suggesting that the IL-4R association may be specific to African-Americans.

Microarray CGH analysis and genotype-phenotype correlation in a patient with subtelomeric 9q deletion syndrome. *T.J. Chen, Y. Wang, J. Chaplin, C.M. Tuck-Muller, W. Wertelecki, J.E. Martinez* Dept Medical Genetics, Univ South Alabama, Mobile, AL.

Subtelomeric deletion of chromosome 9q is a newly recognized microdeletion syndrome. Most patients have a submicroscopic deletion of the gene-rich critical region, which is about 700 kb distal to 9qter but less than 30 cases of this condition have been described so far and most deleted regions have been studied by FISH and/or STR analysis. Therefore, a correlation between the size of the deletion and the severity of clinical manifestations has not yet been determined. We performed microarray analysis on a black female infant with developmental delay and a subtelomeric 9q deletion using high resolution oligo CGH array. She was born with a birth weight of 3.1 kg at term to the first pregnancy of young non-consanguineous parents. Congenital heart anomalies were diagnosed at birth including a VSD, a PDA and at the age of 22 month, she was noted to be developmentally delayed, small and microcephalic, and had the following measurements: OFC 41.5 cm (<2nd%), Height 73.5 cm (<5th%) and Weight 8.6 kg (<5th%). Craniofacial dysmorphism included coarse facial features, prominent forehead, hypotonic face and large mouth. She was also noted to have tracheomalacia and gastro-esophageal reflux and a gastrostomy tube was placed for supplemental feedings. Cytogenetic studies of the patient and her parents were normal. The subtelomeric deletion 9q was first detected by multiple ligation-dependent probe amplification (MLPA) and array CGH analysis revealed a 3.0 MB deletion on 9q34.3, from 137.2 MB to 140.2 MB, which is smaller than previously reported cases. The patients phenotype is consistent with the clinical manifestations reported in cases with deletions in the critical region but our patient did not have brain abnormalities, seizures, joint laxity, trigonocephaly, or furrowed palate, anomalies described in patients with a deletion size larger than 1.2 MB. Thus, a more precise determination of deletion size and molecular location will be needed to clarify the genotype-phonotype correlation in this syndrome.

Robust methods for QTL linkage analysis in nuclear families. *S. Bhattacharjee[1], C. Kuo[2], N. Mukhopadhyay[1], G.N. Brock[3], D.E. Weeks[1,2], E. Feingold[1,2]* 1) Dept of Human Genetics, GSPH, Univ Pittsburgh, Pittsburgh, PA; 2) Dept of Biostatistics, GSPH, Univ Pittsburgh, Pittsburgh, PA; 3) Dept of Bioinformatics and Biostatistics, Univ of Louisville, Louisville, KY.

Variance component (VC) based score statistics for linkage mapping of quantitative traits have been proposed by a number of authors. Apart from being computationally simple, these methods offer robustness to ascertained sampling and non-normality of traits, while preserving the power of the traditional likelihood ratio based VC approach. As a result, they have received substantial theoretical attention and different variations and extensions have been proposed. However, these methods have not been applied to real data as frequently as they should be, mostly due to the fact that some practical implementation issues have not been addressed adequately. In this study we summarized and classified the existing score statistic variants based on their theoretical properties and proposed some new variants that are theoretically expected to have improved performance. We also compared the statistics in terms of robustness of type I error and power using comprehensive simulations. We addressed various practical issues such as choice of denominators, effect of selection, effect of incorporating dominance and sensitivity to mis-specified trait parameters. Our study included standard regression-based statistics such as that implemented in the software *merlin-regress* (Sham *et al*, 2002), as well as the recently proposed GEE-based higher moment statistics (Chen *et al*, 2005). In some cases, our proposed variants of these statistics gave significant improvements over the original versions. Based on our simulation study, we formulated guidelines for choosing powerful and robust score statistic variants in different practical scenarios.

***ZNF750*, a novel C2H2 zinc finger protein associated with seborrheic dermatitis and psoriasis, modulates expression of cytokines and proliferation genes in keratinocytes.** *R. Birnbaum, R. Ofir, V. Chalifa-Caspi, O. S. Birk*
The Morris Kahn Laboratory of Human Genetics, National Institute for Biotechnology and Faculty of Health Sciences, Ben-Gurion University of the Negev, and Genetics Institute, Soroka Medical Center, Beer-Sheva, Israel.

Seborrheic dermatitis and Psoriasis are common dermatoses with overlapping features. An Israeli Jewish Moroccan family presented with autosomal dominant seborrhea-like dermatosis with psoriasiform elements: enhanced keratinocyte proliferation, parakeratosis, follicular plugging, *Pityrosporum ovale* overgrowth, and CD4 lymphocyte infiltrate. We showed that the disease gene is *ZNF750*, encoding a C2H2 zinc finger-like protein. *ZNF750* is normally expressed in keratinocytes (not in fibroblasts) and scarcely in CD4 lymphocytes. We deomonstrate that ZNF750 modulates the expression of specific cytokines by keratinocytes, and we elucidate molecular mechanisms of enhanced keratinocyte proliferation in this disease. Our findings open new insights to the molecular mechanisms of Seborrheic dermatitis and Psoriasis.

Quality of Life Investigation of Tibial Dysplasia in NF1 Patients Shows Differences in Outcome and Provides a Framework for Clinical Trials. *J.C. Carey[1,2], D.A. Stevenson[1,2], D.H. Viskochil[1,2], J. Siebert[2], S. Geyer[2], M. Winn[2], J. Roach[2], J. D'Astous[2], C. Marra[3], L. Colley[3], J. Friedman[3], P. Birch[3], E. Schorry[4], TD Working Group* 1) Dept Ped/Div Med Genetics, Univ Utah Medical Ctr, Salt Lake City, UT; 2) Shriner Hospital for Children, Intermountain, Salt Lake City, UT; 3) University of British Columbia, Vancouver, BC, Canada; 4) Cincinnati Children's Hospital, Cincinnati, OH.

Tibial dysplasia (TD) occurs in about 5% of persons with neurofibromatosis type 1 (NF1) and is one of the criterion for the diagnosis of NF1. TD comprises a continuum of anterolateral bowing to the serious problem of pseudarthrosis (PA). Treatment of PA is complex and often requires multiple surgical procedures with varying degrees of success. Recently medical therapies for TD/PA, including bisphosphonates and dietary modalities, have been proposed. Methods: We have established a 4-yr multicenter study to investigate the natural history of TD/PA and to determine outcome measures for TD in future trials. The study methods involve surveying patients and families with TD/PA and NF1 using standardized health-related quality of life (QOL) instruments. Results: We compared 24 children with NF1/TD to 63 NF1 children without TD using the PODCI and the HUI instruments. Applying the Mann-Whitney U-Test, we demonstrated that the means of Basic Mobility (15.3) and Sports/Physical Function (13.68) were markedly different than controls (46.7, 42.3)($p< 0.001$). Notably the scores for Happiness were no different. Using the HUI, we compared the overall scores and individual domains in cases and controls, and these varied between the groups only for Ambulation. There were no group differences in age distribution or gender. Discussion: This study is the first QOL investigation of the orthopedic aspects of NF1. The overall purpose of the project is to obtain outcome data for design of future medical/surgical therapeutic trials in patients with TD. These data - proof of principle - demonstrate that these QOL measures can be utilized effectively in designing such trials for the treatment of TD in NF and show outcome differences in QOL in NF1/TD patients.

The first report of a *de novo* heterozygous missense *DISP1* mutation in a patient with congenital diaphragmatic hernia (CDH) and additional malformations. *S. Kantarci[1,2], F. O'Neill[1], M.K. Russell[1], K.M. Noonan[1,2], R. Pieretti-Vanmarcke[1,2], L. Mitova[3], J. Wilson[2,3], P. Dickman[4], K. Yboa[5], P.K. Donahoe[1,2], B.R. Pober[1,2,3]* 1) Massachusetts General Hosp., Boston, MA; 2) Harvard Med. Sch., Boston, MA; 3) Children's Hosp., Boston, MA; 4) Phoenix Children's Hosp., Phoenix, AZ; 5) Columbia Univ., New York, NY.

Background: Congenital diaphragmatic hernia (CDH) is a common birth defect with high mortality and morbidity. Although the etiology in many cases is unknown, recent reports suggest that genetic aberrations, including microdeletions and gene mutations, cause or contribute to CDH. We chose to sequence a novel candidate gene, dispatched homolog 1 (Drosophila) [*DISP1*], given its location in the chromosome 1q41 CDH- hotspot region as well as its role in the Sonic Hedgehog (SHH) pathway.

Methods: In 24 patients with CDH plus additional anomalies, including 5 patients with Fryns syndrome, we sequenced the 8 exon *DISP1*. We also used the multiple ligation-dependent probe amplification (MLPA) technique to screen for exon deletions/duplications. Sequence variants not found in SNP databases were genotyped in parents and in 96 controls.

Results: A missense heterozygous *DISP1* mutation, c.4412C>G, was identified in a multiply malformed male patient with left-sided Bochdalek hernia, facial dysmorphism, cleft lip/palate, VSD, developmental delay and additional musculoskeletal anomalies. This mutation, changing an evolutionarily conserved alanine to glycine at position 1471 (A1471G), was predicted to be deleterious by PolyPhen and SIFT. After confirming paternity, we showed that neither parents nor controls, carried this mutation. We did not detect any other *DISP1* point mutations or exon deletion/duplication in the 24 patients screened.

Conclusion: This is the first *DISP1* human mutation identified in a patient with CDH. *DISP1* is an attractive candidate gene as its protein product is required for SHH signaling, a pathway possibly important for normal diaphragm and lung development.

Identification of a novel ZIC3 isoform and mutation screening in patients with congenital heart malformations.

J.E.J. Bedard[1], S. Fernbach[2], J.W. Belmont[2], S.M. Ware[1] 1) Cincinnati Childrens Hospital Medical Center and University of Cincinnati College of Medicine, Department of Pediatrics, Cincinnati, OH; 2) Baylor College of Medicine, Department of Molecular and Human Genetics, Houston, TX.

Congenital heart malformations are the most common birth defect and cause significant morbidity and mortality. Patients with heterotaxy have characteristic cardiovascular malformations, abnormal arrangement of visceral organs, and midline patterning defects due to abnormal left-right patterning during early embryogenesis. Loss of function of the transcription factor ZIC3 causes X-linked heterotaxy and isolated congenital heart malformations, and represents one of the few known monogenic causes of congenital heart disease. Although the birth prevalence of heterotaxy spectrum malformations is significantly higher in males, we have previously demonstrated that this gender bias is not accounted for by mutations in ZIC3. The current investigation identifies an alternatively spliced ZIC3 mRNA (ZIC3-B) with a previously unrecognized exon, suggesting a possible novel genetic cause of X-linked heterotaxy. Characterization of the ZIC3 isoforms indicates that exons 3 and 4 are alternatively spliced and share less than 35% identity, suggesting that exon 4 evolved independently and did not arise by a duplication and divergence of exon 3. Exon 4 is highly conserved across species and results in an isoform with a distinct C-terminus of the protein while maintaining the zinc finger DNA binding domain, protein interaction domains and nuclear localization and export signals. Expression analysis of ZIC3-B indicates that it is expressed in murine embryos at critical stages of cardiac development, suggesting it as a possible cause of heterotaxy and cardiovascular malformations. In adult tissues, its expression pattern overlaps with that of ZIC3-A. To further investigate the role of ZIC3-B in cardiac development, 109 male heterotaxy cases (5 familial and 104 sporadic) were screened. No mutations were identified in ZIC3-B, suggesting that this novel isoform is not a major contributor to heterotaxy spectrum cardiovascular abnormalities.

Suggestive evidence for linkage to a chromosome 13 locus influencing serum IGF-1 levels and body weight in cystic fibrosis mice. *J.C. Canale-Zambrano[1], S.M. Cory[2], C.K. Haston[1]* 1) Meakins-Christie Laboratories, McGill University, Montreal, Quebec, Canada; 2) McGill Centre for Bioinformatics, McGill University, Montreal, Quebec, Canada.

Cystic fibrosis (CF) is the most common, fatal genetic autosomal recessive disease affecting young Caucasians. CF is a multi-organ disease affecting primarily the lungs and the digestive system. As a consequence of intestinal disease, CF patients suffer from failure to thrive and present low body weight relative to the non-CF population. CF mice present the phenotype of low body weight and have been shown to have low serum levels of insulin-like growth factor-1 (IGF-1), as has been clinically reported in CF patients. In addition, we have recently shown CF body weight phenotype to be dependent on intestinal crypt proliferation and apoptosis. The objective of this study is to use CF mice to identify candidate modifier genes influencing body weight in CF disease. To identify these factors we phenotyped a population of 12 week-old CF mice for body weight, serum IGF-1 and crypt changes and conducted a genome-wide mapping study in an F2 population (B6xBALB) of CF mice. Concentrations of serum IGF-1 levels and body weight showed a phenotypic correlation (r=0.55, p=0.03) in female F2 CF mice. These phenotypes were suggestively linked to chromosome 13 with a LOD score of 2.2 for IGF-1 and a LOD score of 2.5 for body weight. At this locus the presence of B6 allele in an F2 mouse decreases the serum levels of IGF-1 in male mice (*Balb/Balb* 475 ng/ml vs *B6/B6* 343 ng/ml; p = 0.01). A QTL for body weight has been described to be at the location for non-CF mice; however, no QTL has been described for IGF-1 in non-CF animals suggesting this locus to be specific to CF mice. The mapping of intestinal crypt changes is ongoing. We conclude that a locus for serum levels of IGF-1 was co-incident with the body weight in CF mice on chromosome 13, providing a possible mechanism linking both phenotypes.

A molecular signature for identification of platinum resistant ovarian cancer. *M. Bonin[1], J. Hoffmann[1], T. Fehm[2], M. Walter[1], K. Sotlar[3], D. Wallwiener[2], O. Riess[1], E. Solomayer[2], H. Neubauer[2]* 1) Medical Genetics Dept, Inst. of Human Genetics, The Microarray Facility, Tuebingen, BW , Germany; 2) Gynecological Hospital, Eberhard-Karls-University, Tuebingen, Germany; 3) Inst. of Pathology, Eberhard-Karls-University, Tuebingen, Germany.

Ovarian cancer is one of the most common malignant tumors in women. So far, there are no histopathological parameters which indicate platinum resistance. Therefore, nearly all patients are treated with platinum-based chemotherapy postoperatively. Patients who suffer a relapse within 6 months are termed as platinum resistant. So far, molecular profiling of platinum resistant ovarian tumors plays no role in the selection of adjuvant therapy. The goal of this study was to identify a set of genes, which can predict resistance to platinum-based chemotherapy in ovarian cancer. 12 platinum resistant and 12 platinum sensitive ovarian carcinomas were selected by a pathologist who defined the subtype and the proportion of carcinoma. Only samples containing at least 50 % malignant tiussue were used to isolate RNA from frozen tissue sections and were analyzed on Illumina Human-6v2 BeadChips to determine differentially expressed genes. Data analysis with Genespring was followed by class prediction with Support Vector Machines (SVM) that was undertaken with a predictive set of 55 genes. It offered a correct classification into platinum resistant and platinum sensitive patients in all samples. Analysis of our findings with Ingenuity Software showed a functional relevance to regulation of transcription, apoptosis and cell cycle. For validation of the predictive gene set, we used qRT-PCR to measure the mRNA expression level of 13 selected genes in 20 samples. Again, we used SVM for analysis and found out that 18 samples were predicted correctly. The mean expression value in 10 of 13 genes was consistent with the trend observed in the microarray data. We can conclude that we found a predictive set of 55 genes that is able to classify ovarian carcinomas according to their sensitivity for platinum-based chemotherapy. The predictive power of the 55-gene set needs to be further validated in an independent set of ovarian cancer specimen.

Smarter clustering methods for high-throughput SNP genotype calling. *E. Feingold[1 2], Y. Lin[2], G. Tseng[2], L.J.H. Bean[3], S.L. Sherman[3]* 1) Dept Human Genetics, Univ Pittsburgh, Pittsburgh, PA; 2) Dept Biostatistics, Univ Pittsburgh, Pittsburgh PA; 3) Dept Human Genetics, Emory University, Atlanta GA.

Many different SNP genotyping technologies are now in common use. Most use clustering methods to "call" the SNP genotypes, but standard clustering methods are not optimal in distinguishing the genotype clusters of a SNP because they do not take advantage of a number of specific features of the genotype calling problem. In particular, prior information about the distribution of the measurements for each cluster can be used to choose an appropriate model-based clustering method and can significantly improve the genotype calls. Furthermore, when family data are available, pedigree information can be used to call all genotypes for a family together. We propose two new methods to call genotypes using family data. The first method is a modification of the K-means method. The second is a likelihood-based method that combines a Gaussian or beta mixture model with a pedigree likelihood. We compare the performance of these methods using simulation studies and demonstrate them on real data. We show that incorporation of external information can improve genotype calls even for "good" data. We also demonstrate the extension of our algorithm to calling genotypes for trisomic individuals.

CTCF binding in *cis* regulates CAG/CTG instability at the spinocerebellar ataxia type 7 (SCA7) locus. *K.A. Hagerman[1], R.T. Libby[2], V.V. Pineda[2], R. Lau[1], J.D. Cleary[1], B.L. Sopher[2], D.H. Cho[3], S. Baccam[2], S.J. Tapscott[2,3], G.N. Filippova[3], C.E. Pearson[1], A.R. La Spada[2]* 1) Genetics and Genome Biology, Hospital for Sick Children, Toronto, ON, Canada; 2) University of Washington Medical Center, Seattle, WA, USA; 3) Fred Hutchinson Cancer Research Center, Seattle, WA, USA.

Since the discovery of disease-associated CAG instability, *cis*-acting sequence elements, genomic context, and epigenetic modification have been thought to contribute to instability. The drastically different levels of repeat instability at different disease loci with repeats of identical sequence (spinobulbar muscular atrophy (SBMA) vs. SCA7) strongly supports the existence of *cis*-acting DNA elements that promote instability at certain loci. Similarly, the distinct patterns of repeat instability between tissues of the same patient argue for tissue-specific epigenetic or *trans*-factor regulation. However the mechanistic basis of this is yet to be described.

Binding sites for the CTCF chromatin insulator protein are adjacent to or flank the unstable CAG/CTG tracts at numerous disease loci. Using a mouse model of SCA7 CAG instability with (CAG)92, we tested the role of the 3'-CTCF binding site by assessing germline and somatic repeat instability in mice with either a wild-type or mutant CTCF binding site, respectively capable or incapable of binding CTCF protein. Transmitted and somatic instability was significantly enhanced in mice with mutant binding sites. CpG methylation, which ablates CTCF binding based on gel shift analysis, also enhanced CAG instability.

Our results thus implicate the CTCF binding site adjacent to the SCA7 CAG repeat as a *cis*-element regulating its instability, and indicate that CpG methylation is an epigenetic regulator of this element. These findings are the first data to implicate CTCF in genetic instability, and therefore have wide-reaching implications for instability at the many other disease loci where CTCF binding sites have been identified.

High Frequency Of Central Nervous System Malformations Associated With Choanal Atresia. *T.A. Burrow, H.M. Saal, R.J. Hopkin* Division of Human Genetics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

Choanal atresia is a common craniofacial defect characterized by absence of the opening between the nasal cavity and the nasopharynx. Embryologically, this defect is a result of failed degeneration of the oro-nasal septum, which normally occurs around the sixth week of gestation. Presenting unilaterally and bilaterally, it occurs with an incidence of approximately 1 in 8,000 live births. Fifty percent of affected individuals have additional associated congenital anomalies. We are currently reviewing cases of choanal atresia and stenosis (CA/S) seen at Cincinnati Childrens Hospital Medical Center over the past 10 years. To date we have completed the analysis of 38 individuals focusing on characterization of malformations of the central nervous system and neurologic deficits. Choanal atresia and stenosis were identified as isolated findings and in association with disorders of various etiologies, including teratogens, chromosomal abnormalities, single gene defects, and deformations. Among all affected individuals, 11 (29%), were noted to have some degree of developmental delay. Likewise, 13 individuals, 34%, were noted to have brain abnormalities on MRI. The most common brain abnormalities on MRI included inferior vermian hypoplasia, increased prominence of the ventricles and subarachnoid fluid space, hydrocephalus, and pituitary abnormalities, with three cases each. None of the individuals with isolated CA/S (3 cases), had associated developmental delays or brain abnormalities on MRI. Of the patients with developmental delay and/or brain anomalies, only 25% had CHARGE syndrome. Interestingly, choanal abnormalities were diagnosed in three individuals with holoprosencephaly sequence. Choanal atresia is the most common craniofacial defect affecting the nose and is frequently associated with developmental delay and brain malformations on MRI, particularly when occurring in connection with other features. This suggests overlapping pathways in embryology contributing to abnormal morphogenesis. We conclude that close developmental monitoring and brain imaging are indicated in cases of CA/S, particularly if additional anomalies are identified.

Multiple OXPHOS deficiency and mitochondrial DNA depletion in the liver of a patient with CblA methylmalonic aciduria sensitive to vitamin B12. *A. Brassier[1,2], V. Valayannopoulos[1], S. Romano[1], M. Sarzi[2], D. Chretien[2,3], P. Hue[2], J. Kaplan[2,3], D. Rabier[4], A. Rötig[2,3], A. Munnich[2,3], Y. de Keyzer[2], P. de Lonlay[1,2]* 1) Metabolic Unit, Necker-Enfants Malades Hosp, Université Paris V, Paris, France Paris, France; 2) INSERM-U781; 3) Genetic Department; 4) Biochemistry Laboratory.

Background: Defects of adenosylcobalamin A, which is the coenzyme of the methylmalonyl-CoA mutase (MUT) is responsible for methylmalonic aciduria (MMA) responsive to vitamin B12. A few reports have supported the hypothesis that secondary respiratory chain deficiency could be the cause of complications observed in MMA patients. Case report: A patient with cblA MMA responsive to vitamin B12 (homozygous c.387, nonsense mutation in exon 2 of the MMAA gene) and considered to have a well-controlled metabolic disease with a very low urinary excretion of methylmalonic acid, presented with an extremely sudden and severe visual impairment due to optic atrophy without retinal degeneration. Six months later, he presented with a severe metabolic distress, with lactic acidosis and multiorgan failure leading to death. Results: A multiple OXPHOS deficiency was found in the patients liver with reduced absolute activity values of mtDNA-encoded complexes (I, III, IV and V) and abnormal activity ratios. A profound mtDNA depletion was also identified in the liver, with a residual mtDNA content of 16%. Conclusion: We describe for the first time multiple OXPHOS deficiency and mitochondrial DNA depletion in the liver of an MMA-CblA, B12 sensitive patient. Deficient methylmalonyl-CoA mutase results in an accumulation of methylmalonyl-CoA, but also in a reduction of succinyl-CoA, which affects the activity of the succinyl-CoA synthase (SCS), known to be responsible for mtDNA depletion, and influences the overall flux of the tricarboxylic acid (TCA) cycle. This hypothesis confers a major role to the TCA cycle in the physiopathology of long-term complications in MMA.

Molecular cytogenetic characterization of an 11q23.3q24.2 duplication in a child with growth/developmental delay. *R.D. Burnside, F.M. Mikhail, E.J. Lose, A.J. Carroll* Dept Genetics, Univ Alabama at Birmingham, Birmingham, AL.

Duplications of the distal part of the long (q) arm of chromosome 11 have been well described, and certain phenotypic features such as growth delay, mental retardation, and microcephaly are consistently seen. However, 11q duplication often results from an unbalanced translocation with another chromosome, making it difficult to determine whether other phenotypic features that may present are the result of the 11q duplication. Here, we present a case with an interstitial insertion resulting in duplication of part of distal 11q in a two-and-a-half year old male child. This patient was referred to our genetics clinic due to dysmorphic features and developmental delay including speech delay. These features alone without addititonal physical findings have a very broad differential diagnosis. Chromosome analysis was performed on GTG banded chromosomes from cultured lymphocytes and showed a darker-staining band in the light-staining 11q13.1 region. In order to determine whether this band was chromosome 11 material, whole chromosome painting was performed on metaphase chromosomes. The result indicated that the extra band was chromosome 11 material. Using a 32K BAC tiling path array CGH chip, we demonstrated an ~8.8 Mb duplication within the 11q23.3q24.2 region. Our patient therefore carries an unbalanced insertion of the 11q23.3q24.2 region into band 11q13.1. These results were confirmed by metaphase FISH using the *MLL* (11q23.3) probe. The patients final karyotype is 46,XY,der(11)ins(11;11)(q13.1;q23.3q24.2).ish der(11)ins(11;11)(q13.1;q23.3q23.3)(*MLL*++). In conclusion, our patient demonstrates the clinical usefulness of whole genome high resolution array CGH analysis as a powerful molecular cytogenetic tool capable of detecting genomic imbalances due to cytogenetically visible but uncertain rearrangements. Parental chromosome and FISH analyses are underway. A detailed description of the patients clinical features and comparison with previously reported distal 11q duplications will be presented.

.

***De Novo* Interstitial Deletion 1p31.1: A Distinct Syndrome?** *A. Battaglia[1,2], J. Palumbos[2], N. Pihl[2], A. Brothman[2], E. Ashton[2], J.C. Carey[2]* 1) Inst Child Neurology & Psych, Stella Maris nst/Univ Pisa, Pisa, Italy; 2) Dept of Peds/Div of Med Genetics, University of Utah Med Ctr, Salt Lake City, UT.

The 1p36 deletion syndrome has become well established as a recognizable entity over recent years. Less well-characterized and delineated are the phenotypes due to more proximal interstitial 1p deletions. An informative patient with an MCA/MR syndrome consisting of global developmental delay/mild mental retardation, microcephaly, short stature, distinctive facial features (telecanthus, epicanthal folds, synophyrs, overfolded small ears, narrowed ear canals), short neck, and accessory left nipple was referred for diagnostic evaluation to the Division of Medical Genetics. On examination, height was far below the 2nd centile; OFC fell below the 2nd centile; weight was just above the 5th centile. He also had severe genu valgum, requiring surgery; and early cryptorchidism with vanishing testes (not found at surgery). HRB chromosomes were apparently normal. Array-CGH was then carried out and showed a deletion at 1p31.1 of 73kb-5Mb in size; 1 BAC deleted RP11-80G24 (not deleted in his parents). Therefore, the patients karyotype shows: 46,XY, arr cgh del1p31.1 (RP11-80G24). To date, 4 cases of visible interstitial deletions 1p31 have been published. All have short stature, microcephaly, developmental delay, and the male individuals have cryptorchidism. However, compared to the patients reported in the literature, our propositus shows more distinctive facial features. Based on the literature and on our patient, there is evidence for a critical region within 1p31.1 for the distinctive facial features and the vanishing testes. We suggest that this chromosome disorder may constitute yet another recognizable microdeletion syndrome.

Whole genome scan revealed responsible loci for responses to short term analgesics in humans. *H. Kim[1], E. Ramsay[1], S. Wahl[2], R.A. Dionne[1]* 1) NINR/NIH, Bethesda, MD; 2) NIDCR/NIH, Bethesda, MD.

Because of the complicated mesh of contributing factors and the thousands of molecules involved in different pain phenotypes, it is challenging to detect responsible genetic variations for an individuals unique susceptibility to pain. Most of genetic associations reported with pain phenotypes so far are weak and debatable. Response to analgesics is one of the most feasible pain phenotypes for the genetic association studies due to its relative simplicity and clinical relevance. To find pharmacogenomic responsible loci for analgesic response on a genome wide scale, we have genotyped 500,768 single nucleotide polymorphisms (SNPs) with comparative genomic hybridization in humans who underwent standardized surgical removal of impacted third molars. Data collected from a total of 112 European American patients were analyzed with Helix Tree and Copy Number Analysis Tool (CNAT). We found 8 loci that showed significant associations with analgesic onset time (AOT) at the level of $p < 4.2 \times 10^{-7}$. Further analysis revealed a genomic region spanning 6 SNPs along with approximately 60 kbs from rs2562456 to rs2562507 that separated by approximately two-order of magnitude ($p < 10^{-9}$) from the next highest associated SNP ($p = 3.5 \times 10^{-8}$). CNAT suggests copy number variations of 7 loci in longer AOT (> 30 min) subjects compared to shorter AOT (< 5 min) subjects. Further characterization of these regions with dense genotyping may identify genetic loci that contribute to interindividual variability in analgesic responses of humans in pain due to tissue injury and acute inflammation following minor surgery.

Characterization and expression of cytoplasmic actins(&)in LLC-PK1-CL4 cells to elucidate the role of -actin mutations causing non-syndromic hearing loss. *S. Korrapati[1], M. Zhu[2], K. Friderici[3]* 1) Genetics Program; 2) Cell & Molecular Biology Program; 3) Microbiology & Molecular Genetics-Michigan State University,East Lansing,MI48824.

Mutations in the isoform of actin cause non-syndromic,post-lingual,autosomal-dominant,progressive sensorineural hearing loss.Localization studies of the actins in the guinea pig and chicken hair cells reveal differential spatial arrangements of the two cytoplasmic actin isoforms (,).Our hypothesis is that -actin is involved in specific functions in the inner ear.Stereocilia are derivatives of actin-filled microvilli found on the surface of many cell types.The pig proximal kidney epithelial cell line,LLC-PK1-CL4(CL4),lacks endogenous actin bundling protein espin,but form long spiky microvilli when transfected with espin.Our goals for this project are to study the function of the actin isoforms using CL4 cells as a model system and to investigate the role of -actin and the mutants in the repair of the microvilli.This study,we hope,will mimic the condition of the hair cells of individuals suffering from age-related hearing loss since aging hair cells constantly undergo damage and repair.Using CL4 cells and confocal imaging,the results obtained so far reiterate the observations(in other cell types)that the cytoplasmic actins are differentially distributed within the cell.-actin is located primarily at the periphery of cells while -actin is abundant in the perinuclear space and cytoplasm of the cell.Exogenous expression of and -actin shows distribution of the actins to all the relevant actin structures in the cell-periphery,stress fibers and perinuclear space.In response to exogenous espin expression,espin and filamentous actin co-localize in the microvilli.Co-immunoprecipitation assay confirmed espin--actin interaction.Co-transfection of espin and the mutants resulted in each of the mutants co-localizing with filamentous actin in the microvilli.Cytochalasin D,a potent inhibitor of actin polymerization,disrupted actin microfilaments in the microvilli following 13hrs of treatment.At a concentration of 100nm,this effect was reversible as the microvilli recovered by 4.5 hrs post drug removal.

An Expanded Ashkenazi Jewish Prenatal Carrier Screening Panel - 16 Diseases. *L. Edelmann, S.A. Scott, L. Liu, Y. Wang, R.J. Desnick, R. Kornreich* Department of Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York, New York, 10029.

Since the 1970s, when prenatal carrier testing for Tay-Sachs disease began, we have performed prenatal carrier testing and counseling for the Ashkenazi Jewish (AJ) population. Due to selection and/or genetic drift, the AJ population are at increased risk for certain severely debilitating and/or fatal autosomal recessive diseases in which specific mutations are present in the majority of affected patients. Previously, our disease panel included eleven disorders: Bloom syndrome, Canavan disease, cystic fibrosis, familial dysautonomia, Fanconi anemia group C, Gauchers disease, glycogen storage disease Ia, maple syrup urine disease, mucolipidosis type IV, Niemann-Pick disease type A, and Tay-Sachs disease. These have carrier frequencies that range from 0.070 (1 in 15) to 0.008 (1 in 125) and have 94 to 99.5% detectability in the AJ population. Recently, we added four disorders (lipoamide dehydrogenase deficiency (E3), Usher type III (USHIII), familial hyperinsulinism (HI), and nemaline myopathy (NM)) to the panel with detectabilities of 90 to 95%. Their AJ carrier frequencies range from 0.012 (1 in 85) to 0.008 (1 in 120) and were determined by screening 1000 anonymous unrelated AJ individuals from the greater New York Metropolitan area using a recently developed multiplex PCR/allele-specific primer extension Luminex FlexMAP bead-based assay. In addition, we also determined the Usher type I (USHI) carrier frequency in this AJ cohort to be 0.006 (1 in 170). Given this disorder has a detectability of 75%, residual risk counseling is required. The cumulative carrier frequency for E3, USHIII, HI and NM mutations in our AJ cohort was 1 in 26 (1 in 23 when including USHI), highlighting the potential benefit in including these disorders in an AJ screening panel. With the clinically approved expanded panel of 15 disorders (16 including USHI), approximately 1 in 4 AJ will be a carrier for at least one of these diseases.

Putative Neurexin 1 and Neuroligin 4 mutations in U.S. Caucasian patients with autism or Asperger syndrome. *J. Feng[1], K. Noltner[1], J. Yan[1], J. Sebastian Saldivar[2], S. Martinez[2], M. Hua[2], J. Picker[3], S. Sommer[1,2]* 1) Dept Molecular Genetics, City Hope Natl Medical Ctr, Duarte, CA; 2) Department of Molecular Diagnosis, City of Hope National Medical Center, Duarte, CA; 3) Department of Medical Genetics, Childrens Hospital, Boston, MA.

The neuroligins are post-synaptic membrane cell-adhesion molecules that bind to pre-synaptic beta-neurexins, a family of proteins that act as neuronal cell surface receptors. A triad of studies reported associations between mutations in the Neuroligin 4 (NLGN4) gene and autism, Asperger syndrome, and mental retardation. Yan et al estimated an attributable risk of 3% in U. S. Midwest and Portuguese Caucasian families. Recently, two studies reported an association of neurexin 1 beta with autism. Feng et al. estimated an attributable risk of 3%. Herein, 78 patient samples with autism or Asperger syndrome submitted for clinical testing from throughout the U.S. were tested comprehensively by direct sequencing for mutations in the NLGN4 gene. In addition, 94 patient samples with autism were sequenced comprehensively for the neurexin 1 alpha gene. Three cases were positive for mutations in the NLGN4 gene that are very likely to be deleterious (~4%). An analysis of the neurexin 1 alpha gene reveals putative mutations. NLGN4 mutations occur at a significant level in a clinical sample of U.S. Caucasian patients with autism and Asperger syndrome. We conclude that NLGN4 and neurexin 1 may have an aggregate attributable risk for autism/Asperger syndrome of 6% or more.

Comparative Evaluation of Conventional Cytogenetics, Flow Cytometry, FISH and Array- CGH in Chronic Lymphocytic Leukemia (CLL) Patients. *A. DWIVEDI[1,2], A. EHSAN[1], R.S. ROBETORYE[1], S.R. GUNN[1], S.G. ADHVARYU[1,2]* 1) Clinical & Molecular Cytogenetics Laboratory,Department of Pathology, UTHSCSA, San Antonio, TX 78229-3900; 2) Department of Pathology, UTHSCSA, San Antonio, TX 78229-3900.

Chronic Lymphocytic Leukemia (CLL) comprises a heterogeneous group of disease representing approximately 70% of lymphoid leukemias and 25% of all leukemias. CLL primarily affects people above 60 years of age and is characterized by mature B- lymphocytosis followed by progressive lymphadenopathy and bone marrow failure. In recent years, there has been increased emphasis on early and accurate diagnosis of CLL patients. In this context, a number of tests are employed for the detection of diagnostic / prognostic markers. Conventional cytogenetics (CC) plays an important role in identifying clonal anomalies in about 50% of CLL cases. During the last decade, fluorescence in-situ hybridization (FISH) tests have proven to be more sensitive (~80%) and specific in the detection chromosomal abnormalities not identified by CC. The most common deletion, del(13)(q14.3) is considered to be clinically favorable when present as the sole abnormality. On the other hand, trisomy12 and deletions of 17p and 11q are associated with more aggressive disease. Recently, array-based comparative genomic hybridization (array-CGH) has emerged as a powerful diagnostic tool for the high throughput, high resolution whole genome analysis of recurrent genomic imbalances like micro-deletions and amplifications. Flow cytometry (FC) is also used for the identification of surrogate prognostic cell markers like CD38 and ZAP-70 in cases of B-CLL. We present here a comparative study encompassing CC, FISH, FC and array-CGH on the bone marrow specimens of CLL patients. The salient findings of our study are: (1) CC demonstrated both normal as well as complex karyotypes. (2) FISH analysis confirmed trisomy 12 and deletions of 13q, 17p and/or 14q32. (3) Array-CGH detected additional genomic losses in chromosomes 1, 6, 13, 14 and gains in chromosomes 2, 5, 7, 10, 11 and 12. (4) FC results were variable for CD38 and ZAP70. Analysis of data with significance and limitations of each technique will be presented.

Information theoretic metrics for visualizing gene environment interactions. *P. Chanda[1], L.E.M. Sucheston[2,3], A. Zhang[1], D. Brazeau[4], J. Freudenheim[5], C. Ambrosone[3], M. Ramanathan[4]* 1) Dept of Computer Science, SUNY-Buffalo, Buffalo, NY; 2) Dept of Biostatistics, SUNY-Buffalo, Buffalo, NY; 3) Dept of Cancer Prevention and Control, Roswell Park Cancer Institute, Buffalo, NY; 4) Dept of Pharmaceutical Sciences, SUNY-Buffalo, Buffalo, NY; 5) Dept of Social and Preventive Medicine, SUNY-Buffalo, Buffalo, NY.

Good interactive, multi-dimensional visualization tools can provide additional perspectives that assist the user in understanding large multidimensional, Gene Environment interaction (GEI) data at an intuitive level, facilitate subsequent hypothesis generation and enhance knowledge discovery. We extend our previous vizualization approach, VizStruct, based on the information theoretic Kullback-Liebler divergence (KLD), to visualizing GEI. We develop and compare two specific information theoretic metrics, the *K*-Way Interaction Information (KWII) and the Total Content Information correlation (TCI), which are related to the KLD, for visualizing GEI in a diverse range of simulated data sets as well as a Crohns disease dataset. The KWII and TCI spectra, which are graphical summaries of the KWII and TCI, were found to detect each known GEI in the simulated data sets for each subset of environmental and genotype variables. The patterns in the KWII and TCI spectra were informative of factors such as affected-unaffected misassignment, locus heterogeneity, allele frequencies and linkage disequilibrium. The KWII and TCI spectra were also found to successfully identify the key disease-associated SNPs in the Crohns disease dataset. Eight of nine significant SNPs identified in previous publications were found. The sensitivity and specificity of these information metrics was further assessed by analyzing KWII/TCI identified SNPs using Pedigree Disequilibrium Transmission (PDT) test in the software package Unphased. Out of the 20 two SNP combinations (treated as haplotypes) and 20 single SNPs, 16 and 15, respectively, were found significant with the PDT. The single SNP and haplotype results indicate good concordance with existing pedigree analysis methods, making both the KWII and TCI promising metrics for visualizing GEI.

Understanding the function of Ataxin1 and its paralog Ataxin1-like, and their role in SCA1 pathogenesis. *J. Crespo-Barreto[1], A.B. Bowman[2], H.T. Orr[3], H.Y. Zoghbi[1,2]* 1) Program in Cell and Mol. Biology; 2) Dept. Mol. and Hum. Genetics, Baylor College of Medicine, Houston, TX; 3) Laboratory Medicine and Pathology, U. Minnesota, Minneapolis, MN.

Spinocerebellar ataxia type 1 (SCA1) is a dominant neurodegenerative disease caused by an expanded polyglutamine tract in ataxin-1. Mice expressing polyQ-expanded *Atxn1* but not $Atxn1^{-/-}$ mice reproduce SCA1, implicating a gain-of-function mechanism. We identified a conserved Atxn1 paralog, Atxn1-like, which lacks a polyQ stretch but contains an AXH domain, a region involved in polyQ-mediated toxicity. Since overexpression of *Atxn1l* suppresses SCA1 phenotypes in $Atxn1^{154Q/+}$ mice, we propose that *Atxn1* and *Atxn1l* are functionally related and that their normal function is likely to modulate SCA1 pathogenesis. To test this, we set out to understand the *in vivo* function of *Atxn1* by studying $Atxn1^{-/-}$ mice. In Open Field Analysis, $Atxn1^{-/-}$ mice stay more at the center of the arena than wt littermates, as determined by the center/total distance ratio (p0.005), and spend more time in the open arms of the elevated plus maze than wt littermates (p0.00001). These data suggest that $Atxn1^{-/-}$ mice are less anxious than wt littermates. In the Conditioned Fear Test, $Atxn1^{-/-}$ mice have decreased fear responses (p0.05), indicating impaired learning and memory. To determine if *Atxn1* and *Atxn1l* genetically interact, we tested the effect of *Atxn1l* overexpression on the behavior of $Atxn1^{-/-}$ mice. Our data show that a duplication of *Atxn1l* partially suppresses *Atxn1-/-* defects both in OFA and CF, suggesting that Atxn1l can compensate for Atxn1's loss-of-function. To determine if the endogenous function of Atxn1 plays a role in SCA1 pathogenesis, we compared the SCA1 phenotypes of $Atxn1^{154Q/+}$ mice to those of $Atxn1^{154Q/-}$ mice. Removing the wt copy of *Atxn1* worsened SCA1 phenotypes in the Rotating Rod and decreased $Atxn1^{154Q/-}$ mice survival by 13 weeks (p0.001), indicating that Atxn1s endogenous function can modulate SCA1 pathogenesis. Taken together, our data show that *Atxn1l* can functionally substitute for *Atxn1*, and that the wild-type copies of *Atxn1* and *Atxn1l* are neuroprotective in a SCA1 knock-in mouse model.

Mapping quantitative traits in pedigrees. *J. Dupuis[1], J. Shi[2], D. Siegmund[3]* 1) Dept Biostatistics, Boston Univ SPH, Boston, MA; 2) Stanford University School of Medicine, Stanford, CA; 3) Department of Statistics, Stanford University, Stanford, CA.

In this project we are developing methods for mapping quantitative traits in moderately large pedigrees, with emphasis on the pedigree structures found in the Framingham Heart Study Cohorts. Our methods are based on the score statistic, which in contrast to the likelihood ratio statistic, can use nonparametric estimators of variability to achieve robustness of the false positive rate against departures from the hypothesized phenotypic model. We have developed simple, accurate approximations to the genome-wide false positive rate that takes account of the skewness in the statistic arising from statistical dependencies or distant relationships within pedigrees, and we develop a simple method for evaluating complex pedigrees in terms of an equivalent number of independent sib pairs. Because the score statistic is much easier to calculate than the likelihood ratio statistic, our basic mapping methods utilize relatively simple computer code in R, which performs statistical analysis on the output of any program that computes estimates of identity-by-descent (e.g., MERLIN). This simplicity also permits development and evaluation of methods to deal with multivariate and ordinal phenotypes, and with gene-gene and gene-environment interaction.

Broad and fine scale recombination rate variation in humans. *G. Coop, W. Wen, C. Ober, J.K. Pritchard, M. Przeworski* Department of Human Genetics, University of Chicago, Chicago, IL.

The crucial roles of recombination in ensuring proper disjunction and maintaining genome integrity suggest that genetic exchanges should be tightly regulated. Yet recent studies in humans have revealed substantial variation in the total number of recombination events among females. At a much finer scale, analyzes of linkage disequilibrium indicate that the recombination landscape of humans and their closest evolutionary relatives, chimpanzees, differ markedly. These observations hint at the existence of tremendous variation in recombination rates within and between primate species, but the extent of variation over different genomic scales and its determinants remain largely unknown. Here, we infer recombination events in 422 male and 422 female meioses from a set of 500k genome-wide SNPs collected in 725 related Hutterites (a founder population of European descent). The refinement of crossover events offered by this dense marker set offers unparalleled opportunities to study fine scale rates of recombination in a pedigree. We find very strong support for the hotspot model of recombination of rate variation based on sperm typing and linkage disequilibrium (LD) studies. Specifically, we estimate that 60% of crossover events in both males and females occur in hotspots inferred from LD data. Strikingly, we further find significant variation among individuals in this proportion, suggesting differences among humans in the genome-wide use of recombination hotspots. The density of SNPs in our study also allows characterization of recombination rate variation over larger genetic scales, as well as association mapping of recombination phenotypes. More generally, this study illustrates how the imminent availability of dense genotyping data in large pedigrees will yield important insights into the recombination process and its effects on fertility.

A more severe Out-of-Africa population bottleneck on chromosome X. *A. Keinan[1,2], J. Mullikin[3], N. Patterson[2], D. Reich[1,2]* 1) Dept. of Genetics, Harvard Medical School, Boston, MA; 2) The Broad Institute, Cambridge, MA; 3) National Human Genome Research Institute, NIH, Bethesda, MD.

We generated and analyzed two large population genetic data sets, each spanning both chromosome X and the autosomes, permitting us to learn how demographic history varies by gender. For the first data set, we identified subsets of SNPs from HapMap that are free of ascertainment bias. For the second data set, we aligned hundreds of millions of base pairs from individuals of known ancestry and estimated the average time since divergence.

Both data sets point to more X-chromosomal than autosomal genetic drift since migration from Africa, but before the European-Asian split: (1) Genetic diversity in non-African populations is reduced on chromosome X compared with the autosomes, more than would be expected based on the autosomal demographic history, combined with the 3/4 effective population size and the different mutation rate. (2) Allele frequency differentiation (F_{ST}) between Africans and non-Africans is much greater on chromosome X than would be expected based on the premise that X-chromosomal genetic drift should be 4/3 that of the autosomes. (3) The X-chromosomal allele frequency spectrum of non-Africans exhibits an unexpected deviation from that of the autosomes, which modeling reveals to be consistent with a more severe Out-of-Africa population bottleneck on chromosome X.

These results can be explained if the Out-of-Africa dispersal involved a larger effective population size of men than women. Due to the higher variability in reproductive success in men, it is difficult to explain the larger effective population size if non-African populations were colonized by a single migration. However, if there were multiple waves of male-biased migration out of Africaso that the non-African gene pool was mostly contributed by male ancestorsthen non-Africans would exhibit a lower effective population size of women. An alternative possibility, extensive X-chromosomal selection in non-Africans, is unlikely to be a full explanation since the results hold after excluding genes and loci identified as being under selection.

Relations between ethymalonic acid and isoleucine / methionine metabolism in ethylmalonic acidemia are unclear. *M. BARTH[1], V. VALAYANNOPOULOS[1], L. HUBERT[2], L. MINAI[2], S. ROMANO[1], D. CHRETIEN[2], A. ROTIG[2], D. RABIER[3], A. MUNNICH[2], Y. DE KEYSER[2], P. DE LONLAY[1,2]* 1) Unité de métabolisme, Hôpital Necker Enfants Malades , France; 2) INSERM U-781, Hôpital Necker Enfants Malades, France; 3) Service de Biochimie, Hôpital Necker Enfants Malades, France.

Background: Ethylmalonic encephalopathy is a rare autosomal recessive metabolic disorder caused by mutation in ETHE1 gene and presenting in infancy with psychomotor retardation, chronic diarrhea, orthostatic achrocyanosis and relapsing petechia. High levels of lactic acid, ethymalonic acid and methylsuccinic acid are detected in body fluids. A decreased cytochrome c oxydase activity has been reported in skeletal muscle. The source of ethylmalonic acid is hitherto unclear. Relations to isoleucin and methionine metabolism have been suggested.

Patient and Methods: We report a 15 months old male born to consanguineous parents, presenting with a typical ethylmalonic encephalopathy phenotype.Oral isoleucin (150mg/kg)and methionine (100 mg/kg) loading tests as well as an isoleucine restricted diet (200mg/d) were performed to analyze the consequences on ethylmalonic excretion.

Results: Cytochrome c oxidase (COX) activity was decreased in lymphocytes. COX deficiency was not associated with an abnormal assemblage of mitochondrial respiratory chain complexes as shown by blue native PAGE. Molecular studies showed a homozygous mutation in the ETHE1 gene, leadingto the deletion of exon 4 in the mRNA. Ethylmalonic acid was increased only after isoleucine loading (99 to 242 mol/mmol creatinine) while the methionine load did not change ethylmalonic acid excretion (105 to 122 mol/mmol creatinine). After isoleucine restricted diet, we neither observed a clinical improvement nor biochemical modifications in ethylmalonic acid excretion and COX activity in lymphoblasts.

Conclusion: Our results suggest that ethylmalonic acid formation is linked to isoleucine metabolism but not to methionine metabolism. The inhibition of COX activity in ethylmalonic acidemia does not involve alterations in assembly of OXPHOS complexes.

Relationship of apolipoprotein H (*APOH*) polymorphisms with susceptibility to systemic lupus erythematosus.

L.S. Corthell[1], F.Y. Demirci[1], A.H. Kao[2], E.Y. Rhew[3], F. Bontempo[4], C. Kammerer[1], R. Ramsey-Goldman[3], S. Manzi[2], M.I. Kamboh[1] 1) Human Genetics, University of Pittsburgh, Pittsburgh, PA; 2) Lupus Center of Excellence, Univ. of Pittsburgh, Pittsburgh, PA; 3) Div. of Rheumatology, Northwestern Univ., Chicago, IL; 4) Dept. of Medicine, Univ. of Pittsburgh, Pittsburgh, PA.

Systemic lupus erythematosus (SLE) is an autoimmune disease of primarily unknown etiology. SLE is 3-4 times more common in African Americans than Caucasians and predominantly affects women of child-bearing age. SLE causes a variable amount of morbidity, shortened life expectancy, and substantial total health expenditures, due to complications such as thrombosis, atherosclerosis, renal disease, and antiphospholipid syndrome (APS). Apolipoprotein H (*APOH*), also known as 2-glycoprotein I, is thought to have anti-atherogenic properties and has been shown to be a major autoantigen for antiphospholipid antibodies present in patients with APS. The purpose of this study was to investigate the role of *APOH* genetic variation in the pathogenesis of SLE. We have genotyped 12 *APOH* SNPs (9 tag SNPs that include 1 promoter SNP and 1 coding SNP and 3 additional coding SNPs) in 399 SLE women (350 Caucasians and 49 African Americans) and 496 healthy control women (454 Caucasians and 42 African Americans) using Pyrosequencing or TaqMan allelic discrimination methods. The allele and genotype association of these SNPs with race, SLE, and lupus nephritis were analyzed. Significant allelic distribution differences were observed between Caucasians and African Americans for 9 SNPs, indicating a race-dependent variation. Due to the small number of African American subjects, association studies were performed only for Caucasian subjects. Haplotype analysis of 9 tag SNPs revealed 6 haplotypes that significantly differed in frequency between SLE cases and controls (*P* 0.001 for overall haplotype distribution). The haplotype with the most striking distribution was present in 15% of cases vs. 1% of controls, suggesting a potential risk factor for SLE. In conclusion, our data suggests that combined effects of *APOH* SNPs may be implicated in modifying the risk of SLE.

Sex-specific differences in blood pressure response to metoprolol by ADRB1 Polymorphisms. *V. Bhatnagar[1,2], D.T. O'Connor[1], N.J. Schork[1,3], M.S. Lipkowitz[4]* 1) University of California San Diego, La Jolla, CA; 2) VA San Diego San Diego, CA; 3) Scripps Institute for Genomic Medicine, La Jolla, CA; 4) Mount Sinai School of Medicine New York, NY.

Purpose: This study explores the relationship between ADRB1 polymorphisms SER49GLY and GLY389ARG and blood pressure response to metoprolol among African American men and women with early hypertensive nephrosclerosis. Methods: 197 men and 131 women randomized to treatment with metoprolol from the African American Study of Kidney Disease and Hypertension were genotyped at SER49GLY and GLY389ARG. Of these, 161 were randomized to an aggressive treatment group and 167 to a usual treatment group. A Cox Proportional Hazards Model was used to determine the hazard rate of reaching a target a mean arterial pressure (MAP) of 107 mmHg, adjusting for baseline MAP, medications and potential co-variates, by genotypes and ADRB1 haplotypes; analyses were stratified by sex and treatment group. Results: Men and women were of similar ages (55 years) and had similar baseline MAPs (113 mmHg). Men had higher baseline glomerlular filtration rates, 48 (standard deviation 12) versus 45 (13) ml/min (p=.02); men had a lower body mass index, 31 (6) versus 32 (7) kg/m2 (p=.05). Genotype distributions were in Hardy-Weinberg Equilibrium. Among women randomized to aggressive treatment only, those with a GLY/GLY genotype at SER49GLY responded significantly faster than those with a SER/SER or SER/GLY genotype; the adjusted hazard rate with 95 percent confidence interval was 3.02 (1.20 to 7.60; p=.02 for genotype coefficient). Though of borderline significance, women with an ARG/ARG genotype at GLY389ARG responded faster that those with an ARG/GLY or GLY/GLY genotype: 2.01 (.95 to 4.23; p=.07). Women without a SER49/GLY389 ADRB1 haplotype responded significantly faster compared to those with this haplotype: 2.52 (1.40 to 4.52; p=.002). Conclusions: African American women (but not men) randomized to aggressive management with a SER49/GLY389 haplotype were less responsive to metoprolol. Genotyping at these sites may help identify women are less responsive to aggressive treatment with metoprolol.

Bioinformatics approach to identification of genes involved in multiple pituitary hormone deficiency: homeotic selector *Ash1l*. *S. Camper[1], N. Solomon[1], A. Mortensen[1], M. Brinkmeier[1], J. MacDonald[1], D. Ghosh[1], P. Carninci[2], Y. Hayashizaki[2], R. Lyons[1]* 1) Dept. Human Genetics, Univ. Michigan, Ann Arbor, MI 48109, USA; 2) Riken Genomic Sciences Center, Yokohama, Kanagawa 230-0045, Japan.

Mouse studies have advanced understanding of the underlying mechanisms pituitary hormone deficiency, often leading to the discovery of lesions in human patients. Mutations in the transcription factors POU1F1 and PROP1 cause pituitary hormone deficits. The progenitor cells in *Prop1* mutant pituitaries fail to migrate to form the anterior lobe, and poor vascularization and enhanced apoptosis are evident. These features contrast with those of *Pou1f1* mutants, which include normal vascularization and pituitaries that are indistinguishable from those of their normal littermates at birth. These differences support the idea that *Prop1* controls the expression of genes besides *Pou1f1* that are important for migration, survival, and differentiation of pituitary cells. These genes are candidates for cases of human hormone deficiencies of unknown etiology. We took several approaches to identify such genes, including construction of full-length cDNA libraries and microarray analysis of gene expression. Comparison of pituitary transcripts from newborn *Prop1* and *Pou1f1* mutants and their littermates revealed Wnt-frizzled signaling, organ morphogenesis, and anterior-posterior patterning processes were significantly different in *Prop1* mutants. The cDNA libraries from *Prop1* mutant and normal embryonic pituitaries contain over 40,000 sequences in a searchable database, implicating genes in some of the same processes, novel homeobox genes, and their regulators. We chose *Ash1l* for functional studies because absent, small, homeotic discs-1, a member of the trithorax gene family, is a critical regulator of homeotic selector genes in Drosophila. *Ash1l* homozygous mice exhibit severe growth insufficiency, anterior pituitary hypoplasia, poor survival, eye and craniofacial anomalies, balance problems, and fragile skeletal structure. This suggests that our bioinformatics approach will continue to contribute to understanding the genes that control pituitary organogenesis.

Patterns of Nucleotide Diversity and Potential Signatures of Natural Selection at *ICAM-1* . *F. Gomez*[1,2], *G. Tomas*[3], *F. Reed*[1], *S.A. Tishkoff*[1,4], *J. Rocha*[3,4] 1) Dept. of Biology, The University of Maryland, College Park, MD; 2) Hominid Paleobiology Doctoral Program, The George Washington University, Washington, DC; 3) Instituto de Patologia e Imunologia Molecular da Universidade do Porto, Portugal; 4) Equal contributors.

Variants at the gene that encodes ICAM-1 (intercellular adhesion molecule-1) are thought to play a role in malaria susceptibility. ICAM-1 is one of the primary vascular endothelial receptors to which *P. falciparum* parasitized erythrocytes adhere in the postcapillary venules of several organs. This observation has led many scholars to suggest that ICAM-1 is an important host receptor responsible for severe malaria pathogenesis. The clinical consequences of *ICAM-1* nucleotide diversity are under contention. A non-synonymous SNP within *ICAM-1*, termed *ICAM-1*$^{\text{Kilifi}}$, has been shown to be associated with either an increased risk or protection against severe malaria in Kenyan and Gabonese populations, respectively. Here we present a preliminary examination of the nucleotide variation within *ICAM-1*, a characterization of haplotype structure in a globally diverse sample of human populations, and a summary of tests of neutrality. A panel of ~100 individuals originating from Portugal, Mozambique, Sao Tome, Tanzania, and Thailand were analyzed for nucleotide variation across a ~6.8 kb region. Twenty-two SNPs were observed and three major haplotypes accounted for the majority of the haplotype variation within *ICAM-1*. From these data we have shown that the measures of nucleotide diversity are slightly lower than the genome average. However, the tests of neutrality do not yield statistically significant results. Haplotype network analyses indicate that the *ICAM-1*$^{\text{Kilifi}}$polymorphism is found in Africa and Thailand on divergent haplotype backgrounds. This result suggests that the Kilifi SNP either arose independently in Asia or was introduced during a migration of modern humans out of Africa, and has since undergone historic recombination events. We are currently examining nucleotide variation within a larger panel of diverse African populations to elucidate the evolutionary history of this locus.

Nonrecurrent MECP2 duplications in neurodevelopmentally delayed males reveal a prone rearrangement region in Xq28. *C. Carvalho[1], A. Patel[1], T. Sahoo[1], C. Bacino[1], S. Peacock[1], A. Pursley[1], S.W. Cheung[1], J.R. Lupski[1,2,3]* 1) Dept Molecular Human Genetics, Baylor College of Medicine, Houston, TX; 2) Pediatrics, BCM, Houston, TX; 3) Texas Childrens Hospital, Houston, TX.

Recent reports suggest not only impaired or abolished gene function, but also increased MECP2 gene copy number, resulting in a developmental delay (DD)and mental retardation(MR)phenotype. Virtually nothing is known about the rearrangements and mechanisms associated with MECP2 copy number alterations. In order to investigate this issue, we designed a tiling path oligonucleotide microarray spanning 4 Mb around the MECP2 region on the Xq28. So far we have analyzed 12 males, each one carrying different duplication sizes, varying from ~ 2.6 Mb to ~ 289 Kb. All duplicated patients have their distal breakpoints inside or near LCR pairs with more than 99% of sequence similarity. Interestingly, ten (83%) out of 12 patients presented the distal breakpoint grouped into the same 233 Kb region, located 35 Kb upstream to MECP2 gene. That region is characterized by a complex architecture with two large (~37 Kb each) low-copy repeats in direct orientation, and two smaller (~11.3 Kb each) inverted repeats. Remarkably, previous reports have shown these inverted repeats are implicated in the deletion of the Emerin gene which causes Emery-Dreifuss muscular dystrophy (EMD) and also generates the inversion present in 33% of females of European descent. We were also able to sequence one patient breakpoint whose duplication in tandem spanned about 1.7 Mb. Its breakpoint junctions occurred amid an Alu sequence and presented just 1 bp of sequence homology between them. In conclusion, these data show that the MECP2 nonrecurrent duplication results from specific genomic architectural features causing susceptibility to such rearrangements. The presence of LCRs in the MECP2 vicinity may generate an unstable non-B DNA structure which induces double-strand break, most probably re-joined by non-homologous end joining (NHEJ). Our study provides evidence that MECP2 duplication events may be stimulated by LCRs and further supports an alternative role of genomic architecture in rearrangements responsible for genomic disorders.

Assessing the transcription factor gene grainy-head like 3 (*GRHL3*) as a candidate for causation of spina bifida meningomyelocele. *K.S. Au[1], M.R. Dewhurst[1], C.C-D. Tsai[1], J.M. Fletcher[2], G.H. Tyerman[3], T.M. King[1], H. Northrup[1,4]* 1) Dept Pediatrics, Univ Texas Medical Sch, Houston, TX; 2) Dept of Psychology, Univ of Houston, Houston, TX; 3) Shriners Hospital for Children, Los Angeles, CA; 4) Shriners Hospital for Children, Houston, TX.

Spina bifida meningomyelocele (SBMM) is a common birth defect with an overall incidence of 7/10,000 live births in the United States. Among known mouse models of neural tube defects (NTDs), the *ct* (*curly-tail*) mouse represents one of the best models for non-syndromic SBMM in humans. Recent findings suggested the ct mice are hypomorphs of the grainy-head like 3 gene (*Grhl3*). *Grhl3* knock-out mice showed thoraco-lumbar-sacral SBMM and curly tail. *Grhl3* is mapped to the same locus as the ct mouse gene and the *Grhl3* knock-out allele failed to rescue the ct phenotype. *Grhl3* mRNA is expressed in non-neural ectoderm adjacent to the neural fold. Globally, *Grhl3* protein is a transcription regulator and functions as a master protein in many aspects of epidermal movement and fusion. In humans the *GRHL3* gene spans a region of 35.9 Kbp on chromosome 1p36.11 and is highly conserved among species. We have selected single nucleotide polymorphic (SNP) sites with known minor allele frequencies greater than 0.1 spanning the *GRHL3* region with a density of 2-3 Kb per SNP to examine the association of this gene with approximately 600 SBMM families and 200 controls. Analyses of the *GRHL3* SNP genotypes of 200 controls using Haploview 3.32 showed two distinct Linkage Disequilibrium (LD) blocks with one 50 Kb block spanning the upstream region from the promoter and the other 12Kb block spanning exons 5 to 15. Analyses of SBMM patient genotypes showed similar patterns except the block at the promoter region is less defined. A lower frequency of the TTG haplotypes (rs3887581, rs4648859, rs1203005) spanning exons 11-13 is observed among SBMM patients. This finding appears to be consistent with our discovery of several synonymous and nonsynonymous variants in exons 11 and 12 among SBMM patients pointing to possible functional defect of these variants may contribute to SBMM risk.

Cis-elements, DNA replication and repeat instability at the human myotonic dystrophy type 1 locus. *J.D. Cleary[1,2], L. Foiry[3], G. Gourdon[3], C.E. Pearson[1,2]* 1) Genetics and Genome Biology, Hospital for Sick Children, Toronto, Canada; 2) Department of Molecular & Medical Genetics, University of Toronto; 3) Inserm U781, Hôpital Necker-Enfants Malades, Université Paris V, Paris, France.

Trinucleotide repeat instability is the cause of a growing number of human disorders including myotonic dystrophy type 1 (DM1). Depending upon the disorder, repeat instability can be observed in somatic and germline tissues for both non-proliferative and proliferative cells suggesting that a variety of DNA metabolic processes contribute to the mutational process. The distinct pattern of instability between tissues suggest a role for epigenetics. The pronounced instability that occurs within proliferative tissues and during periods of rapid proliferation supports a role for DNA replication, either independently or in conjunction with DNA repair, in instability. Proliferation was shown to be required for spontaneous repeat instability in cultured human DM1 patient-derived fibroblasts; this instability was enhanced by agents known to alter DNA synthesis and replication fork progression. We have determined the replication profile at the human DM1 chromosomal locus by quantitative competitive PCR analysis of nascent DNA derived from our patient-derived fibroblasts. In parallel, a similar analysis was done in transgenic mice with 45 kb of human DM1 locus with a tract of 300 CTG repeats. In humans, this analysis suggests that the DM1 locus is located within a region of abundant replication activity, with replication origins located proximal to the repeat. Interestingly, reduced replication activity is associated with the expanded DM1 repeat tract and is demarcated by CTCF binding site flanking the repeat tract. Further analysis of transgenic mice indicates differences in the replication profile between tissues. Taken together these data support a proximal 3 origin of replication at the expanded unstable DM1 repeat tract such that the CAG repeat is the lagging strand template. Changes in the replication origin location, utilization or changes in the progress of the replication fork through the repeat tract may be a significant factor in repeat instability.

Identification of a novel microdeletion involving the entire *NEMO* gene at Xq28 in a patient with Incontinentia Pigmenti. *D. del Gaudio, P.A. Ward, L.L. Meyers, R.A. Lewis, D.L. Nelson, P. Fang, C.M. Eng* Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Incontinentia pigmenti (IP) is a rare multi-systemic disorder characterized by skin, hair, teeth and central nervous system abnormalities. It is inherited as an X-linked dominant trait and is lethal in male fetuses. In females the clinical phenotype varies and is significantly modulated by skewed X-inactivation. Familial IP is caused by loss-of-function mutations in the *NEMO* gene (NF-kB Essential MOdulator or IKBKG) located on chromosome Xq28. NEMO is part of a regulatory complex required to activate the NF-kB transcription factor that is involved in a number of immune, inflammatory, and apoptotic pathways. Approximately 80% of IP patients harbor a common deletion encompassing exon 4 through exon 10 of the *NEMO* gene. This rearrangement appears to be mediated by flanking repeat sequences and can be identified by either Southern analysis or long-range PCR specifically targeted to the *NEMO* gene. Here we report the identification of a 33 year old female with typical IP, harboring a novel microdeletion encompassing the entire *NEMO* gene. Southern analysis indicates that this individual is negative for the common deletion; however, the normal sized fragment showed a significantly reduced intensity, indicating a possible heterozygous full gene deletion. Real time PCR and oligonucleotide-based array-CGH further defined the proximal deletion breakpoint at the 5 of the G6PD gene. X-inactivation study indicated that the patient had complete skewed X-inactivation. This is the first full *NEMO* gene deletion case reported to date. Further characterization of the deletion breakpoints will provide important clues towards understanding the putative mechanism responsible for the recombination event leading to the *NEMO* gene rearrangements, and potentially expand the mutation detection spectrum for IP.

Partial deletion mouse models for Williams-Beuren syndrome. *U. Francke[1], H-H. Li[1], M. Roy[2], U. Kuscuoglu[1], B. Halm[1], K. Carlsmith Harrison[1], J.H. Bayle[3], A. Splendore[1], F. Ding[1], E. Wright[1], C.M. Spencer[4], C.J. Goergen[2], J. Li[1], L. Tsavaler[1], C.A. Taylor[2], R.M. Myers[1], R. Paylor[4], K. Deisseroth[2, 5]* 1) Dept Genetics; 2) Dept Bioengineering; 3) Dept Pathology, Stanford Univ; 4) Dept Mol Hum Genet, Baylor College of Medicine, Houston TX; 5) Dept Psychiatry Stanford Univ, Stanford CA.

Williams-Beuren syndrome (WBS) is caused by recurrent heterozygous deletions of a ~1.5 Mb region at 7q11.23. Features include distinct craniofacial appearance, mental disability with visuo-spatial construction defects and preservation of speech, vascular stenosis, hypotonia, hyperacusis, social disinhibition and anxiety. The conserved syntenic region in mouse is at 5G1-G2. Most single-gene knock-out mouse models for one of the 25 genes in the deletion have no phenotype in heterozygotes. To functionally dissect the WBS deletion region and to identify genes that are truly haploinsufficient, we created two lines of mice that are deleted either from *Gtf2i* to *Limk1* (Proximal - Pd) or from *Limk1* to *Fkbp6* (Distal - Dd) by using *Cre-Lox*P technology. Double heterozygotes (D/P mice) model the complete WBS deletion. All deletion mice are viable, fertile and have normal lifespan. Gene expression microarray and qRT-PCR studies of brain RNA revealed a reduction of transcripts mapped to the deleted segments. Pd and D/P mice have growth delay, Dd and D/P mice have smaller brains, abnormal cerebella and hernias. Micro CT of skulls revealed shortening in D/P females more than in males. Adults with elastin gene deletion (Dd and D/P) have a less compliant aorta, reducing anterior wall motion due to disorganized and thinner elastin sheets. Elastin transcripts are reduced in thorax at P7. D/P, and Pd mice to some extent, have a deficit in motor coordination and performance, partly due to hypotonia, as determined by rotarod and hanging wire tests. A comprehensive behavioral test battery revealed several phenotypic differences among the mutant lines in assays of exploration, anxiety-related responses, and measures of social interactions, which indicate that these *Wbs* mouse lines can be used to model aspects of the human disorder and identify contributing genes.

MRI brain differences in children with 22q11.2 deletion syndrome and siblings. *A. Ho[1], A.P. Crawley[3,4], D.J. Mikulis[3,4], A.S. Bassett[1,2], E.W.C. Chow[1,2]* 1) Clinical Genetics Research Program, Center for Addiction and Mental Health, Toronto, Ontario, Canada; 2) University of Toronto, Department of Psychiatry; 3) University of Toronto, Department of Medical Imaging; 4) Toronto Western Hospital, Department of Medical Imaging.

22q11.2 deletion syndrome (22qDS) is a genetic syndrome associated with a microdeletion at the 22q11.2 region. Individuals with 22qDS are associated with many physical and cognitive features and are at an increased risk for the development of psychiatric disorders. Past imaging studies on children with 22qDS have reported reduction of overall brain volume, the superior temporal gyrus, the hippocampus, and the cerebellum. This study obtained MRI brain scans from 13 children (5 males, 8 females) with 22qDS and 4 siblings (2 males, 2 females) between the ages of 8 - 12 using voxel based morphometry (VBM). A t-test revealed a significant difference in IQ between the 22qDS children and their siblings (mean = 65.6, S.D. = 13.5; mean = 104.3, S.D = 14.9 respectively, $p = 0.001$), No significant difference for total intracranial volume (ICV) was found between the two groups (22qDS group mean = 1449 mL, S.D. = 141 mL; Sibling group mean = 1501 mL, S.D. = 164 mL). Results from a t-test on grey matter with mapwise correction and ICV as a covariate revealed significant volume reduction in the cerebellum ($p = 0.001$), and the cingulate gyrus ($p = 0.004$). In 22qDS, however, results were not insignificant when IQ was included as a covariate. Findings on the cerebellum from this study are consistent with past 22qDS literature that suggest reduced cerebellar volumes may be a core feature of 22qDS. However, the results were possibly attenuated by a small sample size, and the inclusion of IQ as a covariate. Replication with a larger sample may help to further reinforce the findings in this study.

Apoptosis induced in human melanoma cells with a *PAX3* antisense oligonucleotide is associated with down-regulation of BCL2 and CDK2. *M.R. Eccles[1], S. He[1], J. Ineson[1], H.-S. Yoon[1], C.G. Li[1], A. Jeffs[1], E. Marshall[2], B. Baguley[2]* 1) Dept Pathology, University of Otago, Dunedin, Otago, New Zealand; 2) Auckland Cancer Society Research Centre, University of Auckland, Auckland, New Zealand.

Melanoma is an aggressive skin neoplasm involving melanocytes, and frequently metastasised by the time it is detected. The treatment of disseminated melanoma is difficult, as it is often associated with lack of response due to resistance to therapy. This can be largely attributed to the enhanced ability of melanoma cells to survive. *PAX3*, a member of the paired box family of genes, plays a critical role during the development of the neural crest and its derivatives, including melanocyte progenitors, and recently *PAX3* has been demonstrated to play a role in melanoma cell survival. Here we demonstrate that PAX3 protein is not only expressed in melanoma tissues and cell lines, but also in normal skin melanocytes and nevi, and in epidermal melanocytes adjacent to melanoma tissues. In addition, we have used antisense-mediated gene knockdown as a strategy to explore the mechanisms of cell survival in metastatic melanoma cell lines. The treatment of melanoma cell lines with *PAX3* antisense oligodeoxynucleotides specifically decreased the level of PAX3 protein, and induced more apoptosis than in control treatments. The cell death induced by *PAX3* antisense could be prevented efficiently if the cells were immediately pre-treated with Z-VAD-FMK, a caspase-specific inhibitor. Furthermore, treatment with *PAX3* antisense was associated with the down-regulation of pro-survival factors BCL2 and cyclin-dependent kinase, CDK2. Taken together these data suggest that PAX3 transcriptionally regulates an assembly of downstream survival factors, and that coordinated expression of PAX3, BCL2 and/or CDK2 may represent important mechanisms for the survival of melanoma cells in vitro.

Allgrove Syndrome in a Mexican-American Family is Caused by an Ancestral Mutation Derived from North Africa. *A.J. Chang[1], M.M. Kline[1], Y. Currie[2, 3], H. Wijesuriya[2, 3], M. Perez-Ospina[2, 3], J. Hartiala[2, 3], T.B. Buchanan[1], R.M. Watanabe[2], H. Allayee[2, 3]* 1) Department of Medicine; 2) Department of Preventive Medicine; 3) Insitute for Genetic Medicine; USC Keck School of Medicine, Los Angeles, CA.

Allgrove syndrome is an autosomal recessive disorder characterized by alacrima, achalasia, and adrenocorticotropic hormone-resistant adrenal insufficiency. Nearly 30 different mutations have been described in the AAAS gene but it has been difficult to obtain consistent phenotype-genotype correlations due to the rarity of the disorder and phenotypic variability amongst patients. We describe the clinical and genetic profile of a Mexican-American family in which two siblings display classic Allgrove syndrome features, with the older sister becoming symptomatic in adolescence compared to her brother who began displaying abnormalities at approximately the age of seven. Genetic analysis revealed that the mother carries a previously described 1191insA mutation in exon 13. The father is a carrier of a G>A substitution at the first position of intron 14, which abolishes the splice donor site, and was originally identified as a founder mutation in inbred Allgrove patients from North Africa. As expected, both affected siblings are compound heterozygotes. Comparison of haplotypes in the family with those observed in several North African patients using ~10 microsatellite markers dispersed evenly in a 1Mb region flanking the AAAS gene revealed that the fathers haplotype harboring the mutation matched the North African haplotype nearly perfectly. This North African haplotype was present in less than 5% of ~300 individuals from 132 Mexican-American families without Allgrove syndrome. We conclude that previously described mutations are the cause of Allgrove syndrome in this Mexican-American family and that the fathers mutation is most likely derived from an ancestral North African chromosome. This latter notion is consistent with historically known migration patterns of North African individuals into Spain approximately 1200 years ago followed by the subsequent colonization of Central and South America by Spanish explorers.

Assessing tSNP selection: neutral versus disease-based discovery panels. *K. Curtin, N.J. Camp* Genetic Epidemiology, Univ. of Utah, USA.

Discovery panels for tSNP selection are generally population-based, chosen without regard to disease status. However, a diseased population will contain susceptibility alleles at higher frequencies than the general population which may result in unique LD structure and haplotypes, and influence tSNP selection. Using simulation, we investigate the limitations of relying on neutral panels for tSNP selection. 100,000 chromosomes of 20kb sequence were generated under a coalescent model using the program ms (Hudson 2002), assuming a constant diploid population, per-base mutation rate of 10^{-8} and recombination of 1cM/Mb. A variant position was selected as the disease SNP (dSNP). Diploid individuals were created by random sampling with replacement and disease status was generated using a multiplicative genetic model allowing for sporadics. Three single locus models were examined: common, low-penetrance (MAF 0.20); less common, modest-penetrance (MAF 0.05); and rare, high-penetrance (MAF 0.01). Diseased individuals were randomly selected for disease panels and individuals independent of disease were selected for neutral panels of size 100, 50 or 25. From each panel, tSNPs were selected using a principal components method (Horne and Camp, 2004), and the highest correlation between tSNPs and the dSNP was determined using pairwise r^2. This was repeated 1000 times. Mean r^2 for the highest correlation in diseased and neutral panels did not significantly differ under models 1 and 2. However, for rare, high-penetrance disease, neutral panels exhibited significantly lower mean r^2 that declined rapidly with decreasing panel size (neutral vs. disease panel: 0.7 vs. 0.8, n=100; 0.4 vs. 0.7, n=50; 0.2 vs. 0.5, n=25). This preliminary investigation suggests that there are limitations to selecting tSNPs from neutral panels, particularly for rarer predisposition variants. The next step is to assess the subsequent decrease in power in association analyses using the lower correlated neutral tSNPs and to further determine the extent of these limitations for more sophisticated genetic models. The extent of any loss of power could have profound effects on the utility of resources that are based on neutral data (e.g. HapMap, NIEHS SNP Program).

Association of TCF7L2 variants with high serum triglycerides in Mexican dyslipidemic families. *A. Huertas-Vazquez[1], T. Tusie-Luna[2], E. Nikkola[1], C. Aguilar-Salinas[2], P. Pajukanta[1]* 1) Dept Human Genetics, Univ California, Los Angeles, Los Angeles, CA; 2) Instituto de Investigaciones Biomédicas de la UNAM, Instituto Nacional de Ciencias Médicas y Nutrición, Salvador Zubirán, Mexico City, Mexico.

Transcription factor 7-like 2 (TCF7L2) has been shown to be strongly associated with an increased risk of type 2 diabetes in different populations. Familial combined hyperlipidemia (FCHL), characterized by elevated levels of serum total cholesterol (TC), triglycerides (TGs) or both, is the most common mixed dyslipidemia in Mexicans. However, the Mexican population has been underinvestigated for the genetic factors conferring the susceptibility to dyslipidemias. Considering the clear phenotypic overlap between type 2 diabetes and FCHL, both predisposing to high serum triglycerides, glucose intolerance and coronary artery disease, we hypothesized that TCF7L2 may contribute to the genetic susceptibility to FCHL. We investigated the effect of the TCF7L2 variants, rs7903146 and rs12255372, previously associated with T2DM on the most clinically relevant lipid traits in FCHL (TGs and TC) in 759 individuals from 55 extended Mexican FCHL families. For the SNPs rs7903146 and rs12255372, the frequencies of the T allele (0.15 and 0.16 respectively), and linkage disequilibrium between these SNPs (D=0.86, r2=0.7 in spouses) were lower than the corresponding values reported in European and African American populations. Family-based association analyses using the FBAT software showed significant evidence for association with both the qualitative and quantitative TG traits for the SNP rs7903146 (P= 0.002 and P= 0.005). The SNP rs12255372 showed similar results (P= 0.03). These results suggest for the first time that variants in TCF7L2 are significantly associated with high TG levels in Mexican families with FCHL.

Common genetic variation in *CD46* may be associated with susceptibility to *Neisseria meningitidis*. *D.C. Crawford[1], S.M. Zimmer[2], R. Lynfield[3], Q. Yi[4], C. Shephard[4], M. Wong[4], M.J. Rieder[4], R.J. Livingston[4], D.A. Nickerson[4], C.G. Whitney[5], N.E. Messonier[5], J. Lingappa[6]* 1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Department of Medicine, Division of Infectious Diseases, Emory University, Atlanta, GA; 3) Emerging Infections Unit, Minnesota Department of Health, St. Paul, MN; 4) Department of Genome Sciences, University of Washington, Seattle, WA; 5) Department of Medicine, University of Washington, Seattle, WA; 6) CDC, Atlanta, GA.

N. meningitidis is an important cause of bacterial meningitis, with a U.S. incidence of ~1 case per 100,000 individuals. A combination of host, pathogen, and environmental factors likely determines host susceptibility. *CD46* (46.9kb) located on 1q32 has been identified as a host receptor for *N. meningitidis*. To determine if *CD46* variation alters susceptibility or disease characteristics, we used the population-based Active Bacterial Core Surveillance in Minnesota to identify 22 cases of meningococcal disease occurring between 1997-2000. Case-patients were cross matched to the state newborn testing program database; 44 anonymous age, race and birth hospital-matched controls were also identified. Half the case patients were female and the mean age was 5.7 years (range 1-26 years). For genetic variation discovery, 66 blood spot DNAs were re-sequenced as well as 77 reference DNAs. A total of 269 diallelic sites were identified among 143 DNA samples. tagSNPs were chosen from European-American reference samples (n=23; MAF>5%; r^2>0.80), and tests of association were performed among European-descent cases (16) and controls (32). Among the 15 tagSNPs tested, only SNP 6420 (rs41317049) was significantly associated with cases status for both the additive and dominant models (Fisher's exact; $p<0.05$). The G allele frequency was 0.19 in cases versus 0.08 in controls, and 37.5% of cases had either the GT or GG genotype compared with 12.5% of controls. Intronic SNP 6420 is in perfect linkage disequilibrium ($r^2=1$) with intronic SNP 14634 (rs7545126), so it is plausible that either SNP could be the risk conferring marker for susceptibility to *N. meningitidis* if replicated in subsequent studies.

Identification of Late-Onset Alzheimers Disease (LOAD) susceptibility alleles in *VR22* and *LRRTM3* genes. *N. Ertekin-Taner[1, 2], M. Allen[1], C. Cox[1], S. Younkin[1], L. Younkin[1], M. Carrasquillo[1], F. Zou[1], D. Dickson[1], N. Graff-Radford[2], B. Boeve[3], R. Petersen[3], S.G. Younkin[1]* 1) Department of Neuroscience, Mayo Clinic Jacksonville, FL; 2) Department of Neurology, Mayo Clinic Jacksonville, FL; 3) Department of Neurology, Mayo Clinic Rochester, MN.

VR22 (-T catenin) is an excellent functional and positional candidate LOAD gene. We previously found two SNPs within *VR22* which showed significant association with plasma A levels and accounted for our linkage signal on chromosome 10. *LRRTM3* (leucine rich repeat transmembrane protein 3) resides within intron 7 of *VR22*. We genotyped 8 SNPs within *LRRTM3* and 26 in *VR22* in 3 independent LOAD case-control series. *LRRTM3* single SNPs or haplotypes did not significantly associate with LOAD. The *LRRTM3* haplotype pairs formed 25 common multilocus genotypes (MLGs). In the exploratory series, 6 protective MLGs were identified. Compared to these, the remaining *LRRTM3* MLGs were significantly risky in the exploratory series (OR = 3.91, p=0.003). Remarkably, this finding replicated in both follow-up series (ORs= 2.99, 1.97; p=0.006, 0.055). In the combined series, the OR for the risky *LRRTM3* MLGs was 2.71 (p=0.000019). We identified a set of 4 *VR22* SNPs which associated with AD (p=0.01-0.2). The 4 *VR22* SNP haplotypes did not yield significant association, but formed 15 common MLGs, two of which were protective in the exploratory series. Compared to these two protective MLGs, the remaining *VR22* MLGs were significantly risky in the exploratory series (OR=1.33, p=0.0165), with remarkable replication in both follow-up series (ORs=1.92, 1.37; p=0.0001, 0.0198). In the combined series, the *VR22* MLGs were significantly risky (p=0.00003) with OR=1.40 (1.19-1.64). These results strongly indicate the presence of LOAD susceptibility alleles within *LRRTM3* and *VR22* genes. Importantly, the *LRRTM3* and *VR22* SNPs are not in linkage disequilibrium, suggesting independent effects. Studies correlating *VR22* and *LRRTM3* MLGs with A and gene expression are underway.

Correction of arginase deficiency with a helper-dependent adenovirus expressing mouse arginase I. *C. Gau[1], G. Lipschutz[1], J. Livesay[1], V. Cerullo[2], B. Lee[2], W. Grody[1], S. Cederbaum[1]* 1) UCLA, Los Angeles, CA; 2) Baylor College of Medicine, Houston, TX.

Purpose: Arginase I (AI) deficiency is characterized by episodes of hyperammonemia and neurodegeneration. In contrast to the human disease, in which patients survive into adulthood, the current mouse model of AI deficiency dies by 14 days with no visible signs of neurodegeneration. Our goal is to prolong the survival of AI deficient mice with a helper-dependent adenovirus expressing arginase I (Hd-AV mAI) specifically in the liver, in order to examine the effect of AI loss in other organs. *Methods:* An Hd-AV vector expressing mouse AI under a liver specific promoter was created. 1-4 day old pups from an $AI^{+/-}$ cross were injected in the superficial temporal vein with virus. Viral expression was examined by RT-PCR, and mice were analyzed for arginase activity, serum ammonia levels, and tissue amino acid levels. *Results:* We have doubled the life expectancy of the AI knockout mice to 27 days by injection with Hd-AV mAI. The viral DNA was detected in all tissues assayed, but the mRNA was detected only in the liver. Death at 27 days correlated with a loss of total viral DNA. Arginase activity assays showed that Hd-AV mAI injected knockout mouse livers have approximately a third of the activity of heterozygotes at 15 days, and their ammonia levels are normal. Saline-injected knockout mice at this age are on the verge of dying and have elevated ammonia levels. In addition, arginine and ornithine levels in the livers of the injected knockout mice were similar to those of saline injected heterozygous mice. By 26 days, the arginase activity in the Hd-AV mAI injected knockout mouse livers had dropped to less than 10% of heterozygote livers. Ammonia levels of the injected knockout mice began increasing between days 25 and 26, suggesting the cause of death to be similar to that of uninjected knockout mice. *Conclusions:* We have shown that the phenotype of the arginase I deficient mouse can be corrected using a viral vector expressing AI at 30%; of its normal activity, and that death in the injected knockout mice is due to the loss of AI expression.

Mutant mitochondrial genes in *Drosophila*: a model for mitochondrial dysfunction and disease. *B.H. Graham[1], Z. Li[1], E.P. Alesii[1], C.V. Ly[1], P. Verstreken[2], H.J. Bellen[1], W.J. Craigen[1]* 1) Department of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Laboratory of Neuronal Communication, K.U.Leuven, Leuven, Belgium.

Drosophila melanogaster has been established as a powerful genetic model system for many human diseases. To develop models of mitochondrial dysfunction and disease in *Drosophila*, P element alleles of nuclear-encoded mitochondrial genes are being examined as hypomorphic mutants as well as being utilized as mutagenic tools through imprecise P element excision. The first mutant to be examined is the fly functional ortholog (*porin*) of the Voltage-Dependent Anion Channel (VDAC). VDAC is the predominant pore-forming protein of the mitochondrial outer membrane. Analysis of flies homozygous for a P element imprecise-excision allele of *porin* reveals abnormal phenotypes including male infertility, neuromuscular dysfunction manifested by increased sensitivity to mechanical stress (bang sensitivity), and by synaptic abnormalities including a deficiency of mitochondria in pre-synaptic termini of neuromuscular junctions. In order to better understand VDACs functional roles, a genetic screen to identify suppressors of increased bang sensitivity and male infertility has been performed. A series of deletions covering approximately 38% of the genome have been crossed into a homozygous mutant *porin* background and assessed for suppression of these phenotypes. From this pilot screen, several deficiencies that suppress bang sensitivity and/or male infertility have been identified. Interestingly, the strongest suppressor of bang sensitivity in the *porin* mutant background also suppresses increased bang sensitivity observed in P element mutants of two predicted orthologs of human mitochondrial disease genes: *SDHB* and *ATPAF2*. The analysis of *porin* mutant phenotypes validates *Drosophila* as a model for mitochondrial dysfunction that is relevant to mammals. The identification of suppressor loci for mutant mitochondrial phenotypes in *Drosophila* will provide new insights into mitochondrial function as well as potentially identify novel candidate therapeutic targets for mitochondrial diseases.

A genome-wide map of 8.27 million SNPs in the laboratory mouse genome. *B. Karlak[1], K. Frazer[1], C. Wade[2,3], M. Bogue[4], D. Hinds[1], E. Beilharz[1], R. Gupta[1], J. Montgomery[1], M. Morenzoni[1], G. Neilsen[1], S. Osborn[1], C. Pethiyagoda[1], L. Stuve[1], F. Johnson[5], M. Daly[2,3], D. Cox[1]* 1) Perlegen Sciences, Mountain View, CA; 2) Broad Institute of Harvard and MIT, Cambridge, MA; 3) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA; 4) The Jackson Laboratory, Bar Harbor, ME; 5) Toxicology Operations Branch, NIEHS, Research Triangle Park, NC.

A dense map of genetic variation in the laboratory mouse genome will provide insights into the evolutionary history of the species and lead to an improved understanding of the relationship between inter-strain genotypic and phenotypic differences. Using our high-density oligonucleotide array-based technology, we re-sequenced the genomes of four wild-derived and eleven classical inbred strains and identified 8.27 million high quality SNPs. The wild-derived inbred strains are separated from one another by over 3 million discordant SNPs uniformly distributed across the genome, while pairs of classical inbred strains are separated on average by 936,000 discordant SNPs. Analysis of the genetic contributions of the four Mus subspecies to the classical strains surprisingly revealed that collectively the contributions of the three Asian subspecies molossinus (27%), musculus (14%), and castaneus (12%) is larger than that of domesticus (46%). The re-sequencing data, mapped to build 36 of the NCBI Mouse Genome, is available at our web site (http://mouse.perlegen.com/), and includes information on SNP location, genotypes, gene assignment, PCR primer composition, trace files and quality information. The website allows the data to be viewed interactively or downloaded in batch format.

Array comparative genomic hybridization and quantitative PCR identify a novel recurrent 16p11.2 microdeletion in autism spectrum disorder. *R.A. Kumar[1], J. Sudi[1], J. Conroy[2], D. McQuaid[2], S. KaraMohamed[1], J.A. Badner[3], C. Gilliam[1], N.J. Nowak[2], E. H. Cook Jr.[4], W.B. Dobyns[1], S.L. Christian[1]* 1) Human Genetics, University of Chicago, Chicago, IL; 2) Cancer Genetics, Roswell Park Cancer Inst, Buffalo, NY; 3) Psychiatry, University of Chicago, Chicago, IL; 4) Psychiatry, University of Illinois at Chicago, Chicago, IL.

Autism spectrum disorder (ASD) is characterized by impaired social interaction, communication deficits, and restricted and repetitive behaviors and interests. Cytogenetic and array-based studies indicate that ASD may be associated with chromosomal abnormalities, including copy number variants (CNVs), which may be flanked by low copy repeats (LCRs). To identify additional rearrangements associated with ASD, we investigated 180 ASD probands and 260 controls by array comparative genomic hybridization (aCGH) using a novel 19K whole genome tiling path BAC microarray. We discovered a recurrent de novo ASD-specific 16p11.2 microdeletion in 2 probands. We screened an additional 479 probands and 465 controls by quantitative PCR using two probes specific for the deletion and identified 2 probands, but no controls, deleted for both probes. In one family, we detected the 16p11.2 microdeletion in 2 affected siblings but not in an unaffected sibling nor in the unaffected parents, suggesting germline mosaicism. We confirmed all 16p11.2 deletions using FISH, microsatellite analyses, and/or aCGH. In total, we found 4 ASD probands and an affected sibling with a recurrent 16p11.2 deletion that was not identified in 725 controls ($p < 0.047$). The deletion spans ~500 kb, includes 29 genes, and is flanked by ~140-kb LCRs that are >99% identical. High resolution characterization of the deletion breakpoints using a custom designed high-density oligonucleotide array is underway to elucidate the mechanism of the rearrangement. To rank the 29 genes within the deleted region, we used the molecular triangulation method and mapped 8 genes to putative disease-related interaction networks. Our work represents one of the largest case-control CNV analyses in autism and defines 16p11.2 deletions as a novel, recurrent genomic disorder that we hypothesize is causal for ASD.

Detection of known and novel protein interactions with - and -actin using a yeast 2-hybrid screen. *M.C. Drummond[1], T.N. Turner[1], E.T. Boger[2], M. Zhu[1], K.H. Friderici[1]* 1) Microbiology and Molecular Genetics, Michigan State Univ, East Lansing, MI; 2) Section on Human Genetics, National Institute on Deafness and Other Communication Disorders, National Institutes of Health.

Mutations in -actin are known to cause non-syndromic sensorineural hearing loss. In an attempt to identify known and novel actin:protein interactions specific to the isoform of actin, two independent yeast 2-hybrid experiments were performed. In the first experiment, human -actin was used as the bait to screen a prey library constructed from cDNA from the inner ear of a P1 mouse. Over 1.2 million clones were screened and 369 positive interactions identified. The interacting prey were identified as 252 -actin, 76 -actin, 12 ubiquitin E2 conjugating enzyme, 4 cofilin-1, 3 cofilin-2, and 11 different single copy transcripts. The ratio of -actin to -actin prey identified was 3.3:1; a value higher than the anticipated 2:1 based on previous data. In the second experiment, -actin was used as the bait protein to screen the inner ear prey library. While this experiment is still underway, thus far 324,000 clones have been screened and 176 positive interactions identified. Of the 176 positive prey 115 were -actin, 48 -actin, and 13 undetermined. This yields a -actin:-actin ratio of 2.4:1. These results suggest that either the ratio of -actin to -actin in the inner ear is higher than previously reported or that -actin has a higher affinity for itself than -actin. Research plans to address this are currently underway.

Sequential phenotype-genotype analysis improves detection of residual disease in high risk B-cell ALL. *E.L. Enriquez[1], V. Bedell[1], Y. Kim[2], Q. Huang[2], S.J. Forman[3], M.L. Slovak[1]* 1) Cytogenetics, City of Hope, Duarte, CA; 2) Anatomic Pathology, City of Hope, Duarte, CA; 3) Hematology & Hematopoietic Cell Transplantation, City of Hope, Duarte, CA.

Acute lymphoblastic leukemia (ALL) is a hematological disorder characterized by uncontrolled proliferation of immature white blood cells. In B-cell ALL, the presence of t(9;22) or MLL rearrangements is a poor prognostic indicator. Consequently, early detection of MRD is critical for appropriate diagnostic and therapeutic decisions. Current methods for MRD measurements are based on morphologic analyses, flow cytometry, molecular studies and cytogenetics/FISH. While high abnormality rates ease disease detection through standard morphologic and cytogenetic analyses, the presence of affected cells at low quantities hampers diagnosis of disease. We analyzed 78 samples collected from 38 pts using a sequential IHC(phenotype)/FISH (genotype) approach to classify B-cells with rearrangements of BCR/ABL or MLL. Cytospin slides, made from residual bone marrow, were stained with a monoclonal CD19 antibody and scanned on a Bioview Analyzer to target the B-cell population. The slides were subsequently hybridized with FISH probes specific for the genotypic rearrangements mentioned above, with only antibody-targeted cells analyzed. Disease was detected in 33 samples (42%), a finding comparable to the percentage identified by pathology. In samples with positive FISH results, T-FISH outperformed or was comparable to standard FISH in detecting disease in 31 (94%) samples. In two (6%) samples, abnormal cells were not CD19 positive and thus not detected until followup with area scans, which revealed low-level positivity in a subset of progenitor B-cells. Additionally, T-FISH detected residual disease in seven (9%) samples that were negative by other conventional methods; 100% concordance was observed in the four samples that had concurrent Q-RT-PCR results. Cell culture experiments demonstrated that T-FISH consistently identified abnormalities at dilutions of 10^{-3}. These observations suggest that antigen-targeted FISH is an effective way to increase the sensitivity of the assay in detecting residual high risk ALL.

Clinical and Molecular Analysis of Arylsulfatase E in Patients with Brachytelephalangic Chondrodysplasia Punctata. *N. Braverman[1], C. Matos[1], M. Maeda[1], L. Chen[1], J. Allanson[2], C. Armour[2], C. Greene[3], M. Kamaluddeen[3], D. Rita[4], L. Medne[5], E. Zackai[5], S. Mansour[6], A. Superti-Furga[7], A. Lewanda[8], M. Bober[9], K. Rosenbaum[10], M. Nino[1]*
1) Inst. Genetic Medicine, Johns Hopkins Univ., Baltimore, MD; 2) Dept. of Genetics, CHEO, Ottawa, CA; 3) Dept. of Pediatrics, Univ. of Maryland, Baltimore, MD; 4) Dept. of Genetics, Lutheran General Hosp., Park Ridge, IL; 5) Division of Genetics, CHOP, PA; 6) Regional Genetics Dept., St Georges NHS Trust, London, UK; 7) Dept. of Pediatrics, Univ. of Freiburg, Germany; 8) Dept. of Pediatrics, Inova Fairfax Hosp., Falls Church, VA; 9) Dept. of Pediatrics, The Alfred I. duPont Hosp., Wilmington, DE; 10) Division of Genetics, CNMC, Washington DC.

X-linked Recessive Chondrodysplasia Punctata (CDPX1) is due to a defect in arylsulfatase E (*ARSE*), located on Xp22.3. Neither the substrate nor function of the encoded warfarin sensitive arylsulfatase has been identified and molecular analysis remains the only confirmatory diagnostic test. Nevertheless, the majority of patients evaluated have not had identifiable mutations in *ARSE,* and thus far 23 probands have been reported. The major clinical features in these patients are also present in a group now recognized as phenocopies, due to vitamin K deficiency in early gestation or maternal autoimmune disease. We evaluated the *ARSE* gene in 11 probands who met clinical criteria for CDPX1. We amplified all exons and intronic flanking sequence from each patient, and investigated suspected deletions or rearrangements by southern analysis. We identified mutations in 7 probands, including 3 novel mutations and two gene deletions. Of the remainder, 3 of 4 probands had maternal conditions that further expand the phenocopy group. Thus, this group might represent a proportion of the mutation negative patients in previous studies. We extracted clinical information from all prior reports over the past decade and show that there are few distinguishing features on examination between these two groups of patients. This study supports heterogeneity for CDPX1-like phenotypes and sorting these out will help to define the biological pathway and genetic contributors.

Reliable capture of fetal cells from maternal blood and detection of trisomy using a novel cell capture and enrichment device. *F.Z. Bischoff[1,3], R. Wapner[2], J. Williams[4], P. Cotter[3], J.L. Simpson[5]* 1) Baylor College of Medicine, Houston, TX; 2) Columbia Univ, New York, NY; 3) Biocept, Inc., San Diego, CA; 4) Cedars-Sinai Medical Center, Los Angeles, CA; 5) Florida International Univ College of Medicine, Miami, FL.

Recovery and analysis of fetal cells from maternal blood could yield non-invasive definitive prenatal diagnosis. Though many reports support successful detection of common fetal aneuploidies, methods for isolation are inconsistent. The problem may be surmounted by MEMS (microelectromechanical system), whose principle is to capture cells based on attachment chemistry and microfluidics. Attachment is facilitated through antibodies linked to a hydrogel used to coat the post-filled device (75 x 12mm x 30mm).**OBJECTIVE** Determine feasibility of a MEMS based approach to capture and analyze fetal nRBCs by FISH.**METHODS** Under IRB approval, maternal blood (30ml) was obtained from three women suspected of having either trisomy 21 (10.5 and 11.1 wks) or trisomy 18 (12.0 wks); investigators were blinded and unaware of a potential abnormality. Concurrently a sequential series of 15 first trimester maternal samples was studied from patients having CVS (9-12.6 wks). Following ficoll separation, recovered mononuclear cells were passed through the MEMS device coated with glycophorin-A antibodies. Antibody fluorescent staining to epsilon hemoglobin is used to confirm fetal cell origin. FISH (21-specific; 18-, X-,Y- centromeric probes; Vysis Inc.) was performed within the device (FirstCEE) using standard fluorescent microscopy.**RESULTS** Fetal trisomic cells in robust number (7 to 10 cells) were correctly identified in each of the 3 trisomic cases. In the 10 controls from a pregnancy with a male fetus, 8 were informative (3 to 6 fetal cells per 10ml of blood). No false-positive male cells were detected in 5 female cases.**CONCLUSIONS** Our results demonstrate reliable detection of both euploid and aneuploid fetal cells using MEMS technology. Clinical validation studies are currently underway to define sensitivity and specificity. This novel technology can offer most patients a definitive first trimester diagnostic test that is non-invasive.

Genetic diversity of global human populations at STR, SNP, and Indel loci. *S. Guha, R. Chakraborty* Ctr. Genome Information, Univ Cincinnati, Cincinnati, OH.

The impact of variability of pattern and rates of mutations of genomic markers in understanding the history of evolution of modern human is not well-understood. High intra-population gene diversity and multiple measures of genetic variability at the STR loci, compared to the SNP and Indel loci, make them useful in inferring past evolutionary history. But, STR loci, categorized by their repeat motif size, differ in a number of aspects, requiring their separate analyses. We analyzed 1,306 genomic markers (783 STRs, 210 Indels, and 313 SNPs) in 36 worldwide populations to study genome diversity in the present human populations. The loci were grouped by their type and analyzed for each population group separately. At a global level, STRs exhibit lower F_{ST} between geographic groups of populations and higher intra-group diversity compared with SNPs and Indels. When each geographic group was considered separately, small isolated populations (e.g., Native Americans) exhibited similar F_{ST} values for all types of loci, in spite of STRs having higher gene diversity than the SNPs and Indels. Likewise, in Europeans, though gene diversities for all types of STRs are high (about 70%), the low F_{ST} values for all types of loci are suggestive of extensive gene flow among them. Genetic variation defined by gene diversity and allele size variance shows different trends of variation across four types of STRs; namely, little variation of gene diversity, but decreased allele size variance with increasing repeat motifs. While mutation rate decreasing with motif size can explain the trend in allele size variance, a poor correlation of gene diversity and allele size variance across loci in all groups for the di-STRs is probably caused by presence of allele size gaps. In contrast, allele size variance, gene diversity, and number of alleles are strongly correlated for tri- and tetra-STRs. The positive correlation of allele size variance and presence of gaps within the range of allele sizes in the di-STRs alone explains these observations. Unexpected high imbalance index () at the di-STRs due to high allele size variance also supports this assertion.

The role of fluorescence in situ hybridization technique (FISH) in the clinical cytogenetics: 10 years experience of Kuwait Medical Genetic Centre (1995-2006). *S. Abulhasan, A. Al-Adwani, H. Al-Shememaimry, Z. Mohammad, A. Al-Autaiby, K. Al-Kherainej, K. Algareeb, Y. Alfaily, S. Al-Awadi* Molecular Cytogenetics, Kuwait Med Genetics Ctr, Mansauria, 35652, Kuwait.

Fluorescence in situ hybridization (FISH) technique is a direct way and simple procedure for mapping genes and other DNA sequences which enable for rapid detection and reliable assessment of numerical and structural aberrations including markers and fragments. In addition, using appropriate labeled DNA probes FISH technique has the advantages of providing rapid results which can be scored conveniently by eye and precise diagnostic using an epi-fluorescent microscopy. The purpose of this molecular cytogenetics study to analyze the data from 1995-2006, show the importance of FISH technique and other molecular cytogenetics tool in clinical cytogenetics, and how it is usefulness in speeding the diagnosis and prognosis especially in sex determination and cancer genetics conditions. During the period from September 1995 to December 2006 molecular cytogenetics lab at Kuwait Medical Genetics Centre (KMGC) have recieved up to 1431 samples for investigation of different genetics disorders. All samples were referred by government hospitals and health centres, and private hospitals and clinics. All data will be presented later.

Mannose binding lectin codon 54 polymorphism is associated with predisposition to Henoch-Schonlein purpura in childhood. *B. Durmaz[1], F. Ozkinay[1], M. Bak[2], A. Aykut[1], E. Serdaroglu[2], H. Onay[3], C. Ozkinay[3]* 1) Department of Pediatrics, Division of Genetics and Teratology, Ege University, Faculty of Medicine, Izmir, Turkey; 2) Department of Pediatrics, Behcet Uz Childrens Hospital, Izmir, Turkey; 3) Department of Medical Genetics, Ege University, Faculty of Medicine, Izmir, Turkey.

Henoch-Schonlein purpura (HSP) is a systemic small vessel vasculitis characterized by purpura, arthritis, abdominal pain, and hematuria. It is acknowledged to be a type of hypersensitivity vasculitis with an abnormal inflammatory response within the blood vessel, however the etiology of HSP remains unknown. Mannose binding lectin (MBL) is a calcium dependent lectin that has an important role in innate immunity. The aim of this study is to determine the presence of any association between MBL gene variants and HSP in the child population. Codon 54 (allele B) polymorphism in the exon 1 of the MBL gene was investigated by PCR-RFLP method in 66 children diagnosed as HSP (mean age: 10.02.9) and 86 age matched healthy controls. The mutant B allele frequency was significantly higher in the patient group (17.4%) compared to the control group (8.1%); (p=0.014). AB genotype was found to be 28.8% and 14.0% in patient group and healthy control group respectively where the difference was statistically significant (p=0.024). AA genotype was found in 68.2% of the children with HSP and 84.9% of the healthy control group (p=0.014). These results suggest that codon 54 polymorphism in the MBL gene may play a role in susceptibility to HSP in children.

Array-based resequencing of *FMR1* in individuals presenting with a fragile X syndrome-like phenotype. *S.C. Collins, M.E. Zwick, S.T. Warren* Department of Human Genetics, Emory University School of Medicine, Atlanta, GA.

Fragile X syndrome (FXS) is a common form of developmental delay resulting from the functional loss of the *FMR1* gene product, most often due to transcriptional silencing triggered by trinucleotide repeat expansion. However, there is one case in the literature of FXS caused by a missense mutation, wherein the well-characterized I304N mutation was found in a single patient with severe FXS. In comparison to this single clinically-relevant missense mutation in *FMR1*, there are 213 and 64 pathologic missense mutations respectively in *ABCD1* and *RPS6KA3*, two genes similar in size and genomic location to *FMR1*. Because there is no evidence suggesting that *FMR1* is less prone to conventional mutation than these similar genes, it is likely that a significant number of missense and nonsense mutations in *FMR1* have been missed, possibly due to the clinical laboratory standard of testing only for repeat expansion. To assess this hypothesis, we initiated resequencing of *FMR1* in males who present clinically with a FXS-like phenotype but test negative for CGG repeat expansion. All patients were diagnosed with mental retardation and demonstrated at least two additional features consistent with FXS, such as enlarged testes, FXS facies, autism-like behaviors, hyperactivity, and/or a similarly-affected male relative. Resequencing was performed with Affymetrix Resequencing Arrays (RAs), custom-designed to include all 17 exons of *FMR1* and substantial flanking sequence. RA data was analyzed with the automated statistical method ABACUS. Results from 31 patients and two controls indicate that an average of 95.9% of the nucleotides on each RA can be called with 99.9999% accuracy (i.e. quality score of 30). In this initial cohort, twelve novel variants were uncovered. While none of these variants are pathologic, they further define the normal sequence variation within the *FMR1* locus. Additionally, the detection of these variants provides evidence that the RA approach will successfully identify any conventional mutations in *FMR1* in this patient population. We are accepting samples into this ongoing NIH-sponsored study; more details can be found at www.fmr1resequencing.org.

A Murine Model for Mucolipidosis Type IV. *C. Curcio-Morelli[1], B. Venugopal[1], M.F. Browning[1], A. Varro[2], N. Michaud[3], N. Nanthakumar[1], S.U. Walkley[4], J. Pickel[5], S.A. Slaugenhaupt[1]* 1) Massachusetts General Hospital and Harvard Medical School, Boston, MA; 2) University of Liverpool, UK; 3) Massachusetts Eye and Ear Infirmary, Boston, MA; 4) Albert Einstein College of Medicine, Bronx, NY; 5) NIH, Bethesda, MD.

Mucolipidosis Type IV (MLIV) is an autosomal recessive lysosomal storage disorder caused by a disruption in cellular membrane trafficking. The MLIV gene, MCOLN1, maps to chromosome 19p13.2-13.3 and encodes a 580 amino acid protein named mucolipin-1. We have created the first murine model for this disease and our model accurately replicates the human disease phenotype, which includes progressive neurodegeneration, ophthalmologic abnormalities, constitutive achlohydria, and elevated plasma gastrin levels. The *Mcoln1*$^{-/-}$ mice were generated by replacing exons 3, 4 and 72 bp of exon 5 of Mcoln1 with a PGK-neomycin cassette. *Mcoln1*$^{-/-}$ are born at Mendelian ratios and both male and female *Mcoln1*$^{-/-}$ mice are fertile. Electron microscopy of the brain reveals the presence of numerous dense inclusion bodies in all cell types, particularly in neurons. Plasma gastrin, measured by radioimmunoassay, was dramatically increased in *Mcoln1*$^{-/-}$ mice (*Mcoln1*$^{-/-}$ =158.6 pM and *Mcoln1*$^{+/+}$=76.25 pM). Histology of the stomach mucosa showed the presence of vacuolization in parietal cells. Retinas from *Mcoln1*$^{-/-}$ mice were analyzed by electron microscopy and revealed a severe degeneration, presenting a dystrophic outer nuclear layer and a significantly reduced outer plexiform and inner nuclear layer. Analysis of clasping and gait confirmed the presence of a neurological defect in *Mcoln1*$^{-/-}$ mice. The creation of the first murine model for MLIV provides an excellent system for elucidating disease pathogenesis. Moreover, this model will provide an invaluable resource for testing potential therapeutic agents. Recently, two studies have shown resolution of lysosomal storage in MLIV patient fibroblasts following treatment with chloroquine and nigericin. Evaluation of these compounds in *Mcoln1*$^{-/-}$ animals and primary cell cultures is underway and will yield important insights into treatment development for this devastating disorder.

Overwhelmingly activated CNS immunity in MPS IIIB mice and significantly delayed neurological disease progression by immune suppression. *H. Fu[1, 2], J. Etter[1], H. Auer[1, 2], C. Wang[1], J. DiRosario[1]* 1) Center for Gene Therapy, CCRI; 2) Dept. Pediatrics, OSU.

Mucopolysaccharidosis (MPS) IIIB is characterized by progressive and severe neurological manifestations. No treatment is available for MPS IIIB. The mechanism of neuropathology in MPS IIIB is not well understood, though the characteristic pathology is lysosomal accumulation of heparan sulfate (HS), and recent studies suggest cascades of pathology and inflammation secondary to HS storage in MPS IIIB mouse brain. The present study investigates the roles of the CNS immunity in MPS IIIB neuropathology. First, using gene expression microarrays, we observed significant upregulation of an overwhelming number (50) of immune related genes in 6-month-old MPS IIIB mouse brain, involving broad range of immune cells and molecules. The only 3 down-regulated immune genes were associated with acute immune responses. We have confirmed many of these altered gene expression patterns by RT-PCR, western blot and immunohistochemistry, including CD86, CD52, CD45, CD22, C4, Lfi30, and S100. We also saw upregulation of 60, and down-regulation of 30, immune transcripts in blood, with limited overlap of altered transcription (6, 1) between brain and blood. These suggest that the involvement of CNS immune responses in MPS IIIB is broad. Based on these findings, we treated MPS IIIB mice with daily oral administration of low dose prednisolone, to determine whether suppressing the immune response has beneficial impacts. Animal behavior tests demonstrated that the treatment significantly improved the ability of MPS IIIB mice to find a hidden platform in water maze and the latency on an accelerating rotarod. Not surprisingly, prednisolone did not result in the correction of lysosomal storage in any tissues. We demonstrate for the first time that immunosuppression alone can significantly slow the CNS disease progression, and immune responses do indeed contribute greatly to the neuropathology of MPS IIIB. We strongly believe that CNS immunity should be given serious consideration in future therapeutic development, though there is still much to be learned about the role of the immune response in MPS IIIB.

Copy number polymorphisms in the type 2 diabetes linked region at 1q22 in diabetic and nondiabetic Caucasian and African American subjects. *S.K. Das, T.A. Gomes, N.K. Sharma, W.S. Chu, S.C. Elbein* Internal Medicine/Endocrinology, University of Arkansas for Medical Sciences and CAVHS, Little Rock, AR 72205.

Duplication or deletion events involving >1kb of DNA are commonly defined as copy number variants (CNV). Several studies have shown that CNVs are common in the human genome, may be involved in common, complex human diseases, and are present in a ~200 kb region of chromosome 1q22 that is linked to T2DM in eight populations. Furthermore, sequence variation in this region is associated with T2DM in several Caucasian populations, and the region harbors several important candidate genes including PKLR, CLK2, and SCAMP3 among others. We hypothesized that CNV affecting gene dosage might contribute to T2DM and account for the T2DM association in this region. We tested genomic DNA from 128 Caucasians and 128 African Americans, including 64 of each with T2DM and 64 normal control individuals for each group. We tested 4 sets of primers based on known CNV regions (A: chr1:153407866-153407975, B: chr1:153464362-153464455, C: chr1: 153504305-153504420, D: chr1: 153514225-153514331) by quantitative real time PCR (qRT-PCR). Primer sets C and D encompass diabetes candidate genes CLK2 and HCN3. A primer set which amplifies the diploid SPRY3 gene (chrX: 154654501-154654628 and chrY: 57513701-57513828) was used as a reference to normalize and calculate the corrected Ct (KCti) of test primer sets (Weksberg et al., 2005). Additionally, we tested X chromosome gene TEX11 (chrX: 69761280-69761379) as a technical validation of our qRT-PCR technique. Mean Delta KCti value for male and female genomic DNA samples for TEX11 was 0.95. Only 2/128 Caucasian subjects, both controls, showed loss of copy number for primer set A . Gain of one copy number was observed in 11/63 T2DM and 6/56 control subjects successfully evaluated for primer set B in our African American cohort (p=0.309). These observations were validated by analyzing 3 additional DNA aliquots for the same samples. CNVs found in our study were centromeric to known T2DM candidate genes. Our data suggests that CNVs in chromosome 1q22 possibly do not confer susceptibility to T2DM in African American or Caucasian population.

Does Geography influence the phenotype of Fabry disease in females? *M.A. BARBA[1], D. HUGHES[2], P. DEEGAN[3], A. LINHART[4] on behalf of the European FOS Research Group* 1) UNIVERSITY HOSPITAL, ALBACETE, Spain; 2) Royal Free, University College Medical School, London, UK; 3) University of Cambridge, Addenbrookes Hospital, Cambridge, UK; 4) Charles University, Prague, Czech Republic.

Fabry disease (FD) is a lysosomal storage disorder with heterogeneus expression in females. Vascular involvement is prominent in FD. Environmental factors influence atherosclerotic vascular disease, so we hypothesize that similar factors may influence the disease expression in females with FD. To explore differences in the severity of manifestations of females in different European countries, we used the multi-centre Fabry Outcome Survey (FOS). A modified version (FOS-MSSI) of the Mainz Severity Score Index (MSSI) was calculated in females without treatment. That score was compared between patients living in Northern Europe (n=244), and those in Mediterranean Europe (n=125), according the SCORE system. It was performed an analysis of covariance, with age as covariate. **RESULTS**:

	All ages	< 20 years	20-40 years	40-60 years
Northern Europe	12.4 (9.3)	7.5 (6.8)	10.9 (7.5)	13.4 (8.9)
Mediterranean E	7.9 (7.6)	3.4 (4.0)	5.5 (6.0)	10.7 (7.6)
p value	<0.0001	0.0055	0.0010	0.0844

The most consistent difference was in the General and Neurological indexes, but not in the Cardiovascular nor Renal ones. Data on Pain attacks, Muscle Pain, Peripheral Oedema, Angiokeratomas and Diarrhoea, show a significant lower frequency in women from the Southern countries. **CONCLUSION**: The mean severity of females with FD (FOS-MSSI) is greater for females living in Northern Europe compared to the Mediterranean area, except for those aged older than 40. Further studies are required to confirm these data and analyse dietary and environmental factors in more detail.

D409H homozygosity and the cardiovascular form of Gaucher disease: A case report. *K. Cusmano-Ozog, V.T. Sweet, G.M. Enns* Medical Genetics, Stanford University, Stanford, CA.

Gaucher disease, a lysosomal storage disorder, is caused by a deficiency of glucocerebrosidase. There are several subtypes, one of which is the cardiovascular form. We present a 13 year-old female who recently relocated to the United States from Mexico with a seven year history of exertional chest pain and shortness of breath. Family history was significant for a brother who passed away at six months of age secondary to a bleeding abnormality and parental consanguinity. Physical exam was significant for thrombocytopenia and hepatosplenomegaly. An echocardiogram revealed thickened aortic and mitral valves. She was noted to be in congestive heart failure and a decision was made to repair her valves. During cardiac surgery, calcification of the ascending aorta and aortic arch was noted. St. Jude valves and a Dacron graft were placed. She was started on anti-coagulation therapy. Post-operatively, anisocoria was noted and a head CT revealed an intraventricular hemorrhage and hydrocephalus. A ventriculoperitoneal shunt was placed. The anisocoria resolved and a formal ophthalmologic evaluation was normal. She then developed a subdural hematoma that required evacuation. Electron microscopy of thymus tissue obtained during cardiac surgery revealed elongated and distended lysosomes. Beta-glucosidase activity was low at 4 nmoles/hr/mg protein (controls 8-14). *GBA* mutation analysis revealed that she was homozygous for the D409H allele. Following these results, she was started on enzyme replacement therapy (ERT) with imiglucerase. Individuals homozygous for the D409H allele share a common phenotype characterized by calcification of the aortic and mitral valves, splenomegaly, corneal opacities and supranuclear ophthalmoplegia. If patients survive cardiac surgery, improvement of the hematologic abnormalities and organomegaly with ERT has been described. Anti-coagulation treatment for mechanical valves may be challenging, especially with an underlying hematologic abnormality. A diagnosis of Gaucher disease should be considered in individuals with calcification of the aortic and/or mitral valves.

Effects of parameters of microsatellite loci on the distribution of the imbalance index for detecting past demographic changes of population size. *R. Chakraborty, R. Deka* Ctr. Genome Information, Univ Cincinnati, Cincinnati, OH.

With multiple segregating alleles at any microsatellite locus, designated by repeat sizes, several statistics provide information about the same composite parameter that dictates the pattern of their allele frequency distributions. For example, under the stepwise mutation model, expectation of gene diversity and allele size variance at such loci are both functions of the same parameter, = 4Nv, where N is the effective population size (constant over generations) and v, the mutation rate. The ratio of the estimate of from allele size variance, divided by that from gene diversity, is defined as the imbalance index (). A deviation from the constancy of population size makes the expectation of different from 1 (i.e., expected ln 0). While estimation of imbalance index has been worked out, here we performed empirical evaluations of the null distribution of ln to examine how it is influenced by number of loci (L), mutation rate (v), and sample size (n). Coalescence-based simulations were used to generate allele frequencies of a number (L) of microsatellite loci, each from a population under mutation-drift equilibrium (with constant effective size of N, and mutation rate v). The number of alleles sampled (n) was another simulation parameter. Of the various parameters affecting the null distribution of ln, the number of loci (L) appears to have the largest effect. Imbalance index, estimated from a small number of loci, produces asymmetry in the distribution of ln, making observed values of less than 1, or ln < 0, more frequent, under the constant population size model. For detecting signatures of past bottleneck or recent population expansion, 50 to 100 loci are recommended. In contrast, variations in sample size (n) and/or mutation rate (albeit,) have little effects on ln, particularly when n > 50, and/or 1. A computer routine for generating the confidence interval for the null distribution of ln is freely available in our web-site (www.cgi.edu). As an example, we obtained the confidence interval of ln in the Samoan population to detect evidence of recent expansion of this population. (Supported by NIH grant GM41399).

Developmental regression, autism and GABA receptor genes. *M.L. Cuccaro[1], D. Ma[1], E.R. Martin[1], R.K. Abramson[2], H.H. Wright[2], J.R. Gilbert[1], M.A. Pericak-Vance[1]* 1) Miami Inst for Human Genomics, Univ of Miami Miller School of Medicine, Miami, FL; 2) Univ of South Carolina SOM, Columbia, SC.

Autism (AUT) is characterized by significant genetic heterogeneity. Clinical subsetting on diagnostic features (e.g., language) has yielded several candidate loci. We have extended subsetting to an associated feature-developmental regression (DR). DR occurs in 20-49% of individuals with AUT and may co-exist with seizures. The relationship between DR and seizures implicates the GABAergic system, as it believed that GABA transmission influences seizure susceptibility. We reported association in AUT for SNPs in GABA receptor genes on chromosome 4 (GABRA4) in Caucasians (CA) and confirmed these results in an independent African American (AA) sample, although the associated SNPs differed in the two racial groups. We hypothesized that DR may have an effect on association with GABA receptor genes and could clarify the differences in associated SNPs in AA and CA families. Using the ADI-R, a standard interview for features of AUT, we identified a DR subset (N = 263; 35%) from our overall sample of 606 AUT families (54 AA, 552 CA). DR families were those with positive ADI-R regression scores in at least 1 affected individual. Using the pedigree disequilibrium test (PDT) we tested for association in the DR and non-DR subsets in 36 SNPs in GABRA4 and GABRB1. Data were analyzed by race and contrasted with overall findings. In the AA-DR subset (N=17), allelic association (p.05) was detected for the two SNPs in GABRA4 (rs2280073, rs16859786) previously identified in the overall AA group as well as for two additional SNPs in GABRA4 (rs13151769, rs2351299). In contrast, no SNPs identified in the overall CA group showed association in the CA-DR subset (N=246) although three SNPs (rs17599165, rs1912960, rs17599416) in the overall set remained significant in the CA non-DR complement. It appears that subsetting on DR had an effect on association and that DR subsetting may explain the different patterns of associated SNPs in the two racial groups. This is the first study of DR, GABA genes, and AUT. Our results suggest that DR should be explored in other candidate gene studies of AUT.

On the edge of the Bantu expansions: patterns of mtDNA and Y-chromosome variation in southwestern Angola.

M. Coelho[1,2], J. Rocha[1,2], S. Beleza[1] 1) IPATIMUP, Porto, Portugal; 2) Department of Zoology and Anthropology, Faculty of Sciences, University of Porto, Porto, Portugal.

Among the complex series of demographic movements that have shaped the patterns of human genetic variation in sub-Saharan Africa, the massive dispersal of Bantu-speaking farmers across subequatorial regions in the last 4000-5000 years remains one of the most impressive examples of large population movements in our species. In spite of the relative recentness of these dispersals, several important questions about the tempo and mode of demographic events undergone by the ancestors of present-day Bantu farmers still persist. Current studies on Bantu expansions are hampered by poor sampling within the vast region encompassing sub-equatorial Africa. For example, the region of Angola remains a persistent gap in studies of African genetic variation, and only scarce information is available from the broad area beyond the Cuanza River, crucial for understanding the dramatic push of Bantu peoples towards the arid steppes and deserts of Southwest Africa. Here, we present a preliminary analysis of the patterns of Y-chromosome and mtDNA genetic variation in a panel of 359 individuals from different ethno-linguistic groups from the region of the Namibe desert in Southwestern Angola: Kimbundo, Umbundo, Nkhumbi, Mwila, Nyaneka, Nyemba and Herero/Kuvale. Patterns of Y chromosome microsatellite variation were found to be relatively homogeneous across the different Angolan groups and, like in most Bantu populations, were dominated by a small number of E3a* haplotypes with intermediate frequencies. As a whole, mtDNA variation was consistent with the general pattern previously observed in populations located along the western stream of the Bantu expansion. However, we found that, within the southern Angola context, the Mwila and Herero pastoral groups were clear outliers due to the assimilation of significant amounts of L0d/K lineages (15-23%) that are typical of southern Khoisans. These results provide evidence for substantial female driven Khoisan-Bantu interactions that may have important implications in the understanding of the current distribution of pastoralism in Southwest Africa area.

5-lipoxygenase (5-LO), dietary arachidonic acid (AA), and risk of myocardial infarction (MI). *J. Hartiala[1], A. Baylin[2], H. Wijesuriya[1], G. Mendoza-Fandino[1], P.I. Patel[1], H. Campos[3], H. Allayee[1]* 1) Institute for Genetic Medicine, USC Keck School of Medicine, Los Angeles, CA 90033; 2) Department of Community Health, Brown University, Providence, RI 02912; 3) Department of Nutrition, Harvard University School of Public Health, Boston, MA 02115.

5-LO, the rate-limiting enzyme in the biosynthesis of pro-inflammatory leukotrienes from AA, has been associated with the development of atherosclerosis in mouse models and humans. To follow up on these previous observations, we have now tested the effect of a 5-LO promoter polymorphism on risk of MI and whether dietary AA modified the observed results. We genotyped 1,885 MI cases and 1885 controls and used conditional logistic regression to estimate odds ratios and confidence intervals. Dietary intake was assessed by a validated food frequency questionnaire. No differences in the frequency of deletion (DD/WD) or addition (AA/WA) genotype groups were identified: frequencies for DD/WD were 0.29 in cases and 0.30 in controls and 0.024 and 0.031, respectively, for the AA/WA genotype group. However, a significant gene-diet interaction was found between the 5-LO repeats, AA intake, and MI (p=0.014). Compared to the wildtype allele (W), the D alleles were associated with increased MI risk in the high (>0.25g/d) dietary AA group (OR 1.23, CI 0.99-1.53) and with decreased risk in the low (<0.25) AA group (OR 0.79, CI 0.63-0.98). The A alleles were inversely associated with MI in both diet groups, although this association was not statistically significant perhaps due to their low frequency. To determine if functional differences between the alleles could explain the observed results, we measured relative amounts of RNA from the D alleles compared to the W allele in leukocytes from 66 heterozygous individuals from the same population using allele specific quantitation. As a control, DNA from the same individuals for each respective allele was used. Consistent with the results above, the D alleles had ~1.5 fold increased expression relative to the W allele. These results are consistent with the observation that the D alleles are associated with increased atherosclerosis and MI risk, particularly in the context of a high AA diet.

Clinical features in children with microdeletions of the NF-1 gene detected by array CGH. *J.F. Atkin[1], R. Moran[2], E. Edelman[2], C. Rigelsky[2], B. Burton[3], J. Coppinger[4], L.G. Shaffer[4]* 1) Molecular/Human Genetics, Columbus Childrens Hospital, The Ohio State University, Columbus, OH; 2) Cleveland Clinic Foundation, Genomic Medicine, Cleveland, OH; 3) Childrens Memorial Hospital, Dept Genetics, Chicago, IL; 4) Signature Genomics Laboratories, LLC, Spokane, WA.

Approximately 4-5% of individuals with NF-1 have deletions of the entire gene. These individuals are reported to have earlier onset and more significant cutaneous neurofibromas, higher incidence of malignancy, more severe developmental delay/mental retardation, distinctive dysmorphic facial features and congenital anomalies. In some cases, features of connective tissue disease and overgrowth are seen. We report 4 patients detected by array CGH analysis to have a deletion covering the entire gene. These patients had CGH array testing because of birth defects and/or developmental delay and/or dysmorphic features, not for features of NF-1. Only 1 of 4 patients had features that met the diagnostic criteria of NF-1, 6 or more cafe au lait spots and inguinal freckling. No parents were affected. None of the patients had neurofibromas or significant delays. All were of normal size including head circumference. Cafe au lait spots present in all 4 were not of significant number or size. None had malignancies. Consistent clinical findings include normal development or mild delays, specific facial dysmorphic pattern, normal growth parameters, and caft au lait spots (around 5-10 that did not present originally). The age range at original genetics evaluation was 7 weeks to 2 years. The current age range is 4 months to 3.5 years. One chld has polyvalvular heart disease and increased skin folds, one has mild coarctaion of the aorta and shawled scrotum. One has strabismus. No other birth defects were found. Except for the facial features, none of these patients fit the phenotype previously reported for entire gene deletions. This may be related to age of diagnosis. Long term follow-up is needed. Further reports are needed to more precisely assess the microdeletion phenotype and to help with prognosis for these families as well as for surveillance guidelines.

Identification of modifiers of BRCA1/2: results from combined analysis from the Consortium of Investigators of Modifiers of BRCA1/2. *A. Antoniou[1], J. Beesley[2], D.F. Easton[1], G. Chenevix-Trench[2], Consortium of Investigators of Modifiers of BRCA1/2 (CIMBA)* 1) CRUK Genetic Epidemiology Unit, Cambridge, Cambridge, United Kingdom; 2) Queensland Institute of Medical Research, Brisbane, Australia.

Mutations in BRCA1 and BRCA2 confer high risks of breast and ovarian cancer. However, epidemiological evidence suggests that these risks are modified by other genetic or environmental factors. Studies of genetic modifiers of BRCA1/2 have been hampered by small sample size. To address this problem, CIMBA was established to conduct collaborative analyses of genetic polymorphisms as modifiers of risk in BRCA1/2 mutation carriers. To correct for the potential bias from non-random sampling of carriers with respect to their disease phenotype, we analysed the data by modelling the retrospective likelihood of the observed SNP genotypes and disease phenotypes conditional on the disease phenotypes. A SNP in the 5UTR of RAD51, G135C, has been suggested as a possible modifier of breast cancer risk in BRCA1/2 carriers. We pooled genotype data on 8512 mutation carriers from 19 studies for this SNP. We found evidence for an increased breast cancer risk in CC homozygotes (HR=1.92, 95%CI: 1.25-2.94) but not in heterozygotes (HR=0.95, 95%CI: 0.83-1.07, 2df heterogeneity test: p=0.002). When BRCA1 and BRCA2 mutation carriers were analyzed separately, the increased risk was significant only among BRCA2 mutation carriers in whom we observed HRs of 1.17 (95%CI: 0.91-1.51) among heterozygotes and 3.18 (95%CI: 1.39-7.27) among rare homozygotes (2df, p=0.0007). SNPs in FGFR2, TNRC9 and MAP3K1 have been recently shown to be associated with breast cancer risk in the general population through a genome-wide association study of breast cancer. To evaluate whether these SNPs also modify the breast cancer risk in BRCA1/2 mutation carriers we genotyped approximately 11000 mutation carriers from 24 studies. The data are currently being analysed and the results will be discussed. The identification of genetic modifiers of risk may have important implications for the clinical management of BRCA1/2 mutation carriers.

Frequency of chromosomal abnormalities in 99 couples prior ICSI and in 82 couples who fail to conceive after one or more ICSI attempts. *N.B. Abdelmoula[1], M. Meddeb[2], L. Mokaddem[2], F. Bouzid[2], A. Sallemi[2,1], A. Amouri[3], T. Rebai[1]* 1) Histology Laboratory, University of Medicine of Sfax, SFAX, Tunisia; 2) Private Sector, Tunisia; 3) Histology and Cytogenetic Laboratory, Pasteur Institute, Tunis, Tunisia.

We report results of cytogenetic investigations performed in 181 couples prior to ICSI or after unsuccessful attempts, between January 2001 and May 2007. Couples were referred to our laboratory for cytogenetic investigations and genetic counselling. Couples were classified according to the ICSI indications as: Group 1: 99 couples undergoing ICSI for the first time and group 2: 82 couples failing to conceive by ICSI. ICSI was indicated respectively for group 1 and group 2 because OAT(n=42/n=41), azoospermia (n=13/n=5), asthenoteratospermia (n=14/n=13) or other indications with normospermic men (n=30/23). Out of these 362 patients, sixteen had an abnormal karyotype (4,42 per cent patients and 8,84 per cent couples); fourteen men (14/181: 7,73 per cent) and two women (2/181: 1,10 percent). Frequencies of chromosome abnormalities are estimated to 6,06 per cent in group 1 and 12,2 per cent in group 2. If we consider inversions of chromosome 9 and 12 (n=4) and add21p; as minor abnormalities, frequencies became 4,04 per cent in group 1 and 8,53 per cent in group 2. Most chromosomal abnormalities detected were structural rearrangements: 6 reciprocal translocations t(11;22)(q24;q11),t(2;3)(p24;q26),t(11;21)(q13;p11), t(16;22)(q13;q12) and 2 t(1;18)(p21;q12) detected in 2 normospermic men, 2 robertsonian translocations, 5 inversions, one case of add21p and 2 sex mosaicism: 46,XY/47,XXY and 45,X/46,XX/47,XXX. Our results stress the importance of karyotyping both male and female partners before ICSI is started to ovoid couples, unsuccessful attempts. Adequate genetic counselling, followed by preimplantation or prenatal diagnosis, should be offered if a chromosomal abnormality is detected. Thus, much greater overlap between reproductive medicine and genetics is necessary and a close collaboration between professionals working in these two fields is imperative in treating patients with infertility in the best possible way.

Literacy, numeracy, and the development of an Individualized Risk Information System (IRIS): A genetic counseling tool for BRCA+ breast cancer patients. *S. Brown[2], J. Culver[1], D. MacDonald[1], K. Metcalfe[3], H. Burke[4], M. Robson[5], S. Sand[1], A. Thornton[1], M. Grant[1], K. Osann[2], J. Weitzel[1]* 1) City of Hope, Duarte, CA; 2) University of California, Irvine, Irvine, CA; 3) University of Toronto, Toronto, Ontario, Canada; 4) George Washington University, Washington, DC; 5) Memorial Sloan Kettering CA Ctr., New York, NY.

BRCA+ breast cancer (BC) patients face markedly elevated risks of second primary tumors, and clinicians must communicate complex information about these risks and risk-reducing strategies. To enhance patient decision-making, we developed IRIS, a computerized genetic counseling communication tool that calculates and conveys individualized risk predictions associated with various risk reduction scenarios, based on a predictive model from a large cohort of BRCA carriers. IRIS graphical output includes: 1)the absolute risk of second primary BC 2)disease-specific mortality and 3)the effect of risk-reducing mastectomy and/or oophorectomy. An expert panel of genetic counselors, nurses, and physicians evaluated the perceived utility of IRIS as a genetic counseling tool, and lay focus groups of BRCA+ women demonstrated preferences for IRIS graphical representations. As health literacy and numeracy (numerical ability) may be critical to understanding and informed decision-making, 120 women at high-risk for breast cancer were recruited via the FORCE website (www.facingourrisk.org) to interpret graphical breast cancer risk, make hypothetical treatment decisions, and rate each graph using a six-point Likert scale. Health literacy was estimated using the validated instrument, Rapid Estimate of Adult Literacy in Medicine (REALM), and numeracy was estimated using a six-question test. The mean score was 4 out of 6 correct answers. The Pearson correlation between numeracy and graph interpretation was .627, $p<.0005$. Multiple linear regressions showed that 42% of the graphical interpretation variance was explained by numeracy alone, with little additional impact of education level. Based on this input, we are now revising IRIS graphical output as part of an integrated decision support component to facilitate decision-making about risk reduction options.

Initial investigations in genetical genomics. *R.M. Cantor-Chiu[1], B. Kerner[2]* 1) Human Genetics, UCLA School of Medicine, Los Angeles, CA; 2) Psychiatry, UCLA School of Medicine, Los Angeles, CA.

Genetical genomics is an emerging field of investigation focused on analyzing genetic variations, such as SNPs, to better understand genomic phenomena, such as gene expression levels. Sources of variation in gene expression are not well understood. We conducted analyses, as part of Genetic Analysis Workshop 15, to begin to identify and quantify these sources and assess their influence on regulation by cis acting elements. A variance components analysis of the expression levels of 65 genes in 14 CEPH pedigrees revealed that familiality (heritability plus common family environment) of gene specific expression varies considerably. The positively skewed familiality distribution ranged between 0 and .61 with a median of .23 and a mode of .15, indicating that environmental factors may play an important role in the expression levels of a large number of genes. To explore the process of mapping cis regulatory regions using SNP genotypes, we conducted quantitative trait linkage (QTL) analyses of these expression levels. For DDX17 at 43.4 Mb on 22p13, which had the highest estimate of famiality in this sample (.60), its mean expression levels varied widely among the families (7.2-8.6) and these family differences explained .25 of the variance of DDX17. Single point QTL variance components linkage analyses of DDX17 expression, found 6 SNPs (between 32.8 and 46.6 Mb) out of 57 along the entire chromosome linked with LODs > 3.0. Alleles of these SNPs explain .09 of the variance in expression. Stepwise regression was conducted to narrow this potential cis regulatory region, and 2 SNPs (rs80533 at 39.4 Mb, $p<.003$ and rs760482 at 37.7 Mb, $p<.046$) were retained. In multiple regression analyses of DDX17 expression that included factors for family and SNP genotype, family and its interaction with SNP genotype were significant for each SNP, although allelic differences were not. We conclude from these initial studies that gene expression is genetically complex, with multiple genetic and environmental contributions. As with other complex phenotypic traits, these factors are likely to complicate the detection of regulatory elements in genetical genomics investigations.

Patterns of microsatellite variation within the KITLG and TYRP1 genes: Implications for the evolutionary history of skin pigmentation in human populations. *S. Beleza[1], C. Martinho[1], I. Alves[1], E. Parra[2], M. Shriver[3], J. Rocha[1]* 1) IPATIMUP, Porto, Portugal; 2) Department of Anthropology, University of Toronto, Canada; 3) Department of Anthropology, Penn State University, PA, USA.

A major motivation for searching for genes affected by recent adaptation is to determine how different environmental selective pressures have shaped contemporary phenotypic variation. Skin pigmentation has long been considered a trait largely affected by selection, but only recently have several analyses shown signatures of positive selection in pigmentation candidate genes. The Tyrosinase Related Protein-1 (TYRP1) and the Kit Ligand (KITLG) genes are particularly notable in showing large between-population differentiation when compared to other loci and a European-specific decrease in genetic diversity due to the presence of high frequency extended haplotypes in SNP database analyses. To further elucidate the evolutionary history of these two genes, we have characterized the patterns of microsatellite haplotype variation within lineages defined by the tag SNPs rs2733831 (FST=0.49) and rs642742 (FST= 0.70) encompassing 267 kb and 1 Mb around TYRP1 and KITLG, respectively, in 240 chromosomes from European and African ancestry. We have observed two distinct genealogical patterns associated with each gene. In the TYRP1 gene, the rs2733831 genealogy shows a paraphyletic pattern where the derived G lineage encompasses a limited subset of observed haplotype diversity, in spite of its high 0.53 frequency in Europeans, consistent with a very recent incomplete selective sweep. The KITLG gene rs642742 SNP is associated with a reciprocal monophyletic pattern where both the ancestral A and the derived G lineages have identical levels of intra-allelic diversity, suggesting that the rise in frequency of the G allele to 0.80 in Europeans may represent a nearly complete more ancient sweep associated with high levels of diversity recovery. Our data show that microsatellites may be useful markers for elucidating recent evolutionary events and suggest that the multiple selective episodes that might have shaped pigmentary traits occurred over different time scales and/or under diverse selective coefficients.

GJB2 mutation study in Korean patients with hearing loss. *H. Kim[1], Y.H. Choung[2], J.A. Yang[1], J.H. Hong[1], S.Y. Jeong[1]* 1) Dept. of Medical Genetics, Ajou Univ. Sch. of Medicine, Suwon, Korea; 2) Dept.of Otolaryngology, Ajou Univ. Sch. of Medicine, Suwon, Korea.

Congenital hearing loss occurs in approximately 1 in 1,000 live births, over 50% of these cases being hereditary. About 70-80% of genetic deafness is nonsyndromic: autosomal-recessive (80%), autosomal-dominant (20%), X-linked (1%), and mitochondrial (<1%). Mutations in the GJB2 gene, which has a single coding exon encoding for the gap-junction protein connexin-26, a member of the large family of connexins, are the major cause of nonsyndromic autosomal-recessive (DFNB1) and sporadic deafness (as much as 50% of such cases in many populations). GJB2 mutations also cause dominant nonsyndromic sensorineural hearing loss (DFNA3). Several heterozygous GJB2 mutations located in a particular domain of the protein (first extracellular domain) have been reported to segregate with autosomal-dominant hearing loss in a small number of families. Mutations in the GJB2 gene are also responsible for syndromic forms of hearing loss. In this study, we screened total 48 unrelated Korean patients with congenital nonsyndromic (46 cases) and syndromic (2 cases) hearing loss for GJB2 mutation. All subjects were diagnosed to have hearing loss at the Otolaryngology clinic in Ajou University Hospital. Three different mutations, p.E47K, p.T123N, and c.235delC, and three polymorphisms, p.V27I, p.E114G, and p.I203T, were found in the 23 nonsyndromic patients. The p.V27I allele has been reported to be a just sequence variant that is not responsible for hearing loss. But, we found that 20 patients out of 46 cases had this allele with (14 cases) or without the p.E114G allele. These findings suggest that the p.V27I allele in the GJB2 gene may involve in the phenotype of hearing loss. Two syndromic autosomal dominant hearing loss patients with palmoplantar keratoderma (PPK) and keratitis-ichtyosis-deafness syndrome (KID) were revealed to have the GJB2 mutations, p.D50N and p.R75W, respectively. Further study including pedigree analysis with familial mutation study will contribute to a better understanding the genetic and phenotypic heterogeneities of GJB2 mutations in Korean patients with hearing loss.

46,XY/46,X,del(Yq) mosaicism ascertained in a normospermic man by cytogenetic assessment of an early pregnancy loss and a late termination of an anencephaly foetus. *R. Frikha[1], R. Rekik[2], M. Meddeb[2], T. Rebai[1], N.B. Abdelmoula[1]* 1) Histology Laboratory, University of Medicine, Sfax, Tunisia; 2) Private Sector.

Balanced chromosomal rearrangements have been found at an increased frequency in couples with recurrent spontaneous abortions.Most of them are reciprocal translocations. Robertsonian translocations, autosomal inversions and X chromosome mosaicism are less frequent. Structural Y chromosomal abnormalities are exceptional since they are responsible of infertility, low sperm counts or sexual ambiguity. Here, we report an exceptional observation of a normospermic man for who a 46,XY/46,X,del(Yq) mosaicism was detected by cytogenetic assessment of two early pregnancy losses and one late termination of an anencephaly fetus. The patient was a healthy 45 year old man married since 2005. His wife was a 39 year old woman. No familial history of infertility was recorded but the patient had two half brothers affected by neurofibromatosis. The non consanguineous couple has been explored at 2005 and normal reproductive function was recorded for both. After 8 months, two pregnancy losses takes place: At the first pregnancy with a positive hCG test, pelvic ultrasound reported a pregnancy sac but failed to record any heart activity until 10 weeks gestation and pregnancy was ended. The second pregnancy, 3 months later, progressed normally since 18 weeks gestation when, elective termination was decided. In fact, the fetus had major anencephaly. Chromosome analysis revealed a 4,XX karyotype for the wife and two cell lines for the husband. The first cell line (21 cells) was 46,XY while the second cell line (9 cells) was of 46 chromosomes with a small size rearranged Y chromosome with a centromere. It was interpreted as a deleted Yq chromosome but others types of rearrangement as dicentric Y chromosome cannot be excluded. FISH analysis using X/Y centromeres, SRY and Yqh probes will be conducted to assess more precisely mosaicism level and Y chromosome structure. Y chromosome AZF regions will also be explored by multiplex PCR. Our study suggests that there is a potential liaison between Y long arm chromosome and embryo development and that Y chromosome may play a role in pregnancy losses.

Leptin Gene Polymorphisms: Association with Obstructive Sleep Apnea in Children. *M. Kalra[1], P. Pal[3], S. Guha[3], L. Dolan[2], R. Deka[3], R. Chakraborty[3]* 1) Division of Pulmonary Medicine, Cincinnati Children's Hosp, Cincinnati, OH; 2) Division of Endocrinology, Cincinnati Children's Hosp, Cincinnati, OH; 3) Center for Genome Information, University of Cincinnati, Cincinnati, OH.

Obstructive sleep apnea (OSA)is a complex disorder with an interplay between factors related to airway anatomy, airway neuromuscular control, and ventilatory control implicated in its pathogenesis. Although genetic predisposition for this disorder has been demonstrated, the exact genetic underpinning is not yet clear. Reports on the effect of plasma Leptin levels on ventilatory drive support the role of *Leptin* in mediating genetic susceptibility to OSA. The objective of this study was thus to test the association of *Leptin* polymorphisms and OSA status. All Caucasian children diagnosed with OSA at Cincinnati Childrens Sleep Center between January and June 2006 were recruited as cases and ethnicity matched controls were selected from the population-based Princeton School District Study. Three SNPs (rs 7795794, rs 3828942 and rs 2060715) that tag the Leptin gene were selected using SNP browser ver. 3.5. Genotyping was performed using the SNPlex (ABI) high-throughput genotyping platform. OSA was defined as apnea hypopnea index >1 on polysomnogram; cases were then compared to population-based controls. The mean age of the 74 OSA cases was 13.6 years (S.D. 4.3), 60% were males, and mean BMI was 31.9 (S.D. 11.0). The mean age of the 92 controls was 14.3 years (S.D. 2.9), 60 % were males, and mean BMI was 25.7 (S.D. 2.9). The genotype frequencies of all SNPs were in Hardy Weinberg Equilibrium. Structure analysis revealed absence of significant population stratification between cases and controls. Comparison of genotype frequencies between cases and controls revealed significant differences for all 3 SNPs (rs 779574,p=<0.0001; rs 3828942, p= 0.03; and rs 2060715, p= 0.04). Multivariate logistic regression analysis with age and BMI as covariates revealed significant association between OSA status and SNP rs779574 (P=0.0002). This is the first report of association of *Leptin* polymorphisms with OSA in children, supporting the role of Leptin in the pathogenesis of pediatric OSA independent of obesity.

Association of the distal region of the Ectonucleotide Pyrophosphatase/Phosphodiesterase 1 (ENPP1) gene with Type 2 Diabetes enriched for nephropathy in an African American Population. *K.L. Keene[1], J.C. Mychaleckyj[2,3], S.G. Smith[1], T.S. Leak[1], C.D. Langefeld[4], B.I. Freedman[5], S.S. Rich[2,3,6], D.W. Bowden[1,5,7], M.M. Sale[1,2,5,6,8]* 1) Molec Med/Ctr Human Genomics, Wake Forest Univ Sch Med, Winston-Salem, NC; 2) Center for Public Health Genomics; 3) Department of Public Health Sciences,Univ of VA, Charlottesville, VA; 4) Division of Public Health Sciences; 5) Department of Internal Medicine; 6) Department of Medicine, University of Virginia, Charlottesville, VA; 7) Department of Biochemistry; 8) Department of Biochemistry and Molecular Genetics.

Variants in the Ectonucleotide Pyrophosphatase/Phosphodiesterase 1 (ENPP1) gene have shown positive associations with diabetes and several diabetes-related phenotypes including insulin resistance, metabolic syndrome, and type 1 diabetic nephropathy. Additionally, evidence for linkage for type 2 diabetes mellitus (T2DM) in African Americans (AA) was observed at 6q24-27, with the proximal edge of the peak encompassing the ENPP1 gene. To comprehensively evaluate variants in ENPP1 for association with T2DM-ESRD, forty-nine SNPs located in the coding and flanking regions of ENPP1 were genotyped in 577 AA individuals with T2DM-ESRD and 596 AA without a diagnosis for T2DM. Haplotypic association and genotypic association for the dominant, additive, and recessive models were tested by calculating a c2 statistic and corresponding P value using the program SNPGWA. Nine SNPs showed nominal evidence for association ($P < 0.05$) with T2DM-ESRD in one or more genotypic model. The most significant associations were observed with rs7754586 (P= 0.003 dominant model, P=0.0005 additive, and P=0.007 recessive), located in the 3 UTR, and an intron 24 SNP (rs1974201: P=0.004 dominant, P=0.0005 additive, and P=0.005 recessive). This study was the first to comprehensively evaluate variants of the ENPP1 gene for association in an AA population with T2DM and ESRD and suggests that variants in the distal region of the ENPP1 gene may contribute to T2DM-ESRD susceptibility in AA.

***TNFSF13* (*APRIL*) Polymorphisms and Systemic Lupus Erythematosus.** *F.Y. Demirci[1], S. Manzi[2], R. Ramsey-Goldman[3], A.H. Kao[2], E.Y. Rhew[3], F. Bontempo[4], C. Kammerer[1], M.I. Kamboh[1]* 1) Dept of Human Genetics, Univ of Pittsburgh, Pittsburgh, PA; 2) Lupus Center of Excellence, Univ of Pittsburgh, Pittsburgh, PA; 3) Div of Rheumatology, Northwestern Univ, Chicago, IL; 4) Dept of Medicine, Univ of Pittsburgh, Pittsburgh, PA.

Systemic lupus erythematosus (SLE) is a prototypic autoimmune disease with a broad range of clinical manifestations. It predominantly affects women of childbearing age and its prevalence varies across different ethnic groups. SLE has complex genetic basis and is caused by complex interaction of unknown environmental factors and multiple genetic susceptibility loci on different chromosomes. *TNFSF13* (also known as *APRIL*) and *BLyS* (B lymphocyte stimulator) are members of the tumor necrosis factor superfamily. BLyS/APRIL pathway has been strongly implicated in autoimmunity as suggested by mouse studies and observation of increased protein levels in serum and synovial fluids of patients with SLE or rheumatoid arthritis. *TNFSF13* is located on chromosome 17p13.1 (positional candidate for SLE) and its variants have recently been reported to be associated with SLE in Japanese. The purpose of this study was to replicate the reported association of two *TNFSF13* coding SNPs, rs11552708 (Gly67Arg) and rs3803800 (Asn96Ser), in our Caucasian American SLE case-control cohort. DNA samples from 409 SLE-affected female subjects and 509 healthy female controls were genotyped using TaqMan SNP genotyping assays (ABI). The genotype frequencies were in Hardy-Weinberg equilibrium in both case and control groups. None of the two *TNFSF13* coding SNPs showed a statistically significant association with SLE in our Caucasian cohort. Our results do not indicate a major impact of these putative functional *TNFSF13* SNPs on the susceptibility to (or protection from) SLE in Caucasians.

Genetic medicine and physician assistants: Development of a web-based, case-driven educational program. *C.M. Goldgar[1], E. Harvey[2], C. Wolpert[3], K. Healy[4], K. Clarke[5], J.D. McInerney[2]* 1) University of Utah, Salt Lake City, UT; 2) NCHPEG, Lutherville, MD; 3) University of North Carolina, Greensboro, NC; 4) Midwestern University, Downers Grove, IL; 5) Towson, MD.

The explosion of information in genetic medicine holds immediate and future implications for all healthcare providers. Many physician assistants (PAs) already feel the impact of genetics in practice, but lack adequate training to apply genetic information effectively or to answer patient questions appropriately. In 2006, a group of PA educators received a grant from the National Coalition for Health Professional Education in Genetics (NCHPEG) to develop an interactive, case-driven, educational website for use by PAs, PA educators, and PA students.

Key learning objectives of the website include: 1) collecting/recording a family history in pedigree format, 2) recognizing red flags that signal a genetic contribution to disease, 3) accessing valid genetic resources, and 4) referring appropriately to genetic professionals.

Three interactive cases, all in primary care settings, illustrate common conditions that have a genetic component and are designed to reinforce basic genetic principles. PAs work thorough the cases as they would a typical patient encounter, with an emphasis on thinking genetically. Additional components of the site complement the cases, but also introduce stand-alone genetic competencies-e.g., genetics primer, family history exercises, genetic testing modules, and teaching tools.

A pretest/post-test will collect data from clinical PAs who register for CME hours, and from PA students who pilot the program. The presentation will focus on the development and pre-testing of the project's genetic curriculum, with the expectation that the curriculum may be useful for genetics educators working in diverse settings. The website will be available to all PAs in fall 2007.

.

High density SNP screening of the major histocompatibility complex (MHC) in systemic lupus erythematosus (SLE) families demonstrates strong evidence for independent susceptibility regions. *L.F. Barcellos[1], S.L. Clark[1], P.P. Ramsay[1], H. Quach[1], M.F. Seldin[2], J.B. Harley[3], K. Moser[3], T.W. Behrens[4, 5], P. Gaffney[3], L.A. Criswell[6]* 1) Univ of CA, Berkeley, CA; 2) Univ of CA, Davis, CA; 3) Oklahoma Medical Research Foundation, Oklahoma City, OK; 4) Univ of Minnesota, Minneapolis, MN; 5) Genentech, South San Francisco, CA; 6) Univ of CA, San Francisco, CA.

A substantial genetic contribution to SLE risk is conferred by MHC gene(s) on chr. 6p21; the most consistent associations are with class I and II genes, including HLA-A*01, -B*08, -DRB1*0301, -DRB1*1501, and -DRB1*08. Genes within class III and extended MHC regions have also been implicated. Previous studies of MHC variation in SLE have lacked statistical power and genetic resolution to fully characterize MHC influences. We recently completed state-of-the-art MHC SNP genotyping in 446 Caucasian SLE trio families (N=1,338) and 546 additional SLE cases. A total of 2,360 MHC SNPs spanning 4.9 Mb (~1 SNP/2 kb) were investigated, including variants from 159 MHC region genes (~10.7 SNPs/gene). Analyses of LD and haplotype diversity using HAPLOVIEW (v.3.31) revealed a complex architecture; 203 distinct haplotype blocks were identified. Preliminary results from TDT analyses of single SNPs were evaluated. Strong signals emerged from three MHC regions; in particular, significant associations ($p<10-5$) were observed for TCF19 (rs7750641) near HLA-C in class I and loci in class III regions: MICB (rs2516408), complement component 2 (rs497309), and factor B (rs537160). In addition, class II loci (BTLN2, DRA, and DQA1 on the extended DRB1*1501 haplotype) demonstrated strong evidence for association ($p<10-5$). Our results suggest that centromeric and telomeric boundaries of the DRB1*1501 haplotype are marked by BTLN2 and DQA1 loci (320 kb region), and that class I and III associations are independent of DRB1. Full characterization of candidate loci in class I and III regions is underway. Our large family-based study of MHC and HLA variation in 800 families (Total N=2,400) will identify all MHC gene(s) contributing to SLE risk and related phenotypes, such as lupus nephritis.

Application of Bayesian Classification in an Association Study of Impaired Glucose Tolerance versus Impaired Fasting Glucose. *S. Kwon[1], M.O. Goodarzi[1], K.D. Taylor[1], J. Cui[1], B. Hildalgo[1], J.I. Rotter[1], W. Hsueh[2], X. Guo[1]* 1) Cedars-Sinai Medical Center, Los Angeles, CA; 2) UCLA, Los Angeles,CA.

Conventional statistical approaches face challenges when dealing with a large number of single nucleotide polymorphisms (SNPs) (p) with a relatively small sample size (n). We extended the Bayesian classification with binary responses to multinomial ordinal responses using singular value decomposition (SVD). We developed a Markov Chain Monte Carlo based computation algorithm to realize the Bayesian classification with SVD method (BCSVD). Using simulated data with 3 ordinal responses, we demonstrated that the BCSVD method can be reliably used to analyze large scale association data when p>>n. We applied the method to evaluate candidate genes for impaired glucose tolerance (IGT) and impaired fasting glucose (IFG) in a subsample of subjects recruited through a coronary artery disease proband in the Mexican-American Coronary Artery Disease Project. 449 adult offspring and offspring spouses went through detailed phenotyping, including fasting and 2-hr glucose levels; all were genotyped for 91 SNPs from 16 genes selected for a prior relationship to insulin physiology: resistance (R: LPL, CAPN10, PRKAG3, CRP, C5, IL4, IL4R, IL6, NOS3, NPPA, SCNN1A, ADRB2), secretion (S: CAPN10, TCF7L2, SORCS1), and clearance (C: AMPD2, PRKAA2). An individual was defined as IFG if his/her fasting glucose level was between 100 and 125; and defined as IGT if a 2-hr glucose level was between 140 and 199. We generated two sets of data, each having 3 disease stages with 20 samples in each stage (n=60). The first data (V1) has 3 stages: both glucoses normal (N/N), fasting glucose normal and IGT (N/IGT), IGT and IFG (IFT/IGT); the second (V2) was classified as: N/N, IFG/N, and IFG/IGT. Assuming a dominant genetic model, we found that SNPs in 5 R genes (LPL, PRKAG3, C5, IL4R, IL6) and 1 S gene (SORCS1) were associated with both V1 and V2; SNPs in CAPN10 (S) gene, were associated with V1 only; while SNPs in PRKAA2 (C), 2 R genes (NOS3, SCNN1A), and TCF7L2 (S) were associated with V2 only. These results suggest that IGT and IFG may indicate different pathways to diabetes, with different genetic determinants.

Development and validation of a focused oligonucleotide-based BAC emulation microarray for clinical array-CGH analysis. *S.H.L. Kang[1], Z. Ou[1], C. Carmack[2], L. White[1], J.R. Lupski[1], A. Patel[1], A.L. Beaudet[1], S.W. Cheung[1], A.C. Chinault[1]* 1) Baylor College of Medicine, Dept. of Molecular and Human Genetics, Houston, TX; 2) Agilent Technologies, Santa Clara, CA.

Array comparative genomic hybridization (array-CGH) allows genome-wide screening for copy number changes that is limited only by the probes that are present on the array. Recently the trend has been toward the use of commercially manufactured high-density oligonucleotide microarrays to detect these changes. However, major hurdles in transitioning this technology to the clinic include the need to establish a reliable and cost-effective method to 1) confirm copy number changes, and 2) determine whether the observed change is a normal variant or pathological. To overcome this, we have developed and validated an oligo-based BAC emulation array using the Agilent platform for use in clinical practice. This array contains ~44,000 oligos grouped into the same BAC sequences that have been previously used on our array-CGH assay. The microarray was developed by initially selecting 105,000 oligos covering the regions of interest and using empirical hybridization data and oligo distribution analysis to select an optimized 44K oligo array. Therefore, this 44K oligo array remains primarily focused on known disease regions and telomeres combined with backbone coverage of the entire genome and emulates the BAC arrays with which we have generated a valuable database with results from over 8000 patients. Additionally, by maintaining a correlation with BAC sized sequences, FISH analysis with verified clones can still be utilized to confirm the array-CGH results. From parallel analyses on BAC and OLIGO arrays we found that the OLIGO version is more reliable and more sensitive/robust (up to 2-fold) than the BAC version because of improved dynamic range. The increased reliability of the OLIGO data negates the need for parallel dye-swap experiments. The increased sensitivity of the OLIGO data as well as advances in the software used to calculate and display copy number changes permits more accurate determination of smaller genomic imbalances that are not statistically significant on the BAC versions.

DNA methylation profiling in Hodgkin lymphomas using BeadArray technology. *M. Bibikova[1], J.I. Martin-Subero[2], E. Wickham-Garcia[1], J. Richter[2], J.-B. Fan[1], D. Barker[1], R. Siebert[2]* 1) Illumina, Inc., San Diego, California 92121, USA; 2) Institute of Human Genetics, Christian-Albrechts University, Kiel, Germany.

DNA methylation is an epigenetic modification which does not affect the genetic code, but affects gene transcriptional regulation and can be heritable. Epigenetic profiles have been used as markers for disease identification or progression. Tumor suppressor gene inactivation by DNA hypermethylation is a well known phenomenon in most solid and hematological malignancies. In the case of Hodgkin lymphoma (HL), however, the DNA methylation changes have not been well studied. We have performed DNA methylation profiling of HL cell lines using the GoldenGate Assay for methylation (Illumina, Inc.), which allowed the measurement at 1505 individual CpG sites from regulatory regions of 807 genes involved in cell cycle control, differentiation, apoptosis, DNA repair and imprinting. Four classical HLs (cHL) and one nodular lymphocyte predominant HL (NLPHL) as well as eight DNA samples from normal hematological tissues were studied in duplicate. A methylation level ranging from 0 (unmethylated) to 1 (methylated) was calculated, and differences between entities above 0.5 were considered differentially methylated. In comparison with the controls, cHL showed 241 hypermethylated and 40 hypomethylated gene promoters whereas 154 and 80 promoters were hyper- and hypomethylated in NLPHL, respectively. CHL displayed a high number (n=87) of hypermethylated promoters in comparison to NLPHL. Hypermethylated gene promoters in HL included known tumor suppressor genes (e.g. p16, p73, DAPK). Interestingly, CpG-islands from genes involved in B-cell specific pathways (e.g. BCAM, BLK, MME and SYK) were exclusively hypermethylated in cHL. Such epigenetic silencing of B-cell specific genes may be the cause of loss of the B-cell identity characteristic for cHL, and thus, might play a key role in its pathogenesis. The methylation data generated by the array were validated by methylation specific PCRs and bisulfite sequencing. In conclusion, genome-wide methylation profiling revealed a global alteration of the methylome in cHL, being mostly characterized by promoter hypermethylation of a large number of genes.

SnoRNA Pwcr1/MBII-85 deletion mouse model for Prader-Willi syndrome shows growth retardation, hyperphagia and altered metabolism. *F. Ding[1], HH. Li[1], S. Zhang[2], N. Solomon[3], S. Camper[3], E. Mignot[2], U. Francke[1]* 1) Department of Genetics, Stanford University, Stanford, CA; 2) Department of Psychiatry & Behavioral Science, Stanford University; 3) Department of Human Genetics, University of Michigan, Ann Arbor, MI.

Prader-Willi syndrome (PWS) is characterized by neonatal hypotonia, distinct facial features, short stature due to abnormal growth hormone secretion, hypogonadism, obesity due to hyperphagia, developmental delay, insensitivity to pain and other neuropsychological features. It is caused by the lack of paternal expression of imprinted genes on 15q11.2. Our previous work in human and mice suggested that the lack of expression of a small C/D box nucleolar RNA (snoRNA), PWCR1/HBII-85, contributes to the PWS phenotype (Schüle et al BMC Med. Genet. 6:18, 2005; Ding et al. Mamm. Genome 16:424, 2005). To test this hypothesis, we created a new mouse model with a ~150kb deletion of the *Pwcr1/MBII-85* snoRNA cluster. In contrast to the neonatal lethality observed in previous mouse models, our mutant mice survive to adulthood with normal fertility. Apparently normal at birth, they have severe growth retardation before weaning, with moderate growth retardation afterwards. Liver Igf1 mRNA is decreased in 4 and 8 week old mutants. Histological and immunohistochemical studies of pituitary organogenesis and structure revealed no gross abnormalities. Adult male mutants and wild-type littermates were subjected to metabolic and cognitive/behavior tests. Similar to PWS individuals, the mutant mice show hyperphagia and increased anxiety. Unlike human with PWS, they have normal response to thermal pain and are not hypotonic. The mutants outperformed controls initially in rotarod tests, but failed to improve upon training, indicative of a motor learning deficiency. Despite their hyperphagia, the mutants are leaner on regular and high-fat diet. They have less body fat content and are more sensitive to insulin. The cause of this surprising result is revealed by their altered fuel usage. This is the first snoRNA deletion animal model, and the phenotypes indicate an essential role of Pwcr1/MBII-85 snoRNA in neurodevelopment, growth and metabolism.

Genetic association of the epithelial sodium channel -subunit with 25-year follow-up blood pressures in Utah pedigrees - a replication study. *C.J. Büsst[1], K.J. Scurrah[1,2], J.A. Ellis[1,3], Y. Xin[4], E.A. Brinton[4], P.N. Hopkins[4], S.C. Hunt[4], S.B. Harrap[1]* 1) Department of Physiology, University of Melbourne, Melbourne, Australia; 2) Molecular, Environmental, Genetic and Analytic Epidemiology, University of Melbourne, Melbourne, Australia; 3) Murdoch Childrens Research Institute, Royal Children's Hospital, Melbourne, Australia; 4) Cardiovascular Genetics, University of Utah, Salt Lake City, UT.

The -subunit of the epithelial sodium channel (-ENaC), encoded by *SCNN1G*, has been implicated in the Mendelian diseases Liddle's syndrome and pseudohypoaldosteronism type 1, and is the rate limiting step of sodium reabsorption in the kidney. *SCNN1G* is located on a region of chromosome 16 that has been linked to systolic blood pressure (SBP) by a number of independent studies, including the Victorian Family Heart Study (VFHS). At last years meeting we reported the findings from our association analysis of SBP in VFHS subjects from the upper and lower deciles of the SBP distribution, in which we detected association of 4 *SCNN1G* SNPs (rs13331086, rs11074553, rs4299163 and rs5740) and a number of haplotypes with SBP. To replicate these findings, we genotyped six of the SNPs previously typed in the VFHS in 1971 relatives from 68 large Utah pedigrees selected for high risk of cardiovascular disease. Of these, 675 have returned to date for a 25-year follow-up exam. FBAT was used to test for association of individual SNPs and haplotypes while controlling for related observations in families. After adjusting for age, sex and body mass index, we detected significant associations for rs13331086 with DBP at 25-year follow up (p=0.002) and for change in DBP from baseline to 25-year follow up (p=0.003). Haplotypes of rs4299163 and rs5740 also revealed association with change in DBP from baseline to 25-year follow up (p=0.013). Preliminary results for analysis of DBP in the VFHS are consistent with DBP findings in the Utah pedigrees. In conclusion, the *SCNN1G* gene is significantly associated with BP in the Utah pedigrees at 25-year follow up. These results appear to replicate our finding that -ENaC variants contribute to BP variation in the general Caucasian population.

Mitochondrial variation does not affect age at onset of neurologic symptoms of Huntingtons disease. *S. Kishikawa[1], R. Saxena[1, 2], P.I.W. de Bakker[1, 2], R.H. Myers[3], M.E. MacDonald[1], D.M. Altshuler[1, 2], J.F. Gusella[1]* 1) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA; 2) Broad Institute of Harvard and MIT, Cambridge, MA; Department of Genetics, Harvard Medical School, Boston, MA; 3) Department of Neurology, Boston University School of Medicine, Boston, MA.

Huntingtons disease (HD) is inherited as an autosomal dominant neurodegenerative disorder caused by an expanded polyglutamine tract in the huntingtin protein. The expanded polyglutamine tract accounts for up to 70 % of variance in age at onset, but remaining variation is strongly heritable, which indicates that genetic modifiers affect the pathogenic process. Defective energy metabolism and deficiency of respiratory chain complex activity in mitochondria, especially complex II/III and complex IV have been suggested in HD. We tested six hundred and thirty one (279 unrelated singletons and 352 siblings) HD affected individuals with younger or older than expected onset ages (0.5 S.D. from expected repeat adjusted onset age) using tag SNPs in the human mitochondrial genome to test for an effect of mitochondrial genome variation on age at onset of HD. The 64 genotyped SNPs can predict all 114 SNPs that are over 1% frequency in Europeans based on a reference panel of over 900 publicly available European mtDNA sequences. In this genetic test of association, mitochondrial genome common variation captured by tag SNPs failed to explain residual variance in age at onset of neurologic symptoms of HD. The effect of mutant huntingtin on energy metabolism is likely to be indirect rather than a direct inhibition of mitochondrial function.

Overexpression of Helicobactor pylori-associated urease mRNAs in human gastric cancer. *M.Y. Huang[1], C.H. Wu[2], C.S. Yeh[2], T.L. Cheng[3], J.Y. Wang[4], S.R. Lin[5]* 1) Department of Radiation Oncology, Kaohsiung Medical University, Faculty of Medicine,College of Medicine,Graduate Institute of Medicine,and Kaohsiung Medical University; 2) Graduate Institute of Medicine; 3) Faculty of Biomedical Science and Environmental Biology; 4) Departments of Surgery; 5) Graduate Institute of Medical Genetics,and Kaohsiung Medical University,Taiwan.

Background and Purpose: Urease is involved in H. pylori infection and survival in acid circumference. This study explored the overexpression of H. pylori-associated urease mRNAs in human gastric cancers by using a well-established membrane array analysis method in our lab. Method: Analysis of 30 gastric cancer tissue specimens and 30 paired adjacent normal tissues demonstrated that urease genes involved in H. pylori infection were up-regulated in gastric cancer tissues. UreA, G and I are predominant genotypes found in gastric cancer tissues. However, the mRNA levels of UreC and UreE were hardly to be found in both gastric cancer and normal tissues in our study. In addition, we treated NIH-3T3 cells with two kinds of H. pylori exudates (weak urease activity (HP-W) and strong urease activity (HP-S)) which contained 1.6, 3.1, 6.5, 13 and 25.9 pg/ml urease of HP-W exudates and 18, 36, 75, 150 and 300pg/ml urease of HP-S exudates. NIH-3T3 cells were treated with these different concentration components for 24 hours. Result: Cell proliferation rate was elevated 2.7%, 9.9%, 18.9%, 36.6%, and 42.9% respectively after HP-W exudates were treated, and elevated 8.1%, 31.9%, 45.9%, 74.9%, and 81.3% respectively after treatment with HP-S exudates. In further investigation of the time course of NIH-3T3 cells treated with 50ug/mL H. pylori, the exudates revealed that the proliferation rate was elevated 14%, 23.7%, 38.7%, 31.6% and 29% respectively after HP-W treatment and elevated 29.8%, 50.4%, 78.5%, 62.3% and 55.9% after HP-S treatment for 6, 12, 24, 48 and 72 hours respectively. Conclusions: Membrane array promises a new diagnostic tool to detect H. pylori more sensitively than the CLO test. These results suggest that urease may play an important role in the development of gastric mucosal hyperproliferation in H. pylori-induced gastritis.

Attitudes, beliefs and anticipated reactions towards breast and prostate cancer risk genetic testing. *A. Carnevale[1], S. Romero-Hidalgo[1], N. Urraca[1], D. Parra[2], A. Villa[3], R. Lisker[3]* 1) Coord. Medicina Genomica, ISSSTE, Mexico; 2) Hospital Regional "IZ", ISSSTE, Mexico; 3) Instituto Nacional de Ciencias Médicas y Nutrición SZ, Mexico.

The genomic-based technology is rapidly permeating biomedical research; however, translating the genomic information to improve human health requires research into the social consequences. OBJETIVE: The aim of this study was to investigate the attitudes, beliefs and anticipated reactions towards cancer risk genetic testing in a group of non-high risk women and men and to analyze the factors that may influence the intention to test. METHODS: In-person interviews of 859 (397 men and 462 women) outpatients attending to the four tertiary care hospitals of the ISSSTE in Mexico City were conducted. Two different questionnaires, one for women and one for men, explored different aspects about genetic testing of a high risk gene for breast or prostate cancer, respectively. Descriptive statistics, contingency tables and logistic regression were used in the data analysis. RESULTS: About 68% of respondents believe that the test could save their lives and that the results might provide valuable information to their family members. Women were significantly more motivated to get genetic testing, more aware about the benefits of the test, and also more concerned about getting cancer, than men. Adjusted for hospital, the factors: beliefs of benefits, concern about getting cancer, and consequences derived from a positive result were statistically significant with intention to test. People anticipated feeling more guilt, more regret and less relief if they choose not to be tested. More women than men anticipated feeling guilt, sadness and regretful if tested positive. On the other hand, 95% of participants agreed to follow doctors advice in case of a positive result. CONCLUSIONS: The results suggest that the success of genetic testing will depend jointly on peoples knowledge about the benefits of the test and on peoples distress about possible consequences derived from a positive results. It is also important that medical doctors be prepared to provide objective advice to those at high risk of getting cancer.

Association between GSTP1, MDR1, and MTHFR polymorphisms and the outcome of patients with breast cancer treated with FEC (Fluorouracil, Epirubicin, and Cyclophosphamide) adjuvant chemotherapy. *F.Y. Chung[1], M.Y. Huang[2], S.R. Lin[3], J. Y. Wang[4]* 1) Graduate Institute of Medicine, College of Medicine; 2) Department of Radiation Oncology,; 3) Graduate Institute of Medical Genetics and BioMedi Innovation Incubation Center; 4) Department of Surgery, Faculty of Medicine, College of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan.

Purpose: Chemotherapy is an integral part of multi-modality treatment of locally advanced breast cancer. Glutathione S-transferase P1 (GSTP1), multidrug resistance 1 (MDR1), 5, 10-methylenetetrahydrofolate reductase (MTHFR) and thymidylate synthetase (TS) play important roles in chemotherapeutic drug transport, metabolism and target. In the present study, multiple genetic polymorphisms, including GSTP1 A313G, MDR1 C3435T, MTHFR C677T, and TS tandem repeats, were analyzed in breast cancer patients and used combining of gene polymorphism to predict the clinical outcome of breast cancer patients receiving FEC adjuvant chemotherapy. Methods: Genomic DNA was isolated from the blood samples of 192 postoperative breast cancer patients. The genotypes were determined by PCR-RFLP. Patients prognoses of postoperative relapse and analyzed with GSTP1, MDR1, MTHFR and TS phenotype groups. Results: GSTP1 A313G, MDR1 C3435T, MTHFR C677T, and TS tandem repeats showed no significant association with clinicopathological factors and postoperative relapse (all $P > 0.05$). There were no differences in prognosis between each genotype when considered separately. However, we found the association between postoperative recurrence and patients with both MDR1 3435CC and MTHFR 677CC (OR: 2.97, P=0.026), and patients with additional GSTP1 313AA (OR: 3.48, P=0.024) in consideration. Conclusion: The GSTP1, MDR1, and MTHFR genotypes can be prognostic factors in breast cancer patients receiving FEC adjuvant chemotherapy, where gene-gene interactions between the genotypes may occur. Long-term follow-up breast cancer patients in a larger population may be prerequisite for further validate of the actual roles of these gene polymorphisms.

Association of the UBE3A Substrate ECT2 with Autism. *R.J. Delahanty[1], J.A. Smart[2], J.S. Sutcliffe[1,2], L.T. Reiter[3]*
1) Ctr Human Genetics Research, Vanderbilt Univ, Nashville, TN; 2) Molecular Physiology and Biophysics, Vanderbilt Univ, Nashville, TN; 3) Department of Neurology, University of Tennessee Health Science Center, Memphis, TN.

Evidence indicates a predominantly genetic etiology for autism, but locus heterogeneity has confounded the identification of genes contributing to the idiopathic condition. Maternal duplications of 15q11-q13 are the most frequent chromosomal abnormality found in autism. Data indicate that dup(15) autism results in over-expression of contiguous loci including the maternally expressed E6-AP ubiquitin ligase (UBE3A) gene. Maternal deficiency of UBE3A causes the severe neurodevelopmental disorder Angelman syndrome (AS), which can share features with autism. Altered expression of UBE3A is hypothesized to result in dysregulation of UBE3A substrates, which are ultimately responsible for the phenotypic consequences of UBE3A over- or under-expression. However, few attempts have been made to identify the protein substrates regulated by UBE3A. We have used a proteomics approach in Drosophila to identify proteins affected by elevated UBE3A levels, with the aim of identifying genes that could be candidates for harboring susceptibility alleles for idiopathic autism. We previously demonstrated that a RhoGEF involved in cell migration and morphology was significantly down-regulated by UBE3A expression. The mammalian ortholog of pebble (ECT2; 3q26.1) was identified and examined for the presence of autism-associated alleles. Using tag SNPs to detect common alleles (>5%) at both loci, association analyses were performed on a sample of ~700 autism families. Association tests were conducted for six SNPs in ECT2 using FBAT and calculating exact P-values based on Monte Carlo simulations. Two SNPs in intron 22 and the 3UTR of ECT2, showed significant association ($P<0.02$) to autism. The quantitative trait disequilibrium test (QTDT) by ascertainment site indicates that susceptibility alleles at this locus increase risk for social deficits and remain significant after Bonferroni correction. These studies support the hypothesis that the genes encoding proteins regulated by UBE3A may also contribute to idiopathic autism.

Opitz-Kaveggia (FG) syndrome revisited: The clinical phenotype in 10 affected males with MED12 mutation R961W. *R.D. Clark[1], J.M. Graham[2], R.E. Stevenson[3], R.C. Rogers[3], K.L. Jones[4], J.B. Moeschler[5], M.J. Friez[3], C.E. Schwartz[3]* 1) Division of Genetics, Department of Pediatrics, Loma Linda University Childrens Hospital, Loma Linda, CA; 2) Medical Genetics Institute, Cedars-Sinai Medical Center, Los Angeles, CA; 3) Greenwood Genetic Center, Greenwood, SC; 4) Department of Pediatrics, Division of Dysmorphology, UCSD School of Medicine, San Diego CA; 5) Clinical Genetics, Dartmouth-Hitchcock Medical Center, Lebanon, NH.

Given the recent report by Risheg et al. that a recurrent R961W mutation in MED12 causes Opitz-Kaveggia (FG) syndrome, we examined 10 affected males in 7 families to delineate the phenotype of this X-linked mental retardation syndrome. Eight of the 10 cases were previously reported including one 40-year old man from the original FG family and 2 brothers published by Keller et al. (1976). All mothers were heterozygotes for the R961W mutation. Heterozygote females had normal intelligence. The cases show a striking resemblance most evident in childhood. Typical features are small, simple, prominent, cupped or low set ears, narrow external auditory canals, frontal upsweep of hair, dolicocephaly, tall forehead, flat broad thumbs, distally adherent nails and hypotonia. Short stature and relative macrocephaly are common but normal height and HC are also seen. Several cases had anal anomalies, cardiac lesions, typically ASD or VSD, and hypo/aplasia of the corpus callosum. Minor anomalies include inguinal hernias, cryptorchidism, ptosis and single palmar crease. Feeding problems, tracheomalacia and constipation improved with time. Most multiplex families had miscarriages or death of affected males. Mental retardation is moderate to severe but one child has an IQ of 84. An affable personality is characteristic. We will present the evolution of the phenotype over time.

The Opitz-Kaveggia (FG) syndrome has a recognizable phenotype with characteristic facies and a social-oriented affect. Although the diagnosis can be made clinically, the extent of the phenotype is still emerging and molecular testing is recommended on suspect cases.

Genetic risk factors for asbestos-related malignant mesothelioma in a general population study. *I. Dianzani[1], M. Betti[1], M. Giordano[2], M. Bertolotti[3], D. Ferrante[3], S. Guarrera[4], D. Mirabelli[3], G. Matullo[4], C. Magnani[3]* 1) Lab.Patologia Genetica, Dept Med Sci, Univ.Piemonte Orientale, Novara; 2) Lab.Genetica, Dept Med Sci, Univ.Piemonte Orientale, Novara; 3) CPO-Piemonte and Unità di Statistica Medica ed Epidemiologia, Dept Med Sci, Univ.Piemonte Orientale, Novara; 4) Dept.Genetica, Biologia, Biochimica, Univ.Torino.

Malignant mesothelioma (MM) of the pleura is a rare, aggressive tumour associated with asbestos exposure. Only ten per cent of subjects exposed to asbestos develop MM. This behaviour and familial aggregation favour a role of genetic risk factors. Asbestos fibers can be carcinogenic as the result of mechanical effects (such as interference with segregation of chromosomes) and generation of reactive oxygen species, that lead to DNA breaks and base modification. We have performed a case-control epidemiological study to analyse SNPs in genes possibly involved in the protection against asbestos carcinogenicity (i.e. genes involved in DNA repair, in the control of red/ox status or in inflammation) in persons exposed to asbestos, who had or had not developed MM. Patients and controls had the same ethnic origin and were residents at Casale Monferrato, a town highly exposed to asbestos pollution. In a previous study we observed an association between XRCC1-399Q and MM (Dianzani et al. Mutat Res 2006). We report here: 1. analysis of the association between XRCC1-399Q and MM in a different panel of patients and controls; 2. analysis of SNPs in 10 other genes (NBS1, PCNA, APEX, ERCC1, MGMT, OPN, GPX1, SOD2, SEP15, NAT2). Unconditional multivariable logistic regression was used to estimate odds ratios (ORs) and 95 / confidence intervals (CIs). We confirmed the association with XRCC1-399Q (133 cases, 182 controls; increment of mutant alleles: OR=1.46; 95/CI= 1.01-2.11). We found an association with the NAT2 fast acetylator phenotype and thus confirmed the data reported by another Italian group (Neri et al. Mutat Res 2005); pooling the two studies: OR=1.50, 95/CI=1.04-2.15 (171 cases, 381 controls). Other SNPs showed increased, but not significant, ORs. Our data support the hypothesis of a multigenic predisposition to MM.

The molecular mechanism of radiation effect on human colorectal cancer cell lines by using oligonucleotide membrane arrays. *C.W. Kuo[1], M.Y. Huang[2], S.R. Lin[1,3], J. Y. Wang[4]* 1) Graduate Institute of Medical , Kaohsiung Medical University, Kaohsiung , Taiwan; 2) Departments of Radiation Oncology ,Kaohsiung Medical University Hospital, Kaohsiung, Taiwan; 3) BioMedi Innovation Incubation Center, Kaohsiung Medical University, Kaohsiung, Taiwan; 4) Department of Surgery, Kaohsiung Medical University Hospital, Faculty of Medicine, College of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan.

Background and purpose: Hypoxia, glycolysis and DNA damage response were recently suggested highly correlated with resistance to radiotherapy, but the molecular mechanism is still unclear. The purpose of this study is to identify radiation related molecules which can evaluate the effect of radiation for colorectal cancer cell lines Method: Colorectal cancer cell lines were purchased from ATCC, and irradiation with high energy photo beam. Total dose is 16 Gy. Radiation sensitivity was determined by the survival cells using the ATPlite assay. RNA was extracted from nonirradiated and radiated cells, respectively. Gene expression analysis was performed by membrane array containing 60 target oligonucleotides. Result: Analysis of radiation survival curve showed that cell lines SW620, HCT116 and Colo205 were sensitive to radiation; however, SW480, SW403 and T84 were resistant to radiation. The result of membrane array shows that 8 genes significantly overexpress in resistant colorectal cancer cell lines, such as HIF-1, VEGF, and LDH. Conclusions: In the present study, we successfully identify several molecular markers for using to construct a radiation chip that can predict effects of radiotherapy. Comprehensive gene expression of radiation sensitive and resistant cell line might provide a new insight into the mechanisms of resistance or sensitivity to radiotherapy.

The GLI1 gene as a risk factor for ulcerative colitis.*GLI1*. *R.W. Bentley[1], R.L. Roberts[1], R.B. Gearry[2,3], T.R. Merriman[4], M.A. Kennedy[1], M.L. Barclay[2,3]* 1) Department of Pathology; 2) Department of Medicine; 3) Department of Gastroenterology, Christchurch School of Medicine, Christchurch, New Zealand; 4) Department of Biochemistry, University of Otago, Dunedin, New Zealand.

Introduction. Crohn's disease (CD)and ulcerative colitis (UC)are the major forms of inflammatory bowel disease (IBD) and recent work has shown a high prevalence of IBD in New Zealand. For CD, mutations in the *IL23R*, *ATG16L1* and *NOD2* genes have been reported to predict the age of onset, severity and location of disease but no strong genetic marker for UC has yet been found. Preliminary analysis of four SNPs(rs2228224, rs2228225, rs2228226 and rs3817474) of the *GLI1* gene in a Scottish cohort indicated that two of the haplotypes generated had a highly significant association with UC susceptibility. *GLI1* encodes a transcription factor that plays an important role in the formation and maintenance of a healthy gut and defective *GLI1* function in people with IBD suggests that it may be a risk factor for UC.

Aim. To determine whether polymorphic variation in the *GLI1* gene at the four sites described is implicated in susceptibility to IBD in Canterbury, New Zealand.

Methods. SNPs were assayed using allele-specific PCR in controls (n=479), CD (n=525) and UC (n=479). Direct sequencing was used to validate the assay. Haplotypes were estimated and tested for association.

Results. Three haplotypes described the majority (>99%) of the variation in the *GLI1* gene at the SNPs investigated. Comparative analysis of genotype data demonstrated a significant association of the *GLI1* gene with UC ($p<0.05$)but not CD. In addition, a significant association was observed between the major haplotype and susceptibility to UC ($p<0.05$, OR(95% CI)1.227, 1.019-1.479).

Conclusion. Polymorphic variation at the SNP sites investigated suggests a role for the *GLI1* gene in ulcerative colitis, but not Crohns's disease, in a population of IBD patients from Canterbury, New Zealand.

Comparative analysis of chromosome 21 subtelomeric regions between human and chimpanzee. *Y. Kuroki[1], A. Toyoda[2], S. Tatsumoto[2], T. D. Taylor[3], A. Fujiyama[2, 4], Y. Sakaki[1, 2, 3]* 1) Comparative Systems Biology Team, RIKEN Genomic Sci Ctr, Yokohama, Japan; 2) Sequence Technology Team, RIKEN Genomic Sci Ctr, Yokohama, Japan; 3) Genome Annotation and Comparative Analysis Team, RIKEN Genomic Sci Ctr, Yokohama, Japan; 4) National Institute of Informatics, Chiyoda-ku, Tokyo, Japan.

Subtelomeric regions are known as one of the most complicated regions in the human genome because of the interchromosomal segmental duplications and the existence of various repetitive sequences. Recent reports have shown complex patchwork of sequence blocks, human-genome specific segmental duplications, and higher frequency of gene transfer among the subtelomeres. Interestingly, some of these sequence blocks in the human subtelomeres are also found in the subtelomeres of other apes, chimpanzee or orangutan, for example. It means that the most part of the subtelomeric regions were duplicated in species-specific manner, although some sequence blocks were originated from common ancestral genome regions. To identify the origin and the evolutionary processes of the genome duplication in the subtelomeres, we isolated clones covering completely the chimpanzee chromosome 21 subtelomeric region. Comparative analysis of the high quality sequences derived from the subtelomeric regions of human and chimpanzee chromosome 21 revealed that the chimpanzee genome has longer subtelomeric region than the corresponding human subtelomere. The expanded fragment in the chimpanzee subtelomere was also located in other regions mainly in subtelomeres.

Development of a SNP Chip for prediction of steroid-induced osteonecrosis. *W.T. Huang[1], S.R. Lin[2,3], G.J. Wang[4], F.Y. Chung[1]* 1) Graduate Institute of Medicine Kaohsiung, Taiwan; 2) Graduate Institute of Medical Genetics, College of Medicine; 3) BioMedi Innovation Incubation Center, Kaohsiung Medical University; 4) Department of Orthopedics Surgery, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan.

Background: Osteonecrosis (ON) is also called the Avascular Necrosis (AVN) which is an impairment happening in the blood stream in bones and may finally cause bone cell death. There are many risk factors for ON such as the trauma, steroids therapy, alcoholism, blood disease and smoke. The exact pathogenesis mechanism of ON is still unclear so far. The specific aim of this study was to establish a SNP chip to distinguish the risk genotypes of ON for detecting the possible risk factors causing this disease. Methods: The subjects of this study included 106 patients with SLE who had been treated with steroid for at least two years or more. Twenty out of 106 patients were ON patients, and eighty six were non-ON patients. Genomic DNA was isolated from the blood samples of SLE patients. The genotypes were determined by PCR-RFLP and confirmed these results by DNA sequencing. We use membrane array which developed in our lab before to construct the SNP chip. Result: The genotyping of BMP2, VEGF and MTHFR were done and the results were shown as follows BMP2 genotypes of ON vs. non-ON: CC(2.8% vs. 15%), TC(11% vs. 44%), TT(5.5% vs. 22%); VEGF genotypes of ON vs. non-ON: AA(9.6% vs. 22%), AG(9.6% vs. 39%), GG(1% vs. 18%); MTHFR genotypes of ON vs. non-ON: CC(11% vs. 44%), TC(6.7% vs. 33%), TT(1.9% vs. 2.9%). We have also designed the oligonucleotide probe of these candidate genes for constructing the SNP chip. The results of SNP chip are highly consistent with RFLP and DNA sequencing. Conclusion: We have now accomplished the genotyping of three candidate genes. Due to small number of cases, we can not calculate correlation between these risk genotypes and ON. Therefore we may increase case number and investigate more related genes in the future. We believe that the development of the SNP chip in this study can be used in the prediction of ON and with the combination of medical therapy; it may reach to the goal of preventing ON.

Revisiting genetic influences on neural tube defects: extended evaluation of a large dataset with evidence supporting maternal effects. *K.L. Deak[1], T.M. George[2], D.S. Enterline[1], G. Worley[1], D.G. Siegel[1], J.R. Gilbert[1], M.C. Speer[1], and the NTD Collaborative Group* 1) Center for Human Genetics, Duke University, Durham, NC; 2) Children's Hospital, Austin, TX.

Neural tube defects (NTDs) are the second most common birth defect with an incidence of about 1/1000. We analyzed the family structure, genetic inheritance patterns, and evidence for maternal effects in our collection of 1066 NTD families (1467 affected patients). Of these families, 307 are multiplex and have two or more individuals with a neural tube defect. The majority of the patients had myelomeningocele or spina bifida (66.9%) and the next largest group had cranial defects (17.7%). The overall male to female ratio for all affected individuals was 0.82 and when the sex ratios are analyzed according to the NTD level, those individuals with an upper NTD had a greater female excess, with a M:F sex ratio of 0.66. Of the twins in these families, two of the five sets of monozygotic twins and 27% of the like sex twins are concordant for the disease, while only three of 35 (8.57%) dizygotic twin pairs are concordant. Notably, none of the unlike sex twins were concordant for disease and all affected twin pairs were of the same sex and had the same NTD type. We estimated a 6.3% recurrence risk to siblings (CI 0.04 - 0.08), consistent with other reports. In families with two or more related affected individuals, the sex ratios of affected and normal gene transmitting or connecting family members show a higher proportion of female transmitters ($P = 0.0002$), suggesting that affected individuals are more likely to inherit NTD-associated genes from their mother. There were also more than twice the number of affected relatives on the maternal side of the family ($P = 0.006$). We did not observe a difference in the average sibship size of maternal and paternal relatives, however there were significantly more miscarriages, infant deaths, and stillborn pregnancy outcomes in the mothers of aunts and uncles ($P < 0.0001$) and of first cousins ($P = 0.04$) of the probands. Together, these suggest a role for a maternal or imprinting effect in the etiology of NTDs.

Angelman syndrome mouse model with a large chromosomal deletion from Ube3a to Gabrb3. *Y-H. Jiang[1], Y. Pan[1], L. Landa[1], C. Spencer[1], M. Brilliant[2], A.L. Beaudet[1]* 1) Department of Molecular and Human Genetics, Houston, TX; 2) Department of Pediatrics, University of Arizona Health Science Center. Tucson, AZ 85724.

Angelman syndrome (AS) is a neurobehavioral disorder associated with severe mental retardation, absence of language development, epilepsy, happy disposition, and movement disorders. The molecular defects underlying AS are heterogeneous, including large chromosomal deletions of 15q11-q13 of exclusively maternal origin (70%), paternal uniparental disomy (UPD) of chromosome 15, imprinting mutations, and mutations in the E6-AP ubiquitin ligase gene (*UBE3A*). Previously, we have characterized an AS mouse model by inactivation of the *Ube3a* gene in mice. Using chromosomal engineering strategy by the cre-loxP and Hprt technique, we have generated mutant mice with a deletion from *Ube3a* to *Gabrb3* which inactivates both of these genes as well as *Atp10a* as is the case for the majority of human AS patients (70%) with a large chromosomal deletion. Homozygous mutant mice with this deletion died in the perinatal period largely due to the cleft palate resulting from null mutation of *Gabrb3* as previously reported. Mice with a maternal deletion are viable and have no apparent developmental defect. There is no significant difference for the expression *Atp10a* gene is sub-regions of brain between the maternal and paternal deletion which suggest that the *Atp10a* gene is biallelicly expressed in these regions. The behavioral analysis revealed significant impairments in motor function, spatial and fear conditioning memory, open-field, and light dark testing in maternal deletion mice. The hippocampal long-term potentiation is impaired in maternal deletion mice. In addition, we have recorded ultrasonic calls emitted from pups with a maternal deletion. This analysis revealed a significant difference of ultrasonic calls between pups with a maternal deletion and wild type. Thus, mice with a deletion from *Ube3a* to *Gabrb3* provide another valuable mouse model for exploring the potential of treatment strategies or for making comparisons to that of *Ube3a* maternal deficiency mice to dissect the molecular pathogenesis of AS.

Weighted approaches for missing SNP data. *G. D'Angelo*[1], *E. Feingold*[1,2] 1) Dept Biostatistics, Pub Health, Univ Pittsburgh GSPH, Pittsburgh, PA; 2) Dept Human Genetics, Pub Health, Univ Pittsburgh GSPH, Pittsburgh, PA.

Genotype data can be missing in a genetic association study. When modeling the effects of multiple genetic variants simultaneously, typically, complete case analysis is the method of choice leading to significant reduction in sample size and in power. A number of other methods for handling missing data are applicable, but have rarely been used in this context. To address the problem where the SNPs are missing at random (MAR), we compare several standard methods for handling missing data that can be applied or adapted to this problem. The methods compared are the weighted pseudolikelihood, multiple imputation, and the EM algorithm. We apply these methods to an Alzheimer's disease association study. We show that weighting techniques, and specifically the EM algorithm, have the best properties of all the estimators we studied.

Linkage of posterior amorphous corneal dystrophy to chromosomes 8q21.3-8q24.13 and 12q21.33-12q24.21 and exclusion of coding region mutations in *KERA, LUM, DCN* and *EPYC*. *A. Aldave[1], G. Rosenwasser[2], V. Yellore[1], J. Papp[3], E. Sobel[3], M. Chen[1], S. Rayner[1], J. Sassani[4]* 1) Cornea Service, Jules Stein Eye Inst/UCLA, Los Angeles, CA; 2) The Central Pennsylvania Eye Institute, Hershey, Pennsylvania; 3) Department of Human Genetics, David Geffen School of Medicine at UCLA; 4) Department of Ophthalmology, Milton S. Hershey Medical Center, Hershey, PA.

Purpose: To identify the genetic basis of posterior amorphous corneal dystrophy (PACD) through the performance of a genome-wide linkage analysis and to describe the clinical and histopathologic features of a large pedigree with PACD.

Methods: Slit lamp examination of each study subject was performed to determine the affected status. Corneal pachymetry and topography were performed in affected individuals, and light and electron microscopic examination of corneal buttons excised at the time of penetrating keratoplasty were performed. DNA was obtained from affected and unaffected subjects, and a genome-wide linkage analysis was performed. The coding region of four positional and functional candidate genes, *KERA*, *LUM*, *DCN* and *EPYC*, were screened in affected and unaffected family members.

Results: Slit lamp examination and DNA collection was performed for 53 individuals, 15 of whom were diagnosed as affected based on the presence of characteristic clinical features of PACD. Histopathologic examination of excised corneal specimens demonstrated disorganized stromal lamellae, and stromal staining with colloidal iron, but no staining with alcian blue or periodic acid-Schiff. A genome-wide linkage analysis demonstrated significant evidence of linkage with both single point and multipoint analyses to chromosomes 8 and 12, with the largest single point HLOD score of 3.05 obtained at marker D8S1784 and 2.92 obtained at marker D12S351. The largest multipoint HLOD scores obtained were 3.12 at D81784 and 3.44 at D12S78. The support intervals for PACD in the family we report are approximately 26 cM on chromosome 8, between the flanking markers D8S270 and D8S514, and approximately 30 cM on chromosome 12, between the flanking markers D12S351 and D12S79. No coding region mutations were identified in *KERA*, *LUM*, *DCN* or *EPYC*, which are located adjacent to D12S351.

Conclusions: PACD is associated with characteristic corneal and extracorneal anterior segment abnormalities, indicating that PACD should be classified as an anterior segment dysgenesis, rather than a corneal dystrophy. Two genetic loci, a 26 cM interval on chromosome 8q and a 30 cM interval on chromosome 12q, have been identified, and coding region mutations have been excluded in several positional and functional candidate genes on chromosome 12q.

A comprehensive mutational analysis system using resequencing microarray delineates molecular epidemiology of hereditary spastic paraplegias in the Japanese population. *H. Ishiura, Y. Takahashi, J. Goto, S. Tsuji* Dept. of Neurology, Univ. of Tokyo, Tokyo, Japan.

[Objective] To establish a high-throughput comprehensive mutational analysis system for hereditary spastic paraplegia (HSP) and to describe molecular epidemiology of HSP in the Japanese population. [Background] HSP is a neurodegenerative disorder characterized by progressive lower limb spasticity. Up to present, SPGs 1-36 have been identified as the genetic loci and the number of causative genes has been increasing. Since HSP is genetically heterogeneous and little is known about genotype-phenotype correlations, comprehensive analysis system is necessary. [Methods] We established a high-throughput DNA microarray resequencing system based on GeneChip™ (Affymetrix), capable of analyzing complete nucleotide sequences of all the coding exons and splicing junctions of 9 causative genes (SPG1: *L1CAM*, SPG2: *PLP1*, SPG3A: *atlastin*, SPG4: *spastin*, SPG6: *NIPA1*, SPG7: *paraplegin*, SPG10: *KIF5A*, SPG20: *spartin*, and SPG31: *REEP1*). Given the high frequency of insertion/deletion mutations in *spastin*, conventional direct nucleotide sequence analysis was also employed. The study enrolled 80 Japanese HSP patients: 29 patients with autosomal dominant inheritance (ADHSP), 8 patients born to consanguineous parents, 5 patients with possible family histories and 38 apparently sporadic patients. [Results] We identified 15 *spastin* mutations among the ADHSP patients (15/29: 52%), and 1 *atlastin* mutation (1/29: 3.4%). Another *spastin* mutation was found in a patient with family history. Two mutations in *spastin* and 1 novel amino acid substitution in *atlastin* were found among apparently sporadic patients (2/38: 5.3% and 1/38: 2.6%, respectively). Of the 18 patients with *spastin* mutation, 10 were null mutations and 2 were splice site mutations, suggesting that haploinsufficiency is a major mechanism responsible for SPG4. [Conclusions] SPG4 is the most common ADHSP. The frequency of SPG4 among ADHSP is higher than previously reported. SPG3A in young onset ADHSP also exists in the Japanese population. The system is highly effective for comprehensive mutational analysis of such heterogeneous disorders as HSP.

Development of a high-throughput linkage analysis system employing 100K/500K SNP data. *Y. Fukuda[1], Y. Nakahara[1], Y. Momose[1], H. Date[1], Y. Takahashi[1], J. Goto[1], K. Hara[2], M. Nishizawa[2], E. Nakamura[3], H. Adachi[3], S. Tsuji[1]* 1) Department of Neurology, Graduate School of Medicine, the University of Tokyo, Tokyo, Japan; 2) Department of Neurology, Brain Research Institute, Niigata University, Niigata, Japan; 3) Dynacom Co., Ltd, Kanagawa, Japan.

During the recent decade, microarray-based SNP (Single Nucleotide Polymorphism) data are becoming more widely used as markers for linkage analysis in identification of loci for disease-associated genes. Although microarray-based SNP analyses have drastically reduced genotyping time and costs compared with microsatellite-based analyses, applying these enormous data to linkage analysis programs is a time consuming step, thus necessitating a high throughput platform. We have developed a linkage analysis system for microarray-based SNP data. In this system, Affymetrix 100k/500k SNP chip data can be directly imported and passed to pair-wise (mlink) or multipoint (allegro) linkage analysis programs. The system provides all parameter setting functions that are pre-included in the original mlink and allegro programs. Various marker-selecting functions are implemented to avoid the effect of typing-error data or to eliminate uninformative data, where users set threshold for call rate, HWE test and evaluation of MAF (minor allele frequency). Furthermore, inter-marker distance can be flexibly chosen to adopt markers that are not in linkage disequilibrium (LD) each other. We used this system for the linkage analysis of familial multiple system atrophy (MSA), and found that the results using 100k SNP data were comparable or superior to those obtained from microsatellite markers. General personal computers are sufficient to execute the process, as runtime for whole genome analysis was less than a few hours even in multipoint analysis (approximately 100kb of inter-marker distance) or in the case of a family including consanguineous loops. This system can be widely applied for linkage analysis using microarray-based SNP data and there one can expect high-throughput and reliable linkage analysis.

Did They Start The Conversation? An Evaluation of the NSW Family Health History Campaign. *K.K. Barlow-Stewart, K. Dunlop* Centre for Genetics Education, NSW Health, Sydney, NSW, Australia.

Internationally campaigns promote collection of family health history (FHH) by patients. The NSW Health FHH campaign, August 2006, encouraged the community to discuss their FHH with their family and take the recorded information to their doctor. Development included community poll surveys, consumer and General Practitioner (GP) consultations, website development and general media preparation. GPs throughout NSW were informed prior to the campaign through their professional affiliations and articles in the medical media. Posters, pads with tips for collecting FHH and a simple chart Your Family Health History Record were distributed to all NSW GP practices. The limited, small budget media campaign targeted women 40-60 years. It included newspaper and magazine articles, radio interviews, a television interview on Australias most popular breakfast show and promotion of the website. Evaluation methodologies: mail survey of GPs (response 135/606); poll survey (400 community members) and analysis of enquiries, website and media coverage. 28% (112) of the community randomly polled had seen or heard of the campaign; of these 48% reported discussing FHH with family members as a result; 35% had initiated a discussion with their doctor about their FHH. Website activity peaked immediately post the campaign (August: 324 visits) with particular interest in the FHH Record. 30% of responding GPs had heard of the campaign; of these 66% reported an increase in the number of patients who told them about their family history since the campaign. GPs reported the importance of patients finding out about their own FHH information stating that "I feel much more confident about the information I am being given when I ask about their family history and It made me realise that they may not know when I ask them about their FHH. GPs further commented on the benefits of the simplicity of the FHH record and some had made referrals as a result. While awareness of the campaign itself was limited, for those who were aware, the message had a significant impact. The findings support moving towards a national FHH campaign working with both GPs and the community.

Myotonic dystrophy type 2 in Japan: distinct ancestral origin from Caucasian families. *Y. Amakusa[1], T. Matsuura[1], T. Saito[2,3], T. Kimura[2], O. Yahara[2], H. Aizawa[3], K. Ohno[1]* 1) Div Neurogen & Bioinfo, Nagoya Univ Grad Sch Med, Nagoya, Japan; 2) Dept Neurol, National Dohoku Hosp, Asahikawa, Japan; 3) Div Neurol, Dept Internal Medicine, Asahikawa Med Univ, Asahikawa, Japan.

Myotonic dystrophy type 2 (DM2) is an autosomal dominant, adult-onset muscular dystrophy characterized by myotonia and multisystemic features, caused by expansion of the tetranucleotide CCTG repeats in intron 1 of the zinc finger protein 9 (ZNF9) gene on chromosome 3q21. The size of expansion is extremely large and variable, ranging from 75 to 11,000 repeats, with a mean of 5,000. This unprecedented size and somatic heterogeneity of the expansion make the molecular diagnosis of DM2 more complicated. Genetically confirmed DM2 patients are all Caucasians, and haplotype analysis suggests that the mutation arises from a single founder. No DM2 mutation has been identified to date in sub-Saharan or east-Asian population. Herein, we report a Japanese family with the DM2 mutation. No consanguinity or genetic admixture with other ethnicities is documented. The cardinal clinical feature is a combination of adult-onset proximal muscle weakness and myotonia, consistent with the typical DM2 phenotype. PCR-amplification of the DM2-repeat detected a single normal allele at 228 bp and subsequent Southern blot analysis showed an expanded DM2 allele of 18.1kb (corresponding to 3400 repeats) in the proband. To our knowledge, this is the first DM2 family identified in non-Caucasian population. Although DM2 mutations were reported in non-European populations including Morocco, Algeria, Lebanon, Afghanistan and Sri Lanka, all reported DM2 patients were white and likely arose from a single common founder of European descent because they shared an identical haplotype. To investigate the ancestral origin of our DM2 family, we performed a haplotype analysis using SNPs and short tandem repeat markers flanking the DM2 CCTG repeat. Our data suggest this family has an expansion-associated haplotype distinct from that found in the Caucasian DM2.

Chromosome 10(q23-qter) Deletion and Pericentric Inversion 9(p13-q12) in Congenital Lower Lid Entropion. *M. Kumar[1], R. Kumar[2], P. Gupta[3], R. Dada[2], N. Pushker[3], J. Kaur[1]* 1) Ocular Biochemistry, RP Center, All India Institute of Medical Sciences, New Delhiø; 2) Department of Anatomy, All India Institute of Medical Sciences, New Delhiä; 3) Dr. Rajendra Prasad Centre for Ophthalmic Sciences, All India Institute of Medical Sciences, New Delhiê(E-mail: kaurjasbir@rediffmail.com).

Entropion is an inversion of the eyelid (inward turning of the eyelid margin) toward the globe. The lower eyelid is more frequently affected and depending on the underlying disorder, the entropion may be either unilateral or bilateral. Congenital entropion is an extremely rare disorder and usually involves the lower eyelids. It is often familial and is seen more frequently in Asians. The possible causes for this condition include structural tarsal plate defects (horizontal tarsal kink syndrome) and shortened posterior lamella (tarsus, conjunctiva, eyelid retractors). It has been reported that congenital entropion is a part of a syndrome involving multiple systemic anomalies. A case of primary congenital upper eyelid entropion with cardiovascular, musculoskeletal, and central nervous system abnormalities and another with congenital heart defect has been reported. But, to the best of our knowledge there is no report describing the genetic background of the disease. We report a patient of congenital lower lid entropion and corneal opacity with the help of conventional cytogenetics. GTG-banding revealed an interstitial deletion in chromosome 10 and pericentric inversion of chromosome 9. Chromosomal analysis shows 46,XX,del(10q23-qter)/46,XX,inv(9p13-q12) karyotype. Most publications suggest that pericentric inversion of chromosome 9 is a polymorphic variation and its clinical significance is uncertain. Thus our finding raises the possibility that the congenital lower lid entropion locus may be located on chromosome 10. This represents a more severe manifestation of the disease. Finally, a workup of this finding is suggested and more cases of congenital lower lid entropion needs to be screened using cytogenetics.

L1 retrotransposition events occur mainly in early embryogenesis. *H. Kano[1], E.M. Ostertag[1], I. Godoy[1], C.E. Courtney[1], T. Merdiushev[2], G.L. Gerton[2], H.H. Kazazian[1]* 1) Department of Genetics, University of Pennsylvania School of Medicine, Philadelphia, PA; 2) Center for Research on Reproduction and Womens Health, University of Pennsylvania School of Medicine, Philadelphia, PA.

L1s are abundant retrotransposons that comprise ~17% of the human genome. Despite having great impact in the genome, little is understood about L1 natural biology. Several studies of L1 transgenic mice and human retrotransposition events have demonstrated that L1 retrotransposition can occur in germ cells, early embryos and/or somatic cells; however, it is still controversial as to when L1 retrotransposition mainly occurs. To characterize the timing of human L1 retrotransposition, we created transgenic mouse and rat models harboring a human L1 element under the control of its endogenous promoter. Offspring of L1 transgene heterozygotes exhibited high retrotransposition activity in both animals. L1 insertions were seen in more than 60% of the transgene containing offspring and in 5-13% of offspring without the transgene. Nearly all the de novo L1 insertions were somatic, because these L1 insertions were rarely inherited by the next generation. Upon studying spermatogenic cell fractions and pre-implantation embryos, abundant L1 RNA from the L1 transgene was seen in both spermatogenic cells and pre-implantation embryos, consistent with relatively unmethylated L1 transgene in these tissues. On the other hand, L1 retrotransposition was much more apparent in embryos (>10 fold) than in spermatogenic cells. Our data suggest that there is a time lag between L1 transcription and integration, and L1 RNA can be carried over after fertilization and integrate into the genome during early embryogenesis. In addition to our transgenic animal data, there is evidence that a human L1 insertion has occurred during early human development, and because of bias of ascertainment it is difficult to determine the timing of the others. We now speculate that most human L1 retrotransposition events occur in early development rather than in germ line, suggesting a significant role of somatic L1 insertion in human development and biology.

Partial trisomy 16 and genitourinary anomalies. *W.A.R. Baratela[2], L. Martelli[1,2], J.A. Squire[3], C.C. Rebelo[2], J. Huber[1,2], L.A.F. Laureano[2], E.S. Ramos[1,2]* 1) Dept. Genetics, Medical School, Ribeirao Preto, University of Sao Paulo, Brazil; 2) Clinical Hospital of Ribeirao Preto, HCFMRP-USP; 3) University Health Network, Toronto, Canada.

Trisomy 16 is the most common autosomal trisomy in spontaneous abortions. The small number of live births reported are mosaic with multiple malformations. The proband was born to a 35 years old G2P0 woman at 35 weeks gestation after an uncomplicated pregnancy. Prenatal ultrasound revealed intrauterine growth restriction. He was delivered by cesarean section due to fetal distress, weighting 1270g, head circumference 29cm, Apgar scores 3 and 7. The physical examination showed macrocephaly, systolic murmur (3+/6) without facial dysmorphic features, ambiguous genitalia described as reduced phallus, penoscrotal hypospadia, bifid scrotum, with one palpable gonad. Echocardiogram was compatible with Tetralogy of Fallot. CT scan of the brain demonstrated bilateral ventricles dilatation and occipital extra dural hematoma. Abdominal ultrasound was normal and vesicoureteral reflux was diagnosed by cystography. Endocrinologic evaluation with full hormone pathways tests suggested bilateral functional testicles. Cytogenetic analysis of 100 metaphases by GTG banding showed 47,XY with a marker chromosome in all cells. Parental chromosome analysis showed that the patient's mother carried a 46,XX,t(15;16)(p11;p12) balanced translocation. Fluorescence *in situ* hybridization studies and spectral karyotype (SKY) confirmed the cytogenetic diagnosis 47,XY,+der(16)t(15;16)(p11;p12)mat. At 6 months of age the proband has failure to thrive with significant developmental delay. The identification and characterization of patients who have inherited chromosomal rearrengements may help to clarify the genomic origin and molecular consequences of partial trisomies. Our study demonstrates the efficiency of the molecular cytogenetic techniques in the analysis of marker chromosomes and expands the phenotypic presentations of chromosome 16 trisomy.

Epilepsy and Mental Retardation Limited to Females (EFMR): A unique inheritance pattern and linkage to Xq22. *L.M. Dibbens[1,2], I.E. Scheffer[3,4], M.A. Bayly[1], S.J. Turner[3], K. Friend[1], B.L. Hodgson[1], K. Hynes[1,5], E.A. Haan[1], A. Mazarib[6], Z. Afawi[6], M.Y. Neufeld[6], P.I. Andrews[7], G. Wallace[8], S. Kivity[9], D. Lev[10], T. Lerman-Sagie[10], A.D. Korczyn[6], S.F. Berkovic[3], J. Gecz[1,2,5], J.C. Mulley[1,2,5]* 1) Department of Genetic Medicine, Women's and Children's Hospital, Adelaide, South Australia, Australia; 2) School of Paediatrics and Reproductive Health, the University of Adelaide, Adelaide, South Australia; 3) Department of Medicine (Neurology), The University of Melbourne and Austin Health, Heidelberg, Melbourne, Victoria; 4) Department of Paediatrics, The University of Melbourne, Royal Childrens Hospital, Melbourne; 5) School of Molecular and Biomedical Sciences, University of Adelaide, South Australia, Australia; 6) Department of Neurology, Tel Aviv Sourasky Medical Center, Tel Aviv, Israel; 7) Sydney Childrens Hospital, Randwick, New South Wales, Australia,; 8) Mater Medical Centre, South Brisbane, Queensland, Australia; 9) Department of Neurology, Schneider Childrens Medical Centre, Petaq Tikvah, Israel; 10) Metabolic Neurogenetic Clinic, Wolfson Medical Centre, Holon, Israel.

Epilepsy and Mental Retardation limited to Females (EFMR) is a striking disorder following X-linked inheritance where females are affected and males transmit the condition. EFMR is characterized by early onset seizures in previously normal infants, followed by developmental regression of varying severity. The one previously described EFMR family was mapped to Xq22. We aimed to refine the clinical phenotype of the disorder and to ultimately determine the molecular genetic basis of EFMR. We ascertained four new unrelated EFMR families, two Australian and two Israeli, and haplotype analysis was consistent with linkage to Xq22 for each family. Detailed clinical assessment was performed on 58 individuals. EEGs showed generalized and focal epileptiform abnormalities. Five obligate male carriers had obsessional tendencies. We conclude that EFMR is more common than appreciated and the epilepsy syndrome occurs with intellectual disability and psychiatric features. The unique mode of inheritance suggests a novel genetic mechanism for human disease.

Pilot Studies of the Human Variome Project. *R. Cotton[1], and Collaborators[2]* 1) Genomic Disorders Research Centre, St Vincent's Hospital, Fitzroy, Australia; 2) and Collaborators.

The concept of the Human Variome Project (1) (www.humanvariomeproject.org) was developed to draw attention to the importance of collection of variation and its phenotypic effect and to develop programs to put this into effect. The project was initiated in June 2006 (2). The project builds on work and concepts of the HGVS consortium over many years (www.hgvs.org) and will first focus on Mendelian disorder. The project intends to include all those discovering mutations and its effect and then collect the data so that it is instantly available for others who need it to inform clinical decisions and research. A major pilot study and plan has been developed by the inherited colon cancer community InSiGHT (www.insight-group.org) to develop procedures and systems to allow effortless flow of de-identified data from the patient/clinic/diagnostic laboratory via curated locus or gene specific databases to central databases/genome browsers such as dbGaP, UCSC, HGVbase and EBI. The system will be developed so that it is easily adaptable to other genes and to multiple laboratories, states, counties and countries around the world. Other pilot studies developed include specific ethical studies related to mutation collection, loading of LSDB content to dbGaP and funding of curation of LSDBs. 1. What is the Human Variome Project? Nat Genet 39, 423 (2007). 2. Ring, H.Z., Kwok, P.Y. & Cotton, R.G. Human Variome Project: an international collaboration to catalogue human genetic variation. Pharmacogenomics 7, 969-72 (2006).

Mutation spectrum of the RAS/MAPK pathway genes in Noonan, Costello and cardio-facio-cutaneous syndromes. *Y. Aoki[1], T. Niihori[1], Y. Narumi[1], H. Cavé[2], A. Verloes[2], H. Kawame[3], K. Kurosawa[4], H. Ohashi[5], N. Okamoto[6], G. Neri[7], R.C.M. Hennekam[8], G. Gillessen-Kaesbach[9,10], D. Wieczorek[9], M. I. Kavamura[11], L. Wilson[8], K. Nishio[12], I. Kondo[13], P. Lapunzina[14], S. Kure[1], Y. Matsubara[1]* 1) Dept Medical Genetics, Tohoku Univ Sch Medicine, Sendai, Japan; 2) Hôpital Robert Debré (APHP), Paris, France; 3) Nagano Childrens Hosp, Nagano; 4) Kanagawa Childrens Med Ctr, Yokohama; 5) Saitama Childrens Med Ctr, Saitama; 6) Osaka Med Ctr & Res Inst for Maternal & Child Health, Osaka, Japan; 7) Istituto di Genetica Medica, Rome, Italy; 8) Inst of Child Health, London, UK; 9) Univ Essen, Essen, Germany; 10) Univ. Schleswig-Holstein, Lübeck, Germany; 11) Federal University of Sao Paulo (UNIFESP), Sao Paulo, Brazil; 12) Seirei Hamamatsu General Hospital, Hamamatsu; 13) Ibaraki Prefectural Handicapped Children's Ctr., Mito, Japan; 14) Hosp. Univ. La Paz, Madrid, Spain.

Noonan, Costello and cardio-facio-cutaneous (CFC) syndromes are autosomal dominant disorders characterized by a distinctive facial appearance, heart defects, musculocutaneous abnormalities and mental retardation. Recently we discovered proto-oncogene *HRAS* mutations in Costello syndrome and *KRAS* and *BRAF* mutations in CFC syndrome, establishing a new role of RAS/RAF/MEK/ERK pathway in human development. To elucidate the clinical and molecular characteristics of Noonan, Costello and CFC syndromes, we have so far analyzed *PTPN11*, *HRAS*, *KRAS*, *BRAF* and *MAP2K1/2* (MEK1/2) in 54 patients with Noonan syndrome (NS), 39 Costello patients and 78 CFC patients. Mutations in *PTPN11* were identified in 41% NS patients. *HRAS* mutations were detected in 21 patients with typical Costello syndrome. Mutations in *KRAS*, *BRAF* or *MAP2K1/2* were found in 60% of patients with CFC syndrome. We also identified four *SOS1* mutations in two NS patients, two typical CFC patients and one patient between NS and CFC phenotype, suggesting that mutations in *SOS1* are causative for NS and CFC syndrome. It is plausible to speculate that new genetic causes for Noonan-related disorders still remain to be unidentified in molecules in the RAS/MAPK pathway.

Genomic Alterations detected in Colon Cancer Cell Lines by using Array-Comparative Genomic Hybridization.

M.J. Kim[1, 2], S.Y. Park[1, 2], H.J. Hann[1, 2] 1) Department of anatomy, Ewha womans univ, Seoul, Korea; 2) Ewha Global challenge for Medicine, Seoul, Korea.

Cancer is a kind of genetic disease and cancer development is accompanied by genetic event like losses, gains and amplification of certain chromosome regions or alterations of chromatin structure. Colon cancer is one of the most prevalent cancers and the fourth leading cause of cancer death in Korea. In this study, genomic alterations were analyzed by using array-CGH in colon carcinoma cell lines from Korean, SNU-81, SNU-407 and SNU-1047. Array-based CGH(Array-CGH) can be highly comprehensive, agreeable to very high resolution, sensitive and fast. The method allows investigation of general changes in target oncogene and tumor suppressor genes, which should, in turn, lead to a better understanding of the cancer development. We observed numerous chromosomal imbalances from all cell lines. The common chromosomal gains were observed in 1p36.33 ,1q22, 1q32.1, 2q35, 8p12, 8q22.3, 14q32.33, 16p13.3, and 16q24. Chromosomal losses were found in 4q22.1, 9q13, 14q21.1, 14q32.33, 20p12.1, Xq21.1, and Yq11.223. Also, gains of GON4L, YY1AP1, ELF3, EHF, EIF3SI2, AAMP, PNKD, LMOD1, DCTN6, ODF1, SOX8, ZNF276 and FANCA, with losses of CBWD3 and RBMY2SP were found in all colon cancer cell lines. In conclusion, array-CGH demonstrated the complexity of genetic aberrations in several colon carcinoma cell lines. Chromosomal aberrations identified in this study can provide candidate regions involved in the tumorigenesis and progression of colon carcinomas.

Predictive Testing for Multiple Genetic Variants in Common Diseases: A different ELSI landscape from testing for traditional genetic diseases. *A.C.J.W. Janssens[1], M. Gwinn[2], C.M. van Duijn[3], M.J. Khoury[2]* 1) Department of Public Health, Erasmus MC, Rotterdam, Netherlands; 2) National Office of Public Health Genomics, Centers for Disease Control and Prevention, Atlanta, GA; 3) Department of Epidemiology and Biostatistics, Erasmus MC, Rotterdam, Netherlands.

Unraveling the genetic origins of multifactorial diseases is expected to lead to personalized medicine, in which prevention and treatment are based on tests for multiple genetic variants (genomic profiles). Balancing the enthusiasm for this development is concern about ethical, legal, and social implications (ELSI) of genomic medicine. These implications may not be the same as for genetic testing in monogenic disorders. We conducted a simulation study to evaluate the predictive value and inheritance patterns of genomic profiles. We simulated genomic profiles and disease status for 1 million persons. Profiles included 40 genetic variants. Frequencies of risk genotypes varied in separate scenarios from 1% to 50% and odds ratios from 1.1 to 3.0. Population disease risk was 10%. Results were compared with genetic tests for Huntingtons disease and hereditary cancers and their implications for the discourse on ethical, legal and social issues were considered. While genetic tests for monogenic disorders typically have two outcome results (high and low risk), genomic profiling yields a continuum of possible risk estimates, with minimal risk differences between profiles. When each variant in the profile segregates independently, the probability of inheriting the same at-risk profile is very low. It should be anticipated that genetic variants may decrease the risk of some diseases and at the same time increase the risk of others. The wide variation in genetic profiles and their interpretation should reduce the potential for discrimination and stigmatization and could affect privacy issues for family members (e.g., the right not to know). Our simulation studies show that the predictive value and inheritance of genomic profiles differ fundamentally from those of single, high-penetrance genetic variants. These differences have implications for the discourse on ethical, legal, and social issues of genomic profiling.

FISH enhances sensitivity of cytogenetic analysis in evaluation of MDS. *W-T. Hsu[1], K. Szego[1], S. Gregory[2], P. Venugopal[2], H. Fung[2], J. Loew[1], J. Shammo[2]* 1) Pathology, Rush University Medical Center, Chicago, IL; 2) Hematology, Rush University Medical Center, Chicago,IL.

The Myelodysplastic syndromes (MDS) are hematopoietic stem cell disorders, characterized by cytopenia, and risk of progression to acute leukemia. Chromosomal abnormalities are detected in 40-60% of patients with MDS. Cytogenetic findings are critical for diagnosis, prognosis and monitoring therapy. FISH has been reported to detect occult clonal abnormalities in 15-17.8% of karotypically normal patients in some studies, but found to be of limited value in others. In a retrospective study to evaluate whether FISH can be a valuable diagnostic adjunct to conventional cytogenetic (CC) analysis, we identified 41 MDS patients who had both CC and FISH panel tests. Our FISH panel was designed specifically to detect abnormalities in chromosomes 5, 7, 8, 11 and 20. In these patients, clonal chromosomal abnormalities were detected by CC in 20 patients (48.8%), by FISH in 24 (58.5%) and by either CC or FISH in 27 (65.9%). FISH increased the detection rate by 9.7%. Importantly, FISH uncovered occult clonal chromosome abnormalities in 5 of 15 patients (33%) who had either normal karyotype or normal karyotype with non-clonal abnormalities and in 2 of 6 (33%) patients with failed or incomplete CC studies. These 7 patients included 4 with RAEB, 1 with RCMD and 2 with unclassified MDS. In 20 patients with abnormal findings detected by CC, FISH uncovered additional abnormalities in 3 (15%) and changed cytogenetic risk categorization in 1 (5%) patient. FISH failed to show clonal chromosome abnormalities detected by CC in 7 patients, but these abnormalities were not evaluated by this FISH panel. CC also detected a higher percentage of cells with chromosome 5, 8 and 20 abnormalities. These results suggest that FISH increases the rate of detecting chromosomal abnormalities and is a useful adjunct in cases of failed or incomplete CC studies, and in complete CC studies that have failed to reveal clonal abnormalities. In cases with identified cytogenetic abnormalities, FISH was of limited benefit. It is advisable to perform both FISH and CC at diagnosis to establish an accurate baseline.

Association between genetic variation in *Toll-like receptor 1 (TLR1)* gene and adult bronchial asthma. *T. Hirota[1], M. Harada[1], S. Doi[2], A. Miyatake[3], K. Fujita[4], Y. Nakamura[5], M. Tamari[1]* 1) Lab Genetics Allergy, RIKEN SNP Research Center, Yokohama, kanagawa, Japan; 2) Osaka Prefectural Medical Center for Respiratory and Allergic Diseases, Osaka, Japan; 3) Miyatake Asthma Clinic, Osaka, Japan; 4) School of Human Nursing, The University of Shiga Prefecture, Shiga, Japan; 5) The Institute of Medical Science, The University of Tokyo, Tokyo, Japan.

Bronchial asthma is defined as a chronic inflammatory lung disease characterized by airway hyperreactivity and mucus hypersecretion that results in intermittent airway obstruction. TLRs play an essential role in activation of the in innate immune system, which in turn activates adaptive immunity. Recent study has shown that immunization with an antigen in the context of TLR2 ligands can result in experimental asthma and genetic variation in *TLR2* is a major factor in the susceptibility to asthma in children of farmers. Because TLR2 cooperates with TLR1 in the recognition of Pathogen-associated molecular patterns (PAMPs), TLR1 is also likely to be associated with the development of asthma, but the genetic influences of *TLR1* are unclear. To investigate whether variants of *TLR1* were related to adult bronchial asthma in a Japanese population, a case control association study was conducted. We resequenced the *TLR1* gene and carried out linkage disequilibrium (LD) mapping. We identified a total of 27 variants including 5 non-synonymous substitutions (Arg31Gly, Ser44Pro, Leu144Pro, Ser248Asn, Thr685Asn). We used the Tagger (Haploview 3.32) for tagSNP selection and three SNPs, -6375 C/T (5-flanking region), -5755 T/G (5-flanking region), 743 G/A (exon 4, Ser248Asn), were selected for genotyping. We conducted an association study with 467 asthmatic subjects and 747 controls, and found a significant association between -6375 C/T and adult asthma susceptibility (OR=1.42, 95% CI=1.09-1.84, P=0.0086). These results suggest that the *TLR1* gene play important roles in the pathogenesis of adult asthma. Further genetic and functional studies are needed to elucidate the role of TLR1 in the molecular mechanisms underlying adult asthma.

Paternal histoincompatibility effects of the *HLA-G* gene and increased risk for pre-eclampsia. *S.S. Chong[1], C.Y. Tan[1], J.F.V. Ho[1], Y.S. Chong[2], A. Loganath[2], Y.H. Chan[3], J. Ravichandran[5], C.G. Lee[4]* 1) Pediatrics, National Univ Singapore, Singapore; 2) ObGyn, National Univ Singapore, Singapore; 3) Biostatistics, School of Medicine, National Univ Singapore, Singapore; 4) Biochemistry, National Univ Singapore, Singapore; 5) Sultanah Aminah Hospital, Johor, Malaysia.

Hypothesis: Pre-eclampsia (PE) is a leading cause of maternal and fetal mortality and morbidity which occurs only during pregnancy. Alterations in HLA-G function at the maternal-fetal interface have been postulated to affect placental vascular remodeling and predisposition to PE. We postulated that paternal alleles of *HLA-G* may increase risk for PE in susceptible mothers.

Methods: Association between *HLA-G* and PE was tested in a case-control study of 86 PE and 245 normotensive Malay women. Superimposed PE cases were excluded. The *HLA-G* gene was amplified in a single-tube multiplex PCR reaction and genotyped for 18 single nucleotide polymorphisms (SNPs) or variations using a multiplex minisequencing strategy. Haplotype/haplogroup analyses and case-control comparisons were performed statistically using Fishers exact test, and associations with disease were expressed as odds ratios with 95% confidence intervals.

Results: Risk for PE was not associated with maternal *HLA-G* haplotype, but was strongly associated with presence of fetal haplotype G*0106 (p=0.014; OR=3.299, 95% CI 1.317-8.262). The CT heterozygote frequency at the codon 258 SNP, which defines haplotype G*0106, also differed strongly only between case and control babies (p=0.012; OR=3.450, 95% CI 1.316-8.806). Furthermore, the frequency of fetal-maternal genotype mismatch at codon 258, where maternal genotype was CC and fetal genotype was CT, was significantly higher in PE pregnancies compared to normal pregnancies (p=0.016, OR=4.253, 95% CI 1.313-13.779).

Conclusion: Paternal contribution of *HLA-G* G*0106 in the fetus significantly increases risk for PE in mothers who do not carry this haplotype. Maternal immune response to variant paternal HLA-G antigens present in the fetus may be a risk factor for PE in certain pregnancies.

Genomic deletions of the *APC* gene can result both in diffuse and attenuated forms of adenomatous polyposis. *S. Baert-Desurmont[1], J. Bou[1], J. Tinat[1], J. Mauillon[1], O. Bera[2], S. Olschwang[3], T. Frebourg[1]* 1) Department of Genetics, University Hospital and Inserm U614, Faculty of Medicine, Institute for Biomedical Research, Rouen, France; 2) Department of Virology, University Hospital, Fort-de-France, Martinique; 3) Inserm U599, Institut Paoli-Calmettes, Marseille, France.

Germline mutations of the *APC* gene result into familial adenomatous polyposis (FAP) and two clinical forms of FAP can be distinguished : the typical one characterized by hundreds to thousands adenomas developing during adolescence or young adulthood, and the attenuated form called AFAP characterized by fewer than 100 adenomas at a more advanced age. While numerous studies have indicated a genotype-phenotype correlation for some *APC* point mutations, there is no clear evidence for a common phenotype associated with *APC* large deletions. Here we report the phenotypic variability of these *APC* genomic large deletions. In our French series, deletions are involved in 9% of the FAP families. To screen for *APC* genomic rearrangements, we used a QMPSF (Quantitative Multiplex PCR of Short Fluorescent Fragment) assay exploring each exon and dividing exon 15 in 5 fragments numbered 15.a to 15.e. We identified 4 distinct large deletions affecting exons 6-15, exons 11-13, exons 1-15.b, and exons 1-15.e. The three patients harbouring the partial deletions of *APC* presented typical forms of FAP with 100 to 1000 adenomas. In contrast, the complete *APC* deletion was detected in a patient presenting at 23 years of age an AFAP with 50 adenomas located in the distal colon and rectum. Although genomic rearrangements of *APC* are less frequent than point mutations, their presence should be considered in FAP families with not only with classical but also with attenuated phenotypes.

High carrier frequency of an unusual deletion mutation of the *GALT* gene in the Ashkenazi population. *N. Goldstein, Y. Cohen, E. Sigalov, B. Vilensky, Y. Anikster* Metabolic disease unit, Safra Children Hospital, Sheba Medical Center, Tel Hashomer.

Classical Galactosemia is a disorder of galactose metabolism presented in the first weeks of life and characterized by vomiting, diarrhea, lethargy, hypotonia, jaundice, hepatomegaly, septicemia and bleeding tendencies. Galactosemia is inherited in an autosomal recessive manner due to mutations in the *GALT* gene. Loss of GALT enzymatic activity prevents the conversion of galactose-1-phosphate (Gal-1-P) and UDP-glucose into glucose-1-phosphate and UDP-galactose causing the accumulation of Gal-1-P in various organs leading to the clinical signs and symptoms described above. Treatment for this disorder constitutes diet restrictions on galactose during infancy and all lactose-containing foods throughout life. However, long term complications such as cognitive and developmental delays and ovarian failure may not be prevented. Recently, an unusual deletion mutation of the *GALT* gene was characterized. The deletion includes most of the gene, retaining only a short internal segment. The ethnic origin of several unrelated patients having this mutation is Ashkenazi Jewish. Examination of this mutation in our Ashkenazi patients diagnosed with Galactosemia showed that all of the Ashkenazi alleles had the mutation. The aim of this study was to estimate the carrier frequency of this mutation in the Ashkenazi population in Israel. 760 DNA samples from anonymous subjects of Ashkenazi descents were available for molecular diagnosis at our lab. *GALT* gene deletion mutation was genotyped using a chip-based matrix-assisted laser desorption-time-of-flight (MALDI-TOF) mass spectrometer. Using MassARRAY software (Sequenom) we designed a multiplex assay that includes detection of both normal and deleted alleles. Six out of 760 DNA samples screened had the deleted allele. Thus, the carrier frequency in this population is 1 in 127 (0.0079) and the predicted incidence of Galactosemia is 1 of 64,500 live births. Resolving the carrier frequency of this disease and an easy method of molecular diagnosis of Galactosemia in Ashkenazi Jews facilitates prenatal counseling for this population.

NRAMP1 polymorphisms and susceptibility to tuberculosis in Turkish adult population. *A. Y. Ekmekci[1], F. Ozkinay[1], H. Onay[1], F. Bacakoglu[1], A. Sayiner[1], S. Z. Guclu[2], S. Pehlivan[3], O. Cogulu[1], A. Aykut[1], C. Gunduz[1], C. Ozkinay[1]* 1) Ege University Medical Faculty, Izmir, Turkey; 2) Health Ministry Suat Seren Chest Diseases and Thoracic Surgery Education and Research Hospital, Izmir, Turkey; 3) Gaziantep University Faculty of Medicine, Gaziantep, Turkey.

The natural resistance-associated macrophage 1 (NRAMP1) gene has been thought to be a strong candidate gene for human tuberculosis (TB) susceptibility. The results of the study that investigating the association between TB and NRAMP1 gene are controversial. We aimed to investigate the relationships between INT4, D543N and 3UTR polymorphisms of the NRAMP1 gene and TB susceptibility in Turkish adult population. This case-control study included 319 TB patients (mean age: 42.6 16.4) and 273 age matched healthy controls. Three polymorphisms (INT4, D543N and 3UTR) of the NRAMP1 gene were genotyped by using polymerase chain reaction of genomic DNA with specific primers followed by restriction fragment length polymorphism method. Digested samples were analyzed by electrophoresis on 4% agorose gel. No statistically significant association was observed between susceptibility to TB and three investigated polymorphisms of the NRAMP1 gene in the population studied. In conclusion the polymorphisms, INT4, D543N and 3UTR, of the NRAMP1 gene were not associated with TB susceptibility or resistance in Turkish adult population. To clarify the entire role of NRAMP1 gene in TB susceptibility, further studies including clinical analysis of patients and haplotype analysis with the other polymorphisms of this gene are needed.

High resolution melting analysis (HRM) for rapid and sensitive detection of mutations in *BRCA1&2*: comparison of Lightscanner (Idaho Technology) and LightCycler 480 (Roche). *K. Claes, K. De Leeneer, I. Coene, B. Poppe, A. De Paepe* Centre for Medical Genetics, Ghent Univ Hosp, Gent, Belgium.

HRM is an emerging technique for detection of nucleic acid sequence variation. It involves the precise monitoring of the change in fluorescence caused by the release of an intercalating DNA dye from a DNA duplex as it is denatured by increasing temperature. Developments in instrumentation and fully saturating intercalating dyes have made accurate HRM analysis possible. We evaluated two HRM instruments for screening *BRCA1&2* mutations. To cover the complete coding region and splice sites we designed 112 PCR amplicons (lengths: 136-435bp), amplifiable with a single PCR program. LCGreen Plus was used as intercalating dye. HRM was performed on the 96-well Lightscanner (Idaho Technologies) (LS) and the Lightcycler 480 (Roche) (LC) instruments. The sensitivity was evaluated by analysing 212 positive controls scattered over almost all amplicons and the specificity by a blind screening of 22 patients previously screened by other techniques. All 212 known heterozygous sequence variants were detected on the LS by analysis on normal sensitivity. On the LC the standard sensitivity setting of 0.3 had to be increased to 0.5 to detect all variants, hereby decreasing the specificity (96.2% vs. LS: 97.3%). A few amplicons were responsible for the majority of the false positives and we are currently optimizing these fragments. Previously, we screened *BRCA1&2* by direct sequencing of the large exons 11 and DGGE for all other coding exons. By introducing HRM our reporting time can be decreased 3 times: no post-PCR handling is required and the software allows fast analyses. Also the cost price of the consumables is limited (LCGreen Plus: 0.25EUR per reaction; 96-well PCR plate suitable for HRM: 3.5 (LS) -4.8 (LC) EUR). The cost price of the LS instrument is about half of the cost price of the LC, however, the latter can also be used for real-time Q-PCR. HRM is a rapid, cost-efficient, sensitive methodology simple enough to be readily implemented in a diagnostic laboratory. The sensitivity of both instruments evaluated was 100%; the LS scored slightly higher for specificity than the LC.

The phenotypic variability of laminopathies: a trap for the clinicians. *V. Drouin-Garraud[1], L. Guyant-Maréchal[2], A. Bedat-Millet[2], F. Anselme[3], G. Savoure[3], A. Laquerrière[4], P. Richard[5], T. Frebourg[1]* 1) Department of Genetics, University Hospital and Inserm U614, Faculty of Medicine, Institute for Biomedical Research, Rouen, France; 2) Department of Neurology, University Hospital, Institute for Biomedical Research, Rouen, France; 3) Department of Cardiology, University Hospital, Institute for Biomedical Research, Rouen, France; 4) Department of Pathology, University Hospital, Institute for Biomedical Research, Rouen, France; 5) Molecular Cardiogenetics, La Pitié-Salpétrière University Hospital, AP-HP, Paris, France.

Since the identification of *LMNA* mutations in the autosomal dominant form of Emery-Dreifuss muscular dystrophy, *LMNA* mutations have been shown to result in a wide range of phenotypes including autosomal recessive form of EDMD, dilated cardiomyopathy, familial partial lipodystrophy of the Dunnigan type, mandibuloacral dysplasia, Charcot-Marie-Tooth neuropathy, Hutchinson-Gilford Progeria or Werner Syndrome, lethal restrictive dermopathy and other complex phenotypes. We report our clinical experience on the inter- and intra- variability of the *LMNA* mutation phenotype based on the extensive investigation of 38 patients from 13 families. Fourteen patients from 5 families showed a muscular disease associated with cardiac involvement, and 2 had clinical involvement since infancy. Eighteen patients from 3 families had isolated severe cardiac disease and these families were dramatically affected by an autosomal dominant form of sudden death. Three patients had partial lipodystrophy. Finally, 3 patients from 2 families showed an unusual complex phenotype associating cardiac involvement, mild dysmorphic facial features and acrogeria. Most of the patients had a severe cardiac disease. This series highlights that the diagnostic of laminopathies should be considered in patients with supraventricular arrhythmia and conduction system disease, even in the absence of dilated cardiomyopathy. The frequency of ventricular arrhythmia justifies to perform presymptomatic diagnosis in order to implant in mutation carriers cardioverter defibrillators which prevent sudden death.

The importance of recurrent *CEP290* mutations for first-pass mutation screening in Leber Congenital Amaurosis. *F. Coppieters[1], T. de Ravel[2], I. Casteels[3], F. Meire[4], N. Van Regemorter[5], S. De Jaegere[1], A. De Paepe[1], P. Coucke[1], B.P. Leroy[1,6], E. De Baere[1]* 1) Ctr for Medical Genetics, Ghent Univ Hosp, Ghent, Belgium; 2) Ctr for Human Genetics, Catholic Leuven University, Belgium; 3) Dept of Ophthalmol, Catholic Leuven University, Belgium; 4) HUDERF, Brussels, Belgium; 5) Centre de Génétique, Free University of Brussels, Belgium; 6) Dept of Ophthalmol, Ghent Univ Hosp, Belgium.

Recently, the *CEP290* (*NPHP6*) gene was identified as a novel gene for Leber Congenital Amaurosis (LCA), representing one of the most frequent causes of LCA. The major objective of this study was to determine the proportion of *CEP290* mutations in a cohort of 62 LCA patients, mainly of Belgian origin, in whom a first-pass mutation screening was negative for mutations in known LCA genes.
At first, we screened for the recurrent *CEP290* mutation c.2991+1655A>G. This mutation was identified in 17/62 patients (27%), of which 2 were homozygous and 15 heterozygous. Sequencing of the total coding region revealed a second mutation in 14/15 patients. Secondly, the 45 LCA patients who did not carry c.2991+1655A>G, were screened for 4 other recurrent *CEP290* mutations (c.[3310-1G>A;3310C>A], c.5587-1G>C, p.Lys1575X and p.Thr1722GlnfsX2). We found 3 distinct heterozygous mutations in 7 individuals, showing that c.2991+1655A>G is not present in all *CEP290*-related LCA cases. A second mutation was identified in 2 cases. In one patient no second mutation was found. Screening of the remaining 4 is ongoing. Overall, 10 novel *CEP290* mutations were identified. Individuals in whom no second *CEP290* mutation could be identified by screening of the coding region at the genomic level, are being analysed by cDNA screening.
These findings confirm the importance of *CEP290* in LCA, as its mutations were identified in 24/112 (21%) patients from our entire LCA patient population. In addition, we have shown that a significant fraction of mutations (24/62; 39%) can be found through screening of only 4 recurrent mutations in our pre-screened mutation-negative LCA cohort.

Detections of genomic alterations of congenital diseases using BAC microarray. *S. Asakawa[1], Y. Murayama[1, 3], T. Yamamoto[3], Y. Furutani[3], R. Matsuoka[3], N. Shimizu[1, 2]* 1) Department of Molecular Biology, Keio University School of Medicine, Tokyo, Japan; 2) GSP center, The Leading Institute of Keio University, Tsukuba, Japan; 3) The International Research and Educational Institute for Integrated Medical Sciences, Tokyo Women Medical University.

As reported at the last ASHG meeting, we established BAC microarray on which 7718 Keio BAC-DNAs are spotted in triplicate. Using these arrays (GSPArray7700TM), we are examining copy number changes of various cancer tissues (Murayama et al. this meeting). Also, we employed this aCGH system to investigate genomic copy number changes in various congenital diseases and we detected copy number changes of DiGeorge syndrome and Down syndrome patients. We have established about 4,000 cell lines from various congenital diseases including Down syndrome, DiGeorge syndrome, and Williams syndrome patients. Majority of the cases are accompanied by heart abnormalities, but causative genomic alterations of many cases remain unknown. We chose eleven cell lines that showed no known genomic alterations and no point mutations in the selected genes. Of these, one case that exhibited epilepsy, mental retardation, and dysmorphic facial expression showed two large deletions in 7q: One corresponded to Williams syndrome causative region, but the other was a novel deletion. At this meeting, we demonstrate the results of these analyses.

Expression profiling of primary prostate tumor free-relapse and primary prostate tumor with relapse using 44K whole human genome microarray. *S. Jacolot[1], A. Valeri[2], G. Fournier[2], L. Doucet[2], A. Volant[2], G. Fromont[3], O. Cussenot[4], J. Leger[5], C. Ferec[1,2]* 1) INSERM U613, Brest, France; 2) CHU Brest, France; 3) CHU Poitiers, France; 4) Hopital Tenon, Paris, France; 5) Genopole Grand Ouest, Nantes, France.

Prostate Cancer is the most frequently diagnosed cancer in Caucasian men. Screening for prostatic antigen (PSA) has led to an earlier detection of prostate cancer as well as an increasing number of men diagnosed with organ-confined, which are potentially curable. Early diagnosis favors curative surgery. However, up to 30% of men undergoing radical prostatectomy will relapse. DNA microarray technology offers the capacity to screen the expression of thousands of gene at the same time. Gene chips have been widely used for the identification of genes associated with the progression of PCa by assessing expression profiles of clinical samples and cell lines. All the studies show that some primary tumors are pre-configured to metastasize and this propensity can be detected at initial diagnosis, then the clinical outcome of individuals suffering from cancer can be predicted by using the gene-expression profiles of primary tumors at diagnosis. Unlike other studies which compare normal tissue versus primary tumor or primary tumor versus metastasis, we chose to examine gene expression in 60 tumor samples derived from two groups of primary tumors: the first group includes 30 samples from relapse-free patients after at least 3 years and the second group includes 30 patients with relapse. We analysed total RNA of these two groups using 44K whole human genome microarray (Agilent Technology). We used the Significance Analysis of Microarrays (SAM) software and we performed currently hierarchical clustering analysis using Cluster-TreeView software. We have been able to point out a differential expression of 515 probes (out of the 44000 present on the pangenomic chips) between two groups of patients: one representative of an early relapse (before 6 months) and the other relapse-free group beyond 4 years. 308 probes were upregulated and 207 were downregulated. Further studies are necessary to validate this molecular profiling.

The effect of chromosomal rearrangements on gene expression. *L.A.J. Harewood, F. Schütz, M. Delorenzi, A. Reymond* Centre for Integrative Genomics, Genopode Building, Lausanne, Switzerland.

Balanced chromosomal rearrangements, such as reciprocal translocations, resulting in no apparent gain or loss of genetic material are frequently occurring human chromosomal aberrations. An example is the t(11;22)(q23;q11) rearrangement, which is the only known recurrent non-Robertsonian balanced translocation in humans. Carriers are phenotypically normal, but are at risk of having progeny with Emanuel syndrome. It is conceivable that these large chromatin rearrangements influence the transcription levels of genes mapping both near, and distant, to the chromosome breakpoints, even if these genes are present in normal copy numbers. To test this hypothesis, we compared the gene expression profiles of lymphoblastoid cell lines and skin fibroblasts from 13 cytogenetically normal individuals, to those of 9 balanced translocation carriers and 4 Emanuel syndrome patients. This final group of individuals were included as proof of principle for the technique and to determine whether links could be made between the genes with altered expression and the phenotype, thereby providing a deeper understanding of the clinical basis of the syndrome. Comparison of unbalanced individuals with controls revealed twice as many gene expression changes than the balanced/control comparison. The greater number of differences in unbalanced individuals was anticipated as they are partially aneuploid for both HSA11 and 22 and are phenotypically affected. Consistently, a statistically significant fraction of the differentially expressed genes mapped to these two chromosomes. Permutation tests showed, however, that despite being lower, the number of differentially expressed genes between the two groups with complete genome complements is statistically significantly higher than that observed when one compares control samples alone. This suggests that balanced rearrangements have a greater effect on gene expression than normal variation even though individuals are phenotypically normal. Interestingly, the genes that show modified expression cluster to a set of genomic regions, indicating that these may be under a common mechanism of expression modulation.

Identification of a novel chromosome 14 systemic lupus erythematosus (SLE) susceptibility gene. *A. Hellquist[1], C.M. Lindgren[1], S. Koskenmies[2], P. Onkamo[2], E. Widén[2], H. Julkunen[3], U. Saarialho-Kere[2,4], A. Wong[5], D.S. Cunninghame-Graham[5], T.J. Yyse[5], K. Kivinen[1], T. Skoog[1], L. Berglind[6], V. Mäkelä[6], G. Assadi[1], M. Zucchelli[1], M. DAmato[1], J. Kere[1,6]* 1) Karolinska Institute, Stockholm, Sweden; 2) University of Helsinki, Helsinki, Finland; 3) Peijas Hospital and Helsinki University Hospital, Helsinki, Finland; 4) Karolinska Institutet at Stockholm Söder Hospital, Stockholm, Sweden; 5) Imperial College, Hammersmith Hospital, London, UK; 6) Karolinska University Hospital, Huddinge, Sweden.

SLE is a chronic autoimmune inflammatory disease characterized by autoantibody production and tissue injury. SLE exhibits a complex pattern of inheritance involving multiple genes as well as an environmental component. Despite the identification of several loci and candidate genes, most of the genetic background remains unexplained as yet. We have previously identified suggestive linkage on chromosomes 5p, 6q25-q27, 14q21-q23 and HLA on 6p (Koskenmies et al JMG 2004). Further, an excess sharing of a haplotype on 14q and excess transmission of a haplotype on 6q were shown after additional markers were added in the suggestive regions of linkage (Koskenmies et al EJHG 2004). Using a dense microsatellite and single nucleotide polymorphism (SNP) mapping approach we have identified a novel and previously poorly characterized gene within the 14q21-q23 locus associated to SLE in two independent material family materials of Finnish and British origin. The UK material in particular showed strong association to one marker located in the 5 of the gene (T=131, U=71, p=0.000024, OR=1.8, CL@95% 1.6-2.1). This marker, although not significantly associated, showed the same over transmission trend in the Finnish sample set (T=15, U=8, p=0.14, OR=1.9, CL@95% 0.8-4.4). The gene, C14SLEC1, is expressed at low levels in many tissues, including monocytes, and may be involved in adhesion based on similarity to other adhesion molecules. By treating THP-1 monocytes with inflammatory cytokines we found upregulation of C14SLEC1 by tumor necrosis factor alpha (1.9 times, p = 0.008) and gamma-interferon (2.2 times, p = 0.008), suggesting that C14SLEC1 may be regulated through a proinflammatory pathway.

Late-onset Tay-Sachs disease (LOTS): cognitive function. *D. Elstein[1], G. Pastores[2], G.M. Doniger[3], E. Simon[3], I. Korn-Lubetzki[4], E.H. Kolodny[2], A. Zimran[1]* 1) Gaucher Clinic, Shaare Zedek Medical Center, Jerusalem, Israel; 2) Neurogenetics Unit, Department of Neurology, NYU School of Medicine, NYC, NY, USA; 3) Neurotrax Corp., Teaneck, NJ, USA; 4) Department of Neurology, Shaare Zedek Medical Center, Jerusalem Israel.

Objective: LOTS (chronic GM2-gangliosidosis) is a rare, erratically progressive neurodegenerative disorder, due to mutations of the -subunit of Hexosaminidase A gene, with residual enzyme activity. Manifestations include progressive proximal muscle weakness, dysarthria, incoordination, tremor, and psychosis. Onset is in early adulthood. Substrate reduction and chaperone therapy are under investigation. Our purpose is to assess cognitive function using a computerized system that is user-friendly and non-threatening for follow-up of LOTS patients and after therapeutic interventions. Methods: Cognitive testing uses the computerized Mindstreams system (NeuroTrax Corp., NJ) which is inexpensive, brief (<1 hour), and essentially self-administered. Outcome parameters are calculated using automatic algorithms. To permit averaging performance across outcome parameters (e.g., accuracy, reaction time), each parameter is standardized according to age and years of education and fit to an IQ-style scale (mean=100, SD=15). Standardized subsets of outcome parameters are averaged producing 7 index scores: memory, executive function, visual-spatial, attention, information processing, and motor skills, and a Global Cognitive Score (GCS). Results: Mean values of index scores for 16 evaluable patients (age: 23-65 years) from 2 centers ranged from 75.5-91.0; mean GCS was 79.2; one patient skewed results because of scores >104 in all domains. Despite small sample size, testing for the hypothesis that scores are equal to normal populations was rejected (p=.0003). Scores did not correlate with age or education but did correlate with a LOTS-specific severity score assessing neurological, non-cognitive, parameters. Conclusions: The computerized Neurotrax system allowed even moderately impaired patients to complete the battery without frustration. The most affected domains appear to be memory, executive function, and verbal function.

Mitochondrial DNA polymorphism and its association with longevity in the Latvian population. *A. Krumina[1], L. Pliss[2], A. Brakmanis[1], V. Baumanis[2]* 1) Medical Biology & Genetics, Riga Stradins University, Riga, Latvia; 2) Latvian Biomedical Research and Study Centre, Riga, Latvia.

There is increasing evidence that some mitochondrial DNA (mtDNA) polymorphisms of coding region and control regions HVSI and HVSII could affect rate of ageing (Wallace, 2005). mtDNA haplogroup J has been reported to increase the chance to attain longevity in northern Italians and Finns, haplogroup K - in the French and Irish, haplogroup D - in the Japanese. These findings allow to suggest that the association of mtDNA variability with longevity may be population specific, depending on both genetic and environmental background. Studies of the control region HVSII polymorphism in association with longevity so far are very limited.

The aim of our study was to verify if there is any association between mtDNA coding and control region polymorphisms and longevity in the Latvian population.

Objects were 351 healthy unrelated Latvians 18 - 40 years old, 98 individuals aged 74 - 89 years and 44 centenarians. Material of the research was DNA isolated from leukocytes. mtDNA haplogroups depending on mutations in the coding region of mtDNA were determined by PCR - RFLP analysis. Polymorphisms in the control regions HVSI and HVSII were analysed by direct DNA sequencing.

The frequencies of haplogroup I and subhaplogroup U4 were significantly lower and that of subhaplogroup U5a significantly higher in the older age group (74 - 89 years) than in younger individuals. Frequency of HVSII polymorphism at the site 00068 was significantly higher in centenarians with no cases of this type of polymorphism observed in the youngest age group.

Our results support hypothesis that certain population specific inherited mtDNA polymorphisms may promote human longevity.

Defining neocentromere identity: role of L1 retroelements in the epigenetic formation of ectopic centromere chromatin. *A.C. Chueh, K.H. Brettingham-Moore, E.L. Northrop, L.H. Wong, K.H.A. Choo* Murdoch Childrens Res Inst, Royal Children's Hosp, Parkville, Australia.

Human neocentromeres are fully functional centromeres that arise epigenetically from non-centromeric precursor sequences that are devoid of alpha-satellite DNA. Centromere Protein A is a centromere-specific histone H3 variant, which serves as the epigenetic mark for defining the centromere core. Using ChIP-PCR array analysis, we have recently described a hierarchical and symmetrical interspersion pattern of CENP-A-associated nucleosomal blocks, found within a 330 kb domain of 10q25 neocentromere. Here, we investigated the possible DNA motifs or sequence properties that enable or favor the nucleation of neocentromeres. Bioinformatic analysis was performed to make direct comparisons for the percentage of AT content and prevalence of intersperse repeats between CENP-A-associated clusters and non-CENP-A-binding regions. While no difference was found for AT content and the majority of the interspersed repeats analyzed, we observed a 2.5-fold increase in the prevalence of underlying sequences corresponding to L1 LINE retroelements and a cluster of 4 full-length L1s concentrated around 330-kb CENP-A domain. Although most L1s possess 5 end-truncations and are generally not transcribed, recent reports showed that RNA transcripts from full-length L1P elements (~ 6 kb) can be detected in various human cell lines. For transcription studies, we designed RT-PCR primers that specifically target each of the four CENP-A-associated FL-L1 elements (FL-L1a-d) in CHO-human monochromosomal hybrid lines, containing the neocentric mardel(10) marker or the progenitor chromosome 10. Interestingly, transcripts from only one of the four FL-L1s (FL-L1b) were detected and that the FL-L1b locus is actively transcribed both before and following neocentromere formation. Furthermore, RNA-ChIP-qPCR analysis was also performed showing an enrichment of FL-L1b RNA in the CENP-A-associated chromatin. In summary, we hypothesize that FL-L1 retroelements, acting via an RNA intermediate, may be important for the establishment or maintenance of the neocentromere chromatin through currently unknown mechanisms.

Characterization of deletions in the *SPAST* gene. *C. Beetz[1], C. Oubrayme[1], C. Depienne[2], S. Zuchner[3], E. Reid[4], R. Schüle[5], M. Auer-Grumbach[6], S. Klebe[7], J. Schickel[1], A. Brice[2], M. Pericak-Vance[4], L. Schöls[5], T. Deufel[1]* 1) Institut f. Klinische Chemie, Uniklinikum Jena, Jena, Germany; 2) INSERM U679, Groupe Hospitalier Pitie-Salpetriere, Paris, France; 3) Miami Institute of Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 4) Cambridge Institute for Medical Research, University of Cambridge, Cambridge, UK; 5) Hertie-Institut f. Klinische Hirnforschung, Uniklinikum, Tübingen, Germany; 6) Zentrum f. Medizinische Forschung, Medizinische Universität Graz, Graz, Austria; 7) Klinik für Neurologie, Uniklinikum Schleswig-Holstein, Kiel, Germany.

Not much is known about the mechanisms underlying large genomic deletions as they are not easily detected and as only few have been characterized in detail. We here present a comprehensive analysis of *SPAST* deletions which we previously showed to account for >10% of cases of hereditary spastic paraplegia. A total of 55 of these aberrations have been identified to date. They affect 25 different (combinations of) exons. Of the 110 breakpoints, 75 reside in *SPAST* introns, while 16 and 19 lie upstream and downstream of the gene, respectively. In contrast to a number of other deletion-prone disease genes, there is no evidence for a breakpoint hotspot. Instead, the number of breakpoints correlates with intron size (R^2=0.60) and only weakly with the density of Alu elements (R^2=0.09). Sequencing of the junction in 19 intragenic events reveals non-homologous recombination as the mutational mechanism in 10 cases, homologous recombination between repetitive sequences in 7 cases, and complex insertion-deletion events in 2 cases. The latter figure is likely to be higher as extensive screening by long range PCR failed in an additional 5 cases. The apparent lack of a predominant mutational mechanisms is, again, in contrast to the few other genes for which a similar amount of sequence data is available. We expect our world-wide analysis of a comparatively rare disease gene to stimulate similar efforts for other genes. A broader range of this kind of studies may, eventually, lead to a better understanding of the causative events underlying large disease-causing deletions.

AsiDesigner: siRNA design server considering alternative splicing. *Y.J. Kim[1], Y.K. Park[1], S.M. Park[1], Y.C. Choi[2]* 1) Medical Genomics Research Ctr, KRIBB, Daejeon, Korea; 2) 49-3 Moonpyung-dong, Daedok-gu, Bioneer, Co., Daejeon, Korea.

AsiDesigner is a web based siRNA design software system providing siRNA design capability to take into account alter-native splicing for mRNA level gene silencing. We developed a novel algorithm to retrieve a target region so that siRNAs can be designed dependent upon whether a user needed a specific mRNA isoform or combined mRNA isoforms from a target gene. The algorithm incorporates 1) selecting a target region; 2) using genome mapped results of all the isoforms; 3) extracting target sequences dependent upon selected isoforms. The developed algorithm and the AsiDesigner were tested and confirmed as very effective throughout many gene silencing experiments. It is expected that this exon-based siRNA design algorithm will play an important role in functional genomics, drug discovery, and other molecular biology studies.

New role for the neuropeptide galanin in regulation of triglyceride levels. *M. Kyttala[1], C.L. Plaisier[1], A. Huertas-Vazquez[1], B. Aouizerat[2], T.W.A de Bruin[3], C. Aguilar-Salinas[4], T. Tusie-Luna[4], M.-R. Taskinen[5], C. van der Kallen[3], P. Pajukanta[1]* 1) Human Genetics, UCLA, Los Angeles, CA; 2) School of Nursing, UCSF, San Francisco, CA; 3) Dept. of Internal Medicine, Maastricht University, Maastricht, NL; 4) INCMNSZ-UNAM, Mexico City, Mexico; 5) Dept. of Medicine, University of Helsinki, Helsinki, Finland.

Familial combined hyperlipidemia (FCHL) is a common dyslipidemia predisposing to coronary artery disease. Patients with FCHL exhibit high levels of serum total cholesterol and/or triglycerides (TGs). A previous genome-wide scan with Dutch FCHL families identified a region on chromosome 11 linked to FCHL and high TGs. This region was recently replicated in British FCHL families. Our objective was to test the neuropeptide galanin (GAL) which is a regional positional candidate gene for association. Recent findings strongly implicate GAL in pathways involving TGs, although the details of the mechanism have not been completely elucidated. Furthermore, the expression of GAL in the hypothalamus is known to be specifically upregulated in rodents due to a high-fat diet induced increase in TG levels. To investigate GAL as an FCHL candidate gene, we genotyped four tagging SNPs and singletons that covered the common variation of GAL in four different study samples: Dutch, Finnish and Mexican FCHL families and a Caucasian combined hyperlipidemia case/control sample, comprising a total of 2032 subjects. The initial association was tested in Dutch and Finnish FCHL families as well as in the Caucasian combined hyperlipidemia case/control sample. We identified the same haplotype for high TG in all of the initially tested samples ($p = 0.009$ in the Dutch and Finnish FCHL families, and $p = 0.001$ in the case/control study sample). Importantly, this same haplotype was replicated in Mexican FCHL families ($p = 0.04$), and when all the FCHL family study samples were combined, the association with TG became more significant ($p = 0.001$). In conclusion we have identified GAL as a new FCHL candidate gene, influencing serum TG levels in humans. Our future plan is to identify the functional mechanisms by which GAL regulates TG levels.

Enhanced D-HaploDB: definitive haplotypes and extended haplotype information determined by genotyping complete hydatidiform mole samples. *K. Higasa, Y. Kukita, K. Miyatake, T. Tahira, K. Hayashi* Res Ctr Gen Info, Kyushu Univ/Med Inst Bioreg, Fukuoka, Japan.

The Definitive Haplotype Database (D-HaploDB) is a web-accessible resource of genome-wide definitive haplotypes determined from a collection of Japanese complete hydatidiform moles (CHM), each of which carries a genome derived from a single sperm. Here, we strengthened the database by genotyping an additional SNP set (Affymetrix 500K) and some results of population genetical analyses were implemented. We particularly focused on extended haplotypes, because those common in a population may be the evidence of recent positive selection. In HapMap project, African and European samples were from trios, and the reconstructed haploytpes are highly accurate. However, the East Asian samples were from arbitrarily collected individuals, and haplotypes inferred from relatively small samples may contain significant error, when the data is used in error-sensitive analyses such as extended haplotype homozygosity (EHH) mapping. To assess the impact of this for detecting selected region, we compared some statistics. First, the integrated EHH (iHH) score was greater than those of HapMap. Second, unstandardized integrated haplotype score (iHS) showed more extreme values than HapMap, which means HapMap data is more likely to be neutralized. Third, the correlation (r) of iHS value between CHM and JPT was 0.79, which suggest that selected alleles are likely to show more outlier values in our data. Lastly, the comparison of length distribution of extended haplotypes of our haplotypes with those of HapMap showed serious fragmentation of long haplotypes in HapMap, and some consanguinity in three of the four HapMap populations. Taken together, selected haplotypes were more extended than previously reported. These haplotypes identified by D-HaploDB can be thought of as promising selection candidates and strongly complement the results from HapMap data. The D-HaploDB is freely accessible via the internet at http://finch.gen.kyushu-u.ac.jp.

An investigation into why the T877A androgen receptor mutant found in prostate cancer grows in the absence of androgens. *B. Gottlieb[1,3,5], J. Southwell[1], S. Chowdhury[2], L.K. Beitel[1,3,4], R. Lombroso[1], E. Purisima[2], M. Trifiro[1,3,4]*
1) Dept Cell Genetics, Lady Davis Inst Medical Res, Montreal, PQ, Canada; 2) Biotechnology Research Institute, National Research Council of Canada,Montreal, PQ, Canada; 3) Dept of Genetics, McGill University, Montreal, Canada; 4) Dept of Medicine, McGill University, Montreal, Canada; 5) Dept of Biology, John Abbott College, Montreal, PQ, Canada.

Prostate cancer (PCa) may progress by circumventing ablation therapy due to mutations in the androgen receptor (AR) gene. The most intensively studied is the mutation T877A in the ligand binding domain (LBD) which causes the AR to become promiscuous, i.e., respond to a number of different ligands. The T877A mutation alters; the inverse relationship between the N-terminal CAG repeat length, and transactivation; increases N/C terminal interactions; and decreases binding of TIF2, a coactivator that plays a critical role in N/C terminal interactions. We have used a molecular dynamic (MD) modeling approach involving the AR and TIF2 to investigate how altered N/C terminal interactions might affect the binding of different ligands. We compared the MD structures of the wild type (wt) and T877A AR bound to dihydrotestosterone. In T877A this revealed an increase in flexibility of amino acid residues in the ligand-binding domain (LBD), as well as a larger solvent accessible surface in the LBD compared to the wt. Thus, the improved induced fit of the N-terminal domain FXXLF containing peptide into the LBD, that would explain its promiscuity, could be due to the increased flexibility and solvent accessibility of the residues present in the C-terminal peptide-binding pocket of the mutant LBD. These new observations clearly help explain T877As promiscuity and further our understanding of hormone-refractory PCa.lp.

Patterns of genetic variation in miRNA genomic regions: haplotype block structure and its application to association studies. *Y. Espinosa-Parrilla[1], M. Muiños-Gimeno[1], M. Montfort[1], M. Bayés[1], X. Estivill[1, 2]* 1) Genes and Disease Program, CeGen and CIBERESP (CRG-UPF), Barcelona; 2) Pompeu Fabra University, Barcelona, Catalonia, Spain.

MicroRNAs (miRNAs) have a crucial role as posttranscriptional regulators of genes, being involved in the regulation of at least a third of mammalian genes. Allelic variants involving miRNAs or their regulator machinery may be an important source of genetic variation and contribute to complex disease susceptibility. Association studies using single SNPs in miRNA genomic regions might help to evaluate miRNA allele variants with respect to disease. We constructed a panel of SNPs covering miRNA regions and studied their pattern of variation in the population. We first analyzed the genomic organization of miRNAs and have defined 164 regions spanning 2 Mb of genomic DNA and containing 326 known human miRNAs (MiRBase, 7.1), including the precursor sequence as well as at least 5 kb upstream and downstream of the miRNA. Forty-nine clusters containing 192 miRNAs were defined at a 2-kb inter-miRNA distance with two large clusters in chromosome 14 and 19, containing 23 and 44 miRNAs, respectively. Considering the SNP coverage of HapMap data (Rel 19/phase II), the SNP density of miRNA regions was considerably lower than in the average of the genome, with only 8 SNPs in miRNA precursor sequences (0.3 SNPs/kb). For an optimal selection of informative SNPs, we combined tagSNP and random SNP selection methods to design a panel of 768 SNPs. Only 18 out of the 768 SNPs were located in premiRNAs sequences (8 SNPs from HapMap and 10 from dbSNP). Genotyping in 340 Spanish unrelated individuals was performed using a custom Golden Gate assay from Illumina. Half of the SNPs located in the premiRNAs were monomorphic in the studied population, which is suggestive of strong selective constraint on miRNAs. Similar allele frequencies and LD patterns between the Spanish population and the HapMap CEU sample was shown confirming the applicability of our SNP panel to the study of the association of miRNAs in complex disorders and common traits. Supported by Spanish Government (FI05/00061, R&C program) and Generalitat de Catalunya.

Coding sequence mutations of the GFAP gene, and variants of flanking regulatory regions, in Alexander disease patients. *I. Ceccherini[1], T. Bachetti[1], F. Caroli[1], R. Biancheri[2], D. Pareyson[3], R. Fancellu[3], L. Farina[3], G. Uziel[3], M. Savoiardo[3], M. Filocamo[2]* 1) Lab Molecular Genetics, G. Gaslini Inst, Genoa, Italy; 2) DPPM Lab & Dept Neurosciences, G. Gaslini Inst, Genoa, Italy; 3) Neurological Inst C. Besta Foundation, Milan, Italy.

Alexander disease is a progressive devastating leukoencephalopathy characterized by presence of Rosenthal fibers, which contain glial fibrillary acidic protein (*GFAP*), *a*B-crystallin and heat shock protein 27. Infantile, juvenile and adult forms of the disease, showing a progressively decreasing severity of the disease and more restricted MRI and pathologic abnormalities, are all associated with heterozygous mutations of the *GFAP* gene. It has been shown that *GFAP* overexpression may lead to intracellular inclusions, resembling Rosenthal fibers, and interfere with the proteasome-mediated degradation, thus suggesting that GFAP accumulation plays a crucial role in Alexander disease pathogenesis. We analyzed a panel of individuals, recruited according to MRI and clinical findings consistent with Alexander disease, for the 9 GFAP coding exons, finding a total of 22 mutations, either already reported in the literature or detected in our laboratory for the first time, in 21 unrelated patients half of whom affected by the adult form of the disease. In addition, we found a synonymous SNP allele (p.P47P) in 5 of these patients (11%), a proportion much higher than that reported in the general population (2.6%), likely reflecting a functional association with the disease development. To enlarge the mutational spectrum of *GFAP* in Alexander disease, we are focusing our investigations on a few individuals with suggestive phenotypes, mostly affected by adult and juvenile forms of the disease but carrying no *GFAP* mutations. In particular, both the 5 regulatory and the 3 untranslated regions are being sequenced to identify nucleotide variations that could enhance *GFAP* expression by interfering with either transcriptional regulatory pathways or *GFAP* messenger stability. Results obtained so far have only demonstrated heterozygosity for SNPs located upstream of the *GFAP* transcription start site (-986T>C, -1312T>C, -504T>A and -1926G>A).

Population genomics of human gene expression. *E.T. Dermitzakis[1], B.E. Stranger[1], A. Nica[1], M.S. Forrest[1], A. Dimas[1], C.P. Bird[1], C. Beazley[1], C. Ingle[1], M. Dunning[2], P. Flicek[3], D. Koller[4], S. Montogomery[1], S. Tavare[2], M.E. Hurles[1], P. Deloukas[1]* 1) Department of Informatics, Wellcome Trust Sanger Institute, Cambridge, United Kingdom; 2) Department of Oncology, University of Cambridge, Cancer Research UK Cambridge Research Institute, Li Ka Shing Centre, Robinson Way, Cambridge CB2 0RE, UK; 3) European Bioinformatics Institute, Hinxton UK; 4) Computer Science Department, Stanford University, Stanford, CA 94305-9010, USA.

Genetic variation influences gene expression, and this can be efficiently mapped to specific genomic regions and variants (e.g. Stranger et al. Science 2007, 315: 848-853). We used gene expression profiling of lymphoblastoid cell lines of all 270 individuals of the HapMap to elucidate the features of genetic variation underlying gene expression variation. A detailed association analysis of over 2.2 million common SNPs per population (5% frequency HapMap) with gene expression identified at least 1348 genes with association signals in cis (FDR=5%)and at least 180 in trans (FDR= 30%). Replication in at least one independent population was achieved for 37% of cis- signals and 15% of trans- signals, respectively. Our results strongly support an abundance of cis-regulatory variation in the human genome. Detection of trans- effects is limited but suggests that cis- regulatory variation may be the key primary effect contributing to phenotypic variation in humans. We have expanded our previous analysis of effects of copy number variation (CNV) on gene expression looking for longer distance cis and trans effects. Trans effects of CNVs on gene expression come in two flavours: i) those where the CNV DNA is trans to the insertion point (e.g. duplicative transposition) but the effect on gene expression occurs in cis; ii) those where the insertion point is local to the CNV DNA (tandem duplication) but there is a trans effect on expression through a biological pathway. We will present new results on cis and trans CNV associations and data to distinguish the two trans scenarios. Finally, we explore a variety of statistical methodologies that provide new insights into gene expression genetics.

A genome-wide association study of Kawasaki disease identifies multiple new loci validated in a family based follow-up study. *D. Burgner[1], S. Davila[2], T.W. Kuijpers[3], S.B. Ng[2], W.B. Breunis[3], M. Levin[4], J.C. Burns[5], V.J. Wright[4], M.L. Hibberd[2], US KD Genetics Consortium* 1) Sch Pediatrics, Univ Western Australia, Perth, Australia; 2) Genome Institute of Singapore; 3) Emma Children's Hospital,Netherlands; 4) Paediatrics,Imperial College London; 5) Pediatrics,UCSD,La Jolla,CA.

Background: Kawasaki disease (KD) is a common pediatric vasculitis that damages the coronary arteries in 25% of untreated and 5% of treated children. Epidemiologic data suggest that KD is probably caused by unidentified infection(s) in genetically susceptible children. We undertook a genome-wide association (GWA) study to identify novel genetic determinants. **Methods:** In a staged study design, 119 Dutch Caucasian KD cases and 136 matched controls where genotyped using the Affymetrix 250K NSP chip. SNPs that deviated significantly from HWE, had significant Mendelian errors or failed genotyping QC were excluded. Nominally associated SNPs were ranked by significance and 1,176 top variants were genotyped in 1,903 members of 583 KD families from Australia, UK and US, including 498 trios, by a custom Illumina Oligo Pool Assay. Analysis of the 1,087 SNPs successfully genotyped was performed with Illumina BeadStudio software. Associated genes were investigated for putative biological relationships by gene ontology using PANTHER. **Results:** At replication, 61 SNPs remained significant, of which 31 lie in or within 50 kb of 29 known genes. These include an intronic SNP in an expressed gene (P= 2x10-4) and 2 SNPs within introns of a known transcription factor (P= 1.6 and 2.3x10-3). Systems analysis identified function for 26 of 29 genes and clustered 4 of them to calcium-mediated signaling (Pc = 0.005). **Discussion** This is largest GWA study of any paediatric inflammatory disease. Our initial power and genome coverage were modest, but we used a large replication sample to minimize type I errors. We describe several novel biologically plausible variants in KD in gene regions that are currently being fine-mapped. Functional KD-associated variants may lead to novel interventions and may highlight common pathways in adult cardiovascular disease.

Molecular Characteristics of X-linked retinoschisis(XLRS) in Koreans. *S.Y. Kim[1], H.S. Ko[1], Y.S. Yu[2], J.M. Hwang[3], J.Y. Kim[1], M.W. Seong[1], S.S. Park[1]* 1) Department of Laboratory Medicine, Seoul National University Hospital and Seoul National University Hospital Clinical Research Institute, Seoul, Korea; 2) Department of Ophthalmology, Seoul National University Hospital, Seoul, Korea; 3) Department of Ophthalmology, Seoul National University Bundang Hospital, Sungnam, Korea.

X-linked retinoschisis(XLRS) is one of the most common causes of juvenile macular degeneration in young males. It is characterized by a mild to severe decrease in visual acuity, foveal schisis due to splitting of the retinal layers, progressive macular atrophy, and reduction in the ERG b-wave. The gene RS1 has been identified as a cause of XLRS. We investigated mutation spectrum of the RS1 gene in Korean patients diagnosed with XLRS. A Total of 13 unrelated probands were included in this study with their available family members. All six exons of the RS1 gene were amplified by polymerase chain reaction and directly sequenced. We identified 13 genetic variations. Nine missense mutations and one intronic polymorphism have previously been reported: c.214G>A(Glu72Lys), c.305G>A(Arg102Gln), c.426T>G(Cys142Trp), c.544C>T(Arg182Cys), c.589C>T(Arg197Cys), c.590G>A(Arg197His), c.625C>T(Arg209Cys), c.638G>A(Arg213Gln), c.647T>C(Leu216Pro) and c.184+35T>C. Three sequence variations were novel: One missense mutation(c.227T>G, Val76Gly) and two splice-site variations(c.78+1G>T and c.78+5G>A). Ten patients had one or more mutations. No sequence variation in RS1 was detected in three patients. All the missense mutations were located within the discoidin domain of retinoschisin protein. The clinical diagnosis of XLRS can be challenging. Therefore, population genetic studies of XLRS and identification of the causative mutations in the RS1 gene will be helpful for confirmation of the diagnosis and in genetic counseling.

Analysis of promoter methylation for 15 genes in different types of leukemias. *K. Bodoor, A. Alkhateeb, Y. Haddad*
Biology Department, Jordan Univeristy of Science and Technology, Irbid 22110, Jordan.

Leukemia is classified according to the differentiation stage of blood precursor cells into acute lymphoid (ALL), acute myloid (AML), chronic lymphoid (CLL) and chronic myeloid (CML). Epigenetic modifications including DNA hypermethylation of tumor suppressor genes and global genomic hypomethylation is thought to play a major role in carcinogenesis. A growing number of genes are being identified to be inactivated through aberrant methylation in different types of cancers including leukemia. Identification of these genes and studying their methylation profile will shed light on the biology of leukemia and might offer novel therapeutic opportunities. In this study we investigate the methylation status of 15 cancer-related genes in patients of different leukemia types. After obtaining confirmed consent, 71 leukemia patients were recruited. Patients were classified as 15 ALL, 12 AML, 23 CLL, 12 CML and 9 with unclassified type. Genomic DNA is extracted from blood samples and target genes are analyzed using methylation-specific polymerase chain reaction (MS-PCR) technique. MS-PCR entails initial modification of genomic DNA by treatment with sodium bisulfite which chemically converts cytosine residues into uracil and leaves methylated cytosines unchanged and thus provides a means of differentiation between methylated and unmethylated DNA. Results are visualized by gel electrophoresis using ethidium bromide or by realtime PCR using SYBR green. The genes investigated are ATF2, DAPK, ECad, GSTP1, hMLH1, MGMT, p14, p15, p16, RAF1, RASSF1A, RAR2, THBS1, TIMP3, TMS1. These genes play a role in different cellular processes like apoptosis, cell cycle regulation, and DNA repair and have been shown to be differentially methylated in leukemias and/or other malignancies. Preliminary data for the genes p14, p15, p16, and RASSF1A showed aberrant methylation of these genes with different types of leukemia. A comprehensive methylation pattern for the 15 genes in these 71 patients would be correlated with variables such us leukemia types, sex, and drug treatment in order to develop methylation criteria for differentiating and monitoring leukemia types.

A Genome-wide methylation study in Epstein-Barr Virus Oncoprotein Latent Membrane Protein 1 Transfected Lymphoma Cells. *Y.F. Chen[1], W.C. Hsiao[2], C.L. Tung[2], I.J. Su[3], H.S. Sun[1, 2]* 1) Institute of Basic Medical Sciences, National Cheng Kung University Medical College, Tainan, Taiwan; 2) Institute of Molecular Medicine, College of Medicine, National Chung Kung University, Tainan, Taiwan; 3) Division of Clinical Research, National Health Research Institutes, Tainan, Taiwan.

Epigenetic mechanisms, which involve DNA and histone modifications, result in the heritable silencing or activation of genes without a change in their DNA sequences. Recent studies have revealed the changes in DNA methylation that include influence genome integrity, hypermethylations of tumor suppressor genes and/or hypomethylation of oncogenes may lead to tumor development. Epstein-Barr virus (EBV) is a herpesvirus that infects more than 90% of the human population and mainly through the infections of B-lymphocytes and epithelial cells. Although EBV was associated with many human malignancies including nasopharyngeal carcinoma (NPC), Burkitts lymphoma and T cell lymphoma, the underlying mechanism of EBV-associated tumorigenesis remains unclear. It was reported that EBV-encoded latent membrane protein (LMP1) can affect DNA methyltransferases 1 expression and alter mRNA level of few specific genes in LMP1-overexpressed NPC cells. These results may partially explain the EBV effect in tumor development. To examine whether similar effect exists in LMP1-overexpressed lymphoma cells, this study investigates the whole genome methylation profile in LMP1-transfected BAJB and H9 cells. The global DNA methylation degree, methyl-cytosine level and expression of different DNA methyltransferases were determined in LMP1-expressing BAJB and H9 cells. Furthermore, we have established a database of genome-wide NotI-tagging sites to document the whole genome methylation profile based on differentially methylated CpG island sequences. Our current data showed the global methylation patterns, unlike the epithelial cell model, is not significantly changed in LMP1-overexpressed lymphoma cells.

Molecular analysis of additional partner chromosome-*BCR* junctions of complex *BCR-ABL1* rearrangements.

S.M. Benjes[1], *C.M. Morris*[1, 2] 1) Cancer Genetics Research Group, University of Otago at Christchurch, Christchurch, New Zealand; 2) Cytogenetics Unit, Canterbury Health Laboratories, Christchurch, New Zealand.

It is well established that in chronic myeloid leukaemia (CML) recombination occurring between the *BCR* gene on chromosome 22 and the *ABL1* gene on chromosome 9 creates a *BCR-ABL1* fusion protein responsible for the clinical phenotype. However, the molecular mechanism underlying *BCR-ABL1* recombination remains poorly understood. In about 90% of CML patients recombination results in a cytogenetically visible, simple reciprocal exchange involving the long arms of chromosome 9 and 22. In the remaining cases, recombination between *BCR* and *ABL1* can be more complex involving additional chromosomal sites that may be visible cytogenetically or cryptically concealed within a normal appearing karyotype. These complex translocations are of interest because they give the opportunity to study recombination sequences not only within the *BCR* and *ABL1* genes, but also on the other chromosome sites involved. Previously, we have isolated *BCR* gene fragments linked to other participating chromosomes from four patients with complex rearrangements and identified Alu repeat sequences as a common feature at the additional chromosome recombination sites. A combination of inverse-PCR and DNA sequence analysis has now been applied to isolate and characterise sequence features at *BCR* recombination sites in a new series of 20 CML patients having complex *BCR-ABL1* rearrangements. By this approach, *BCR* fragments linked to additional participating chromosomes have been isolated from seven further patients. Alu, L1 and other repetitive sequences were found at or within 441 bp of the additional partner chromosome breaks. Analysis of ~10 kb of DNA sequence extracted from databases and surrounding the recombination sites identified GC composition ranging from 38% to 62% and repetitive DNA content from 13% to 69%. Distribution of these elements and recombinogenic motifs identified at the additional partner recombination sites will be presented in context of current understanding of DNA alignment, disruption and end-joining processes.

The yin and yang of T2D and cancer risk: evidence of pleiotropy from genome-wide association studies. *K.S. Elliott[1], E. Zeggini[1], N.W. Rayner[1], M.N. Weedon[2], C.M. Lindgren[1], N.J. Timpson[3], T.M. Frayling[2], C.J. Groves[1], R.M. Freathy[2], J.R.B. Perry[2], H. Lango[2], B. Shields[2], A.T. Hattersley[2], M.I. McCarthy[1]* 1) Wellcome Trust Ctr Human Genetics, Oxford, UK; 2) Peninusula Med Sch, Exeter, UK; 3) Uni of Bristol, UK.

Many of the T2D-susceptibility genes identified to date (*PPARG*, *TCF7L2*, *CDKN2A*, *HHEX* and *IGF2BP2*) are also implicated in neoplasia. Furthermore, several of the genes causal for monogenic forms of diabetes also have oncogenic potential. One possibility (consistent with the opposing effects of *CDKN2A* over- and underexpression) is that at some such variants, one pro-proliferation allele predisposes to cancer, whilst the other is associated with poor cellular regeneration which reduces the complement of pancreatic beta-cells with age (predisposing to diabetes). To test this hypothesis, we used data from the Wellcome Trust Case Control Consortium genome-wide association (GWA) scan (1924 cases, 2938 controls, 393,453 SNPs) to determine whether common variants impacting on cancer risk are also associated with T2D. We found strong evidence that this was true for the prostate-cancer-susceptibility SNP, rs4242382, on 8q24. The G-allele (low risk for prostate Ca) is associated with T2D in the GWA scan (OR 1.19 [1.07-1.29], p=0.002), a finding replicated in 3,757 further cases and 5,346 controls (p=0.036) (combined data: OR=1.17 (1.08-1.42), p=0.0003). We extended these findings to other recently-published cancer associations (6 loci for breast and 4 for prostate [the latter all on 8q24] and found evidence for T2D-associations affecting the low-risk breast cancer allele of rs2107425 near *H19*, *IGF2* and *INS* (p=0.0009). More extensive examination of genome-wide data for T2D and cancer susceptibility is in progress. Since we would only expect a subset of cancer susceptibility genes to be expressed in the pancreatic islet (and therefore would not expect reciprocal risk to be a feature of all such genes), these findings are consistent with the idea that variants which influence proliferative and regenerative processes may have pleiotropic effects on cancer and diabetes.

Analysis of 16784 individuals shows that BMI-altering *FTO* genotypes are associated with obesity-related quantitative traits in the general population. *R.M. Freathy[1], N.J. Timpson[2,3], D.A. Lawlor[3], P. Elliott[4], A. Pouta[5], A. Ruokonen[5], S. Ebrahim[6], B. Shields[1], Y. Ben-Shlomo[3], L. Ferrucci[7], G. Paolisso[8], M.J. Neville[2], F. Karpe[2], C.N.A. Palmer[9], A.D. Morris[9], M.R. Jarvelin[4,5], G. Davey Smith[3], M.I. McCarthy[2], A.T. Hattersley[1], T.M. Frayling[1]* 1) Exeter,UK; 2) Oxford,UK; 3) Bristol,UK; 4) Imperial College,UK; 5) Oulu,Finland; 6) London Sch Hygiene & Trop Med,UK; 7) NIA, NIH,USA; 8) Napoli,Italy; 9) Dundee,UK.

We recently showed that common variation in the *FTO* gene alters body mass index (BMI;$P=3\times10^{-35}$) and type 2 diabetes risk (T2D;odds ratio 1.27; $P=5x10^{-8}$). Raised BMI is associated with alterations in obesity-related traits, but their relationship with *FTO* genotype is not known. We aimed to test the association between *FTO* genotype and obesity-related traits in the general population. We hypothesised that the changes in quantitative traits associated with the *FTO* risk allele would reflect the *FTO*-BMI association and the correlations between BMI and the traits. We studied the association between *FTO* genotype and obesity-related traits by analysing 16784 white Europeans. Each copy of the rs9939609 A allele was associated with a 0.09SD (95%CI 0.07-0.11) higher BMI ($P=4x10^{-16}$), as well as with higher fasting glucose (0.03SD [0.002-0.05]; P=0.04), insulin (0.04SD [0.01-0.06]; P=0.005), triglycerides (0.03SD [0.004-0.05]; P=0.02), systolic (0.02SD [-0.004-0.04]; P=0.1) and diastolic (0.02SD [-0.001-0.05]; P=0.06) blood pressure and lower fasting HDL-cholesterol (0.03SD [0.01-0.06]; P=0.01). Effect sizes were all consistent with those expected for the per-allele change in BMI. Our results suggest that common *FTO* variation is associated with altered obesity-reated traits to an extent that is entirely consistent with its effect on BMI, strengthening evidence that raised BMI is causal to these adverse outcomes. The associations observed are modest, despite the variants large impact on BMI and T2D risk and the use of >16000 subjects. This highlights the importance of large sample sizes for identifying effects of established diabetes risk alleles in the general population.

Syndromic isolated growth hormone deficiency in a patient with a splice mutation in the GHRHR gene. *L. Hilal[1], Y. Hajaji[1], M-P. Vié-Luton[2], Z. Ajaltouni[2], B. Benazzouz[1], M. Chana[3], A. Chraibi[3], A. Kadiri[3], S. Amselem[2], M-L. Sobrier[2]* 1) Neuroendocrin Genetic and Physiology, Ibn Tofail University, Kenitra, Morocco; 2) Inserm U654, Hopital A Trousseau, Paris, France; 3) Endocinology Diabetology and Nutrition, CHU Ibn Sina, Rabat, Morocco.

Isolated growth hormone deficiency (IGHD) may be of genetic origin. One of the very few genes involved in that condition encodes the growth hormone releasing hormone receptor (GHRHR), which, through its ligand (GHRH), plays a pivotal role in the regulation of GH synthesis and secretion by the pituitary. We investigated two siblings born to a consanguineous union presenting with a marked growth retardation (> 5SD) associated with anterior pituitary hypoplasia and severe GH deficiency. In addition to these classical phenotypic features for IGHD, one of the patients had a Chiari I malformation, an arachnoid cyst and a dysmorphic anterior pituitary. No abnormality was found in the GH-N gene. However, sequencing of all GHRHR coding exons and their flanking intronic regions led to the identification, in both patients, of a homozygous sequence variation located in the consensus donor splice site of intron 1 (c.57+2T>G). Using in vitro transcription assays, we showed that this mutation results in abnormal splicing of GHRHR transcripts that, if translated, would lead to the synthesis of a severely truncated protein lacking all transmembrane and intracellular domains. Such developmental abnormalities, which were not already described for this type of IGHD, point to the possible role of the GHRHR in the proper development of extrapituitary structures, through a so far unknown mechanism that could be direct or secondary to severe GH deficiency.

Powerful Bayesian gene-gene interaction analysis. *T. Ferreira[1,2], P. Donnelly[1], J. Marchini[1]* 1) Department of Statistics, University of Oxford, Oxford, United Kingdom; 2) Department of Mathematics, Faculty of Science and Technology, University of Coimbra, Coimbra, Portugal.

Most statistical methods that are used to detect associations for complex traits proceed by looking for marginal effects at each locus or set of loci in each small region and effectively ignore the possibility of interaction between genes. Our previous work has shown that when the underlying genetic model involves biologically plausible interactions between different genes this may not be the most powerful strategy.

We have developed a Bayesian method that assesses the probability that each locus acts to increase disease risk by averaging over a small set of plausible genetic models (both single and 2-locus models). Using simulated data, we show that this approach has more power to detect the disease loci involved in the disease for a large class of genetic models in which there is gene-gene interaction and has no loss of power when no gene-gene interactions exist. This approach is computationally tractable for genome-wide studies but we also show that two-stage approaches and MCMC-based approaches for our model can offer computational advantages in some situations. We illustrate the approach using the genome-wide association data from the Wellcome Trust Case-Control Consortium.

Identification of susceptibility genes for Myocardial Infarction following the combined analysis of two large genome scans in German and UK samples. *P. Deloukas on behalf of CARDIOGENICS* Human Genetics, Wellcome Trust Sanger Inst, Cambridge, United Kingdom.

CARDIOGENICS (EU F6 programme) has combined the data generated by the Wellcome Trust Case Control Consortium (WTCCC) which tested 500,000 SNPs (Affymetrix) in 2000 British Caucasian samples with coronary artery disease (CAD; BHF collection with family history; 70% MI cases)and 3000 controls (1500 each from the 1958 Birth Cohort and the UK Blood Services collection), and the German MI (GMI) study which scanned 875 MI cases with family history and 1644 controls (MONICA/KORA Augsburg survey) with the same SNP array. Analysis by the WTCCC at the level of single marker tests (469,557 pass QC) yielded six loci with significant association signals ($p < 10^{-5}$) for CAD. The strongest signal was in the CDKN2A/2B locus on 9p21.3 (p 1.79E-14 for the trend test - OR 1.47). The same locus has an independent signal in T2D (WTCCC, DGI, FUSION). SNPs with $p<10^{-3}$ for association to CAD in the WTCCC were assessed for the false positive report probability (FPRP; modification of method by Wacholder et al.) and those with FPRP <0.5 were further tested for replication in the GMI study. The CDKN2A/2B locus and two further ones on 2q36.3 and 6q25.1 replicated with nominal p values $<10^{-3}$. A combined analysis of the two scans revealed four additional loci that had not exceeded the 10^{-5} threshold in WTCCC analysis. In total, we identified 11 loci with significant evidence for association corresponding to SNPs in both intra- and intergenic regions, no evidence of a coding SNP as yet. We conducted a fine mapping experiment in three of the loci interrogating 20 (9p21.3), 31 (6q25.1) and 30 (5q21.1) tagSNP that capture all known common variants in dbSNP for the respective loci. We identified two variants with additional signal to the lead SNP rs1333049 in the UK sample. The CDKN2A/2B locus harbours a non-coding RNA transcript with expression in many tissues including heart. Combined with the single marker and haplotype analyses performed on all loci we selected a total of 40 SNPs for replication in 8000 cases and 8000 controls. Our findings will be presented at the meeting.

Exploring cryptic genomic aberrations related to multiple congenital anomaly with mental retardation using in-house CGH-arrays. *S. Hayashi[1,2], S. Honda[1,2], I. Issei[1,2], J. Inazawa[1,2]* 1) Dept Molecular Cytogenetics, Tokyo Medical & Dental Univ, Tokyo, Japan; 2) Core Research for Evolutional Science and Technology (CREST), Japan Science and Technology Agency, Saitama, Japan.

We have constructed several types of bacterial artificial chromosome (BAC)-based CGH-arrays and screened genomic aberrations in patients with multiple congenital anomalies with mental retardation (MCA/MR) including congenital disorders. Our purpose is not only to explore copy-number aberrations (CNAs) responsible for such disorders but also to establish a system for diagnosis of MCA/MR using array-CGH. For primary screening of unknown MCA/MR cases without cytogenetic abnormalities in conventional karyotyping, we used MCG Genome Disorder (GD) Array containing BAC clones covering loci associated with known genomic disorders and subtelomeric regions of all chromosomes except short arms of acrocentric chromosomes, and detected CNAs in 24 of 244 cases (9.8%). In cases without any CNAs by GD Array, we next employ MCG Whole Genome (WG) Array, which harbors 4523 BACs throughout human genome, and detected CNA in 10 of 35 cases (28.6%). In addition to this cohort, we have performed array-CGH in MCA/MR cases and other congenital disorders without known causative genes, and identified CNA in 43 of 118 cases (36.4%). In a patient with Norrie disease with atypical characteristic, for example, cryptic deletion involving genes which would explain their phenotypes was detected. In MCA/MR patient with congenital sclerocornea glaucoma and syndactyly cryptic deletion including a candidate causative gene was detected. During these analyses, we also created a database accumulating phenotypes of congenital disorders we have analyzed to identify new disease entries with common features and their correlation with specific genomic abnormalities. In conclusion, array-CGH provides a useful strategy to investigate cryptic genomic aberrations responsible for unknown MCA/MR, and/or to establish a new syndrome.

Joint Effects of Interleukin 6 Pathway Genes and the Risk of Cardiovascular Disease. *M. Alanne[1], K. Auro[1], K. Kristiansson[1], K. Silander[1], K. Kuulasmaa[1], J. Saarela[1], L. Peltonen[1,2,3], V. Salomaa[1], M. Perola[1,2]* 1) Molec Med, National Public Health Inst, Helsinki, Finland; 2) Med genet, Faculty of Med, Univ of Helsinki, Finland; 3) The Broad Institute, MIT, MA.

Interleukin 6 (IL-6) is a cytokine regulating a wide range of inflammatory responses. Our aim was to identify cardiovascular disease (CVD) risk-modifying variations and their joint effects in the IL-6 pathway in two independent case-cohort samples from prospectively followed population-based cohorts, FINRISK 92 and 97 (n=999 and 1223, respectively). We selected 33 common (>5%) SNPs in angiotensin receptor 1, angiotensin I converting enzyme, IL-6, C-reactive protein, and fibrinogen alpha (FGA), beta and gamma genes based on haplotype information and previous reports. To identify joint effects of these genes, we first analyzed them by using recursive partitioning techiniques and random sampling. All SNPs (n=15) present in >10% of the classification trees and their pairwise combinations were then analyzed with Coxs model, using false discovery rate (FDR) and replication to control for the number of tests. The results indicate that men carrying the minor alleles of both a SNP in IL-6 and in FGA gene have decreased risk of CVD compared to men that carry a minor allele of either of the SNPs: a hazard ratio 0.27 (95% CI: 0.12-0.61) was observed in the FINRISK 97 cohort, and the trend was similar in the FINRISK 92 cohort (0.52 (0.22-1.19). The association was significant after FDR when both male cohorts were combined (0.35 (0.20-0.62)) and when both sexes from both cohorts were combined (0.40 (0.25-0.63)). Meanwhile the comparison between individuals with no copies of the minor alleles and carriers of minor allele from either of the SNPs was nonsignificant. The IL-6 SNP minor allele associated risk was 0.80 (0.60-1.09) and for the FGA SNP 0.66 (0.46-0.93) in combined male cohorts. The results were nonsignificant in females. Our two-stage strategy revealed a new combination of genetic polymorphisms in a biological pathway influencing the risk of CVD consistently in two separate samples from Finland. The method can be applied to larger datasets to identify interacting SNPs in other pathways as well.

Sarcosinemia: Analysis of the *SARDH* Gene in Three Patients. *Y. Anikster[1], N. Goldstein[1], H. Reznik-Wolf[2], E. Pras[2]* 1) Metabolic Disease Unit, Safra Children's Hosp, Tel-Hashomer, Israel; 2) Danek Gartner Institute of Human Genetics, Sheba Medical Center, Tel Hashomer.

Sarcosinemia is characterized by increased levels of sarcosine in plasma and urine and is inherited in as an autosomal recessive trait. Previous reports have associated sarcosinemia with a variety of symptoms such as mental retardation,cranisinosyosis,hepatomegaly and cardiomyopathy. However the vast majority of the individuals with sarcosinemia are symptom free and therefore it is assumed that Sarcosinemia by itself is a benign condition and that the associated symptoms are due to a referral bias. Sarcosinemia was suspected to be caused by a defect in Sarcosine dehydrogenase (SARDH) activity, a liver mitochondrial matrix flavoenzyme that catalyzes the oxidative demethylation of sarcosine, however in humans this hypothesis was never proven. We have analyzed the SARDH gene in 3 sarcosinemia female patients all born to consanguineous parents. The first, a 15 years of age, was diagnosed as suffering from cardimyopathy since an early age with no signs of CHF or developmental delay. The second, 9 months old, presented with developmental delay, hypotonia, deafness and a cherry red spot.The third patient, a 2 years old girl was evaluated due to global developmental delay. Sequence of the SARDH gene in the first patient, revealed a homozygous G to T substitution at nucleotide 211 (from the ATG initiation codon) substituting Valine for Phenylalanine at codon 71. This amino acid was found conserved throughout evolution. Analysis of the patients family showed that both parents and one brother were heterozygous for the mutation, one sister (asymptomatic) was homozygous for it, while 2 additional brothers and one sister did not carry this mutation. The results were compatible with the family members sarcosine level test. No mutations were found in the second and third patients and segregation studies performed with closely linked markers ruled out the SARDH gene in one of the families, implying genetic heterogeneity. The mutation described above is the first identified in the SARDH gene and strongly suggests that this gene is implicated in the pathogenesis of this disorder.

Fine breakpoint mapping using Affymetrix Human Mapping 500K Array of two unrelated patients with rare de novo overlapping interstitial deletions of chromosome 9q. *A.S. Kulharya[1,2], D.B. Flannery[1], K. Norris[2], C.M. Lovell[1], B. Levy[3], G.V.N. Velagaleti[4]* 1) Pediatrics, Medical College of Georgia, Augusta, GA; 2) Pathology, Medical College of Georgia, Augusta, GA; 3) Pathology,Columbia University, New York, NY; 4) Pediatrics, University Texas Medical Branch, Galveston, TX.

Chromosome 9 comprises 5% of the total human genome with several clinically significant genes. Approximately, 20 cases of interstitial deletions of 9q have been reported in the literature spanning the breakpoints from 9q21 to 9q34. Unlike the 9q subtelomeric deletions, the interstitial deletions do not demonstrate a specific recognizable phenotype, although up to half of the patients had microcephaly. Lack of precise molecular delineation of the extent of deletions in the published cases makes it difficult to develop an accurate genotype phenotype correlation. We report fine mapping of breakpoints using the Affymetrix Human Mapping 500K Array Set in two unrelated female patients with an overlapping de novo deletion in 9q presented here previously (A902; 2004). SNP Oligonucleotide Microarray Analysis (SOMA) indicated these to be large deletions with patient 1 having a 9.7Mb deletion (>60 genes) spanning 9q31.3-q33.1 and patient 2 having a 6.6Mb deletion (>20 genes) localized to 9q32-q33.1. In patient 1 the proximal breakpoint appears to map to a region where the cytoskeletal protein tyrosine phosphatase gene, PTPN3 is localized and the distal breakpoint appears to interrupt the DBC1 gene. For patient 2, the proximal break maps to a region where the RGS3 gene, a regulator of G-protein signaling, is localized and the distal break appears to map to the region bordering the microcephaly gene, CDK5RAP2. FISH analysis with BAC clones containing these genes is underway. The interruption/deletion of these genes might explain some of the phenotypic features seen in these patients (particularly microcephaly) and may also provide a guideline for clinical management.

Recognition of the first causative gene for epilepsy with continuous spike-and-waves during slow-wave sleep, a late-childhood epileptic encephalopathy. *C. Godfraind[1], M. Coutelier[2], S. Andries[3], G. van Rijckevorsel[3, 4], C. Raftopoulos[4], S. Gargani[3], F. Scaravilli[5], M. Vikkula[2]* 1) Neuropathology Laboratory, Université catholique de Louvain, Brussels, Belgium; 2) Laboratory of Human Molecular Genetics, de Duve Institute, Université catholique de Louvain, Brussels, Belgium; 3) Centre William Lennox, Université catholique de Louvain, Ottignies, Belgium; 4) Cliniques universitaires St-Luc, Université catholique de Louvain, Brussels, Belgium; 5) Department of Neuropathology, Institute of Neurology, London, UK.

Point mutations in the gene neuroserpin or PI12 (protease inhibitor 12), located at 3q26, have been associated to 5 familial cases of autosomal dominant presenile dementia named Familial Encephalopathy with Neuroserpin Inclusion Bodies (FENIB: OMIM #604218). Severity of clinical course is linked to the location of point mutations. Exon 2 PI12 mutations have been associated to later clinical onset than exon 9 mutations. Clinical spectrum includes progressive cognitive decline, myoclonus, seizure, tremor, dysarthria and chorea. Neuropathology is characterized by intra-cytoplasmic neuronal inclusions of polymerized mutant protein called Collins body. These inclusions are strongly periodic acid-Schiff (PAS) positive and diastase resistant, similar to the ones observed in the liver of alpha-1-antitrypsin deficiency. We report a female patient, who at 8-years of age developed aggressive behaviour, intellectual decline and intractable epilepsy with continuous spike-and-waves during slow-wave sleep, for which she underwent neurosurgical sub-pial transections. A brain biopsy was performed and showed classical histological aspects of FENIB. PI12 sequencing revealed a novel exon 9 mutation. Paternity test was in concordance with a de novo mutation. This is the first causative gene implicated in continuous spike-and-waves during slow-wave sleep. It is the first proof of a de novo mutation in this gene and the youngest reported patient. Thus neuroserpin should be considered as candidate gene in this and other refractory epilepsies associated with cognitive impairment. catherine.godraind@anpg.ucl.ac.be.

Delivery and retention of an episomal Herpes Simplex Virus type 1 amplicon vector containing the entire *HPRT* genomic locus in embryonic stem cells. *P. Edser[1], M. Quail[2], D. Adams[2], R. Wade-Martins[1]* 1) Univ of Oxford,UK; 2) Sanger Institute,Cambridge,UK.

Regulation of gene expression is controlled by a variety of elements found within genes including promoters, introns, and cis acting sequences. Many viral vectors used for gene delivery have a limited transgene capacity and cannot deliver an entire genomic DNA locus resulting in unregulated transgene expression. Herpes simplex virus type 1 (HSV-1) amplicons are able to carry inserts of up to ~150 kb. This capacity means that 95% of human and mouse genes can be delivered using the infectious bacterial artificial chromosome (iBAC) delivery method. HSV-1 amplicons can be packaged by a helper virus-free system and infect many different cell types. Inclusion of *oriP/EBNA1* Epstein Barr virus retention elements allows the HSV-1 iBACs to remain episomal, avoiding transgene silencing or cell transformation by insertional mutagenesis. Multipotent stem cells offer the possibility of cell replacement therapy. Embryonic Stem Cells (ESCs) are pluripotent and unrestricted as to which cells they can differentiate into given the correct signals. For example, ESCs are known to differentiate efficiently into neurons following established protocols. The ability to transduce ESCs would allow gene correction prior to cell transplantation and differentiation. We have previously infected mouse ESCs with a HSV-1 iBAC amplicon with an efficiency of up to 50%. Here we have infected the hypoxanthine phosphoribosyltransferase (*HPRT*) deficient ESC line, E14tg2a, with an iBAC containing the entire *HPRT* genomic locus. We used MOIs from 2 to 20 and saw high levels of delivery. Vector transduction was confirmed using the *EGFP* reporter gene. Infected cells were selected using hygromycin for prolonged periods and individual stable clones containing the iBAC were isolated. The long term retention of the episome is being assessed. We plan to differentiate ESC containing an HSV-1 iBAC vectors into neurons to follow transgene expression and phenotype correction. Our work demonstrates for the first time the transduction of mouse ES cells with a complete BAC genomic locus via the HSV iBAC delivery system.

Genome-wide screen for sex-specific fertility genes in humans. *G. Kosova[1], T. Hyslop[2], C. Ober[3]* 1) Committee on Genetics, University of Chicago, Chicago, IL; 2) Biostatistics Section, Thomas Jefferson University, Philadelphia, PA; 3) Dept. of Human Genetics, University of Chicago, Chicago, IL.

Infertility is a major health problem, affecting 15% of couples world-wide. Previous genetic studies of infertility in humans have been largely limited to candidate gene approaches. To more broadly survey the genetics of human fertility, we have conducted genome-wide linkage and association mapping using 1500 autosomal markers (STRPs and SNPs) in the Hutterites, a founder population of European descent that proscribes contraception and has large family sizes. We considered two measures of fertility. The first (reproductive capacity) is the number of births, corrected for the years from marriage until the last birth, wifes birth year and wifes age at first birth; the second (reproductive rate) is the number of births per year of marriage, corrected for the same covariates as above. Reproductive capacity was heritable in women (H^2=0.52, s.e. 0.24) whereas reproductive rate was heritable in men (H^2=0.85; s.e. 0.23). We mapped each trait in women and men, respectively, using homozygosity-by-descent linkage and association methods (Abney et al. AJHG 2002;70:920). Genome-wide significance is assessed by a permutation test. Three linkages reached genome-wide significance in men: chromosome 4q encompassing *PCDH10*, chromosome 6p at the location of *HLA-G*, and chromosome 9p at the type I interferon cluster. Homozygosity at each locus was associated with reduced birth rate in men. In women, four associations reached genome-wide significance, including an intronic SNP in *CFI*, two intronic SNPs in *ITGAM*, and an STRP in an intergenic region on chromosome 16q. Homozygosity at each locus was associated with reduced family size in women. Further studies showed that homozygosity for the associated *ITGAM* allele is also associated with increased pregnancy loss rates (P=0.036) in Hutterite women participating in a prospective study. This is the first genome-wide study of fertility in humans, and our results suggest that there are distinct and diverse processes affecting this trait in males and females. Supported by HD21244.

Functional characterization of mutations causing disease in Familial Hypercholesterolemia. *A.C. Alves[1], S. Silva[1], M.A. Duarte[1], D. Patel[2], A.M. Medeiros[2], A.K. Soutar[2], M. Bourbon[1]* 1) UIC, INSA, Lisboa, Portugal; 2) MRC-Lipoprotein Group,CSC, London, UK.

Familial hypercholesterolaemia (FH) is an inherited disorder of cholesterol metabolism and FH patients present an increased risk of premature cardiovascular disorders. FH is caused mainly by mutations in the LDLR. Many different mutations have been identified worldwide in FH patients, but not all give rise to a defective LDLR. The Portuguese FH Study (EPHF) has identified 54 different LDLR mutations in more than 200 affected individuals. The aim of this study was the functional characterization of novel missense and putative splicing mutations in LDLR found in patients of the EPHF. Different LDLR mutants were generated by site-directed mutagenesis and expressed in CHO-ldlA7 cells lacking endogenous expression of LDLR. To determine the effects of mutations on LDLR function, saturable binding plus uptake and degradation of 125I-labelled LDL was measured at 37ºC. The putative splicing mutations were analysed by RNA extraction from patient lymphocytes and RT-PCR. Eleven novel missense mutations and 11 putative splicing mutations were found in EPHF. The functional studies for 4 missense mutations (V408L, W469R,S627P,V838M) revealed that all but V838M, are mutations causing disease showing decreased LDLR activity. It was possible to perform RNA studies for 6 putative splicing mutations c.313+6TC, c.1359-5CG c.1061-8TC and c.2140+5GA, c.2389GT (V776L) and c.1185GC (V374V). Alterations c.313+6TC, c.1359-5CG and c.2389GT showed splicing defects and c.1185GC was not found in RNA from the patient suggesting that only one allele is being expressed, but the gene defect in this patient does not seem to be a splicing mutation and needs further investigation. The remaining mutations are still under study. The simple finding of an alteration in the LDLR gene does not mean that it is the cause hypercholesterolaemia in a patient, as proven by our results. Despite the knowledge about the structure and function of the LDLR gene and protein, this is not enough to predict about pathogenicity of novel mutations, justifying the need and importance of functional characterization studies.

Fast and highly accurate haplotype inference for genome-wide datasets. *B.N. Howie, J.L. Marchini, P. Donnelly*
Department of Statistics, University of Oxford, Oxford, United Kingdom.

A number of genome-wide association studies are currently being planned or underway, and it will be essential to develop fast and accurate haplotype phasing methods if we are to realize the full potential of these massive datasets. Some existing methods can handle datasets of this size, but their speed often comes at the expense of accuracy; conversely, the most accurate methods are far too slow for genome-wide analyses. One largely untapped source of information is the population genetic variation catalogued in the HapMap: the highly accurate haplotypes and recombination rates curated there provide strong prior knowledge about the patterns of linkage disequilibrium in human populations. We have designed a novel phasing method that aggressively exploits this information to infer highly accurate haplotypes in a fraction of the time needed for other comparable methods. On multiple simulated and real datasets, our algorithm consistently generates solutions as good as or better than those provided by fastPHASE (a leading method in the field) and runs ~20 times faster. Our method can process at least 50,000 SNP genotypes per minute on a standard desktop computer, with computation scaling linearly in the number of markers and the number of individuals, and yields error rates only slightly worse than PHASE, the gold standard in the field. We have used this approach to phase 17,000 individuals at ~500,000 SNPs as part of the Wellcome Trust Case Control Consortium; this is the largest set of phased human haplotypes ever created, and we envisage that it will be an invaluable resource for population genetic studies.

Effect of lysososomal protein glucocerebrosidase on -synuclein turnover. *O. Goker-Alpan[1], D. Urban[1], B. Stubblefield[1], M. Cookson[2], B. Giasson[3], E. Sidransky[1]* 1) MGB/NHGRI, NIH, Bethesda, MD; 2) LNG/NIA/NIH, Bethesda, MD; 3) Dept. of Pharmacology, UPenn, Philadelphia, PA.

The synucleinopathies which include Parkinson disease(PD), are characterized by aberrant -synuclein fibrillization resulting in the formation of pathological inclusions. In PD, inclusions in neuronal cell bodies and processes are termed Lewy bodies(LBs) and Lewy neurites (LNs). Studies in familial PD implicate that abnormalities in protein clearance can lead to neurodegeneration. Although defects in the ubiquitin-proteosome system (UPS) may contribute to PD, alternate pathways such as lysosomal degradation are also involved in modulating -synuclein accumulation. Recent evidence indicates an association between mutations in glucocerebrosidase(GBA), the lysosomal enzyme deficient in Gaucher disease, and PD as well as dementia with LB(DLB). We explored possible mechanisms to explain why -synuclein might accumulate when GBA is mutated. To examine the effects of GBA mutations on the two pathways implicated in -synuclein metabolism, brain samples from 7 subjects with PD or DLB carrying GBA mutations were studied with immunofluorescence. Ubiquitin and lysosomal markers were used with antibodies against glucocerebrosidase and -synuclein. Although in some LBs, mutant glucocerebrosidase was present at the core, only 40-60 % of glucocerebrosidase positive LBs were ubiquinated. However, all LBs and LNs positive for both -synuclein and glucocerebrosidase displayed antigenicity to the lysosomal markers. Proteosome function was examined using the small degron CL-1, which demonstrated no influence of either wild-type or mutant GBA on the UPS. -synuclein solubility and turnover were studied in Cos-7 cell co-transfected with h-A53T -synuclein and wild-type or mutant GBA. Detergent fractionation demonstrated higher levels of soluble -synuclein in cell lines carrying wild-type GBA. In pulse-chase experiments, there was also more effective clearance of -synuclein in the presence of wild-type GBA. These data suggest that glucocerebrosidase may affect -synuclein catabolism, and when mutated, may interfere with the lysosomal clearance of -synuclein aggregates.

Enrichment and variability of PIWI-interacting RNAs (piRNAs) in segmental duplications and copy number variants (CNVs) suggest a functional role in the integrity of the genome. *L. Armengol[1], M. Caceres[1], A. Brunet[1], X. Estivill[1,2,3]* 1) Genetic Causes of Disease Group, Genes and Disease Program, and CIBERESP, Center for Genomic Regulation (CRG-UPF), Barcelona, Catalonia, Spain; 2) Genetics Unit, Department of Health and Experimental Life Sciences, Pompeu Fabra University (UPF), Barcelona, Catalonia, Spain; 3) National Genotyping Center (CeGen) Barcelona Genotyping Node, CRG, Barcelona, Catalonia, Spain.

PIWI-interacting RNAs (piRNAs) are a novel class of small (30 nt) noncoding RNAs identified in mammalian germline cells and constitute the most abundant known class of genes with over 32,000 elements in humans. We have examined piRNAs' organization in the human genome and have found that currently known human piRNAs map to 70,736 sites and are structured in about 400 clusters, containing each at least 10 piRNAs. A large proportion of the piRNA loci (about 65%) are located within repeat sequences, mainly LTRs and LINE sequences, and over 50% contain repeated units of a single piRNA, 71 being composed of tandem copies of a unique piRNAs. Surprisingly, over 25% of total piRNAs are located in regions that contain segmental duplications (SDs) and about 37% are within copy number variant (CNVs) regions. In addition, 233 (58%) and 220 (55%) piRNA clusters are within SDs and CNVs, respectively. Similarly, a significant subset of SDs (43%), especially those with the highest level of nucleotide identity, contains piRNAs. Finally, we have confirmed experimentally that the genomic sequences in which piRNAs are embedded in vary in copy number in humans. Since SDs and CNVs account for 5% and 12% of the human genome sequence, respectively, the significant enrichment of piRNAs is suggestive of a functional role of these elements. Interestingly, we have found a similar relationship for piRNAs and SDs in the mouse genome. This association provides the first link between SDs and CNVs with elements that could have a putative functional role in the integrity of the genome.
Supported by EU AnEUploidy grant and by Catalan Government.

Using LD to predict CNVs and test for disease associations. *N. Cardin[1], C. Barnes[2], V. Plagnol[3], D. Clayton[3], M. Hurles[2], P. Donnelly[1], J. Marchini[1] on behalf of the WTCCC CNV Analysis Group* 1) Dept Statistics, Univ Oxford, Oxford, United Kingdom; 2) Genome Dynamics and Evolution, The Wellcome Trust Sanger Institute, United Kingdom; 3) Diabetes and Inflammation laboratory, Cambridge Institute for Medical Research, United Kingdom.

There has been recent and growing evidence that copy number variants (CNVs) within human populations are a major source of genetic variation. An extremely important aspect of CNVs is that such variation in the genome is a strong candidate for increased risk of disease and reports of CNV associations are starting to emerge in the literature. Detection and typing of copy number variants in humans remains a difficult task and there is currently no consensus on the best analysis methods. This work is focussed on an approach which uses linkage disequilibrium to allow imputation of copy number polymorphisms by drawing on previously called variation in the International Hapmap data. We have shown that this method is highly effective at inferring bi-allelic CNVs using cross-validation to assess performance on a set of 65 bi-allelic CNVs within the Hapmap data. This is a substantial improvement in prediction over simpler approaches: the median r2 using our method was 0.81, while the median for a single-marker approach was only 0.64. The algorithm is extremely fast and this allows imputation to be performed in very large samples. We illustrate the method by applying it to predict copy number and test for CNV associations in all 7 genome-wide studies carried out as part of the Wellcome Trust Case-Control Consortium.

Noonan and Cardio-facio-cutaneous syndromes: two clinically and genetically overlapping disorders. *M.L. Bondeson[1], A.M. Nystrom[1], S. Ekvall[1], M. Olsson-Engman[2], H. Enell[3], G. Anneren[1]* 1) Dept of Genetics & Pathology, Rudbeck Laboratory, Uppsala University Children's Hospital, Uppsala, Sweden; 2) Dept of Paediatrics, Regional Hospital of Karlskrona, Sweden; 3) Dept of Paediatrics, Regional hospital of Halmstad, Sweden.

Noonan and Cardio-facio-cutaneous syndromes are clinically related disorders associated with dysregulated RAS/RAF/MEK/ERK signalling. Noonan syndrome (NS), characterized by facial dysmorphism, heart defects and short stature is associated with mutations in the genes *PTPN11*, *SOS1* and *KRAS*. The clinically overlapping Cardio-facio-cutaneous (CFC) syndrome is distinguished from NS by the presence of ectodermal abnormalities in addition to the NS phenotype. The genetic aetiology of CFC was recently assigned to four genes, *BRAF*, *KRAS*, *MEK1* and *MEK2*. Here, we present a comprehensive mutation analysis of *BRAF*, *KRAS*, *MEK1*, *MEK2* and *SOS1* in 31 unrelated patients (7 CFC and 24 NS) without mutations in *PTPN11*. Mutations were identified in 6 CFC patients (1 in *BRAF*, 1 in *KRAS*, 1 in *MEK1*, 2 in *MEK2* and 1 in *SOS1*). Three of the mutations were novel. The *SOS1* mutation, identified in a patient with the original diagnose CFC, has previously been reported in a patient with NS. We also identified *BRAF* mutations in two patients diagnosed as NS. Both of the mutations have previously been reported in patients with CFC. To our knowledge, this is the first time mutations in *BRAF* have shown to be linked to the NS pathogenesis. Taken together, our results indicate that the molecular overlap between CFC and NS is more complex than previously suggested and that the syndromes might even present as allelic disorders. To facilitate diagnosis of these patients, we therefore propose that the recently designated name Neuro-cardio-facio-cutaneous syndromes (NCFC) should be used for diagnosis of patients presenting with any of the NCFC syndromes. As the genetic defect is established, the diagnosis can be refined to, e.g., NCFC-*SOS1*-associated.

Simultaneous genotyping of 51 SNPs in 35 genes encoding molecules involved in inflammation: their role in determining Crohn disease susceptibility and phenotype. *P. Borgiani[1], S. Romano[1], C. Perricone[1], L. Biancone[2], C. Petruzziello[2], L. Steiner[3], C. Ciccacci[1], F. Pallone[2], G. Novelli[1]* 1) Dept. of Biopathology, Genetics, University Tor Vergata, Rome, Italy; 2) Gastroenterology, Policlinico Tor Vergata, Rome, Italy; 3) Roche Molecular Systems, Alameda, CA, USA.

Crohn disease (CD; OMIM #266600) is a chronic inflammatory bowel disease of unknown etiology. We cooperated with Roche Molecular System to optimize a genotyping system for the simultaneous detection of 51 SNPs in 35 genes encoding for molecules involved in inflammation. These variants were studied to investigate their influence on disease susceptibility/phenotype. We also considered CARD15 CD susceptibility SNPs (R702W, G908R, L1007fsinsC). 190 CD patients were diagnosed in accordance with international guidelines. 190 Caucasian healthy subjects served as controls. The genotyping method was based on Reverse Dot Blot technique on solid support and colorimetric revelation. We demonstrated a highly statistically significant association between CD and ICAM1, G241R ($P<0.001$) and IL10, -571 ($P<0.005$). SDF1, +800 ($P<0.03$) and IL4R, I75V ($P<0.05$) are other susceptibility variants. The associations remained unchanged when stratified for the CARD15 mutations that were found highly associated with CD susceptibility ($P<0.001$). Multivariate analysis confirmed the high contribution of ICAM1, IL10 and CARD15 L1007fsinsC SNPs. ICAM1, IL10, TCF7, LTA, SELP, ADRB2, NOS3, C3 SNPs were found to be significantly associated with different disease phenotypes in terms of site and behaviour. When stratified for age at diagnosis we found ICAM1, IL4R, ADRB2, SELE, IL1A SNPs to be associated with early disease onset (age at diagnosis<30y), while IL10 and LTA SNPs were associated with late onset (age at diagnosis>40y). The genotyping method revealed to be easy, quick, accurate and could be useful in a variety of inflammatory diseases. CD demonstrated to have a strong genetic component, especially when early onset. ICAM1, G241R and IL10, -571 were found to be major susceptibility variants in CD, together with CARD15, L1007fsinsC. Other SNPs, independently or in cooperation with CARD15, were found to be capable of modulating the disease phenotype.

Molecular karyotyping of terminal 4q deletions: first attempts towards a genotype-phenotype correlation. *A. Dufke[1], D. Wieczorek[2], G. Gillessen-Kaesbach[3], R. Voigt[3,4], B. Albrecht[2], S. Singer[1], S. Poths[1], O. Riess[1], M. Bonin[1]* 1) Institut für Humangenetik, Abteilung Medizinische Genetik, Universitätsklinikum Tübingen, Tübingen, Germany; 2) Institut für Humangenetik, Universitätsklinikum Essen, Universität Duisburg-Essen, Essen, Germany; 3) Institut für Humangenetik, Universität zu Lübeck, Lübeck, Germany; 4) Gemeinschaftspraxis für pränatale Diagnostik und Humangenetik, Hamburg, Germany.

Terminal deletions distal to 4q31 are associated with a specific phenotype including Robin sequence and pathognomonic hypoplastic terminal phalange of fifth finger with symphalangism and hooked nail. They are usually associated with a wide spectrum of less specific minor anomalies, growth retardation, congenital heart defect, and varying degree of mental retardation. Few reports described familial inheritance of microscopically visible terminal 4q deletions with mild clinical effects and normal development. We performed molecular karyotyping in four patients with terminal 4q deletions with breakpoints ranging from 4q33 to 4q35 and a wide clinical spectrum: The first female patient had a severe classical 4q- phenotype and a de novo deletion 4q33-qter. Two familial microscopically visible deletions with breakpoints in 4q34 and 4q35, respectively, were diagnosed in patients with minor anomalies and nearly normal development at least in the carrier mothers. A fourth patient with a familial deletion 4q35-qter had no apparent clinical features, but infertility. However, his father carrying the same aberration was not infertile. Using the Illumina HumanHap300-Duo Genotyping BeadChip we were able to characterize the chromosomal breakpoints and deletion sizes in all patients revealing substantial inconsistencies between the molecular and cytogenetic results in two of the four patients. We thus show that molecular karyotyping is essential for establishing a reliable genotype-phenotype correlation.

A novel retrotransposon that was recently inserted into exon 67 of the dystrophin gene. *H. Awano, M. Yagi, Y. Okizuka, Z. Zhang, Y. Takeshima, M. Matsuo* Pediatrics, Kobe University Graduate School of Medicine, Kobe, Hyogo, Japan.

Background Retrotransposons are transposable elements that can spread autonomously on the human genome. L1 and Alu elements are well-known retrotransposons in the human and have been shown to cause diseases. Here, we identified a novel retrotransposon that was inserted into the dystrophin gene of a Duchene muscular dystrophy (DMD) patient. Case The proband is a six years old Japanese boy. He had no family history of neuromuscular diseases. At three years old high CKnemia (14780IU/L) was found. At four years old muscle biopsy was performed to disclose no dystrophin staining and he was diagnosed as DMD. Results and Discussion The patient was found to carry an insertion of approximately 320bp in exon 67 of the dystrophin gene, and mRNA analysis disclosed exon 67 skipping, thereby producing out-of-frame dystrophin mRNA. The identified insertion sequence consisted of long poly T tract, 212bp unknown sequence encoding a poly adenylation signal and target site duplications (TSDs). Though these findings strongly suggested retrotransposon However, the inserted unknown sequence was found not homologous to any known retrotransposons like L1 or Alu element. Instead, homology search disclosed one perfectly homologous sequence in chromosome 11q, suggesting the origin of the insertion segment. In fact, the homologous sequence encodes a poly adenylation signal but no poly A sequence. These results suggested that mRNA transcribed from the sequence in chromosome 11q was reverse-transcribed and integrated into exon 67 of the dystrophin gene. Remarkably, his parents had no insertion mutation in exon 67 of the dystrophin gene, so the insertion event was decided to have occurred at his generation, indicating recent event of retrotransposition. Therefore, the inserted sequence was concluded as a novel retrotransposon.

A general approach to combining genomewide association datasets. *J.C. Barrett[1], S. Purcell[2], M.J. Daly[2], L.R. Cardon[1]* 1) WTCHG, Oxford University, Oxford, United Kingdom; 2) CHGR, Massachusetts General Hospital, Boston.

Genome-wide association (GWA) studies in 2007 have yielded an unprecedented number of novel genotype-phenotype associations to complex diseases such as diabetes, breast cancer, Crohns disease and heart disease. In addition to these primary discoveries, many studies are making their data publicly available for other researchers to use, allowing for at least two exciting possibilities: (1) Meta-analysis of several scans of the same phenotype with excellent power to detect modest effects missed in the individual datasets. (2) Inexpensive future GWA scans genotyping only new cases and comparing them to already genotyped control samples. The potential benefit of such approaches must be considered in light of the possible risks, however. We examine results from the control samples of the Wellcome Trust Case Control Consortium (3000 UK samples) and the controls from the NIMH Center for Collaborative Genetic Studies on Mental Disorders (1700 caucasian US samples). Initial analysis reveals that, despite having broadly similar ethnic ancestry, these samples cannot be naively merged: the two groups have a genomewide inflation of differences in allele frequencies (=1.5) and hundreds of loci show dramatic frequency shifts (individual p values 10^{-6}). We present analyses to address these issues and unlock the full potential of these datasets. First we discuss the necessity to update the standard for distribution of genotype data to include detailed strand and allele information as well as raw intensity (pre genotype calling) data. Next we present a series of genotype quality control and matching techniques to detect and remove the large number of spurious associations. Finally, we use multidimensional scaling and identity by state (IBS) clustering to correct the genomewide inflation (likely due to a blend of population structure and technical artifacts). We also evaluate the effect on 'replication' vis a vis meta-analysis of shared samples. We believe this approach has widespread and general applicability to the problem of re-using and combining genome scans performed on different populations, in different laboratories, using different genotype calling algorithms.

A germline SDHB start codon mutation in a patient with abdominal paraganglioma and two renal cancers. *K. Heimdal[1], A. Silye[2], S. Ariansen[2], S. Raicevic[3], T. Schreiner[3], H. Scott[4], O.J. Nilsen[5], A. Schultz[5], P.A. Andresen[2]* 1) Dept Medical Genetics; 2) Lab Molecular Patology; 3) Section of Endocrinology, Dept Internal Medicine; 4) Dept Pathology; 5) Section of Urology, Dept Surgery, Rikshospitalet-Radiumhospitalet Medical Center, Oslo, Norway.

Germline mutations in the SDHB gene are associated with paragangliomas, phaeochromocytomas, renal cancers of varying histology and thyroid cancer. We report on a family with a start codon mutation SDHB c.3G>A (p.Met1Ile) heterozygote. Start codon mutations have not been reported in this gene previously.
The proband was a 25 yr old male who presented with an abdominal paraganglioma (extra-adrenal phaeochromocytoma) and two tumors in one kidney (one carcinoma not classifiable, one mixed oncocytoma/chromophobe carcinoma). Investigations revealed that the mutation was inherited from the paternal side. LOH-analyses with markers from 1p32.1-1p36.32 (including the SDHB-locus) showed that all three tumors had lost the maternal allele, retaining the mutated paternal allele. Attempts to perform mutation analyses in tumor DNA have been unsuccessful so far due to inability to amplify a PCR-product. LOH-analyses with markers on 3p (covering the VHL locus) showed LOH in one out of two blocks from the renal carcinoma NOS and retention of heterozygosity in the other two tumors.
A renal tumour removed recently from a younger brother (age 23) is undergoing molecular investigations.
Another brother and the father have increased/borderline catecholamines but no detectable paragangliomas at ages 28/52.
Conclusions: Our data support the notion that the start codon mutation is pathogenic and that loss of SDHB gene function is important in the tumorogenesis in hereditary paraganglioma type IV. Somatic loss of VHL does not seem to be critical to the development of these tumors. Predisposition to renal cancer may be strong in some SDHB-families.

Associations of HNF4 Variants with Type 2 Diabetes in Hong Kong Chinese. *J. Ho[1], S. Germer[2], M. Ng[1], R. Ma[1], W. So[1], M. Martin[2], J. Chan[1]* 1) Department of Medicine & Therapeutics, The Chinese University of Hong Kong, Shatin, Hong Kong; 2) Human Genetics Department, Roche Molecular Systems, Alameda, CA 94501, USA.

Hepatic nuclear factor 4 (HNF4) is a transcription factor that regulates both lipid and glucose metabolism. Mutations in this gene are partly responsible for maturity-onset diabetes of the young (MODY). In addition, populations of European and Asian ancestries demonstrated association of common polymorphisms at the P2 promoter region of *HNF4* with type 2 diabetes (T2D). In this study, we aimed to investigate the association of common variants at *HNF4* with T2D in Hong Kong Chinese.

We selected 19 tag SNPs (single nucleotide polymorphism) from HapMap CHB data that span the exons, introns and two promoter regions of *HNF4*. Using the allelic specific *Tm shift* assay, we genotyped 487 young-onset T2D diabetic patients and 294 healthy controls from Hong Kong.

We found that three common SNPs (rs4812828, rs1884614 and rs2144908) were significantly associated with T2D in our Chinese samples (*P* 0.05). These associated SNPs are located within a single linkage disequilibrium block (D 0.97, r^2 0.69) at the P2 promoter region that is specific to pancreatic cells. Rs4812828 showed the strongest allelic association with the C allele conferring increased risk for T2D (odds ratio [OR] = 1.3, 95% CI 1.09-1.60, *P* = 0.006), in addition to T allele of rs1884614 (OR = 1.3, 95% CI 1.05-1.60, *P* = 0.014) and A allele of rs2144908 (OR = 1.29, 95% CI 1.05-1.60, *P* = 0.017). Haplotype analysis did not reveal stronger associations than single marker associations.

In summary, we found that common polymorphisms at P2 promoter region of *HNF4* were associated with type 2 diabetes in Hong Kong Chinese. The risk alleles at rs1884614 and rs2144908 in our study replicated findings from other populations including Danish, Finnish, Ashkenazi Jewish and Japanese.

A common copy number variant (CNV) associated with psoriasis. *R. Cid[1], L. Armengol[1], E. Ballana[1], M. Garcia[1], R. Pujol[2], X. Estivill[1,3]* 1) Genes and Disease Program, CeGen and CIBERESP, Center for Genomic Regulation (CRG-UPF), Barcelona, Catalonia, Spain; 2) Dermatology Service, IMIM-Hospital del Mar, Barcelona, Catalonia, Spain; 3) Pompeu Fabra University, Barcelona, Catalonia, Spain.

Psoriasis is a chronic skin disorder characterized by the presence of immune, red, scaly and patch skin lesions. Psoriasis affects most ethnic groups with the highest prevalence (3%) in northern European populations. The biology of psoriasis is poorly understood, and it is characterized by recruitment of inflammatory cells to the skin and hyperproliferation of keratinocytes. Nowadays psoriasis is regarded as a systemic immune-mediated, genetic disease of unknown cause. It is believed that psoriasis is the result of genetic predisposition and environmental factors, which involve skin lesions, infections, stress or medications. Despite the strong genetic basis for psoriasis, the genes responsible for the disorder have not yet been fully identified. We present here evidences of copy number variation (CNV) for a gene expressed in the epidermis in a significant subset of patients with psoriasis. Through comparative genome hybridization and pooling DNA of psoriatic patient samples we have identified that several chromosome regions contain consecutive sequences that vary in signal intensity. One such region spans a gene specifically expressed in the skin and is present in a lower copy number in patients than controls. The link between this region and psoriasis was further confirmed by single nucleotide polymorphisms (SNPs) tagging this region and the gene that it contains. Analysis of gene dosage in a larger number of subjects with psoriasis confirmed that a large proportion of psoriatic patients carry lower copy numbers of this gene. This CNV, which also shows ethnic differences in allele distribution, and the variations it contains, could be used to evaluate genetic predisposition to psoriasis and could be a target for pharmacological and biological treatment and prevention of psoriasis. Supported by Catalan Government (Generalitat de Catalunya).

The Pharmacological Chaperone AT1001 Reduces Globotriaosylceramide Substrate Levels in Fabry Transgenic Mice and Increases -Galactosidase A levels *in vitro, in vivo* and in Healthy Volunteers. *R. Khanna, E.R. Benjamin, R. Soska, H.H. Chang, A. Schilling, Y. Lun, S.A. Sitaraman, D.J. Palling, D.J. Lockhart, andK.J. Valenzano* Amicus Therapeutics, 6 Cedar Brook Drive, Cranbury, NJ 08512.

Fabry disease is an X-linked lysosomal storage disorder caused by inherited mutations in -galactosidase A (GLA). Mutations in GLA lead to reduced catabolism and consequent lysosomal accumulation of the natural substrate, globotriaosylceramide (GL-3), which contributes to disease pathology. It has been shown that the pharmacological chaperone, AT1001 (migalastat hydrochloride), can increase mutant GLA (R301Q) levels both *in vitro* and *in vivo*. In the current study, the effect of AT1001 on GL-3 levels was tested using GLA deficient mice that express the mutant R301Q human transgene (R301Q GLA Tg/KO). Daily oral administration of increasing doses of AT1001 (10, 30, 100 and 300 mg/kg) to R301Q GLA Tg/KO mice for 2 or 4 weeks resulted in a dose-dependent and significant increase in GLA levels in disease-relevant tissues (skin, heart and kidney). Importantly, tissue GL-3 levels were significantly reduced in all three organs after 4 weeks of treatment. The ability of AT1001 to affect other mutated forms of GLA was also evaluated in lymphoid cell lines derived from male Fabry patients (missense mutations leading to both classic and variant phenotypes). A majority of the tested cell lines showed a response (1.5- to 20-fold increase in GLA levels; EC50 values from 600 nM to greater than 1 mM). In a Phase 1 clinical study in healthy male volunteers, AT1001 was generally well-tolerated at all doses with no serious adverse events. Oral administration of AT1001 at 50 or 150 mg twice daily for 7 days resulted in a dose-related increase in GLA levels in white blood cells that persisted for 7 days after drug withdrawal. Collectively, these data indicate that AT1001 merits further evaluation as a treatment for patients with Fabry disease.

Evolutionary conservation of a coding function for D4Z4, the tandem DNA repeat mutated in facioscapulohumeral muscular dystrophy. *J.E. Hewitt[1], J. Clapp[1], L.M. Mitchell[1], D.J. Bolland[2], J. Fantes[3], A.E. Corcoran[2], P.J. Scotting[1], J.A.L. Armour[1]* 1) Institute of Genetics, Queens Medical Centre, Univ Nottingham, Nottingham, UK; 2) Laboratory of Chromatin & Gene Expression, Babraham Institute, Cambridge, CB2 4AT, UK; 3) MRC Human Genetics Unit, Western General Hospital, Edinburgh, EH4 2XU, UK.

The autosomal dominant neuromuscular disorder facioscapulohumeral muscular dystrophy (FSHD) is caused by an unusual type of mutation; deletions within the polymorphic DNA tandem array D4Z4. Each 3.3kb D4Z4 repeat unit has an open reading frame (ORF), termed *DUX4*, containing two homeobox sequences. However, because the repeat appeared to be poorly conserved and there has been no evidence for a transcript from the array, D4Z4 is generally believed to have only a non-coding function. Accordingly, D4Z4 deletions are thought to cause FSHD by a chromatin position effect on the expression of genes in *cis* on chromosome 4q. We used data from whole genome sequencing projects to identify D4Z4 homologues in the genomes of rodents and Afrotheria (elephants and related species). We found conservation of both the *DUX4* ORF and the tandem array organization in these homologues. This is the first identification of D4Z4 sequences in any species other than apes. Phylogenetic analysis indicates that primate and Afrotherian D4Z4 arrays are orthologous and originated from a retrotransposed copy of an intron-containing DUX gene. RT-PCR, RNA fluorescence and tissue *in situ* hybridization data indicate transcription of the mouse Dux array. Our data strongly supports a coding function for human D4Z4 and necessitates re-examination of current models of the FSHD disease mechanism.

Characterization of chromosome aberrations in meningiomas combining standard cytogenetic and array CGH technique. *J. Han[1], K.E. Kim[1], R.Y. Goh[1], K.S. Woo[1], J.E. Sim[2], K.U. Kim[2], L.G. Shaffer[3]* 1) Department of Laboratory Medicine, Dong-A University College of Medicine, Busan, Korea; 2) Department of Neurosurgery, Dong-A University College of Medicine, Busan, Korea; 3) Health Research and Education Center, Signature Genomic Laboratories, LLC, Washington State University, Spokane, WA, USA.

Meningioma is the most frequent tumor of neuroectodermal origin in humans. It is usually benign. However, certain histological variants show more aggressive biological behavior and are clinically associated with a high risk of local recurrence and a less favorable prognosis. Cytogenetic and molecular biological studies are important to identify characteristic genetic aberrations associated with meningioma tumorigenesis and progression. We studied 40 meningioma tumor samples. On the cytogenetic level, we observed abnormal karyotypes in 30 (75.0%) patients, while two cases did not produce enough metaphases and 8 of 40 (20.0%) patients had normal karyotypes. The most common numerical alterations were loss of chromosome 22 (about 73.3% of abnormal cytogenetic cases). In 10 cases, monosomy 22 was found as a single primary abnormality and in the rest of 12 patients, it was combined with another numerical or structural chromosome abnormalities. Hyperidploidy and hypodiploidy were observed in three and one case, respectively. The remaining four abnormal cases included two balanced and two unbalanced rearrangements.A complex karyotype with more than three chromosome abnormalities was found in nine patients, eight of which contained monosomy 22. In cases with complex structural rearrangements, array CGH technique has permitted the best identification of abnormalities. At present, it is well established that meningiomas are genetically heterogeneous tumors. Our results also indicate that meningiomas show variable patterns of chromosomal instability. Conventional cytogenetic techniques may hamper the identification of all tumor cell clones present in samples due to the relatively low percentage of neoplastic metaphases. In turn, array CGH analyses can be systematically employed to reveal a combination of aberrations not seen by using one method alone.

Common Mitochondrial Haplogroups Do Not Predict Risk of Morbidity, Mortality, or Longevity in the General Population. *M. Benn[1], M. Schwartz[2], B.G. Nordestgaard[3, 4], A. Tybjærg-Hansen[1, 4]* 1) Dept. Clinical Biochemistry, Rigshospitalet, Copenhagen University Hospital; 2) Dept. Clinical Genetics, Rigshospitalet, Copenhagen. University Hospital; 3) Dept. Clinical Biochemistry, Herlev University Hospital; 4) The Copenhagen City Heart Study, Bispebjerg University Hospital.

Recently there have been numerous reports suggesting a role for mitochondrial haplogroups in the pathogenesis of common multifactorial disease and in longevity. These studies have in common that they are all case-control studies with a limited number of participants, and therefore are prone to selection bias and have limited power. In the present study, we tested the hypothesis that mitochondrial haplogroups predict risk of morbidity, mortality, and longevity in a large prospective study of a general population of European descent. We genotyped 9254 individuals from the Danish general population, The Copenhagen City Heart Study, for six polymorphisms (mt7028, mt10398, mt11719, mt12308, mt12612, mt15607) defining eight mitochondrial haplogroups, and determined the ability of these haplogroups to predict risk of morbidity, mortality, and longevity with, respectively, 25 and 11 years follow-up. Haplogroup frequencies were: H(45.9%), U(15.9%), T(9.9%), J(9.1%), K(6.2%), V(4.5%), W/I(3.8%), and Z(3.5%). Hazard ratios for hospitalization due to infectious diseases, respiratory disorders, cardiovascular disorders, malignant neoplasms, digestive disorders, musculoskeletal disorders, neuropsychiatric disorders, and miscarriages as a function of haplogroups were not significantly different from the most common haplogroup H. Multifactorially adjusted hazard ratios for death of all causes as well as for major causes of death as a function of haplogroups were also not significantly different from haplogroup H. Finally, longevity defined as percent surviving as a function of age by haplogroups did not differ when comparing each haplogroup with haplogroup H. Our results suggest that mitochondrial haplogroups are not major predictors of morbidity, mortality, or longevity in a general population of Northern European Descent.

A polymorphism of the -opioid receptor influences analgesic response in labor. *J.-L. Blouin[1], C. Kern[2], M.O. Columb[3], R.M. Smiley[4], R. Landau[2]* 1) Genetic Medicine , Univ Hosps Geneva, Geneva, Switzerland; 2) Anesthesiology, Univ Hops Geneva, Geneva, Switzerland; 3) Dept. Anesthesia, University Hospital of South Manchester Wythenshawe, UK; 4) Dept. Anesthesiology, Columbia University College of Physicians and Surgeons, New York, NY.

Opioids are increasingly used to provide analgesia to women in labor. However a substantial inter-individual variability in the analgesic response is observed and could be explained by sequence variants in the -opioid receptor gene (OPRM1). It has been shown in vitro that minor allele (G) of the non-synonymous SNP rs1799971 (c.304A/G, p.102Asn/Asp), increases the binding affinity and potency of -endorphin (3-fold). The aim was to determine whether the 304A>G variant could modify the analgesic (fentanyl) dose requirement during combined spinal-epidural analgesia in labor. Nulliparous women (n=224) were genotyped at 33 to 37 weeks gestation and clustered in 2 groups (Group A =genotype A/A, Group G =A/G, G/G). To determine the median effective dose of fentanyl (ED50), women were allocated to either up-down sequential (SA) or random dose (RA) allocation approaches. For the SA, initial dose was 18g (interval of 2g); for the RA, doses ranged 2.5-35g (log increments). ED50 was estimated with the Dixon-Massey method and probit regression for SA and probit and logistic regression for RA with $P<0.05$ as significant. Prevalence of the G allele was 33%. In the SA part, ED50 was 26.8g (95%CI, 22.7-30.9) in group A (n=26) and 17.7g (95%CI, 13.4-21.9) in group G (n=24) ($P<0.001$); the G allele increased sensitivity to fentanyl by factor of 1.51 (95% CI 1.18-2.01). In the RA part, the ED50 was 27.4g (95% CI 22.5-32.2) in group A (n=80), and 12.8g (95% CI 5.5-20.0) in group G (n=24), $P<0.002$. The G allele (RA study) increased the sensitivity to fentanyl by a factor of 2.14 (95% CI 1.30-5.17). We have demonstrated a 1.5 fold highly significant potentiation of spinal fentanyl effect by 304G allele of OPRM1 using the up-down sequential allocation method and replicated these results using random dose allocation. These findings suggest that OPRM1 polymorphism plays a significant role in inter-individual spinal opioid requirements.

Identification of an exon 15 duplication in BRCA1 in a familial ovarian cancer patient using an improved method: upQMPSF. *S. Azrak[1], R. DiCioccio[1], K. Rodabaugh[2], P. Liang[1]* 1) Dept Cancer Genetics, Roswell Park Cancer Inst, Buffalo, NY; 2) Dept Gynecologic Oncology, Roswell Park Cancer Inst, Buffalo, NY.

Genetic mutations such as SNPs and small deletions/insertions do not explain all genetic causes for cancer. Recent studies have demonstrated that other types of genetic changes are also responsible for cancer etiology. Among these are the large genomic rearrangements existing as deletions or duplications involving one or more exons of a gene. This type of aberration is believed to be more frequent than currently known due to the limited availability of superior methodologies for their detection. We have, therefore, developed an improved version of Quantitative Multiplex PCR Short fluorescent Fragment (QMPSF), called Universal Primer QMPSF (upQMPSF). The improvements include replacing the individually labeled fluorescent primers by one universal fluorescent primer and maximizing the multiplex PCR capacity to allow up to 15 products per set. For example, we covered all exons of BRCA1 using only two sets. Furthermore, the primers were designed to cover the entire exon regions, such that the method can also be used to detect small deletions and insertions in the exons. These improvements dramatically improve the cost efficiency, making it possible to use the method for the first round screening of genomic rearrangements, as well as small insertions/deletions. Using upQMPSF, we screened 88 familial ovarian cancer patient samples, which had previously tested negative for point mutation and small deletions/insertion in BRCA1, for large genomic rearrangements. We detected a novel 3 kb duplication spanning exon 15 of BRCA1, which is predicted to generate a truncated protein. The result was verified using MLPA and Mutation-specific Multiplex PCR (MM-PCR) and the breakpoints of the duplication were fully characterized at the sequencing level. Validation of several additional genomic rearrangement cases are in progress. Our results validate the utilities of upQMPSF and important contribution of genomic rearrangements to cancer susceptibility. This research is supported by grants from NCI (CA16056 and CA101515) and from Roswell Alliance Foundation and Gynecological Cancer Foundation.

Hydrolethalus syndrome: From molecular genetics to functional studies. *H. Honkala[1], J. Lahtela[1], K. Wartiovaara[2], R. Salonen[3], L. Peltonen[1,4,5], M. Kestilä[1]* 1) Department of Molecular Medicine, National Public Health Institute, Helsinki, Finland; 2) Developmental Biology, Institute of Biomedicine, University of Helsinki, Helsinki, Finland; 3) Department of Medical Genetics, Väestöliitto, Helsinki, Finland; 4) Department of Medical Genetics, University of Helsinki, Helsinki, Finland; 5) The Broad Institute, MIT, Boston, MA, USA.

Hydrolethalus syndrome (HLS) is a severe malformation syndrome of the fetal stage belonging to the Finnish disease heritage which leads to stillbirth or death shortly after birth. HLS is characterized by multiple developmental defects including CNS malformations such as hydrocephaly and absent midline structures, polydactyly and defective lobation of the lungs. The disease-causing mutation in the *HYLS1* gene in chromosome 11 is an A to G transition that causes the D211G change in the 299 amino acid polypeptide with so far unidentified function. Mutation analysis has also been performed for several foreign cases with the phenotype resembling HLS, but no mutations have been found. Although the precise function of the protein is currently unknown, the severe effects of the mutation suggest an important role of HYLS1 in fetal development.

Present studies include *in silico* expression array and pathway analyses, initial results showing downregulation of several genes involved in lipid metabolism whereas upregulation of genes related to cell cycle events in patient cells. We have studied e.g. cell cycle regulation by using cultured neuronal progenitor cells obtained from an aborted HLS fetus and from normal fetuses from the pregnancies terminated for social reasons. The results indicate an increased cell proliferation rate of the patient cells. In addition, experiments with the existing transgenic knock-in *D. melanogaster* model expressing human *HYLS1* have been started recently, the purpose being to compare both the overall morphology as well as the central nervous system of *HYLS1* wt and mutant flies using HYLS1 specific antibody. These results will give us novel information about the function of HYLS1 and about the essential molecular events during the embryonic development in general.

Comprehensive analysis of breakpoints of PARK2 rearrangements in patients with autosomal recessive juvenile parkinsonism (AR-JP) employing a high-density tiling array-based comparative genomic hybridization (array-CGH) system. *J. Mitsui[1], Y. Takahashi[1], H. Tomiyama[2], H. Yoshino[2], J. Goto[1], Y. Mizuno[2], N. Hattori[2], S. Tsuji[1]* 1) Department of Neurology, the University of Tokyo, Tokyo, Japan; 2) Departmen of Neurology, Juntendo University, Tokyo, Japan.

[INTRODUCTION] Autosomal recessive juvenile Parkinsonism (AR-JP) is one of the most common hereditary Parkinson diseases, which is caused by mutations in PARK2. Among PARK2 mutations, 50-90% of mutants have been reported to be gross deletions involving exons. Although PCR-based gene dosage analysis has been commonly employed to identify rearrangements, there are limitations in the accuracy of the quantification of the gene dosage, in the sensitivity for identification of compound heterozygous deletions and in the determination of the exact breakpoints. To overcome these limitations, we have developed a high-density tiling array-based comparative genomic hybridization (array-CGH) system focusing on PARK2. [SUBJECTS AND METHODS] 124 AR-JP patients with exon rearrangements determined by the TaqMan assay were enrolled in this study. For the array-CGH analysis, we originally designed 35,668 probes consisting of 45-60 mer oligonucleotides to cover the entire PARK2 gene with its flanking regions of 300 kb employing the Agilents platform. The average interval between the neighboring probes was 112 bp. [RESULTS] We determined exact breakpoints of 199 mutated alleles of the 124 AR-JP patients consisting of 100 deletion and 6 duplication breakpoints. 92 breakpoints were observed individually, suggesting that founder effects account for relatively limited proportions and many deletions occur independently. The 5 and 3 ends of breakpoints were clustered within intron 2 and intron 4, respectively. [DISCUSSION] With the array CGH analysis system, we were able to precisely determine the rearrangements including those in compound heterozygous states. The clustering of breakpoints clearly indicated existence of the hotspots. Interestingly, the hotspots are located in the center of the common fragile site, FRA6E, raising the possibility that the hotspots of rearrangements in PARK2 share properties as the common fragile site.

Mutation analysis of SIX3, ZIC2, SHH and TGIF in a series of holoprosencephaly patients. *J. Herbergs, A. Paulussen, S. Spierts, D. Tserpelis, H. Smeets* Dept Clinical Genetics, Academic Hosp Maastricht, Maastricht, Netherlands.

Holoprosencephaly (HPE) is a common severe malformation of the brain that involves abnormal formation and septation of the developing central nervous system. The prevalence is 1:250 during early embryogenesis, but the live born prevalence is only 1:16000. The etiology of HPE is extremely heterogeneous and can include both a teratogenic and/or genetic basis. We studied four genes known to be involved in HPE, namely SHH, ZIC2, SIX3 and TGIF by sequence and MLPA analysis. A series of in total 66 sporadic and familial HPE cases with a variable clinical spectrum has been analysed. We detected 14 pathogenic mutations (21%), 4 out of 58 sporadic cases and 7 out of 9 familial cases. One of the familial cases was caused by a mutation in parental germ cells. Seven mutations were detected in the SIX3 gene, four mutations in the ZIC2 gene and three mutations in the SHH gene. The familial mutations displayed great phenotypic heterogeneity of the disease, which makes it difficult to establish genotype-phenotype correlations. This phenotypic variability may be due both to environmental factors and to potential modifier genes. HPE development is probably a multihit process , which implicates more genes; illustrating the importance of further identification of new genes.

Crisponi Syndrome and Cold-Induced Sweating Type 1: Two Syndromes - One Genetic Entity. *L. Crisponi[1], A. Meloni[2], M. Marongiu[1], F. Chiappe[2], M. Deiana[1], L. Marcia[1], G. Zampino[3], P. Nürnberg[4], G. Crisponi[5], F. Rutsch[6]* 1) INN/CNN, Cittadella Univ di Monserrato, Monserrato (CA), Italy; 2) University of Cagliari, Italy; 3) Departments of Pediatrics, Catholic University, Rome, Italy; 4) Cologne Center for Genomics, Cologne, Germany; 5) Casa di cura Sant' Anna, Cagliari, Italy; 6) General Pediatrics, University Children's Hospital, Muenster, Germany.

Crisponi syndrome (CS) is a severe autosomal recessive condition, characterized by abnormal, paroxysmal muscular contractions, hyperthermia and sudden death in most cases. Recently we identified *CRLF1* as the gene implicated in the pathogenesis of CS. We extended our cohort of patients affected by CS and up to now we detected 1 novel mutation. *CRLF1* is also involved in the pathogenesis of cold-induced sweating syndrome-1 (CISS1). CS and CISS1 belong to a group of conditions with overlapping phenotypes, also including cold-induced sweating syndrome type 2 and Stüve-Wiedemann syndrome. Since genotype/phenotype correlations are not clear for CS and CISS1,we performed functional studies on mutated CRLF1 constructs for the mutations pW76G, pP238RfsX6 and pK368X found in Crisponi patients, and tested the patients with CS for the presence of cold-induced sweating. We mutagenized the wt CRLF1 with the 3 indicated mutations. After transfection of the constructs in COS-1 cell lines, the mutant proteins derived from the missense and nonsense mutations were expressed and secreted, whereas the mutant protein derived from the frame-shift mutation was produced, but not secreted. The patients phenotype did not differ from protein-secreters to non-secreters. All surviving patients with CS developed scoliosis and cold- induced sweating. The presence of many overlapping clinical features in adolescence, including cold-induced sweating and scoliosis and the association of the diseases with mutations in the same gene, point to the fact that CS and CISS1 are two variations of the same genetic entity. However, the severity in the clinical phenotype of CS vs CISS1 does not seem to depend on the type of mutation, and more studies are in progress to clarify this difference.

Association of Renin gene polymorphisms with Essential Hypertension in Koreans. *E. Kim[1], J. Kim[1], J. Han[2], C. Park[2], D. Shin[2], Y. Jang[2], B. Han[3], S. Yoon[1]* 1) Biomedical Sciences, The Catholic University of Korea, Seoul, Korea; 2) Cardiovascular Genome Center, Yonsei University Medical Center, Seoul, Korea; 3) Division of Genome Resources, NGRI, NIH, Seoul, Korea.

Renin (Ren) is a protease that acts in the rate limiting step of the cascade in the production of angiotensin II, a potent vasoconstrictor and stimulator of aldosterone release. Renin gene plays a crucial role in the regulation of blood pressure and has been shown to be involved in the underlying cause of essential hypertension in an ethnic group. The aim of the present study was to investigate the association between human rennin gene and EH in Koreans. None of six SNPs (rs# 2368564, 1464816, 2272237, 10900555, 11240688, and 6682082) of rennin gene were in linkage disequilibrium in Koreans. We carried out a case-control study of 644 hypertensive (EH) and 1329 ethnically- and age-matched normotensive (NT) subjects with rs2368564 and rs6682082. The distribution of genotype and allele for rs2368564 did not differ significantly between two groups, whereas the overall distribution of rs6682082 was significantly different between EH and NT, specifically in females. The frequencies of G allele as well as GG genotype were significantly higher in EH (p=0.0159 and 0.0383, respectively). Logistic regression analysis indicated that the GG homozygote was strongly associated with EH in the female subjects (OR, 1.454; 95% CI, 1.047-2.018, p = 0.0253). In our study, we suggest that rennin rs6682082 polymorphism is a positive genetic marker of predisposition for EH in Koreans.

Transcriptional regulation of 14-3-3. *A. Kasinski[1,2], H. Fu[1]* 1) Department of Pharmacology, Emory University, Atlanta, GA; 2) Graduate Program in Genetics and Molecular Biology, Emory University, Atlanta, GA.

The seven isoforms of 14-3-3 play an intricate role in the signaling events leading to cell survival, cell-cycle progression, oncogenesis, and apoptosis. The activity of many proteins involved in proliferation and apoptosis is attenuated by the binding of 14-3-3. The binding typically sequesters the client protein away from its site of activation rendering it inactive. Since 14-3-3 proteins inhibit death promoting proteins, and in contrast act to induce functions of proteins involved in growth and proliferation it is not surprising that upregulation of 14-3-3 proteins has correlated with tumor progression. The 14-3-3 isoforms exhibit a remarkable degree of amino-acid sequence conservation, between species and isoforms, however they differ substantially at the nucleotide level. Minimal work has been reported on the transcriptional regulation of the 14-3-3 genes; however, the link between increased 14-3-3 protein levels and oncogenesis has made it a compelling area. Genetic data from all isoforms has been compiled and evaluated. A more detailed analysis of zeta was performed due to its role in tumor progression. Four independent splice variants of zeta were identified, two of which are novel to this study. Their transcriptional profiles have been confirmed. Data conclusively show that the variants are regulated independent from each other and in a tissue specific fashion. Additionally, luciferase reporter assays addressed the fundamental regions within the promoter of 14-3-3 zeta that are necessary and sufficient for expression from each of the four variants. The zeta variants were also found to be regulated by a putative CpG island. Elevated protein levels of this highly conserved gene family have been implicated in tumor progression, however the cause for this elevation has been left undiscovered. Due to the high degree of functional and structural similarity of the isoforms, targeting them individually at the protein level is quite trying. Identification of mechanisms that control transcription of these genes will help to identify independent molecular targets that can be used to modulate the 14-3-3 genes in an isoform specific manner.

Genomic and genetic approaches identify IREB2 as a novel susceptibility gene for chronic obstructive pulmonary disease. *D.L. DeMeo[1,2], T. Mariani[2], C. Lange[1], S. Bhattacharya[2], S. Srisuma[2], S. Shapiro[3], R. Bueno[2], E. Silverman[1,2], J. Reilly[1]* 1) Channing Laboratory; 2) Pulmonary/Critical Care Division, Brigham and Women's Hospital,Boston,MA; 3) University of Pittsburgh School of Medicine, Pittsburgh, PA.

As a complex human lung disease, chronic obstructive pulmonary disease (COPD) is influenced by genetic and environmental factors. To date, the only proven genetic cause is a severe deficiency of alpha 1-antitrypsin. We integrated results from gene expression microarrays of lung tissue samples from 56 individuals with a broad range of pulmonary function values to select 69 genes for association studies. LD-tagging SNP panels were genotyped in 389 severe COPD cases from the National Emphysema Treatment Trial (NETT) and 424 smoking controls with normal spirometry from the Normative Aging Study (NAS). After a case/control analysis of 1052 SNPs, 88 SNPs in 16 genes demonstrated nominal significance (p=1x10-5 to 0.05). These 88 SNPs were evaluated for associations with spirometric phenotypes in a family-based study of 127 probands with severe, early-onset COPD and 822 of their family members in the Boston Early-Onset COPD Study. Forced expiratory volume in the first second (FEV1), an important quantitative spirometric phenotype for COPD severity, was the primary phenotype in the family-based association analysis. We used Fishers exact method for combining p values from the case/control analysis of COPD susceptibility and the family-based analysis of FEV1, setting p=5 x 10-5 as the threshold for significance for the combined p value after Bonferroni correction. Three SNPs in iron regulatory protein 2 (IREB2) met this stringent threshold for significance, with 4 other SNPs in IREB2 demonstrating combined p values < 0.01. IREB2 controls iron metabolism in vivo, with murine data suggesting that iron regulatory protein family genes are modulated by tissue oxygen tension. Hypoxemia is a common feature in individuals with COPD, suggesting that polymorphic variation in a key iron metabolism gene may contribute to phenotypic features of COPD. Support:NIH K08 HL072918,HL71885,HL72303,P01 HL083069.

Genome-wide scan in affected sibling pairs identifies two novel susceptibility regions for venous thrombosis.

M.C.H. de Visser[1], R. van Minkelen[1], V. van Marion[1], J.C.J. Eikenboom[1], H.L. Vos[1], P.E. Slagboom[2], J.J. Houwing-Duistermaat[3], R.M. Bertina[1] 1) Dept of Thrombosis and Haemostasis; 2) Dept of Molecular Epidemiology; 3) Dept of Medical Statistics and Bioinformatics, Leiden University Medical Center, Leiden, The Netherlands.

Venous thromboembolism (VTE) is a common disorder with an annual incidence of 1-3 per 1000 individuals. Both environmental and genetic risk factors are involved in the development of the disease (reported heritability about 50 to 60%). At present, few genetic risk factors are known (e.g., Factor V Leiden [FVL]). However, in most thrombophilic families these currently known genetic risk factors can not explain the familial clustering of thromboses, indicating that genetic risk factors are missing. The Genetics In Familial Thrombosis (GIFT) study aims at identifying novel thrombosis susceptibility alleles using an affected sibling pair approach. Via Dutch anticoagulation clinics 224 sibships with VTE at a young age (45 years) were recruited. Sibship size ranged from 2 to 4 affected siblings and in total 306 affected sibpairs were included. All affected sibs were typed for the 402 microsatellites of the ABI Prism linkage mapping set MD10 and for 5 SNPs (FVL, prothrombin 20210A and 3 ABO blood group SNPs). Multipoint linkage analysis (using the NPL S-all statistic) was performed with Merlin for the autosomes and with MINX for the X chromosome. The study population was enriched for the genetic risk factors FVL (35% in GIFT index patients vs. 20% in consecutive thrombosis patients) and ABO blood group non-O (83% vs. 57%), but not for prothrombin 20210A (6.7 % vs. 6.2%). Interestingly, linkage analyses did not show evidence for linkage at the FVL and ABO blood group loci. Because of suggestive linkage results at chromosome regions 7p and Xq these regions were followed up with extra markers, that were also typed in 375 parents and/or unaffected sibs to improve the information content. The linkage results support the presence of novel thrombosis susceptibility loci on 7p (maximum LOD score = 2.6, genome-wide p=0.0003) and on Xq (LOD score = 2.1, p=0.0009). This study was supported by grants NHS 2005T055 and NWO 912-02-036.

Treating symptomatic spinal cord compression with intratechal enzyme therapy in three Brazilian patients with MPS: What has happened so far. *R. Giugliani[1], D. Horovitz[2], L. Jardim[1], R. Costa[3], S. Fagondes[3], T. Vieira[1], A.B. John[3], L. Vedolin[4], J. Llerena[2], M.V.R. Munoz[1]* 1) Medical Genetics Serv, Hosp Clinicas Porto Alegre, Porto Alegre, RS, Brazil; 2) Instituto Fernandes Figueira, FIOCRUZ, Rio de Janeiro, RJ, Brazil; 3) Pulmonary Diseases Service, Hospital de Clínicas, Porto Alegre, RS, Brazil;; 4) Neuroradiology Department, Hospital Mãe de Deus, Porto Alegre, RS, Brazil.

BACKGROUND: In MPS, deficiency of specific enzymes can cause spinal cord compression due to storage of glycosaminoglycans within the cervical meninges. In 2005, we used intrathecal infusions of recombinant human -L-iduronidase to treat a MPS I adult patient with spinal cord compression (P1) and recently we conducted the use of IT-ERT in pediatric patients with MPS I (P2) and MPS VI (P3). To our knowledge, these were the first MPS I adult, the first MPS I child and the first MPS VI patient who received IT-ERT. METHODS: The patients underwent a series of 4 monthly courses of IT-ERT (specific enzyme dilluted on Elliotts B solution). Patient P1 performed follow-up evaluations at 12 and 18 months post-IT ERT, including 12 MWT, pulmonary function exams, imaging studies and complete neurological examination. P2 and P3 performed the same evaluations as P1 on baseline and on the immediate follow- up, but were not able to perform reliable pulmonary function tests nor 12 MWT. Pre-infusion CSF pH of P2 and P3 were measured. RESULTS: Neurological symptoms improved on all cases. On patient P1, after an initial improvement, it was noticed on the 12-month evaluation an evidence of neurological worsening; after 18 months this worsening was evident also on pulmonary function tests, especially on pulmonary diffusion.Pre-infusion CSF pH were above 8,0 on both cases. CONCLUSIONS: This procedure seems to be a safe treatment for spinal cord compression in MPS. We speculate that, after an initial set of monthly infusions, a protocol with longer intervals between infusions (2 to 4 times a year) could be enough to maintain the clinical benefits. Further studies are required.

Influence of gender on mtDNA quantity in cerebrospinal fluid following traumatic brain injury. *Y. Conley, M. Henning, D. Ren, S. Alexander* Univ Pittsburgh, Pittsburgh, PA.

Considerable variation exists in outcomes attained following a severe traumatic brain injury (TBI)and the nature of this variability is not well understood. Mitochondrial function is altered follwing TBI and amount or condition of mtDNA may play a role in this altered function, which may play a role in outcomes. This study was designed to obtain cerebrospinal fluid (CSF) drained as standard of care from TBI victims for the five days following injury and extract mtDNA for evaluation. Our preliminary evaluation of mtDNA quantity, measured using RT-PCR and normalized with simultaneous RT-PCR for betaglobin, indicates that considerable variation exists in mtDNA quantity over day 2-5 following a TBI and that females have an adjusted average of 40 times the amount of mtDNA compared to males. This difference almost reaches statistical significance ($p=.063$) with an $n=19$, 15 males and 4 females. Age did not impact quantity (age range 17-69) and initial extent of injury measured by Glasgow Coma Score did not impact quantity (GCS range 3-8). We are in the process of collecting data on additional subjects as well as investigating mtDNA quantity in reference to long term functional outcomes attained.

Genetic analysis of 50 quantitative traits (QT) in 9 isolated villages. *M.P. Concas[1], L. Portas[1], F. Murgia[1], S. Milia[1], N. Pirastu[2], G. Maninchedda[2], M. Cosso[2], A. Picciau[2], M. Whalen[2], M. Pirastu[1,2]* 1) Institute Population Genetics, Alghero, Sassari, Italy; 2) Shardna Lifesciences, Cagliari, Italy.

Isolated founder population, which exhibit great genetic and environmental homogeneity, provide an attractive setting for the study of complex traits. Our project is focused on 9 isolated villages of the secluded Ogliastra region, all of them characterised by few founders, distinct genetic makeup and a different distribution of common diseases. The study aim was to investigate through heritability if QT associated to these diseases present a different genetic component in the 9 villages. First we estimated the heritability, using SOLAR, of 50 normalised traits related to blood phenotypes and anthropometric measures in a total of 15521 individuals clustered in 471 pedigrees of 3-5 generations. We constructed a dendrogram based on the correlations between traits: the QT which belong to the same biological pathways do indeed cluster together. High heritability was observed for mostly of the traits (70% with heritability between 0.3 - 0.9) with no striking differences among the villages. Similar results were observed either using larger families or pooling together the 9 village datasets.To identify the genetic factors that underlie QT we carried out GWS in one of the villages (Talana) with 1000 microsatellites in 77 families (1107 members) using the variance component approach. In addition a GWS with 16K SNPs (average of 150kb) was performed with MERLIN. Linkage analyses using microsatellites revealed 158 loci with LOD>1.3, 50 loci with LOD>2 and 15 loci with LOD>3. SNP linkage analyses confirmed 42% of loci with LOD>2 and 73% of loci with LOD>3 in addition to several new loci: 61 with LOD>2 and 8 with LOD>3. Several related traits shared identical loci. A dendrogram based on linkage results shows that some clusters match the phenotypic correlation while other unexpected clustering could reflect some common unknown genetic bases. Several loci, even some with low LOD score, contained genes that appear to be involved in the physiological pathways of related traits. For example leptin levels are associated to 3 loci which contain known genes involved in appetite control.

HUMAN PBX1 INTERACTING PROTEIN (HPIP) PROMOTES PRIMITIVE HEMATOPOIETIC CELL GROWTH. *P. Kaur[1], N. Arseni[1], F. Ahmed[1], C. Abramovich[2], W. Hiddemann[1], K.R. Humpheries[2], C. Buske[1], M. Feuring-Buske[1]* 1) Klinische Kooperationsgruppe am Hämatologikum der GSF, Medizinische Klinik III, Klinikum der LMU München-Grohadern, München; 2) The Terry Fox Laboratory, Vancouver, Canada.

Hematopoietic PBX interacting protein (HPIP) is a 731 amino acid protein recently discovered as a novel partner of the key Hox transcription factor co-factor PBX, in hematopoietic cells (Abramovich C. et al 2000, 2002; Oncogene).HPIP has been implicated as a nuclear-cytoplasmic shuttle molecule and shown to have the capacity to bind to the cytoskeleton. Intriguingly, HPIP was found to be highly expressed in human CD34+ progenitor cells, but silenced in differentiated CD34- cells.To gain further insights into the possible functional role of HPIP and its domains HPIP cDNA was cloned in pMSCV-IRES-YFP cassette. Umblical cord blood CD34+ enriched population of stem cells was obtained to perform in vitro and in vivo experiments. HPIP induced a significant increase in erythroid colony formation ($p=0.002$, $n=6$) in colony forming unit(CFC) assay. In order to test the impact of HPIP in vivo, infected cells were transplanted into NOD/SCID mice and engraftment of HPIP expressing cells was traced back by YFP expression. HPIP induced a significant increase in the proportion of engrafted myeloid cells compared to the control ($p<0.005$) and decrease in lymphoid cells ($p=0.03$) Intriguingly, there was no significant increase observed in Competitive Repopulation Unit frequency as compared to control in transplanted (6 weeks post) NOD/SCID mice. However, a significant increase in CD16/56 ($p=0.02$) positive and CD10 ($p=0.04$) positive cells and a disequilibrium in Lymphoid/Myeloid cell ratio was observed.Our data point to HPIP as a previously unrecognized potent regulator of primitive haematopoietic cell growth and lineage commitment. These findings together with the potential of HPIP to intersect with both the Hox regulatory network through its interaction with PBX and with key signalling pathways as an adapter molecule (recently described by Manavathi B. et al PNAS 103: 15981, 2006) add impetus to further studies to further elucidate HPIPs function in both normal and leukaemia hematopoiesis.

Deficiency of mitochondrial respiratory activity in 6 patients with organic acidemias. *P. de Lonlay[1,2], V. Valayannopoulos[1], M. Sarzi[2], D. Chrétien[2], JB. Arnoux[1,2], S. Romano[1], D. Rabier[3], A. Munnich[2], A. Rötig[2], Y. de Keyzer[2]* 1) Pediatric Dept, Hosp Necker-Enfants Malades, Paris Cedex, France; 2) INSERM U781; 3) Biochimie.

Organic acidemias (OA) result from a defect of methylmalonic-CoA mutase (MMA) and propionyl-CoA carboxylase (PA). A few reports have supported the hypothesis that secondary respiratory chain deficiency could be the cause of complications observed in the long term follow-up of OA. Here, we report on respiratory chain deficiency and mitochondrial DNA depletion in several tissues of 6 patients with OA.

Case reports : Six patients, two with PA and four with MMA, were followed at Necker-Enfants malades Hospital. Both patients with PA developed severe cardiomyopathy. One improved quickly after a liver transplantation. Patients with MMA eventually developed neurological disease (3/4) and renal failure (2/4).

Results: A OXPHOS deficiency was found in the liver (multiple deficiency in 1 MMA, CII deficiency in 1 PA; CIII deficiency in 1 PA), skeletal muscle (CIII and CIV deficiency in 1 PA), heart (CII and CIII deficiencies in 2 PA), and kidney (generalized in 2 MMA). A mtDNA depletion was identified in the liver and skeletal muscle of these patients, with a residual mtDNA content of 9.2% and 24.8% in the liver of PA patients, and 11.5% in skeletal muscle (MMA).

Discussion: In OA, not only conversion of propionyl-CoA into methylmalonyl-CoA and succinyl-CoA but a reduction of the production of succinyl-CoA also occurs. This therefore affects the activity of the succinyl-CoA synthase (SCS) and the overall flux of the tricarboxylic acid (TCA) cycle. Because SCS deficiency is associated with mtDNA depletion, and accumulation of propionyl-CoA leads to hyperproduction of methylcitrate, an inhibition of the TCA cycle is suggested in the pathophysiopathology of long-term complications in OA.

Conclusion: We describe OXPHOS deficiency and mitochondrial DNA depletion in several tissues of 6 patients with OA, likely to be due to a reduced flux through the TCA.

Underexpression of the GABAergic system in the fragile X syndrome: a novel target for treatment? *F. Kooy[1], C. D'Hulst[1], P.P. De Deyn[2]* 1) Medical Genetics, Univ Antwerp, Antwerp, Belgium; 2) Neurochemistry and Behavior , Univ Antwerp, Belgium.

In the recent past, we have demonstrated decreased expression of 7 out of 18 known subunits of the GABAA receptor in cortex of fragile X mice, including the major isoforms, using real time PCR. To investigate whether the entire pathway was evolved, We measured mRNA levels of enzymes responsible for GABA synthesis (GAD), transport (GAT1-4) and degradation (SSADH) in the fragile X mouse model and found approximately 50%; under expression of the main components of GABA metabolism, transport and degradation As $GABA_A$ receptors are the major inhibitory neurotransmitter receptors in the mammalian brain, implicated in anxiety, depression, epilepsy, insomnia and learning and memory, processes also disturbed in fragile X patients, we argue that an overall dysfunction of the GABAergic system has neurophysiologic and functional consequences that might relate to the behavioural phenotype associated with fragile X syndrome. This hypothesis is supported by western blotting and electrophysiological findings from other groups. We propose a model demonstrating the involvement of the GABAergic system in epilepsy (decreased presence of specific subunits), in sleeping problems (through interactions of the $GABA_A$ receptor with the master circadian clock and melatonin) and in behavioural problems (through the influence of GABA on the HPA-axis mediated stress response). We postulate that the well described $GABA_A$ receptor pharmacology might open new powerful opportunities for treatment of the behavioural and epileptic phenotype associated with fragile X syndrome.

Quality assessment of spermatogenesis in treated hypogonadotropic hypogonadic (HH) men. *K. Krabchi, S. Chantot-Bastaraud, I. Berthaut, C. Ravel, P. Bouchard, S. Christin-Maitre, J. Mandelbaum, J.P. Siffroi* Universite Pierre et Marie Curie- Paris 6, EA 1533, Paris, F75020, France.

Background: Hypogonadotropic hypogonadism is characterized by failure of gonadal function secondary to deficient gonadotropin secretion, resulting from either a pituitary or hypothalamic defect. The therapeutic use of commercially available FSH and LH appeared to be an adequate way to treat male infertility problems of these patients achieving an apparently normal spermatogenesis. To our knowledge, the quality of such induced spermatogenesis has never been investigated. Because routine semen analysis are not suitable for the measure of nuclear integrity of sperm cells in these cases, we have performed an extensive study to evaluate this aspect. Subjects and methods: Twenty six treated HH patients were recruited. Spermatogenesis has been achieved in 19/26 cases (73%). Spermatozoa were retrieved surgically in testicular samples in 3 cases of azoospermia. A semen cryopreservation has been realized in 14 cases and 7 sperm samples were available for the study. They were compared to 7 normospermic controls. The sperm cells were processed by FISH using probes for chromosomes specific loci of chromosome 13, 21, 18, X and Y. In order to quantify sperm DNA fragmentation, a TUNEL assay was performed. Both FISH and DNA fragmentation results were observed using fluorescence microscopy. Results: FISH analysis revealed that 97 to 99% of induced spermatozoa were normally haploid. TUNEL assay results were also in the range (2 to 10%) of physiologically normal sperm. There was no significant difference in the quality of nucleus status observed between the 7 patients and the 7 normal fertile men (controls). Discussion: The high outcome of a complete spermatogenesis was achieved with a remarkable high success rate owing to the gonadotropins treatment in HH men, which allows either spontaneous fathering or efficient ART. We evaluated the nuclear quality of sperm cells after treatment in 7 patients. No enhancement in the rates of aneuploidy or DNA fragmentation could be shown after this induced spermatogenesis suggesting their nuclear integrity.

Evidence that a region of chromosome 10 linked to sodium-lithium counter-transport also influences plasma triglyceride level. *K.L.E. Klos[1], R. Ferrell[2], A.C. Morrison[1]* 1) Human Genetics Center, Univ Texas Health Science Center Houston, Houston, TX; 2) Dept Human Genetics, Univ Pittsburgh, Pittsburgh, PA.

Measures of sodium-lithium countertransport (CNT), a risk factor for hypertension, are highly correlated with plasma triglyceride (TG) levels. We hypothesized that genomic regions containing CNT quantitative trait loci (QTL) may contain common genetic variation that also influences inter-individual variation in plasma TG level. We identified at least one common SNP (minor allele frequency > 0.05) in each of the 55 genes within a 35 Mb region of chromosome 10 linked to CNT. We genotyped 1,582 Caucasian individuals ascertained without regard for health through households with two or more children enrolled in primary and secondary schools of Rochester, MN as part of the community-based Rochester Family Heart Study. Plasma TG was measured by standard enzymatic methods and log transformed prior to analysis. Individuals who had not fasted for at least 8 hours prior to the clinic evaluation were excluded. TG was adjusted for age and BMI within gender (children separately from adults) prior to analysis. A generalized estimating equation (GEE) approach was used to test for association among related individuals. Variation in the two-handed zinc-finger homeodomain transcription factor 8 (TCF8), was associated ($p<0.01$) with TG level in this sample. A repeat polymorphism in TCF8 has been previously linked to obesity, while mutation in this gene may cause posterior polymorphous corneal dystrophy. TCF8 has been previously shown to be involved in smooth muscle cell differentiation and to repress t-lymphocyte-specific IL-2 gene expression. Since application of IL-2 to natural killer cells stimulates secretion of lipoprotein lipase, a key enzyme of triglyceride metabolism, the association of TCF8 variation with plasma TG level may provide a link in the connection between inflammatory pathway genes and lipid metabolism.

Crosstalk between the angiotensin II, TGF and Wnt signaling cascades inhibits preadipocyte differentiation in Marfan syndrome. *E.C. Klein, R.D. Cohn, C. van Erp, T.M. Holm, J.P. Habashi, L. Myers, D.L. Huso, H.C. Dietz* Inst Genet Med, Dept Comp Med, HHMI,Johns Hopkins Univ Sch Med, Baltimore, MD.

Marfan syndrome (MFS) is caused by a deficiency of the connective tissue protein fibrillin-1 and a subsequent increase in TGF signaling. Losartan, an angiotensin II type-1 receptor antagonist, attenuates TGF signaling and prevents these manifestations. Individuals with MFS lack the ability to deposit fat stores despite adequate nutrition. Here we show that mice heterozygous for a fibrillin-1 missense mutation showed a wider variation in adipocyte size than wild-type (WT) mice, with many tiny adipocytes. Given that TGF has been shown to inhibit preadipocyte differentiation *in vitro*, we hypothesized that increased TGF signaling may underlie the fat phenotype in MFS. We observed increased expression of thrombospondin-1 (TSP-1), an activator of TGF, increased phosphorylated Smad2 (pSmad2), an effector of TGF signaling, and increased expression of Pref-1, a marker of preadipocytes and an inhibitor of preadipocyte differentiation, in mutant fat. Wnt signaling has been shown to regulate adipocyte differentiation in culture systems, and defective signaling can contribute to obesity-related phenotypes. We now show that fibrillin-1 deficient mice show excessive canonical Wnt signaling, as evidenced by increased steady-state abundance of unphosphorylated -Catenin. Remarkably, losartan normalizes the levels of TSP-1, pSmad2, Pref-1 and -Catenin, and corrects the size distribution of adipocytes in mutant mice. Given that losartan had no effect on these parameters in WT mice, this suggests that TGF is not a significant physiologic regulator of preadipocyte differentiation in adult mice. Rather, unanticipated crosstalk between the angiotensin II, TGF and Wnt signaling cascades emerges as the predominant pathologic inhibitor of preadipocyte differentiation in MFS. In vivo treatment with TGF neutralizing antibody normalized Wnt signaling, defining AngIITGFWnt as the order for these interactions. This pathogenic sequence may be related to other disease states associated with increased TGF signaling and reduced fat stores including scleroderma and Camurati-Engelmann disease.

Inter-and intrachromosomal distribution of 13 different types of structural chromosome aberrations localized on acrocentric chromosomes. *L. Kalz, G. Schwanitz* Institute of Human Genetics, University of Bonn, Germany.

Chromosome investigations were performed in 532 probands, 432 showing constitutional aberrations and 100 with heterochromatic variants in the short arm regions of the acrocentrics. The constitutional aberrations comprised Y-autosome translocations, intrachromosomal abnormalities (del, dup, r, der, i, inv) and interchromosomal rearrangements (rob, rcp, der, CCR) with breakpoints in heterochromatin, euchromatin, and a combination of both. The 13 different types of aberrations each showed an aberration- and chromosome- specific pattern of the abnormalities. Hot spots of aberration and specific frequencies of combination of the chromosomes involved could be delineated. The relation of de novo and familial aberrations was different for the 5 chromosomes investigated. Our results were compared to a large study from literature. We found comparable results for some peculiarities but also differences in frequencies of aberrations, which can be explained by the different ways of documentation. The polymorphisms analyzed were stable in the chromosomes with rearrangements, and in Robertsonian translocations a selection of specific polymorphisms could be excluded.

Post-marketing surveillance of miglustat in patients with Type 1 Gaucher disease (GD1). *B. Bembi[1], D. Hughes[2], B. Schwierin[3], C.E.M. Hollak[4]* 1) Unità Operativo Dipartimentale, Istituto per l'Infanzia, "Burlo Garofolo", Trieste, Italy; 2) Royal Free and University College Medical School, London, UK; 3) Actelion Pharmaceuticals Ltd, Allschwil, Switzerland; 4) Academic Medical Center, Amsterdam, The Netherlands.

IS^3 is a non-interventional post-marketing surveillance programme aimed at enhancing awareness of safety precautions and stimulating appropriate monitoring during miglustat use in patients with GD1.

From March 2003 to 9 March 2007, information was available on the first 98 GD1 patients (60% female) prescribed miglustat across 11 European countries (45 centres).

Overall exposure to miglustat represented a cumulative period of 147 patient-years, with a median exposure (range) of 17.9 (1.3-107.7) months. Mean patient age (SD) was 44.3 (15.9) years. At baseline, 65 patients (66%) had previously been treated with enzyme replacement therapy, with a median duration (range) of 64.0 (1.0-176.0) months. Baseline neurological assessments were available in 89 patients (91%), amongst whom 23% displayed one or more neurological manifestations (17% tremor, 9% neuropathy, 12% memory problems, 13% cognitive abnormalities). Fifty-three percent of patients had bone manifestations at baseline, the most frequent being osteopenia (41%), bone pain (28%) and avascular necrosis (16%). During follow up, no safety signals were reported in 48 patients (49%). Twenty-three patients (23.5%) discontinued, most frequently due to gastrointestinal disturbances (14 patients); most of these cases occurred during the first 6 months of treatment. New tremor was reported in 13 patients (13%), and memory problems occurred in 7 patients (7%). Bone pain was observed in 5 patients, two of whom exhibited skeletal symptoms at baseline.

In conclusion, long-term miglustat therapy was well tolerated in patients with GD1. Most gastrointestinal side effects occurred during the first weeks of treatment. No new safety concerns were identified.

Whole genome based estimation of the probability to develop a complex disorder and application to Crohn's disease. *S. Hansoul[1], C. Sandor[1], V. Botta[2], L. Wehenkel[2], T. Meuwissen[3], M. Georges[1]* 1) Department of Animal Genomics, University of Liège, Liège, Belgium; 2) Department of Bioinformatics, University of Liège, Liège, Belgium; 3) Institute for Animal Science and Aquaculture, As, Norway.

Thanks to the HapMap project and to recent improvements in genotyping techniques, an increasingly large number of whole genome association studies of complex disorders are currently conducted. Some of them already released new insights about the genetic architecture of the studied disorder, but generally have limited power. Only the biggest effects are currently identified and they are by essence overestimated. Prediction of the genetic susceptibility to develop a complex disease based on these loci only remains inaccurate.

With a sufficiently dense marker map (>100K SNPs), one might expect most of the true disease signals to be captured in the study, whereas not necessarily associated to a significant p-value. In order to predict a probability of disease outcome, one must take into account all the information contained in the sample. To that aim, we investigated three different methods. One of them is a data mining technique based on decision trees and the two other ones work within a Bayesian framework.

These approaches have been applied to a data set consisting in 527 Crohn's Disease patients and 928 healthy controls, all of Caucasian origin. This cohort has been genotyped for more than 300K SNPs using the Illumina HumanHap300 Genotyping BeadChip. With all methods, the correlation between disease status and the estimated probability to develop the disease increases as more SNPs (ordered by p-value) are included in the model. This hints that there is valuable information contained in markers that classical methods wouldn't pick out.

.

Contribution of the neurotrophic tyrosine kinase receptor type 3 (NTRK3) gene to genetic susceptibility to obsessive-compulsive hoarding. *M. Alonso[1], M. Gratacos[1], J.R. Gonzalez[1], J.M. Menchon[2], R. de Cid[1], C. Segalas[2], M. Bayes[1], A. Pertusa[2], E. Real[2], J. Labad[2], J. Vallejo[2], X. Estivill[1,3]* 1) OCD Clinic, Department of Psychiatry, Hospital Universitary de Bellvitge, Barcelona, Catalonia, Spain; 2) Genes and Disease Program, CeGen and CIBERESP, Center for Genomic Regulation (CRG-UPF), Barcelona; 3) Pompeu Fabra University, Barcelona, Catalonia, Spain.

Hoarding, defined as the collecting of, and inability to discard, excessive quantities of useless or valueless items, is present in approximately 18-42% of those suffering from obsessive-compulsive disorder (OCD). Recent work suggests that hoarding syndrome may constitute a neurobiologically distinct variant of OCD with specific clinical and neuroanatomical correlates as well as a different pattern of genetic inheritance involving basically the dopaminergic pathways. To test the involvement of neurotrophic tyrosine kinase receptor type 3 (NTRK3), the high affinity receptor of neurotrophin 3 (NT-3), in obsessive-compulsive hoarding, we have performed an association study of 52 TagSNPs covering the whole gene in a sample consisting on 120 patients (OCD Clinic of Bellvitge University Hospital) and 342 controls. TagSNPs were selected from the HapMap project (Phase I data freeze, dbSNP b124) considering the genotypes corresponding to the 60 individuals from the 30 HapMap trios of European ancestry. We performed both single case-control association and haplotype analyses. Thirty-six of our patients (30%) exhibited hoarding obsessions and compulsions. A significant association of two SNPs in the 3' downstream region of NTRK3 gene and obsessive-compulsive hoarding was identified ($p = 0.0002$), with a protective effect associated with both of them. No other significant results emerged from the haplotype analysis. Our findings suggest that NTRK3, which plays a role in survival and differentiation of dopaminergic neurons, may contribute to genetic susceptibility to obsessive-compulsive hoarding. Supported by the Catalan and the Spanish Governments.

Family-based association analyses of positional candidate genes from a region showing significant linkage to atopic rhinitis on chromosome 3q. *C. Brasch-Andersen[1,2], A. Haagerup[3], K. Brøsen[1], J. Vestbo[4], T.A. Kruse[2]* 1) Clinical Pharmacology, Institute of Public Health, University of Southern Denmark, Odense, Denmark; 2) Dept. of Biochemistry, Pharmacology and Genetics, Odense University Hospital, Denmark; 3) Dept. of Paediatrics, Sygehus Viborg, Denmark; 4) Dept. of Cardiology and Respiratory Medicine, Hvidovre Hospital, Denmark.

Allergic rhinitis is a common disease of complex inheritance and is characterized by mucosal inflammation caused by allergen exposure. It often affects patients with other coexisting manifestations of allergy, suggesting overlapping disease etiology. We have previously shown significant evidence for linkage to chromosome 3q13.31 for rhinitis, atopy and atopic rhinitis after finemapping the region suggested by a genome-wide scan using Danish atopy sib pair families. Highest identity by descent sharing at the locus was seen for the phenotype atopic rhinitis. The region of maximum LOD score - 1.5 spans approximately 3 centiMorgan and harbors only two genes; Growth Associated Protein 43 (GAP43) and Limbic System- Associated Membrane Protein (LSAMP). Both genes seem to be involved in neural growth. One sib from all pairs with atopic rhinitis used in the linkage analysis (n=76) were screened for polymorphisms using denaturing high-performance liquid chromatography (DHPLC). All exons and exon-intron boundaries of GAP43 and LSAMP were screened. DHPLC analyses revealed a polymorphism in the untranslated region of exon 3 in GAP43 and a single nucleotide polymorphism (rs14360) was identified by sequencing. Furthermore, a GT-repeat polymorphism was identified in intron 1 of LSAMP by DHPLC and sequencing. Both polymorphisms were genotyped in the full sample containing 1021 individuals in 159 Danish families. Screening of the genes did not reveal any polymorphisms in the coding regions of GAP43 and LSAMP. Association between genotypes and rhinitis, atopy and atopic rhinitis were analysed using the Family-Based Association Test (FBAT) program but failed to show association ($p>0.05$). As linkage analysis strongly suggests a susceptibility gene for rhinitis at 3q13.31 further analysis of the region is needed to identify susceptibility variants.

C2 and BF genes in Age-Related Macular Degeneration and joint action with CFH and LOC387715 genes. *M.B. Gorin[1,2,5], Y.P. Conley[3,5], J. Jakobsdottir[4], R.E. Ferrell[5], D.E. Weeks[5,4]* 1) Dept Ophthalmology, Jules Stein Eye Inst - UCLA, Los Angeles, CA; 2) UPMC Eye Center, Department of Ophthalmology, School of Medicine, University of Pittsburgh, PA; 3) Department of Health Promotion and Development, School of Nursing, University of Pittsburgh, PA; 4) Department of Biostatistics, Graduate School of Public Health, University of Pittsburgh, PA; 5) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, PA.

The Y402H variant in the complement factor H (CFH) gene on 1q32 and the S69A variant in the LOC397715 (LOC) gene on 10q26 have been consistently shown to be strongly associated with age-related macular degeneration (ARM). The C2 and BF genes, closely linked on 6p21, have recently been shown to harbor ARM-associated variants. We typed 4 SNPs in those genes (rs9332739 and rs547154 in C2; rs4151667 and rs2072633 in BF) in case-control and family-based data (white subjects only). The data include a total of 601 ARM families (including 494 affected sib pairs, 5 affected half-sib pairs, 60 affected cousin pairs, and 38 affected avuncular pairs) and 149 unrelated controls and 172 unrelated cases. All SNPs were in Hardy-Weinberg equilibrium in both cases and controls. We used Fishers exact test to test for differences in genotype distributions between cases and controls, and the CCREL test to compare ARM families vs. controls. The C2 SNP rs547154 was associated with ARM in the case-control data (p-value 10^-4) and family-based data (p-value 0.00001). We used logistic regression models to investigate the joint action of C2 and CFH and LOC, using the controls, cases, and one randomly selected case from each family. First, we tested the joint action of all pairs of genes and found that the most parsimonious models (model with lowest AIC) of the action of the locus pairs CFH and LOC, CFH and C2, and LOC and C2, were, in all cases, additive models without interaction between the two loci. The most parsimonious three locus model was the additive model of all 3 genes. The addition of C2 to a model of CFH and LOC significantly improved the model (p-value of likelihood ratio test 0.005).

Glucocerebrosidase gene mutations are associated with Parkinson's disease in a population from Southern Italy.

Messina[1], F. Novellino[2], M. Morelli[2], A. Quattrone[1,2] 1) Institute of Neurological Sciences, National Research Council, Mangone Cosenza, Italy; 2) Institute of Neurology, University Magna Graecia, Catanzaro, Italy.

Recent studies have reported clinical, neuropathological and genetic associations between Parkinsons disease (PD) and Gauchers disease (GD). Screenings for GBA mutations in PD subjects belonging to different populations have suggested that heterozygosity may be a susceptibility factor predisposing to PD. Until now, no data exist in the Italian population. We screened 395 PD patients coming from Calabria for the N370S and the L444P mutations. A control group consisting of 483 subjects coming from the same geographical area of the patients was used to determine the mutation frequency in the general population. Genotyping was performed by using PCR amplification followed by restriction enzyme digestion with XhoI for the N370S substitution and NciI for the L444P substitution. Mutation frequencies in cases and controls were compared using Fishers exact test. We found 11 patients (2.7%) carrying a heterozygous mutant GBA allele: three of them had the N370S mutation and eight had the L444P mutation. In the control group 1 subject (0.2%) carried a heterozygous L444P mutation. These distributions were significantly different between patients and controls (p=0.0018). Carriers of a GBA mutations had an increased risk of developing PD (OR = 13.6; 95% CI, 1.8 to 105.8; p = 0.001). Clinical characteristics were similar in patients with or without GBA mutations. The present study demonstrates a significant association of some GBA mutations with PD in a sample from Southern Italy. Differing from previous reports, the most common mutation detected in our study was the L444P (eight patients and one control), while the N370S substitution (three PD patients) was never found in 483 control subjects. Our results support evidence that altered GBA may represent a risk factor for developing PD in our population.

Molecular genetics of Meckel syndrome. *T. Attié-Bitach[1,2], L. Baala[1], S. Saunier[3], S. Audollent[2], M. Delous[3], R. Khaddour[1], C. Ozilou[2], J. Martinovic[2], A. Munnich[1,2], F. MacDonald[4], M-C. Gubler[3], S. Schneider-Maunoury[5], F. Encha-Razavi[1,2], C. Johnson[6], M. Vekemans[1,2]* 1) INSERM U781, Hopital Necker-Enfants Malades, Paris, France; 2) Département de Génétique, Hopital Necker-Enfants Malades, APHP, Paris, France; 3) INSERM U574, Hôpital Necker-Enfants Malades, Paris, France; 4) West Midlands Regional Genetics, Birmingham Womens Hospital Birmingham, U.K; 5) CNRS UMR7622, Laboratoire de Biologie du Développement, Paris, France; 6) Section of Ophthalmology and Neuroscience, St. Jamess University Hospital, U.K.

Meckel syndrome (MKS) is a lethal autosomal recessive syndrome characterized by cystic kidneys, brain malformations, polydactyly, and liver bile duct proliferation. Recently, two genes have been identified: MKS1/FLJ20345 on 17q and MKS3/TMEM67 on 8q. Both encode ciliary proteins. Our molecular studies of MKS1 and MKS3 in a large fetal cohort of 120 MKS and 45 MKS-like indicate that MKS1 and MKS3 genes are each responsible for about 10 % of MKS cases. A strong phenotype-genotype correlation is observed regarding the type of CNS malformation, the frequency of polydactyly and bone dysplasia. In addition, MKS3 mutations were identified in fetuses with vermis agenesis and patients with Joubert syndrome (JS) defining MKS3 as the sixth JS locus (JBTS6). A genome wide linkage study performed in consanguineous MKS families excluding MKS1-3 showed homozygozity on chromosome 12q21 in 4 families. CEP290 homozygous truncating mutations were identified in 3/4 families, and compound heterozygote mutations were found in MKS cases and in 4 families presenting a cerebro-reno-digital syndrome, with a phenotype intermediate between MKS and JS, demonstrating a continuum spectrum from JS to MKS. Finally, using SNP mapping in MKS and JS, we mapped a new locus on chromosome 16q12 and identified truncating mutations in the novel gene RPGRIP1L in MKS fetuses with severe craniofacial defects. Inactivation of its mouse orthologue recapitulates the cerebral, renal, liver, craniofacial and limb defects of MKS. Mutations of this ciliary encoding protein in both JS or MKS syndromes identify novel JS (JBTS7) and MKS (MKS5) loci.

Genome-Wide Analysis of Alterations in Histone Methylation and Gene Expression in Hutchinson-Gilford Progeria Syndrome. *K. Cao, D. Faddah, M.R. Erdos, B.C. Capell, F.S. Collins* National Human Genome Research Institute, National Institutes of Health, Bethesda, MD.

Hutchinson-Gilford progeria syndrome (HGPS) is a rare genetic disorder with widespread phenotypic features of premature aging. Classic HGPS is caused by a de novo point mutation in exon 11 of the LMNA gene, activating a cryptic splice donor and resulting in a mutant lamin A protein termed progerin that lacks 50 amino acids near the carboxyl terminus. During interphase, progerin anchors to the nuclear membrane, disrupting the nuclear scaffold and causing nuclear blebbing that has been referred to as the cellular hallmark of HGPS. Given the known interactions between the nuclear lamina and transcription factors, as well as the evidence that changes in modified histones predate the blebbed nuclear morphology in HGPS, we hypothesized that progerin causes cell damage not only by its structural effects, but in the way it alters chromatin structure and transcriptional regulation. To test our hypothesis, we have implemented a combined approach using expression array analysis and ChIP-chip (chromatin immunoprecipitation coupled with DNA microarray technology). We studied fibroblasts from normal and HGPS individuals, and generated tet-inducible cultured cells expressing progerin to assess the early events following progerin expression. Expression microarray analysis defined a set of 235 genes that show at least a two-fold, statistically significant change in HGPS. Parallel ChIP-chip analysis using ENCODE and human promoter arrays generated high-resolution maps for the distribution of H3K4, H3K27, and H3K36 trimethylation. Combining these data sets led to the identification of an initial list of differentially active and suppressed genes that may explain some of the cellular phenotypic features of HGPS. Furthermore, we have recently employed the Illumina/Solexa sequencing technology to map histone methylation patterns across the entire genome in HGPS. This study provides novel insights into the complex relationship between transcriptional regulation and chromatin organization in both HGPS and normal aging.

The tau H2 haplotype contributes to susceptibility to Parkinson disease in a Southern Italian population. *D. Civitelli[1], G. Annesi[1], P. Tarantino[1], E.V. De Marco[1], F. Annesi[1], G. Nicoletti[1,2], F. Condino[1], I.C. Ciró Candiano[1], S. Carrideo[1], F.E. Rocca[1], V. Scornaienchi[1], V. Greco[1], G. Provenzano[1], A. Quattrone[1,2]* 1) Institute of Neurological Sciences, National Research Council, Mangone, Cosenza, Italy; 2) Institute of Neurology, Department of Medical Sciences, University Magna Graecia, Catanzaro, Italy.

The microtubule-associated tau protein is involved in common neurodegenerative pathways and a number of association studies have been conducted to clarify the role of the tau gene in neurodegenerative diseases, including Parkinsons disease (PD). Several polymorphisms localized along the entire tau gene length are inherited in complete linkage disequilibrium, forming two distinct extended haplotypes designated H1 and H2, respectively. Recombination between these two haplotypes is rare. The H1 haplotype appears to be related to an increased risk for progressive sopranuclear palsy, cortical degeneration, frontotemporal lobar degeneration syndromes and primary progressive aphasia. A contribution of the H1 haplotype to PD susceptibility was also suggested. Here, we assessed the distribution of the tau haplotypes in a group of 262 sporadic PD patients from Southern Italy and in 197 healthy controls from the same area. We reconstructed tau haplotypes by genotyping three SNPs (BanII in exon 3, MspI in exon 9, AluI in exon 11). Moreover, we tested a GT dinucleotide polymorphism located in intron 9 and inherited as allele 0 (11 repeats), allele 1 (12 repeats), allele 2 (13 repeats), allele 3 (14 repeats) and allele 4 (15 repeats). Of interest, we found a significant overrepresentation of the H2 haplotype in PD patients (OD 2.26 - 95% CI 1.64-3.18). Despite PD is not primarily considered a tauopaty, the tau gene could play a role in PD pathogenesis. The significant overrepresentation of the H2 haplotype in the examined PD patients suggests that the this haplotype is a risk factor for PD in our sample. Thus, southern Italian population appears to be different from most of other Caucasian populations in which the tau H1 haplotype contributes to susceptibility to PD.

Use of a genetic isolate to characterize genome wide profile behind multiple sclerosis. *E. Jakkula[1,2], S. Purcell[2,3], J. Saarela[1,4], S. Kallio[1,4], P. Tienari[5], K. Koivisto[6], A. Palotie[2,7], MJ. Daly[2,3], L. Peltonen[1,2,4]* 1) Dept of Molec. Medicine, National Public Health Institute, Helsinki, Finland; 2) The Broad Institute of MIT and Harvard, Cambridge, MA, USA; 3) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA, USA; 4) Research Program in Molec. Medicine at Biomedicum Helsinki, Helsinki, Finland; 5) Dept. of Neurology, Helsinki Univ. Central Hospital, Helsinki, Finland; 6) Central Hospital of Seinäjoki, Seinäjoki, Finland; 7) The Finnish Genome Center, Univ of Helsinki, Helsinki, Finland.

Multiple sclerosis (MS) shows very high incidence in the Western Ostrobotnia sub-isolate of Finland and genealogical research suggests limited number of founders. We therefore hypothesize that one or more relatively penetrant variants predisposing to MS may be regionally enriched and that shared haplotype analysis can be used to identify MS loci using a genome wide, high density SNP screen.

Using genealogical information reaching up to 15 generations back in history, two regional megapedigrees were constructed and 72 MS cases (and 68 regional controls) were genotyped using the Illumina 317K HumanHap panel. A five SNP sliding window haplotype option in PLINK was used to scan each chromosome. When comparing all haplotypes between cases and controls two regions with global p-value $<10^{-6}$ were detected (11q12.1, 12q24.33) and six regions that had single haplotype association p-values $< 10^{-6}$: the HLA region and regions on 1q25.3, 1q41, 11q12.1, 17q11.2 and 22q13.2. These regions are 61-500 kb in size and limited by probable recombination hotspots. We are currently following these initial findings in the Finnish study sample of 700 MS families. One region of special interest locates on 5p representing a previous linkage region identified in these MS families. A shared risk haplotype covers the complement component 7 gene *(C7)* and this risk haplotype has been validated in an enlarged sample from Southern Ostrobotnia. This approach should provide insight especially to the rare, high impact alleles in the genetic background of MS.

Geleophysic Dysplasia: clinical, radiological and ultrastructural studies. *C.A. Bacino[1], N. Brunetti-Pierri[1], J. Hicks[2], L. Potocki[1], J.G. Leroy[1], B. Lee[1]* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Pathology, Baylor College of Medicine, Houston, TX.

Geleophysic dysplasia (GD; MIM 231050) is an autosomal recessive disorder characterized by short-limbed dwarfism, brachydactyly and a "happy-looking" facial appearance. Based on the detection of lysosome-like inclusions in different tissues, the underlying cause of GD is considered to be a lysosomal storage defect. We report the clinical and radiological features of four GD cases confirmed by the presence of skin fibroblast inclusions on electron microscopy (EM) analysis. Two of the four cases are siblings and exhibited significant variability especially with regards to the cardiac involvement. Short stature and brachydactyly were present in all four patients, while laryngeal stenosis was present in two patients and Perthes disease in one patient. Taken together, these findings show a significant interfamilial and intrafamilial clinical variability consistent with a broad disease spectrum. No gene is currently known for this disorder and the diagnosis of GD is often difficult and mostly based on clinical and radiological findings. We provide evidence that EM of cultured skin fibroblasts is useful and reliable as an adjuvant tool for the diagnosis of GD. In an attempt to identify the defective pathway and ultimately the gene responsible for GD, using a proteomic approach, we have evaluated the differential expression protein profiles of GD fibroblasts and controls. This analysis allowed us to identify up to 24 proteins that are differentially expressed between GD patients and controls. Mass spectrometer analysis is currently in progress to determine the identity of the affected proteins.

Haplotype reconstruction in pedigrees using the Cluster Variation Method. *C.A. Albers, H.J. Kappen* Dept. Biophysics, Radboud University, Nijmegen, Netherlands.

Haplotyping is an important tool for mapping susceptibility genes of complex diseases. Application of exact likelihood-based methods is generally not feasible in complex pedigrees with many markers. We present a probabilistic approach for approximately optimal haplotype reconstruction in general pedigrees. We reconstruct the haplotypes by assigning in every iteration a fixed number of the ordered genotypes with the highest marginal probability, conditioned on the marker data and ordered genotypes assigned in previous iterations. We use the Cluster Variation Method (CVM) to estimate the marginal probabilities. The CVM is an analytical variational approximation method designed for efficient estimation of marginal probabilities in complex Bayesian probability models, through optimization of marginal distributions on overlapping subsets of variables (the clusters) for which exact probability calculus is feasible. In data sets simulated in a pedigree with 53 individuals, 5 SNPs and missing genotype rates of 30-70 percent where exact computation was feasible, the haplotyping accuracy, measured as the percentage of inferred ordered genotypes equal to the true simulated ordered genotype, was as high as that of the exact maximum likelihood haplotyping program Superlink. In data sets with 20 SNPs and 13 genotyped individuals where exact computation was not feasible, our approach was significantly more accurate than SimWalk2 when both methods assigned a subset of the alleles and equally accurate when both methods assigned all alleles. Computation time of our approach increased approximately linearly with the number of markers, while that of SimWalk2 increased faster than linear. In a real data set for a complex mouse pedigree of 331 individuals with 322 typed for 10 SNPs (Valdar et al.), our approach reconstructed haplotype configurations with on average (N=10) 2.5 percent higher log-likelihoods than SimWalk2, at respective mean computation times of 54 and 2481 minutes. Thus, our approach is at least as accurate as SimWalk2 and significantly faster for large problem instances, and provides more detailed information about uncertainty in the haplotype reconstruction.

Non-syndromic cleft lip with or without cleft palate (CL/P): Multipoint posterior probability of linkage (PPL) analysis sequentially updated over phenotypic subgroups reveals a Philippines-specific linkage to a region on chromosome 6q. *M. Govil[1], S. Daack-Hirsch[2], A.C. Lidral[3], V.J. Vieland[4], J.C. Murray[3], M.L. Marazita[1]* 1) Center for Craniofacial and Dental Genetics, University of Pittsburgh, Pittsburgh, PA; 2) College of Nursing, The University of Iowa, Iowa City, IA; 3) Department of Pediatrics, University of Iowa, Iowa City, IA; 4) Columbus Children's Research Institute & Ohio State University, Columbus, OH.

Non-syndromic CL/P, the most commonly occurring congenital craniofacial anomaly, presents a challenge for testing and identifying contributory genes due to its complex etiology and ethnicity-specific prevalence. Sequentially updating over population of origin, a two-point genome-wide PPL analysis of 487 ethnically diverse families from 8 study populations estimated that there was an 80% probability of at least one CL/P risk gene located in specific regions of chromosomes 1, 2, 6, 9 and 12 encompassing about 50cM total (Govil et al, ASHG, 2005), with a 43% probability of a gene on chromosome 6 alone. A multipoint PPL analysis of these select regions with a three-point sliding windows approach indicated a striking 88% probability of a gene linked to a 14cM region on 6q14.1-6q16.1 (Govil et al, ASHG, 2006). In both these analyses, the Philippines population, with 258 families, provided the strongest signal, with a 41% (two-point) and 80% (multipoint) PPL for the 6q14.1-6q16.1 region. Since CL/P has considerable phenotypic variability and is also considered to be etiologically distinct from isolated cleft palate (CP), we subdivided the 258 Filipino families into 4 non-overlapping cleft phenotype groups (PG). Sequentially updating over PG provides a second peak in the 6q25.2 region with a 2-point PPL of 28%, where the cleft lip only (CL) PG has a PPL of 35%. The peak imputed PPL for the 6q24.3-6q25.3 region is 47% with sequentially updated three-point sliding windows. While the previously reported results identify our primary region for further analysis, the results presented here indicate the possibility of a second region on chromosome 6 specific to the Philippines population. NIH grants: R37-DE08559, P50-DE016215, R03-DE017167, R01-DE014667, K02-DE015291.

Population Structure in the Britain. *D. Davison, C. Spencer, J. Marchini, P. Donnelly* Department of Statistics, University of Oxford, Oxford, United Kingdom.

Population structure is of interest in its own right, and for the light it can shed on population and demographic history. It is also well known to be a confounding effect in genetic association studies, although to date only limited empirical data have been available to assess this effect in some geographical locations. The Wellcome Trust Case-Control Consortium genotyped over 16,000 British individuals at 500,000 SNPs. The data provides an unprecedented opportunity to assess genetic population structure in this context. Thirteen genomic regions were shown to exhibit extensive geographical variation across Britain. For some, including Lactase, natural selection has previously been implicated in generating these differences. We assess the role of natural selection at the novel loci, and describe choices of ancestry informative markers for association studies. We also develop and apply other statistical methods for understanding the much less extensive population structure throughout most of the genome.

Hepatic lipase variants have sex-specific associations with metabolic syndrome and its risk factors in the NHLBI Family Heart Study. *M.F. FEITOSA[1], R.H. Myers[2], I.B. Borecki[1]* 1) Washington Univ, St. Louis, MO; 2) Boston Univ, Boston, MA.

Metabolic syndrome (MetS) is a clustering of abdominal obesity, high triglycerides (TG), low levels of high-density lipoprotein cholesterol (HDL-C), high blood pressure (BP) and elevated fasting glucose (GLU) levels, and is a major risk factor for diabetes and cardiovascular disease. The gene for hepatic lipase (LIPC) resides on15q21 and the enzyme plays a major role in lipoprotein metabolism. However whether LIPC variants influence risk of MetS and its related phenotypes has not been explored. We selected 19 tag SNPs across 593 kb of LIPC that were typed in 433 families (2,192 subjects) to evaluate associations to MetS (defined by National Cholesterol Education Program), central obesity (waist circumference, (WC) and waist-to-hip-ratio (WHR)), glucose metabolism (GLU, insulin (INS), and HOMA), lipid profile (TG, HDL-C, LDL-C, total cholesterol, APOA-1, and APOB), and BP (SBP and DBP). Family-based methods were used for both qualitative (e.g., MetS and dichotomizations of the quantitative variables at clinically-relevant thresholds) and the actual quantitative phenotypes. Significant associations were observed mainly in the large first intron for most of these phenotypes, many of which exhibited sex-specific effects. SNP associations were found in women (vs. men, MetS: p=0.0013 vs. p=0.3314, TG: p=0.0040 vs. p=0.3613, HDL-C: p=0.0022 vs. p=0.7109, and WC: p=0.0190 vs. p=0.8295), as well as in men (vs. women, MetS: p=0.0279 vs. p=0.365, GLU: p=0.0163 vs. p=0.573, SBP: p=0.0235 vs. p=0.977). Similarly, sex-specific association patterns were found between several SNPs and quantitative traits (e.g. for women vs. men, HDL-C: p=0.00018 vs. p=0.1964, WHR: p=0.00674 vs. p=0.6660, GLU: p=0.00714 vs. p=0.71003, INS: p=0.00304 vs. p=0.1197, HOMA: p=0.00195 vs. p=0.1252, TG: p=0.0022 vs. p=0.5514). Associated haplotypes in different LD blocks were identified, which exhibited sex-specific effects suggesting that not only might there be more than one region in LIPC with variants influencing MetS traits but that these variants have differing effects depending upon the sex of the individual.

Zygosity determination using DNA prepared from saliva. *K. Duvefelt[1,2], A. Lindstedt[1], U. Hannelius[2], C. Lagerberg[2], G. Tybring[2], J. Kere[1,2]* 1) Karolinska University Hospital; 2) Karolinska Insitutet.

We investigated how DNA derived from saliva, collected with Oragene DNA kit, performed in SNP genotyping using the Sequenom MALDI-TOF technique. Subsequently zygosity was determined using our SNP panel.

The motivation for the analysis was to find out:

a) How did this DNA work with the genotyping methodology?

b) Was it possible to genotype using a large range of DNA concentrations?

c) How did the zygosity analysis perform with the generated data?

Saliva was collected using Oragene DNA self-collection kit from 44 twin pairs and DNA extraction was performed on the Gentra Autopure LS instrument using Puregene. The DNA concentration was measured with OD as well as PicoGreen. The correlation between these measurements was: R^2=0,59, probably due to impurities leading to absorbance giving an overestimation of the DNA content. One concern with saliva DNA is contamination of bacterial DNA that could lead to incorrect measurements of human DNA content. The PicoGreen quantification gave a range from 0-1002 ng DNA /l with a mean of 97 ng/l. Corresponding OD measurement ranged from 7-1364 ng/l, mean 221 ng/l. We selected 10 samples with PicoGreen measured concentrations from 6 to 1002 ng/l for genotyping, with 24 different SNPs in one multiplex reaction, using eight different concentrations ranging from 2,5 ng to 320 ng. The success rate of genotyping for the different concentrations ranged from 87 to 98% (mean 97%). There was a 100% correlation of the genotypes over the concentration range. Subsequently all 88 samples were genotyped with our zygosity panel of 47 SNPs distributed in three multiplex reactions. The measured amount of DNA per reaction ranged from 0,25 ng to 250 ng. The success rate per sample was between 77 and 100% (mean 99%); per marker it had a mean of 98% (range: 93 to 100%). Zygosity could unambiguously be determined from 43 of the 44 twin pairs studied. We conclude that SNP genotyping of DNA originating from saliva collected by Oragene kit yields reproducible results using the Sequenom MALDI-TOF technique. The analysis could be performed over a wide range of DNA concentrations and subsequent analysis of the zygosity can be performed with reliable results.

Adams-Oliver Syndrome: Clinical Variability in a Four-Generation Family. *N. Brunetti-Pierri[1], J.T. Hecht[2], I. Van den Veyver[1], T. Eble[1], C.A. Bacino[1]* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Pediatrics, University of Texas Medical School at Houston, Houston, Texas, USA.

Adams-Oliver syndrome (MIM 100300) is a rare disorder characterized by congenital scalp defects, terminal transverse limb defects, and cutis marmorata telangiectatica. Limb abnormalities are typically limb truncation defects affecting the distal phalanges, entire digits and/or distal limbs. Cardiac and vascular malformations have also been frequently reported in this disorder. Autosomal dominant inheritance is the most frequently reported mode of inheritance for Adams-Oliver syndrome, although autosomal recessive inheritance has also been suggested. We report a new family of Mexican ancestry with Adams-Oliver syndrome with multiple affected individuals in four generations that segregates in an autosomal dominant fashion. The affected members exhibit significant phenotypic variability ranging from distal phalangeal involvement to severe limb reduction defects. The absence of congenital scalp defects in some family member suggests that this feature is not an invariably finding in Adams-Oliver syndrome patients. The etiopathogenesis of this disorder remains unclear, but genes involved in vasculogenesis/angiogenesis during limb development have been proposed as possible candidates for this disorder. An Agilent 244K Whole Human Genome CGH Microarray analysis failed to reveal any significant copy number changes to suggest loss or gain of genetic material in affected patients of this family. Currently linkage studies on this large family are underway to identify the gene responsible for Adams-Oliver syndrome.

Facilitating DNA diagnostics by collecting human disease gene variation using an open source LSDB-in-a-Box platform - LOVD 2.0. *I.F.A.C. Fokkema, P.E.M. Taschner, G.J.B. van Ommen, J.T. den Dunnen* Human and Clinical Genetics, Leiden University Medical Center, Leiden, Nederland, http://www.DMD.nl/.

Locus-Specific mutation DataBases (LSDB) play an important role in DNA diagnostics facilitating proper evaluation of the variant, i.e. being pathogenic or not. For LSDBs to be of highest value, it is evident that all variants identified world-wide, pathogenic or not, should be collected and made available without delay. Although everybody realizes that only a complete and fully up-to-date LSDB is most helpful, daily practice shows that the reporting of mutations identified, outside scarce publication in scientific journals, is rather infrequent. With a local focus on genes involved in muscular dystrophies we have tried several approaches to improve the collection and curation of these variants. First, we have developed the Leiden Open Source Variation Database (LOVD[1]) software (http://www.LOVD.nl). The software is fully web-based, platform-independent, open source, built as an LSDB-in-a-Box and follows current HGVS guidelines. To promote initiation of LSDBs we offer free server space and installation on the Leiden server. LOVD currently stores 18,000 variants in 51 genes contributed by 150 submitters world-wide. In collaboration with UCSC, variants can be viewed in the genome browser using the Locus Variants track, linking directly back to the original data collected in LOVD. To improve consistency and reduce the numbers of errors we have implemented error-checking using the Mutalyzer mutation nomenclature checker module (http://www.LOVD.nl/mutalyzer). In the latest version of LOVD we have enhanced flexibility and e.g. included the possibility to store information about sequence variants in multiple genes per patient. LOVD 2 has a dynamic structure allowing curators to add per gene any column. These features allow the use of LOVD 2 for federated LSDBs as suggested in the recent recommendations of the Human Variome Project meeting[2].

A robust statistical method for genome-wide Copy Number Variation association studies. *C. Barnes[1], V. Plagnol[2], N. Cardin[3], J. Marchini[3], D. Clayton[2], M. Hurles[1] on behalf of the WTCCC CNV Analysis Group* 1) Human Genetics, Wellcome Trust Sanger Institute, Cambridge, UK; 2) Department of Medical Genetics, Cambridge Institute for Medical Research, University of Cambridge, Cambridge, UK; 3) Department of Statistics, University of Oxford, Oxford, UK.

Copy Number Variation (CNV) is pervasive in the human genome, and has previously been demonstrated to be involved in the aetiology of all classes of genetic disease. The functional impact of CNV cannot be captured in its entirety through linkage disequilibrium with SNPs. These two observations motivate the development of efficient statistical methods for performing direct CNV association studies. CNV can be mined from the quantitative allele intensity data underlying the current generation of genome-wide SNP genotyping platforms. We show through simulation that current chi-square testing of CNV association are prone to substantial inflation if underlying quantitative data are noisy, as is generally the case with current technologies. These simulations motivate the development of a more robust methodology for performing CNV association from quantitative data. We present a general statistical framework for performing case-control CNV association studies. This framework entails the fitting of mixture models separately to quantitative data from cases and controls and performing significance testing of the proportions of each population with different copy numbers at a given locus. We show that our method does not produce inflated p values. Moreover, we have integrated genetic models within this association testing framework, thus improving statistical power. The power of this approach is exemplified through the analysis of the Affymetrix 500k data on the ~17,000 samples of the Wellcome Trust Case Control Consortium, which represent two control and seven case populations.

Graphical browsing for whole-genome association studies of global gene expression. *W. Chen[1], L. Liang[1], M. Lathrop[2], W.O.C Cookson[3], G.R. Abecasis[1]* 1) Department of Biostatistics, University of Michigan, Ann Arbor, MI, U.S; 2) Centre National de Genotypage, Evry, France; 3) Imperial College, London, U.K.

We describe an interactive package that provides graphical overviews of whole-genome association studies of datasets with very rich phenotypic information, such as global surveys of gene expression. The software incorporates a generic eQTL database and provides a graphic interface for browsing association between transcript levels and SNPs. For each transcript, our browser can tabulate and plot association test statistics, estimates of effect size and allele information across the genome. The browser automatically links results to the UCSC genome browser where users can examine each transcript in its genomic context. In addition to browsing the results by transcript or by position, results can be searched for information on specific SNPs. LD and tag information is provided for SNPs not in our database but evaluated by the International Hapmap Consortium. To illustrate the utility of our approach, we show how our database can be used to browse results of an association study of global gene expression. This study genotyped 408,298 SNPs to identify eQTLs associated with levels of 54,675 transcripts representing 20,599 known genes in EBV-transformed lymphoblastoid cell lines in ~400 children. Using their data, we constructed a database to summarize association results between transcripts and individual SNPs. The browser facilitates integration of the results with other gene mapping projects. For example, in a recent GWA association scan, a series of SNPs in an intergenic region on chromosome 5p were associated with Crohn's Disease (Libioulle, C. et al. 2007). The SNPs are more than 200 Kb away from the nearest annotated gene. Our database shows that these SNPs regulate expression of PTGER4 (e.g. association with rs4495224 can explain 4.7% of the variance in PTGER4 levels, $p < 7*10^{-5}$). In the future, the software has a potential to be scalable tool to browse even larger gene-expression genome-wide scans. The software can be downloaded at http://www.sph.umich.edu/csg/liang/asthma/.

Agalsidase alfa reduced cardiac mass in Fabry disease patients with left ventricular hypertrophy. *C. Kampmann[1], A. Linhart[2], R. Schiffmann[3], R. Devereux[4]* 1) University Children's Hosp, Mainz, Germany; 2) Charles University, Prague, Czech Republic; 3) National Institutes of Health, Bethesda, MD, US; 4) Weill Cornell Medical College, NY, NY, US.

Left ventricular hypertrophy (LVH) is a common finding in Fabry disease. This retrospective study was conducted to assess the effect of agalsidase alfa (Replagal (Shire HGT, Cambridge, MA, US), 0.2 mg/kg, every other week) on left ventricular mass index (LVMi) in male and female Fabry patients with baseline LVH. All 45 adult patients (34 male, 11 female) had participated in clinical trials and/or had received at least 3 years of commercial treatment with agalsidase alfa. Serial echocardiograms were obtained at baseline and at 1 and/or 3 years of treatment, and were assessed in a blinded fashion by a single investigator (RD). LVMi change from baseline was evaluated with a sign-rank test. At baseline, 14 patients had LVH (mean LVMi=55.45.7 $g/m^{2.7}$; in the remaining 31 patients, mean LVMi=39.16.5 $g/m^{2.7}$). In 9 baseline LVH patients who had 1-year data, LVMi had declined by 9.27.9 $g/m^{2.7}$ (P=0.008), and in 10 patients who had 3-year data, LVMi had declined by 5.17.5 $g/m^{2.7}$ (P=0.037). In 28 patients without baseline LVH, a small increase in LVMi was observed after 1 year of treatment (3.65.7 $g/m^{2.7}$, P=0.002), but the average LVMi remained well within the normal range. In 26 patients without baseline LVH, a small and statistically insignificant increase in LVMi was seen after 3 years (2.17.9 $g/m^{2.7}$, P=0.27). Although no untreated patients were included in this study, another group of male and female Fabry patients had serial examinations in a separate natural history study. These patients with baseline LVH demonstrated an increase in LVMi of 6.013.3 $g/m^{2.7}$ (n=13; P=0.17) and 20.311.7 $g/m^{2.7}$ (n=8; P=0.008) in LVMi after 1 and 3 years, respectively. In contrast, LVMi in natural history patients without baseline LVH did not change after 1 year (-0.83.7 $g/m^{2.7}$, n=10, P=0.32) and increased after 3 years (4.85.0 $g/m^{2.7}$, n=21, P<0.001). In conclusion, treatment with agalsidase alfa for 1 or 3 years reduced LVM in Fabry disease patients with baseline LVH.

Estimating significance thresholds for genomewide association scans. *F. Dudbridge, A. Gusnanto* Biostatistics Unit, Medical Research Council, Cambridge, United Kingdom.

The question of what significance level is appropriate for genomewide association studies is somewhat unresolved. Permutation testing is advocated, but does not resolve the difference between the genomewide multiplicity of the experiment, and the subset of markers actually tested. A standard significance level would facilitate reporting of results and reduce the need for permutation tests. We used genotypes from the Wellcome Trust Case-Control Consortium to estimate a genomewide significance level. We sub-sampled the genotypes at increasing densities, using permutation to estimate the nomimal p-value for 5% family-wise error. By extrapolating to infinite density, we estimated the genomewide significance level to be about 6.39E-8. We compared this to two estimators of the effective number of tests. The first fits a beta distribution to permutation replicates, and the second is based on an eigenvector decomposition of the genotype data. The beta distribution is not exact, but we found that it provides a workable approximation for calculating genomewide significance. Patterson's eigenvalue estimator requires less computation but was found to be an order of magnitude too low, leading to increased type-1 errors. We found that this estimator is only accurate when the effective number is closer to the actual number of tests. We conclude that permutation is still needed to obtain genomewide significance levels, but with sub-sampling, extrapolation and estimation of an effective number of tests, the significance level can be standardized for all studies of the same population.

Evidence for an etiologic role of WNT gene family in nonsyndromic cleft lip with or without cleft palate. *B.T. Chiquet[1,2], S.H. Blanton[3], D. Ma[3], S. Stal[4], J.B. Mulliken[5], J.T. Hecht[1]* 1) University of Texas Medical School at Houston, Houston, TX; 2) University of Texas Dental Branch, Houston, TX; 3) University of Miami Miller School of Medicine, Miami, FL; 4) Texas Childrens Hospital, Houston, Houston, TX; 5) Childrens Hospital, Boston, MA.

Nonsyndromic cleft lip with or without cleft palate (NSCLP) is a common complex birth disorder with a prevalence of 1/700 live births. Genetic and environmental factors have been implicated and studies have begun to delineate genetic contributions. The Wnt gene family plays an integral role during embryogenesis, including regulating midfacial development and upper lip fusion. Also, the clf1 region in A/WyN clefting susceptible mice contains two Wnt genes. Both suggest that Wnts are biologically plausible NSCLP candidate genes. To determine if Wnt genes are associated with our NSCLP cohort, we interrogated seven Wnt genes: Wnt3, -3a, -5a, -7a, -8a, -9b, and -11. These genes are either (a) mutated in a orofacial clefting syndrome, (b) expressed in the developing craniofacial region or (c) interact with other known NSCLP candidate genes. Thirty-eight single nucleotide polymorphisms (SNPs) and two microsatellite markers were genotyped in 63 multiplex NSCLP families and 287 simplex parent-child trios. All SNPs were in HWE. Allele frequencies were significantly different between our Caucasian and Hispanic cohorts; therefore the data was stratified by ethnicity and analyzed using the pedigree disequilibrium test (PDT) and genotype-PDT. At least one SNP in each gene was significantly associated to NSCLP. The most significant results were found for SNPs in Wnt11 (p=0.002), Wnt3a (p=0.0054), and Wnt5a (p=0.0004). Wnt11 directs neural crest cell (NCC) migration and Wnt3a controls the fate of NCC migration; NCCs are part of the craniofacial processes that form the upper lip and palate. Likewise, Wnt5a is highly expressed in the developing craniofacial processes. Alteration in Wnt gene function may perturb craniofacial process formation/fusion and may predispose an individual to NSCLP. The results of this study suggest that variation in Wnt genes plays an etiological role NSCLP and gene-gene interaction studies are underway.

Detecting Loci That Confer Susceptibility to Dust Mite-Induced Asthma Using a Combined *In Vivo* and *In Silico* Approach. *S.N.P. Kelada[1], D.M. Brass[2], S. Maruoka[2], D.A. Schwartz[2,3], F.S. Collins[1]* 1) Genome Technology Branch, National Human Genome Research Institute, Bethesda, MD; 2) Laboratory of Environmental Lung Diseases, National Heart Lung and Blood Institute, Research Triangle Park, NC; 3) National Institute of Environmental Health Sciences, Research Triangle Park, NC.

Asthma is a disease of major public health concern. The etiology of asthma is multifactorial in nature, and involves interactions between genes and environment. Allergen exposure is a well known inciting factor for asthma among atopic individuals. In particular, house dust mite (HDM) exposure has consistently been linked to the development of asthma and exacerbations of symptoms. We aim to identify loci that confer susceptibility to HDM-induced asthma by examining the effects of HDM exposure *in vivo* across thirty inbred strains of mice whose genetic variation has previously been well characterized by a public mouse HapMap effort.

Mice are sensitized by two intra-peritoneal injections (on days 0 and 7) of purified natural dust mite allergen (nDer p 1), followed by oro-tracheal administration of the allergen on day 14. Forty-eight hours after airway challenge, cytokine levels and inflammatory cell influx into the lungs are measured, as well as pulmonary function by means of the Flexivent technique. Changes in gene expression in airway epithelial cells and T cells from lymph nodes are also examined. Strain-dependent responses (phenotypes) can then be mapped to loci *in silico* using a newly developed genome-wide association method that accounts for the population structure of the inbred strains of mice and employs a set of approximately 150,000 publicly accessible haplotype tagging SNPs. Both cis- and trans- expression determinants can be mapped using this method. Results from these experiments will be used to guide candidate gene selection in a case-control study of asthma susceptibility in humans.

Nonsense-mediated mRNA decay modulates cellular fate in response to DNA damage. *D. Huang, F. Spencer, H.C. Dietz* Inst Genetic Med, Johns Hopkins Univ Sch of Med, Baltimore, MD.

All eukaryotes degrade transcripts harboring PTCs through the action of the nonsense-mediated mRNA decay (NMD) pathway. NMD protects the organism from the deleterious effects of truncated peptides that would be expressed from nonsense alleles if the transcripts were stable. The rare occurrence of nonsense mutations could not plausibly account for complete evolutionary maintenance of this function. Recent evidence suggests that NMD can coordinate cell survival pathways in response to environmental stress such as starvation. In yeast, as in higher eukaryotes, the core NMD machinery is composed of three gene products termed UPF1, UPF2 and UPF3. In an attempt to further define physiologic functions of NMD, we performed a synthetic lethal screen in S. cerevisiae with a *upf1* strain. This screen identified known and novel factors that genetically interact with UPF1. The only known function of one of these factors (ESC2) is a weak contribution to mating type locus silencing. Here we show that *esc2upf1* cells show a severe synthetic-sick phenotype and demonstrate a dramatic increase in sensitivity to DNA-damaging agents including bleomycin, hydroxyurea and MMS. This phenotype was also observed upon targeting of the other UPF genes in *esc2* cells, documenting that the genetic interaction was with the NMD pathway *per se*. Untreated *esc2upf1* cells showed an increase in spontaneous double-stranded DNA breaks, as evidenced by increased YAC telomeric marker loss that was resolved by de novo telomere addition. Exponentially growing *esc2upf1* cells revealed accumulation of large-budded cells with one nucleus and also showed increased loss of large YACs, indicative of unequal chromosome segregation. These data infer a role for NMD in determining cellular susceptibility and/or response to DNA damage, expanding the repertoire of survival responses coordinated by this pathway. Parallels between the DNA damage susceptibility and aneuploidy predisposition in *esc2upf1* cells and early phases of tumorigenesis warrant further scrutiny.

Analysis of familial recurrence patterns of nonsyndromic oral clefts in Denmark: a registry study with 6,811 probands. *C. Chevrier[1,2], D. Grosen[1], C. Bille[1,3], J.C. Murray[4], K. Christensen[1]* 1) Epidemiology, Institute of Public Health, Univ Southern, Odense, Denmark; 2) Inserm, U625, GERHM, Univ Rennes I, IFR 140, Rennes, France; 3) Plastic Surgery Dep, Odense University Hospital, Odense, Denmark; 4) Paediatrics Dep, Univ Iowa, Iowa, USA.

Oral clefts (congenital anomalies that affect 1/700 live births) are genetically complex. This study provides an analysis of their familial recurrence patterns from Danish registries. Two groups are distinguished: cleft lip with/without cleft palate (CL/P) and cleft palate only (CP). Based on the theory developed by Risch (1990), we compute familial risk ratios defined as the risk to a type of relative of an affected individual divided by the population prevalence and we compare the observed values with the predicted values under various genetic models. We also use the method of Schliekelman and Slatkin (2002) for estimating the number of susceptibility loci involved. From 4,685 CL/P probands and their 37,749 relatives, we observe the following risk ratios to 1st, 2nd and 3rd degree relatives: respectively, 22.3 (confidence interval: 20.0-24.6), 4.5 (3.6-5.5) and 2.7 (1.9-3.7). From 2,126 CP probands and 16,744 relatives, the observed risk ratios are: 41.3 (34.5-48.6), 6.6 (4.3-9.4) and 1.9 (0.6-4.0). These results exclude single-locus inheritance of both conditions CL/P and CP, rejecting also models assuming multiple additive loci and multiple independent loci. We observe that both conditions are likely to be determined by several loci acting in multiplicative fashion. Numerous models are plausible but no single locus appears to account for more than a threefold increase in risk to 1st-degree relatives of CL/P proband and the maximum effect of the CP susceptibility loci is to increase the risk to 1st-degree relatives by a factor of six. We estimate a number of loci between 1 and 5 for CL/P and between 1 and 9 for CP. These results benefit from a well-defined population, high-quality data and accurate estimates of the population prevalence in Denmark. They provide the most accurate indication of the mode of inheritance of nonsyndromic oral clefts. Such analyses are now needed on other single geographic populations.

Candidate gene screening of a locus on chromosome 14 and analysis of anticipation in familial Ménière disease.

M.E.S. Bailey[1], Y. Lowe[1], A.W. Morrison[2], G.A.J. Morrison[3] 1) Div Molecular Genetics, IBLS, Univ Glasgow, Glasgow, U.K; 2) Dept. of Otolaryngology, Royal London Hospital, London, U.K. (formerly); 3) Dept. of Otolaryngology, Guys and St Thomas Hospitals, London, U.K.

Ménière disease (MD) is a late-onset, multifactorial disorder characterised by episodic hearing loss, tinnitus, and rotatory vertigo and associated with a significant reduction in quality of life. Its aetiology may involve endolymphatic hydrops, whereby increased hydrostatic pressure in the endolymph compartment probably leads to dysfunction and destruction of cochlear and vestibular hair cells. Approx. 7% of cases are familial, and our series consists of 46 confirmed families with two or more cases of definite MD. A genome scan using 18 of these MD families yielded significant evidence for linkage (HLOD 4.19, = 55%, 80% penetrance) to a region on chromosome 14q. A critical region of 5Mbp containing 16 identified genes has been defined in 14q21.2-q21.3. Ranking of these genes as positional candidates has been carried out using PROSPECTR and SUSPECTS, and screening of each candidate for mutations is ongoing, with 5 of the genes completed so far. Novel polymorphisms have been recognised, but no likely causative variants. We have also carried out an analysis of age-of-onset anticipation. The mean difference in AOO between parent-offspring generations was 16.5yrs in all suitable MD families in our series. Corrections to the analysis to reduce known ascertainment bias factors yield results that are consistent with real anticipation. We have embarked on a screening programme of potentially expanding microsatellite repeats in the critical region; all screened thus far appear invariant in the patient set and this is currently being confirmed in individuals from the general population. There is no evidence so far for an expanding repeat being responsible for the disorder in the chr.14-linked MD families in this sample. The identity of the predisposing gene at this locus thus remains elusive. Its identification should suggest candidates to screen in the remaining families and illuminate pathways contributing to susceptibility to the more common, sporadic cases of MD.

Inference of the peopling of the world under sequential bottlenecks with admixture. *G. Hellenthal, D. Falush*
Department of Statistics, University of Oxford, Oxford, UK.

Extracting information about migrations from autosomal data represents a formidable statistical challenge. We here present a statistical approach, based on the copying model introduced by Li and Stephens (2003), that uses the detailed information on ancestry provided by the structure of variation in haplotypes to infer patterns of colonization. In inferring a human history, our approach has two principal advantages over most previous models. Firstly, it makes no geographical assumptions but instead infers a pattern of colonization using genetic data alone. Secondly, our model allows each population to have multiple sources, allowing us to detect both geographically near and distant sources of admixture and hence to provide a richer approximation to the complex historical processes of human migration. We demonstrate the accuracy of our approach using data simulated under a coalescent with recombination model with various migration scenarios.
We apply our model to the SNP data for the 52 populations of the Human Genome Diversity Project described in Conrad et al. (2006). Our results are broadly consistent with existing serial dilution out-of-Africa models but add several interesting details. For example: (1) while European populations have received multiple independent contributions from both the Near East and Central Asia, Far Eastern populations derive most of their ancestry from two central Asian populations; (2) there is evidence for gene flow between populations on opposite sides of the Arctic Circle; (3) the Melanesians have an important source of ancestry from African hunter-gatherer populations independent of the main out-of-Africa bottleneck; (4) North and South Americans have important ancestral contributions from distinct Asian sources, implying multiple waves of migration into the Americas. A detailed depiction of the peopling of the world is available in animated form.
.

Association study of SNPs in the PHF11 gene in Italian families with allergic asthma. *C. Bombieri, P. Zorzi, G. Malerba, L. Xumerle, P.F. Pignatti* Sec Biology & Genetics, Dpt. Mother and Child, and Biology-Genetics, University of Verona, Verona, Italy.

In an our previous genome wide scan for asthma in 123 Italian families, phenotyped for clinical asthma and rhinitis, skin prick test positivity to common aeroallergens, total serum IgE levels (IgE), bronchial hyperresponsiveness to methacholine, linkage on chromosome 13q14 has been detected for elevated IgE. Association of the PHF11 gene with IgE and atopic dermatitis (AD) was found in two recent studies (Nat Genet 34:181;2003; Genes Immun 6:264;2005). We have now performed a linkage and association study of the PHF11 gene polymorphisms in a subset of 24 families (144 subjects) which have shown positive linkage for IgE. The following 7 SNPs, located inside the gene and reported to be associated with IgE and AD in the above mentioned studies, were selected and analysed: 185306b7_2 (intron1); rs2031532 (ex2); rs2247119 (intron3); rs2274276 (intron4); 185752b4_2 (intron5); 185752b5_2 (intron9); rs1046295 (3UTR). SNPs were genotyped by minisequencing (SNaPShot Multiplex kit, Applera, on ABIPRISM 310 sequencer using Genescan software) or by enzymatic restriction. Linkage analysis was perfomed using MERLIN software and association study was performed by Transmission Disequilibrium Test (TDT) using the unphased software: //www.mrc-bsu.cam.ac.uk/personal/frank/software/unphased. A correction for multiple test of the obtained data was applied. Statistical analysis results confirmed our previous findings of linkage of this chromosomal region to IgE in allergic asthma, but did not show significant association of the PHF11 gene SNPs with any of the studied phenotype. In our population, association might be due to other polymorphisms of the PHF11 gene or to other genes located in this chromosomal region.

Bezafibrate cures clinical and metabolic symptoms of the muscular form of CPT2 deficiency. *F. DJOUADI[1], J. BASTIN[1], P. LAFORET[3], F. AUBEY[1], A. MOGENET[4], S. ROMANO[5], A. VASSAULT[5], S. GOBIN[2], B. EYMARD[3], JL. BRESSON[5], JP. BONNEFONT[2]* 1) CNRS UPR 9078 and; 2) INSERM U781,Université Paris-Descartes; 3) Myology Institute, Hopital de la Pitié; 4) CIC Necker and; 5) Metabolism and Biochemistry Department, Hopital Necker; Paris, France.

Carnitine Palmitoyltransferase 2 (CPT2) is a key-enzyme of mitochondrial fatty acid beta-oxidation (FAO), involved in the control of long-chain fatty acids (LCFA) entry into mitochondria. CPT2 deficiency has 2 clinical presentations: a neonatal form with fatal hepatocardiac failure, or an adult myopathic form with myalgia, exercise intolerance, and recurrent attacks of rhabdomyolysis triggered by exercise, fever, starvation.... The phenotypic variability correlates with residual CPT2 activity, degree of impairment of long-chain FAO (LCFAO), and CPT2 gene mutations. Management of patients based on reduced lipid intake or exercise limitation has little effect on clinical condition, and there is no established therapy for this disorder We recently showed that exposure of CPT2-deficient fibroblasts or myoblasts to bezafibrate, a widely prescribed hypolipidemic drug acting as PPAR agonist, could up-regulate CPT2 gene expression and residual enzyme activity, and possibly led to correct LCFAO flux in the deficient cells. This led us to set up a clinical trial in 6 patients with the muscular form of CPT2-deficiency, who received a daily 600-mg dose of bezafibrate for 6 months. Clinical tolerance of the treatment was excellent. Clinical condition dramatically improved in 5/6 patients, with a marked decrease in myalgia intensity and frequency, and a strong improvement in exercise tolerance and life quality. In vitro analyses were carried out on lymphocytes and skeletal muscle, sampled prior to- and at the end of the trial. LCFAO in isolated muscle mitochondria was strongly induced in 6/6 patients, and this effect was shown to result from drug-induced up-regulation of CPT2 mRNA and protein levels. For the first time, a pharmacological approach impacting the cause of the disease and not only its consequences has proven to be efficient in treating a mitochondrial FAO disorder.

De novo interstitial inverted duplication 1q41-q42 delineated by molecular cytogenetic techniques. *S. Chantot-Bastaraud[1,2,5], K. Krabchi[1,2], E. Pipiras[3], A. Guet[4], A. Afenjar[4], K. McElreavey[5], B. Benzacken[3], JP. Siffroi[1,2]* 1) AP-HP, Hopital Tenon, Service dHistologie, Biologie de la Reproduction et Cytogenetique - Universite Pierre et Marie Curie, Paris6, France; 2) Universite Pierre et Marie Curie- Paris 6, EA 1533, Paris, F75020, France; 3) AP-HP, Hopital Jean Verdier, Service dHistologie-Embryologie et Cytogenetique - UFR-SMBH, Bondy, France; 4) AP-HP - Hopital Trousseau- Service de Neuropediatrie- Universite Pierre et Marie Curie, Paris6, France; 5) Unite de Reproduction, Fertilite et Developpement, Departement de Biologie du Developpement, Institut Pasteur, Paris, France.

Partial duplications of the long arm of chromosome 1 are uncommon cytogenetic anomalies. Most of them arise from de novo unbalanced translocations or from the unbalanced inheritance of a parental balanced rearrangement. However, involvement of other chromosomes may confound the phenotype of trisomy 1q. Thus, pure trisomy are particularly useful for establishing a karyotype-phenotype correlation . We report the case of a 10 month-old male who was referred to clinic because of dysmorphic features and psychomotor retardation. Traditional G-band chromosome studies of the patient was interpreted as 46,XY,dup(1)(q42q41) and subsequently confirmed by fluorescence in situ hybridization using whole chromosome paint 1. No terminal deletion was found. To further evaluate the extent of the chromosome 1 duplication, a series of fluorescence in situ hybridization probes were used . The characterization by multiple locus specific FISH probes allowed a more refined delineation of the phenotypic findings and clinical significance associated with this rare partial trisomy 1q with inverted duplication 1q41-q42. The clinical similarities and differences between previously reported cases with trisomies of the long arm of chromosome 1 are discussed.

Accurate prediction of *BRCA1* and *BRCA2* heterozygous genotype using expression profiling of lymphocytes after irradiation induced DNA damage. *Z. Kote-Jarai[1], S. Jugurnauth[1], L. Matthews[2], I. Giddings[2], E. Bancroft[3], Carrier Clinic Collaborators[3], P. Agius[4], M. Girolami[4], C. Campbell[5], R. Eeles[1,3]* 1) Translational Cancer Genetics, Inst Cancer Research, Sutton, Surrey,UK; 2) Molecular Carcinogenesis, Inst Cancer Research, Sutton, Surrey,UK; 3) Royal Marsden NHS Foundation Trust, London, UK; 4) Computational Intelligence Unit, University of Bristol,UK; 5) Bioinformatics Research Centre, University of Glasgow,UK.

Germline mutations in *BRCA1* and *BRCA2* genes predispose women to an increased risk of breast/ovarian cancer. Both genes have important roles in DNA damage repair and are implicated in gene expression regulation. We have previously shown that normal fibroblasts from mutation carriers can be distinguished from non-carriers following radiation-induced DNA damage. In this new study we used lymphocytes to find out if these also show differential response to induced DNA damage and if expression profiling using microarray technology could be used to accurately predict the BRCA genotype. Short-term lymphocyte cultures were established from fresh blood samples from 20 *BRCA1* and 20 *BRCA2* mutation carriers and 10 negative controls (individuals tested negative for the mutation present in the family). Lymphocytes were subjected to 8 Gy ionizing irradiation to induce DNA damage and RNA was extracted one hour post-irradiation. For expression profiling genome-wide (30 K) spotted cDNA microarrays manufactured by the Cancer Research UK Microarray Facility were used. We applied Support Vector Machine (SVM) classifier with statistical feature selection to determine the best feature set for predicting *BRCA1* and *BRCA2* heterozygous genotype. We also investigated the prediction accuracy using a non-probabilistic classifier (SVM) and a probabilistic classifier (a Gaussian Process Classifier:GPC). In general we achieved high accuracy (96%) in predicting the mutation carrier status. We will present the detailed outcome of using SVM and GPC in the task of distinguishing between the 3 classes, *BRCA1* and *BRCA2* mutation carriers and non-carriers, and evaluate if this microarray technology can be used to facilitate the clinical detection and classification of mutations.

Globin Gene Mutations in Turkey. *M.A. Curuk* Biochemistry, C.U. Medical Faculty, Adana, Balcali, Turkey.

Hemoglobinopathies are the most common genetic abnormalities causing health problems in the world. Beta thalassemia (-thal)and sickle cell anemia (SCA)constitute the majority of hemoglobin (Hb) disorders in Turkey. -thal is seen throughout the country but SCA is prevalent in the Çukurova Region, Southern Part Turkey. The overall frequency of -thal is 2 per cent. The highest frequencies are observed in Antalya and Mugla (10 and 4.8 per cent). The incidence of -thal trait is 3.7 per cent and of HbAS 10 per cent in the Çukurova region (Adana, Hatay and Mersin). The sickle cell gene is very common in Çukurova and prevalent among Eti-Turks living in this region. The frequency of sickle cell trait (HbAS) ranges from 0.5 to 44.2 per cent. In addition to HbS [6;GluVal] more than 42 abnormal Hb variants have been reported in Turkey. Furthermore, about 40 different -thal mutations were characterized in Turkish population. The most common -thal mutation is IVS1-110 (GA) and almost ten of the mutations constitute about 90 per cent all of the cases. Since, there is no cure for -thalassemia and sickle cell disease at present, the type of the mutation must first be identified for prenatal and preimplantation diagnosis. The incidence of alpha thalassemia (-thal) is about 1-2per cent in Turkey. HbH disease is a severe form of -thalassemi but is compatible with life. Combinations of -thal-1 (--/)and -thal-2 (-/) determinants cause HbH (4) disease. A patient who inherited a single -globin gene (--/-) has HbH disease with a chronic hemolytic anemia. HbH disease in the Turkish population is most commonly produced by the deletions of three structural -globin gene (--/-) and rarely by the combination of -thal-1 and nondeletional mutations (--/)affecting the -globin genes (2 or 1). Three -thal-1 (-17.4 kb, -20.5 kb and -26.5 kb), two -thal-2 (-3.7 kb and -4.2 kb) and four nondeletional mutations PA1, PA2 [(PA1: AATAAAAATAAG or PA2: AATAAAAATGAA) -5nt, and codon 59 (GGCGAC)] have been reported in Turkey. The molecular basis of HbH disease is quite heterogeneous in Turkey. The presences of 12 different genotypes in 32 patients with HbH have been presented in this study.

Timing of BRCA1/BRCA2 genetic testing in women with ovarian cancer. *M.S. Daniels[1], D.L. Urbauer[2], J.L. Stanley[1], K.G. White[1], K.H. Lu[1]* 1) Gynecologic Oncology, U.T. M.D. Anderson Cancer Center, Houston, TX; 2) Quantitative Sciences, U.T. M.D. Anderson Cancer Center, Houston, TX.

Introduction: 10-15% of women with ovarian cancer have a germline BRCA1/BRCA2 mutation. Women with ovarian cancer are often diagnosed at advanced stages, when overall prognosis is poor. Results of BRCA genetic testing are both important to family members, and could impact ovarian cancer treatment. **Purpose:** To determine when, during the course of their treatment, women with ovarian cancer were seen for BRCA1/BRCA2 genetic testing, and what factors influenced timing. **Methods:** We identified 100 women who underwent treatment for ovarian cancer and had BRCA1/BRCA2 genetic testing at a single institution. Data were collected retrospectively. **Results:** 33 (33%) women were seen for genetic counseling before or during their initial treatment, 34 (34%) were seen while in first remission, and 33 (33%) were seen at or after first recurrence. Of those seen at or after recurrence, 4 (12%) died prior to disclosure of genetic test results. Women who had a history of breast cancer were seen earlier in the course of their treatment than women who never had breast cancer ($p<0.05$). 45 (45%) women tested positive for a BRCA1 or BRCA2 mutation, and women who had a history of breast cancer were more likely to test positive than women who never had breast cancer ($p<0.05$). **Conclusion:** Women with ovarian cancer are seen for genetic counseling throughout the course of their treatment, with an even distribution. Women with a prior history of breast cancer were seen earlier in the course of their treatment, implying that they are being appropriately flagged as high risk. The mutation detection rate among women with ovarian cancer seen for genetic counseling is high, and is even higher among women who had breast cancer. One third of women with ovarian cancer were not seen for genetic counseling until first recurrence or later. These women should be seen earlier in the course of their treatment, both to alleviate the difficulties of direct disclosure of results to next of kin, as well as to provide them with the opportunity to potentially benefit from therapeutics targeted to BRCA-positive patients.

Sapropterin dihydrochloride (sapropterin) increases phenylalanine (Phe) tolerance in children with phenylketonuria (PKU) maintained on a Phe-restricted diet. *D. Gruskin[1], A. Dorenbaum[2], J. Bebchuk[3], N. Longo[4]*
1) Emory Univ Schl Med,Decatur,GA; 2) BioMarin Pharmaceutical Inc.,Novato,CA; 3) Statistics Collaborative Inc,Washington,DC; 4) U Utah,Salt Lake City,UT.

Intro:Current PKU management focuses on blood Phe control using a Phe-restricted diet, but non-compliance with the diet may increase as children approach adolescence. This double-blind, placebo-controlled, Phase 3 study investigated the efficacy of sapropterin on Phe tolerance in children with PKU on diet therapy who respond to sapropterin. Methods:In Part 1, 90 subjects (4-12 yrs) with a diagnosis of PKU with hyperphenylalaninemia (1 blood Phe measurement 360mol/L) and controlled (blood Phe 480mol/L) on a Phe-restricted diet for 6 months received sapropterin 20mg/kg/day, for 8 days. Responders (30% reduction in blood Phe and blood Phe 300mol/L[5mg/dL] on Day 8, arbitrarily defined) entered Part 2 and were randomized 3:1 to sapropterin or placebo for 10 weeks. Phe supplement was prescribed at Wk 3 and adjusted bi-weekly according to blood Phe levels. Primary endpoint was daily Phe supplement tolerated during 10 weeks while maintaining adequate blood Phe control (360mol/L[6mg/dL]). Results:Of 89/90 patients in Part 1, 50 were responders eligible for Part 2, 46 were randomized (sapropterin=33;placebo=12) and 1 did not receive drug. At Wk 3 prior to Phe supplementation, mean (SD) decrease in blood Phe compared with Wk 0 was 148.5(134.2)mol/L with sapropterin ($p<0.001$) and 96.6(243.6)mol/L with placebo ($p=0.2$). By Wk 10, mean (SD) daily Phe supplement tolerated was significantly increased from Wk 0 (0 mg/kg/day) with sapropterin (20.9[15.4]mg/kg/day; $p<0.001$) and with placebo (2.9[4.0]mg/kg/day;$p=0.027$). Mean (SD) daily Phe intake (dietary+supplement) increased (Wk 0-Wk 10) from 16.8(7.6) to 43.8(24.6)mg/kg/day with sapropterin ($p<0.001$), and from 16.3(8.4) to 23.5(12.6)mg/kg/day with placebo ($p=0.079$). In the sapropterin group, mean (SD) blood Phe at Wk 10 was 340.0(234.5)mol/L. Sapropterin had an acceptable safety profile (Grange et al). Concl:Sapropterin significantly increases Phe tolerance while maintaining adequate blood Phe control in children with PKU on a Phe-restricted diet.

A case of myeloma with *C-MYC* double minutes. *J.M. Cowan* Cytogenetics Laboratory, Tufts-New England Medical Ctr, Boston, MA.

Double minutes (dmin) are rare observations in a variety of malignant cells. They have been shown to be acentric, circular fragments of DNA that pass to daughter cells by random assortment. Dmin are more frequent in fresh cultures than in cultured cells and may transform into homogeneously staining regions after prolonged culture. The amplicon often involves *C-MYC* region, though *C-MYC* may not be the target gene. C-MYC rearrangements have been reported in 15% of primary multiple myeloma. We present a rare case of myeloma with *C-MYC* amplification in the form of dmin.

HF is a 56 yo. female, who presented with a history of progressive multiple myeloma-plasmacytoma, diagnosed 12/2005. As part of a workup for stem cell transplantation, her bone marrow aspirate was sent to the lab.

03/2006: 47,XX,t(11;14)(q13;q32),der(17)t(1;17)(q21;p13),+18[3]/47,idem,-X,add(5)(q33),+7,+8,add(13)(q34),+der(14)t(11;14)[1]/39-43,X,-X,del(5)(q13q33), del(6)(q15), t(6;15)(p23;q22),der(12)t(12;13)(q24.3;q12), del(13)(q21q33),-20[3] /46,XX[15]. FISH with a *C-MYC* probe revealed amplification in 79/415 cells. Review of metaphases revealed rare double minutes.

08/2006: following autologous stem cell transplant May 2006: 46,XX[20].nuc ish(MYCx2)[300]

02/2007: following stem cell transplant from brother October 2006: 46,XX,del(5)(q31q33),t(11;14)(q13;q32),add(13)(q34),add(17)(p13),20~40dmin [12]/46,idem,del(6)(q15q21)[2]/46,XY[6].nuc ish(CCND1x3),(IGHx3)(CCND1 con IGHx2)[212/336]/(MYCx2)(5MYC sep 3MYCx2)(5MYCx20~40)[105/300]

04/2007 46,XY.nuc ish(CCND1,IgH)x2[300]/(MYCx2)[300]

It has been demonstrated previously that cells become more chemosensitive after the loss of dmin. In this case the remaining cells lack dmin but are also male (donor) cells, suggesting that the observed response to therapy is the result of increased drug sensitivity. Since the number of dmin per cell increased with time, it is suggested that the response is linked to the presence of dmin in the cells.

The Alzheimer gene FE65 forms a transcriptional repressor complex with Teashirt-family proteins: Evidence for association of Teashirt genes with Alzheimer disease. *J.D. Buxbaum[1,2], G.W. Beecham, Jr.[3], J.L. Haines[4], M.A. Pericak-Vance[3], Y. Kajiwara[2]* 1) Psychiatry, Mount Sinai Sch Medicine, New York, NY; 2) Neuroscience, Mount Sinai Sch Medicine, New York, NY; 3) Miami Inst for Human Genomics, U Miami Miller Sch Medicine, Miami, FL; 4) Center for Human Genetics Research, Vanderbilt Univ Medical Ctr, Nashville, TN.

FE65, an Alzheimer amyloid precursor protein (APP)-binding protein, has been postulated to be involved in both nuclear signaling and in transcriptional regulation. Here we identified and characterized the interaction of the Teashirt family of transcriptional factors with the first phosphotyrosine binding domain (PTB1) of FE65. Teashirt proteins can function as transcriptional repressors and inhibit transcriptional activity mediated by FE65 in heterologous reporter assay. Moreover, we demonstrate that Teashirt proteins can directly recruit histone deacetylase (HDAC) 1 and 2, contributing to the repression activity of Teashirt. Moreover, components of inhibitor of acetyltransferase (INHAT) can be recruited to FE65, together with Teashirt/HDAC, leading to a powerful gene-silencing complex. Genetic association analyses indicate that two Teashirt genes (TSHZ1 and TSHZ3) are associated with Alzheimer disease in a first study (also see Beecham et al., this meeting). The data support a role for FE65 in regulating gene expression and provide further support for a genetic role for the APP-FE65 pathway in the etiology of Alzheimer disease.

Mutations in the brand-new lebercillin gene account for 7.9 % of Leber congenital amaurosis (LCA) type II. *S. Gerber[1], S. Hanein[1], I. Perrault[1], N. Delphin[1], J.-L. Dufier[2], C. Leowski[3], A. Munnich[1], J. Kaplan[1], J.-L. Rozet[1]* 1) Genetics Dpt & Research Unit INSERM U781, Hopital Necker, Paris, France; 2) Ophthalmology Dpt, Hopital Necker, Paris, France; 3) Institut d'Education Sensorielle, Paris, France.

Purpose: Leber congenital amaurosis (LCA) is the earliest and most severe form of inherited retinal dystrophy responsible for blindness or severe visual impairment at birth or within the first months of life. Up to date, ten LCA genes have been identified. Three of them account for ca. 43% of families and are responsible for a congenital severe stationary cone-rod dystrophy (Type I, 60 % of LCA in our series) while the seven remaining genes account for 32% of patients and are responsible for a progressive yet severe rod-cone dystrophy (Type II, 40 % of LCA in our series). The purpose of this study was to evaluate the involvement of the brand-new LCA gene Lebercillin and to look for genotype-phenotype correlations. Patients & Methods: 95 LCA families including one large multiplex and consanguineous families (5/7 affected sibs)linked to LCA5 were considered. LCA genes were excluded in all 95 families prior to the present study. Mutations in the lebercillin gene were searched by direct sequencing. Results and discussion: Two lebercillin mutations were identified in 3/95 families. The p.Q204X mutation was homozygous in the multiplex consanguineous family linked to LCA5 and heterozygous in a French family while the p.E396X mutation was homozygous in a multiplex consanguineous Maroccan family (2/7 affected sibs). The natural history of the disease in the 3 families allowed drawing preliminary genotype-phenotype correlations as all three were affected with a severe LCA type II: early-onset yet progressive disease, night blindness followed by photophobia, no hyperopia, fundus appearance of RP with macular rearrangement, visual acuity measurable at early stages and reduced to light perception or counting fingers by the end of the second decade onwards. Conclusion: The 11th LCA gene, lebercillin, accounts for about 3% of all LCA cases. Interestingly, lebercillin is the 8th gene responsible for LCA type II (7.9%).

Expression and association study of histidine triad nucleotide-binding protein 1 with schizophrenia. *Q. Chen[1], X. Wang[1], F.A. O'Neil[2], D. Walsh[3], K.S. Kendler[1], X. Chen[1]* 1) Psychiatry, Virginia Commonwealth University, Richmond, VA; 2) The Queens University, Belfast, Northern Ireland; 3) The Health Research Board, Dublin, Ireland.

Background: The histidine triad nucleotide-binding protein 1, HINT1, hydrolyzes adenosine 5'-monophosphoramidate substrates such as AMP-morpholidate. Recently it was found to be associated with dysregulation of postsynaptic dopamine transmission, thus suggesting a potential role in several neuropsychiatric diseases. The human HINT1 gene is located on chromosome 5q31.2, a region implicated in linkage studies of schizophrenia. HINT1 has been shown to have different expression in postmortem brains of schizophrenia patients versus controls.

Methods: In this work, we studied 8 SNPs (rs7735116, rs2526303, rs4696, rs3864283, rs2551038, rs2189663, rs7728773, rs3891636) covering 66.7kb of the HINT1 gene region using the Irish study of high density schizophrenia families (ISHDSF, 1350 subjects and 273 pedigrees) and the Irish case-control study of schizophrenia (ICCSS, 655 affected subjects and 626 controls). Expression studies of HINT1 were carried out in postmortem brain cDNAs from the Stanley Medical Research Institute from 35 schizophrenic patients, 34 with bipolar disorder and 35 unaffected controls by real time PCR.

Results: We found significant differences in allele frequencies in several SNPs for the ISHDSF and ICCSS samples in sex-stratified analyses; however the sex effect differed between the two samples. In expression studies, we found that affected male subjects had lower expression than female ($p=0.0063$). For subjects with a 1/1 genotype at rs386428, a marker showing male-specific association in the ICCSS, affected male subjects had lower expression than normal male controls ($p = 0.036$).

Conclusion: Data from both association and expression studies suggested that variants at HINT1 may impact on risk for schizophrenia.

Identification and analysis of positive selection in the FoxC subfamily of forkhead transcription factors. *C.D. Fetterman, M.A. Walter* Dept Medical Genetics, Univ Alberta, Edmonton, AB, Canada.

Forkhead gene family members are defined by a DNA binding domain termed forkhead and act as transcription factors in processes such as development and metabolism. Subfamilies, which are delineated by the letters A-R, have been defined using phylogenetic methods. The FoxC subfamily contains two human genes, *FOXC1* and *FOXC2*, both of which function as transcription activators and contain self-regulating inhibitory domains. Mutations in *FOXC1* lead to Axenfeld-Rieger syndrome, a disorder with anterior segment of the eye, craniofacial and dental anomalies, while mutations in *FOXC2* lead to lymphedema-distichiasis. We have utilized *in silico* methods to identify selection pressures on codons in FoxC subfamily members and *in vitro* methods to characterize a positively selected site that was identified. The *in silico* analyses included 13 FoxC sequences from six different species. An alignment and phylogeny were created and input into the codeml program, contained in the PAML package, to identify selection pressures on individual amino acid sites. One site, within the inhibitory domain of FOXC1, was under positive selection and all other sites were under negative selection. We are utilizing *in vitro* methods to study the hypothesis that positive selection of an amino acid indicates that the site is functionally important and that changes at a positively selected site will result in improper protein function. The positively selected site was changed from the wild type amino acid Ala to Gly, Pro, Phe, Glu and Arg, as well as deleted from FOXC1. Expression of the altered FOXC1 proteins indicated that these amino acid changes do not abolish protein production or alter FOXC1 localization within the cell. However, transactivation assays have shown that amino acid changes may reduce the transactivation capacity of FOXC1. The positively selected site may therefore be important for control of negative regulation of FOXC1 activity by the inhibitory domain. The reduction in transactivation supports the hypothesis that a positively selected site is important for proper function and that changes at a positively selected site may result in abnormal protein function.

DNA methylation alterations in males with Klinefelter syndrome. *B. Coffee, I. Albizua, S. Warren* Dept Human Genetics, Emory University, Atlanta, GA.

Klinefelter syndrome (47,XXY) is the most common chromosome abnormality in humans with an incidence of 1 in 600 males. The phenotype in Klinefelter syndrome is relatively mild with males presenting with hypogonadism, learning difficulties, gynecomastia after puberty and infertility in adulthood. Because of the mild phenotype, approximately 75% of males with Klinefelter syndrome go undiagnosed. Males with the Klinefelter variants 48,XXXY, 48,XXYY, and 49,XXXXY have a similar, but a more severe, phenotype than 47,XXY males. The mechanism of how additional sex chromosomes leads to the phenotypic features exhibited by Klinefelter males in not known. We present here evidence that the presence of supernumerary sex chromosomes result in the alterations of DNA methylation at various loci in the genomes of Klinefelter patients. Aberrant changes in DNA methylation can result in alterations in chromatin structure leading to changes in gene expression. Aberrant DNA methylation changes are associated with many human diseases, such as imprinting disorders (Prader-Willi, Angelman, Beckwith-Wiedemann and Russell-Silver syndromes), fragile X syndrome, and many types of cancers. The alteration of DNA methylation in Klinefelter patients suggest that additional sex chromosomes may act as a methylation sink, interfering with the establishment and maintenance of DNA methylation patterns in the human genome altering gene expression leading to the phenotypic features seen in Klinefelter patients.

Molecular and functional analysis of paraplegin gene (SPG7) mutations in patients with familial and sporadic spastic paraplegia. *D. Di Bella[1], C. Mariotti[1], M. Plumari[1], C. Gellera[1], F. Lazzaro[2], M. Muzi-Falconi[2], V. Fracasso[1], R. Fancellu[1], S. DiDonato[1], D. Pareyson[1], S. Baratta[1], F. Taroni[1]* 1) Div Biochem & Genetics, Fondazione IRCCS Istituto Neurologico C. Besta, Milan, Italy; 2) Dept of Biomol Sci & Biotechnol, University of Milan, Italy.

Hereditary spastic paraplegias (HSP) are a clinically and genetically heterogeneous group of neurodegenerative disorders. SPG7 mutations are responsible for autosomal recessive (AR) HSP with both pure and complex phenotypes. This gene encodes paraplegin, a component of mitochondrial mAAA metalloprotease. SPG7 was sequenced in 81 unrelated HSP patients [58 sporadic (S) and 23 AR cases]. A further group of 51 HSP patients (38 S and 13 AR) were screened for reduced paraplegin protein levels in lymphocytes. SPG7 gene was sequenced in the 7 patients exhibiting absence or severe reduction of paraplegin protein. The majority of patients presented a complex phenotype characterized by spastic gait and clinical and MRI signs of cerebellar involvement. Overall, pathogenic mutations (11 nonsense and 10 missense including A510V) were found in 19 sporadic patients and in 4 of the 36 familial cases but in none of 200 controls. Thirteen patients in the sporadic group (13.5%) and 4 in the familial group (11.1%) had mutations on both alleles. The remaining 6 sporadic patients carried a mutation on a single allele. Our study showed that: 1) analysis of paraplegin levels in lymphocytes from HSP patients is an efficient method for identifying mutated patients; 2) SPG7 mutations account for at least 13% (17/132) of HSP patients, an overall frequency higher than previously reported; 3) Western blot analysis demonstrated absence of paraplegin in patients carrying two null alleles and a severe reduction in patients with missense mutations including the A510V; 4) functional analysis of the mutant protein in a yeast cell system in which the human m-AAA is functionally reconstituted clearly indicated that the A510V, previously described as a polymorphism and more recently identified in numerous HSP patients (including 10 in our series) is a disease-causing mutation. [Partly supported by Telethon GUP04009 and Fondazione Mariani R0544 to FT].

Comparison of the performance of single- versus multi-SNP tags in an independent European sample. *S.P. Dickson[1], M.R. Nelson[2]* 1) Bioinformatics, North Carolina State University, Raleigh, NC; 2) Genetic Epidemiology and Analysis, GlaxoSmithKline, RTP, NC.

Current association study designs rely heavily on data from the International HapMap project to assist in the selection, application, and interpretation of genetic markers. These data have been particularly informative in the selection of population-specific tagging SNPs (tSNPs) and in the assessment of linkage disequilibrium (LD) between markers in fixed panels and common genetic variation. Recent methods have been proposed to increase the efficiency of the tag selection process and increase the information available from fixed panels by using haplotypes of typed SNPs (multi-SNP tags, or MSTs) to infer the allelic state of unmeasured variants. Multiple studies have been carried out to demonstrate that single SNP tags selected in the HapMap European sample (CEU) provide comparable genetic coverage in most other populations of European origin. Similarly, we set out to determine the relative value of MSTs by evaluating the performance of MSTs selected in the CEU sample from among SNPs on the Affymetrix 500K SNP panel in an independent sample of 203 individuals of European origin. MSTs are shown to have a larger selection bias than tSNPs, which appears to increase linearly from 2- to 3-SNP tagsthe median r^2 value in tSNPs was 0.09 lower in the independent sample than it was in CEU, while the median r^2 value decreased by 0.14 and 0.18 in the 2- and 3-SNP MSTs. Although the use of MSTs for aggressive tagging can reduce the number of SNPs typed by up to 20%, we find that this savings is partly offset by the corresponding reduction in genetic coverage. However, MST performance does support their application as an efficient and readily interpretable way to extend the coverage of fixed panels.

Oligo Fluorescence in situ hybridization (Oligo-FISH), a new strategy for enumerating chromosomes in interphase nuclei. *J. Aurich-Costa, P. Keenan, L. Zamechek, S. Bradley* Research and Development, One Cell Systems/Cellay, Cambridge, MA.

Objectives: Development of FISH probes using labeled oligonucleotides (ODNs) for 5 color chromosome enumeration in interphase nuclei. 10-20 ODN for chromosomes X, 15, 17 and 20 -satellite repeats and for chromosome Y alpha 3 repeat were designed in regions where the satellite 3 pentamer or the -satellite consensus sequence was underrepresented, 5 end labeled, and tested individually on human metaphases from 5 chromosomally normal individuals. Only ODNs exhibiting signal specific for the target region were selected for each chromosome cocktail. For each chromosome, ODNs were mixed together and hybridized on human cells and signal to noise ratio (S/N), sensitivity and specificity were assessed according to the Standards and Guidelines for Clinical Genetic Laboratories of the American College of Medical Genetics. Only probes exhibiting S/N >2 calculated on 30 interphase nuclei, and sensitivity and specificity 98% were included in each chromosome specific cocktail. Next, we selected 5 fluors that could be simultaneously assessed using epifluorescence. To rank fluor intensity, chromosome Y probe was labeled with all 5 fluors, and S/N was assessed. S/N obtained for each probe labeled with A568, was inversely matched with the ranking of the fluors. Finally, all the probes were mixed together, and varying hybridization times were tested until the shortest time giving the same S/N was found.

Results: We designed specific ODNs for 5 chromosomes. After probes were labeled with the 5 fluors and combined, all probes exhibited S/N >2. Hybridization time was determined at < 1hr.

Conclusions: FISH ODN probes short length permits rapid hybridization, a significant advantage for time critical procedures such as enumeration of chromosome in interphase nuclei for preimplantation genetic diagnostics. Due to the oligo size, hybridization time was < 1hr, a significant advantage for FISH.

Support: NIH grant: 1R43 HD052597-01.

***OSBPL11* Gene Polymorphisms are Associated with Obesity-Related Metabolic Complications and Diabetes in Obese Individuals.** *L. Bouchard[1,2,3], G. Faucher[1,2,3], A. Tchernof[2,3,4], Y. Deshaies[5], S. Marceau[6], O. Lescelleur[6], S. Biron[6], M.-C. Vohl[1,2,3]* 1) Lipid Research Center; 2) Nutraceuticals and Functional Foods Institute; 3) Department of Food Science and Nutrition; 4) Molecular Endocrinology and Oncology Research Center; 5) Department of Anatomy and Physiology and Laval Hospital Research Center; 6) Department of Surgery, Faculty of Medicine and Laval Hospital, Laval University, Quebec, Canada.

Hyperglycemia, dyslipidemia and hypertension are commonly observed in obese individuals and define the metabolic syndrome (SM). Although heritability studies provided evidence for a significant contribution of genetic factors in MS, only a limited number of genes have been consistently associated with this condition. Recently, an inventory of MS candidate genes has been generated by comparing the omental adipose tissue gene expression profile of non-diabetic obese men with and without MS. Of the genes found to be differentially expressed, the oxysterol-binding protein-like protein 11 (*OSBPL11*) was found to be slightly but significantly overexpressed in the MS group (1.34-fold, $P<0.05$). **Objective**: To determine whether *OSBPL11* gene polymorphisms are associated with MS and its individual components. Methods: *OSBPL11* gene promoter and coding regions were sequenced in 25 obese men and common tagging SNPs ($r^2<0.75$ between the SNPs; rs7625936, rs1055419, rs2979382, rs12496976, rs12487030 and IVS12+95) were genotyped in a sample of 958 obese individuals. Chi-square tests were applied to compare genotype frequencies between low and high-risk groups according to MS as defined by the NCEP-ATPIII guidelines. **Results**: rs7625936, rs2979382 and IVS2+95 were associated with diabetes ($p=0.039$, $p=0.008$ and $p<0.0001$), whereas significant associations were observed between diastolic blood pressure and rs1055419, rs12496976 and rs12487030 ($p=0.014$; $p=0.042$ and $p=0.006$). Moreover, IVS2+95 was associated with fasting plasma glucose ($p=0.001$), HDL- ($p=0.011$), LDL- ($p=0.001$) and total-cholesterol ($p=0.011$) levels as well as with MS ($p=0.006$). **Conclusion**: These results suggest that *OSBPL11* gene polymorphisms are associated with obesity-related metabolic complications and diabetes.

The homolog of the intraflagellar transport protein, IFT80, is mutated in Jeune Asphyxiating Thoracic Dystrophy (JATD). *P.L. Beales[1], E. Bland[1], J.L. Tobin[1], C. Bacchelli[1], B. Tuysuz[2], J. Hill[1], S. Rix[1], C.G. Pearson[3], M. Kai[4], J. Hartley[5], C. Johnson[5], M. Irving[1], N. Elcioglu[6], M. Winey[3], M. Tada[4], P.J. Scambler[1]* 1) Molecular Medicine Unit, UCL Institute of Child Health, London, United Kingdom; 2) Department of Pediatrics and Genetics, Cerrahpasa Medical School, University of Istanbul, Turkey; 3) MCDB, University of Colorado, Boulder, Boulder CO 80309-0347 USA; 4) Dept of Anatomy and Developmental Biology, University College London, London, WC1E 6BT UK; 5) Section of Medical and Molecular Genetics, Department of Paediatrics and Child Health, University of Birmingham Medical School, Birmingham, UK; 6) Department of Pediatric Genetics, Marmara University Hospital, Istanbul, Turkey.

JATD is an autosomal recessive chondrodysplasia that often leads to death in infancy because of a severely constricted thoracic cage and respiratory insufficiency; retinal degeneration, cystic renal disease and polydactyly may be complicating features. A bioinformatic approach combining clinical and proteomic searches supported the idea that JATD could be a ciliopathy and enabled prioritization of genes within a 3q24-3q26 linkage interval. Mutations of IFT80 were detected, the first association of a defective intraflagellar transport protein in human disease. Knockdown of IFT80 in zebrafish resulted in abnormal hedgehog signalling and cystic kidneys, and knockdown in Tetrahymena thermophila resulted in shortened or absent cilia. An *Ift80*$^{-/-}$ mouse model was lethal around E9.5 as might be predicted.

A Sequence Variant Adjacent to *CDKN2A* and *CDKN2B* Affects the Risk of Atherosclerosis in Several Vascular Beds. *A. Helgadottir[1], K.P. Magnusson[1], S. Gretarsdottir[1], G. Thorleifsson[1], A. Manolescu[1], K. Kostulas[2], R. Pola[3], B. Lindblad[4], G. Tromp[5], N. Sakalihasan[6], R.E. Ferrell[7], J. Hillert[2], J. Powell[8], H. Kuivaniemi[5], E. Valdimarsson[9], S.E. Matthiasson[9], G. Atherosclerotic cardiovascular disease is the leading cause of death worldwide. We have previously described a highly significant association ($P = 1.2\times10^{-20}$) between myocardial infarction (MI)/coronary artery disease (CAD) and a common sequence variant on 9p21. Approximately 21 percent of the Caucasian population is homozygous for this variant and they have an estimated 1.64-fold greater MI risk than non-carriers. The corresponding risk is 2.02-fold for early onset MI. The variant is located adjacent to the *CDKN2A* and *CDKN2B* genes, which have a critical role in regulating cell proliferation, cell aging/senescence, and apoptosis, that are all important features of atherogenesis. To explore the effect of this sequence variant on other atherosclerosis related phenotypes we have extended the association analysis to include subjects with peripheral arterial disease, large vessel disease stroke, and abdominal aortic aneurysm. For each of these phenotypes the association to the variant at 9p21 was analyzed in two to five different Caucasian case-control samples. All tested atherosclerotic phenotypes show significant association with similar effect as previously described for MI/CAD. The risk variant did not show association to T2D. This is intriguing because we and others have identified variants in an adjacent LD block beyond the recombination hotspot, showing significant association to T2D, but not to other atherosclerotic phenotypes without diabetes.

Phenotypic and genetic characterization of a family with autosomal dominant autoimmunity resembling autoimmune polyendocrine syndrome type 2. *A. Ballarini[1], A. Näke[1], A. Herr[2], L. Senenko[1], K. Engel[1], M. Gahr[1], F. Rüschendorf[3], N. Hubner[3], M. Lee-Kirsch[1]* 1) Klinik für Kinder- und Jugendmedizin, Technische Universität Dresden, Dresden, Germany; 2) Institut für Klinische Genetik, Technische Universität Dresden, Dresden, Germany; 3) Max-Delbrück-Centre for Molecular Medicine, Berlin-Buch, Germany.

Autoimmune diseases affect 3-5% of the general population and are due to defects in the development or the maintenance of self-tolerance mechanisms. Despite the identification of common gene variants (e.g. in CTLA-4) and genes causing monogenic autoimmune syndromes (e.g. AIRE/APECED and FOXP3/IPEX), the genetic basis of autoimmunity remains largely unknown.

We describe a non-consanguineous German family with 22 members, 5 of which are affected with one or more of the following organ-specific autoimmune diseases: type 1 diabetes, thyroid disease, Addison's disease, or celiac disease. Moreover, 5 additional members were found to have autoantibodies only. There was no hypoparathyroidism or candidiasis and a mutation in AIRE was excluded. Including all individuals with evidence for autoimmunity, pedigree analysis suggests a dominant trait resembling autoimmune polyendocrine syndrome type 2. In search for genes involved in autoimmunity we performed a SNP-based genome-wide linkage analysis on 15 family members. In parallel, we investigated changes at the transcriptional level using the GeneChip U133 plus 2.0 arrays in $CD4^{+}CD25^{+}$ regulatory T cells isolated from affected individuals and controls. Parametric linkage analysis led to the identification of two loci with suggestive linkage on chromosomes 3 and 4 with LOD-scores of 2.45 and 2.4, respectively. Bioinformatic analysis of gene expression data revealed several differentially expressed genes that are involved in cell proliferation, migration, and cytokine production.

These findings may contribute to our understanding of the molecular mechanisms underlying this familial form of autoimmunity and may also provide insight into the pathogenesis of common complex organ-specific autoimmune diseases. .

Genetic similarity matching for genome-wide association studies. *W. Guan, L. Liming, G.R. Abecasis, M. Boehnke*
Dept Biostatistics, Univ Michigan, Ann Arbor, MI.

Recently, genome-wide association studies have been used to great effect to dissect complex diseases such as diabetes, obesity and multiple sclerosis. These studies require particular care in dealing with population stratification, which can lead to spurious association or mask true signals. We have developed a similarity score matching method for efficient matching of cases and controls after genotyping a large number of genetic markers in a genome-wide association study or large-scale candidate gene association study. Our method is comprised of three steps: 1) calculating similarity scores using the genotype data; 2) conducting optimal matching based on the scores so that matched cases and controls have similar genetic background; 3) using conditional logistic regression to perform association tests.

Here we present an evaluation of our method using simulated data and genome-wide data from the Finland-United States Investigation of NIDDM Genetics (FUSION) study of type 2 diabetes. We evaluate the effectiveness of our matching strategy by evaluating the proportion of matched FUSION samples that originate from the same province in Finland. We also illustrate how our approach affects conclusions of the study by comparing association signals using our method to those using a standard chi-square test and examining the ranks of true association signals. Our results show that our approach provides a simple and effective way to guard against population stratification when GWA data are available.

Phosducin, a novel candidate gene for human essential hypertension. *M.D. Harrison[1], M. Stoll[2], K. Maresso[1], R. Lorier[1], E. Virlee[1], L. Hein[3], P. Hamet[4,5], D. Gaudet[4], O. Seda[5], J. Tremblay[4,5], M. Kaldunski[1], T. Kotchen[1], A.W. Cowley[1], U. Broeckel[1]* 1) Medical College of Wisconsin, Milwaukee, WI; 2) University of Münster, Germany; 3) University of Freiburg, Germany; 4) Université de Montréal, Canada; 5) Centre Hospitalier de lUniversité de Montréal, Canada.

Hypertension and its complications represent leading causes of morbidity and mortality and evidence suggests that a significant portion of risk is determined by genetic factors. Recently, phosducin (PDC) emerged as a novel candidate, since a knockout mouse model develops profound hypertension particularly during stress. The aim of this study was to test whether SNPs in phosducin influence blood pressure (BP) phenotypes in humans. We studied French-Canadians (FC) in a unique founder population, and African-Americans (AA), for 849 and 341 individuals, respectively. To dissect BP as a complex phenotype, we measured resting as well as various stress induced and other related BP measurements as intermediate phenotypes. To describe the haplotype structure for the PDC region, we resequenced PDC and genotyped 21 SNPs covering a region of 500,000 base-pairs centered on PDC. Several new SNPs were found that could be functionally important. Significant associations ($p<0.01$) for BP phenotypes were found in both populations at markers in the PDC, and SNPs in strong linkage disequilibrium (LD) extending into the neighboring prostaglandin G/H synthase 2 (PTGS2), the gene encoding cyclooxygenase 2. High levels of LD in the FC population cover the entire region, but LD is broken down between the 2 genes in the AA population. By focusing on 6 traits, we found PDC to be associated with resting BP in FC ($p=0.0002$) and BP response to stress in AA ($p=0.00005$). PTGS2 is associated with stress BP in FC ($p=0.0003$) and overall BP regulation in AA ($p=0.001$). To conclude, PDC is associated with BP phenotypes in both human populations with an emphasis on resting BP in FC and stress BP in AA. The presence of candidate genes in close proximity, PDC and PTGS2, supports the notion of functional gene units. Our findings provide further evidence that PDC is involved in the control of BP, and is therefore an important new candidate gene for hypertension.

Human PON1 During Development: Effects of Age and Genotype. *K. Huen[1], K. Harley[1], A. Bradman[1], C. Furlong[2], B. Eskenazi[1], N. Holland[1]* 1) Sch Public Health,Univ of California, Berkeley, CA; 2) University of Washington, Seattle, WA.

Paraoxonase 1 (PON1) is a high density lipoprotein (HDL) - associated enzyme, which can detoxify organophosphate (OP) pesticides. Additionally, it can prevent LDL oxidation, a marker of oxidative injury resulting from oxidative stress. Studies in both animals and humans report significantly lower serum and liver PON1 activity at birth in comparison to adults. Therefore, young infants may be more susceptible to OP pesticide exposures and oxidative stress. PON1 provides a distinctive example of a gene containing a common missense SNP (Q192R) that dramatically affects functional activity. PON1 activity is easily quantified by measuring rates of hydrolysis of various substrates. Previously, we showed that haplotype analysis of PON1 polymorphisms did not provide an advantage to analysis of individual genotypes when examining the effects of PON1 genotypes on PON1 functional activity. Here, we genotyped several PON1 polymorphisms in the coding and promoter regions and measured PON1 enzyme activity and PON1 levels in n=172 children at birth, 24 months, and 60 months of age. Hierarchical linear models were used to examine how PON1 levels and activity change over time from birth through 60 months of age and to determine if PON1 polymorphisms affect this age-related change. Both age and PON1 Q192R genotype were associated with PON1 levels and PON1 activity although no significant interaction between the two variables was identified. Contrary to previous reports that children reach a plateau comparable with adults at 24 months, average PON1 levels measured by arylesterase activity increased from birth through 39 months ($p<0.005$) while PON1 activity towards the substrate paraoxon, continued to increase from birth through 47 months ($p<0.005$). Further, children with the PON1 192 RR genotype have slightly lower PON1 levels than children with fewer R alleles ($p=0.003$) after adjusting for age. In contrast, mean PON1 activity was highest in children with the PON1 192 RR genotype after adjusting for age ($p<0.005$). Thus, early childhood represents a critical period of vulnerability to OP exposures and oxidative stress which is further influenced by PON1 genotypes.

Sequencing of PKHD1 in Autosomal Recessive Polycystic Kidney Disease/Congenital Hepatic Fibrosis (ARPKD/CHF). *D. Adams[1], H. Edwards[1], A. Garcia[1], E. Font-Montgomery[1], M. Huizing[1], P. Choyke[3], T. Heller[5], P. Mohan[6], K. Daryanani[7], L. Guay-Woodford[4], W. Gahl[1], M. Gunay-Aygun[1,2]* 1) Section on Human Biochemical Genetics, Medical Genetics Branch, NHGRI; 2) Intramural Office of Rare Diseases, NIH; 3) NCI, NIH; 4) Univ. of Alabama, Birmingham AL; 5) NIDDK, NIH; 6) CNMC, Wash., DC; 7) NIH Clinical Center.

ARPKD/CHF, a form of PKD with onset primarily in childhood, is typically associated with CHF complicated with portal hypertension (PH). ARPKD/CHF results from mutations in PKHD1, one of the largest genes in the human genome. PKHD1 exhibits a complex splicing pattern. The longest open reading frame, composed of 66 exons, encodes fibrocystin, a 4074 amino acid protein located on the primary cilia-basal body/centriole complex. PKHD1 also has 19 alternate exons. Although the diagnosis of ARPKD/CHF is still made clinically in most patients, confirmation of diagnosis with DNA analysis is increasingly employed, especially in atypical patients and for prenatal diagnosis. The current mutation detection rate ranges from 75-85%. To date, more than 300 PKHD1 mutations throughout the gene have been reported. As part of an ongoing NIH natural history study on ARPKD/CHF and other ciliopathies (www.clinicaltrials.gov, trial NCT00068224), we have sequenced the PKHD1 gene in a total of 66 patients, including 45 clinically typical ARPKD/CHF, 17 atypical/unknown PKD/CHF, 3 CHF/PH associated with ADPKD, and 1 Carolis disease. The pathogenicity of the missense mutations was evaluated using existing databases, intraspecies sequence conservation, and the conservation of amino acid chemistry. In the 84 typical ARPKD/CHF proband alleles, 70 potentially pathogenic mutations were detected. Sixteen of these had not been previously reported. In the 34 atypical/unknown alleles, 10 potentially pathogenic mutations were detected. No pathogenic PKHD1 mutations were found in the 6 alleles of patients with CHF and PH associated with ADPKD or in the 2 with Carolis disease. We continue to sequence DNA from more ARPKD/CHF and related ciliopathy patients, enrolling new patients in an effort to improve diagnostic accuracy and better characterizing these disorders.

Screening of Interferon Regulatory Factor 6 (*IRF6*) in European Patients with Van der Woude / Popliteal Pterygium Syndrome or Non Syndromic Cleft Lip and Palate. *L. Desmyter[1], M. Ghassibe[1], N. Revencu[1,2], B. Bayet[2], C. Verellen[2], O. Boute[3], M. Lees[4], K. Devriendt[5], K. Claes[6], G. Mortier[6], M.C. Addor[7], M. Bouma[8], D. Genevieve[9], A. Goldenberg[10], A. Gözü[11], M. McEntagart[12], A. Sanchez[13], C. Vilain[14], L. Van Malderghem[15], M. Vikkula[1]* 1) de Duve Institute, Université catholique de Louvain, Belgium; 2) Cliniques universitaires St Luc, Belgium; 3) Hopital Jeanne de Flandre, France; 4) Institute of Child Health, UK; 5) KUL, Belgium; 6) UZ-Gent, Belgium; 7) C.H.U. Vaudois, Suisse; 8) Groningen university hospital, The Netherlands; 9) Hopital Necker-Enfants malades, France; 10) Hopital Charles Nicolle, France; 11) Plastik vr reconstrüktif, centrahl Uzmani, Turkey; 12) St Georges hospital, UK; 13) Hospital clinic Mejia Lequerica, Spain; 14) U.L.B., Belgium; 15) IPG, Belgium.

Orofacial cleft is one of the most common birth defects in humans. It can be divided into syndromic and non-syndromic cleft (NSC). Based on epidemiological, embryological and genetic data, cleft lip with or without palate (CLP) is considered distinct from cleft palate only (CPO). Van der Woude (VWS) syndrome is a cleft syndrome characterized by pits in the lower lip present in 85% of cases. In addition to the signs of the VWS, the Popliteal Pterygium syndrome (PPS) includes popliteal and oral webs, syndactyly and genital abnormalities. The *IRF6* gene, localized to *1q32.2*, is mutated in patients with VWS and/or PPS. We screened 41 VWS and 13 PPS patients mainly from Europe by Denaturing High Performance Liquid Chromatography (DHPLC) and sequencing. We identified mutations in the coding region in the majority of our VWS patients and in all our PPS patients. More than 80% of the mutations are located in the conserved DNA and the less-well-conserved protein binding domains. This data confirms that mutations in the IRF6 gene are responsible for VWS and PPS syndrome in the majority of the patients. Since IRF6 has also been associated with NS-CLP, we screened 39 patients with familial history of NSC. However we have found no *IRF6* mutations in such patients. In contrast, some were identified in the novel CPO gene that we recently identified (see abstract by Ghassibe et al.).

UMD-predictor, a new prediction tool for missense mutation pathogenicity; application to the FBN1 gene. *C. Beroud[1,2,3], M. Frederic[1,2], M. Lalande[1], C. Boileau[4,5], D. Hamroun[3], M. Claustres[1,2,3], G. Collod-Beroud[1,2]* 1) INSERM, U827, Montpellier, F-34000 France; 2) Université MONTPELLIER1, UFR Médecine, Montpellier, F-34000 France; 3) CHU Montpellier, Hôpital Arnaud de Villeneuve, Laboratoire de Génétique Moléculaire, Montpellier, F-34000 France; 4) INSERM, U383, Paris, F-75000 France; 5) AP-HP, Hôpital Ambroise Paré, Laboratoire de Génétique Moléculaire, Boulogne, F-92000 France.

Among the millions of nucleotide substitutions reported in the human genome, thousands are localized in the coding sequence of various genes and result in a synonymous or a non-synonymous change at the protein level. In parallel it has been shown that half of the gene lesions responsible for human inherited diseases are due to missense mutations. One of the biggest challenges in human genetics is therefore to distinguish neutral variations from disease causing mutations. We thus developed the UMD-predictor tool that allows the analysis of all substitutions. For each variation, the prediction is based on the combination of several arguments: its location at protein level, its conservation and biochemical properties (data from SIFT, BLOSUM62 and Biochemical data) and search for creation/suppression of potential splice sites or regulator splice sequences. Each variation is predicted to be a pathogenous mutation, a probable pathogenous mutation, a probable polymorphism or a polymorphism. To evaluate the performances of this new tool, we compared it with the different existing programs (SIFT, BLOSUM62, Biochemical Value and PolyPhen), using data from the UMD-FBN1 database that contains 1249 mutations among which 709 missense mutations corresponding to 528 mutational events. Our results show that the UMD-predictor algorithm is the most efficient tool to predict pathogenous mutations for the FBN1 gene with a positive predictive value of 99.4% (sensitivity of 95.6 % and specificity of 94.4 %). The UMD-predictor tool is available at http://www.umd.be/UMD-predictor and can be applied to all human genes. It can thus be useful to evaluate the pathogenous impact of all SNPs localized in the coding sequence as well as variations found in patients.

Safety of sapropterin dihydrochloride (sapropterin) in children with phenylketonuria (PKU) on a phenylalanine (Phe)-restricted diet. *D. Grange[1], C. Whitely[2], H. Christ-Schmidt[3], A. Dorenbaum[4], H. Levy[5]* 1) St Louis Child Hosp,St Louis,MO; 2) U Minnesota Med Ctr,Minneapolis,MN; 3) Statistics Collaborative Inc,Washington,DC; 4) BioMarin Pharmaceutical Inc, Novato, CA; 5) Child Hosp, Boston, MA.

Intro:Sapropterin, an oral formulation of tetrahydrobiopterin, can lower blood Phe in PKU. We report safety data from a double-blind, placebo-controlled Ph 3 study in children with PKU controlled on a Phe-restricted diet. Methods:Children (4-12yrs) diagnosed with PKU with hyperphenylalaninemia (1 blood Phe measurement 360mol/L), controlled (blood Phe 480mol/L) on a Phe-restricted diet for 6months received sapropterin 20mg/kg/day, for 8 days (Part 1). Responders (30% reduction in blood Phe and blood Phe 300mol/L [5mg/dL] on Day 8, arbitrarily defined) entered Part 2 and were randomized 3:1 to receive sapropterin 20mg/kg/day or placebo for 10 wks. Phe supplement was prescribed at Wk 3 and adjusted bi-weekly according to blood Phe level. Safety was monitored by adverse events (AEs), physical exam and clinical lab tests. Results:89/90 children had known responder status (Part 1), 50(56%) were responders and 46(51%) were randomized (sapropterin=33,placebo=12,1 did not receive drug). Most AEs were mild and considered unrelated to study drug; 15/90(17%) subjects in Part 1 and 9/33(27%) sapropterin subjects and 3/12(25%) placebo subjects in Part 2 had AEs considered possibly/probably related to treatment. Compared with placebo, the sapropterin group had a higher incidence of mild AEs in the respiratory and gastrointestinal (GI) disorder System Organ Classes (rhinorrhea[21%vs0%] and cough[15%vs0%]; diarrhea[9%vs0%] and vomiting[12%vs0%]) and reported more mild headaches (21%vs8%). No child reported a severe AE or withdrew due to an AE. 2 serious AEs were reported in Part 2 (sapropterin, infection; placebo, appendicitis), both considered moderate in intensity and unrelated to study drug, and both resolved during the study. Concl:Sapropterin 20mg/kg/day, has an acceptable safety profile in children with PKU on a Phe-restricted diet despite higher incidences of mild respiratory, GI and neurological AEs than for placebo.

Susceptibility loci for blood pressure detected in adults from the Samoan islands. *K. Aberg[1], G. Sun[2], S.R. Indugula[2], D. Smelser[2], Q. Zhang[2], R. Deka[2], D.E. Weeks[1,3], S.T. McGarvey[4]* 1) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 2) Center for Genome Information, Department of Environmental Health, University of Cincinnati, Cincinnati, OH; 3) Department of Biostatistics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 4) International Health Institute, Brown University, Providence, RI.

Using variance component linkage analysis, we performed genome-wide scans for systolic (SBP) and diastolic (DBP) blood pressure in sample sets from Samoa (S) and American Samoa (AS), respectively. The two sample sets have a common population history but, in contrast to S, the environment in AS has been extensively modernized during the last decades. In an attempt to explore gene-environmental interaction we investigate a combined dataset including both S and AS. In total, we studied 71 families including 1156 adults (18 years of age) phenotyped for SBP and DBP and genotyped for 368 microsatellite markers. We used SOLAR/Loki to calculate multipoint LOD scores. To explore gene-environmental interaction we created a material life style index (MLSI) to measure individual modernization. The MLSI, education, alcohol and cigarette consumption, physical activity, age, sex, agesex, age^2, age^{2}sex and body mass index (BMI) were included as covariates. When adjusting the traits in the 3 datasets for significant covariates, the heritability estimates for SBP and DBP ranged from 0.16-0.31 and 0.10-0.22, respectively. Interestingly, neither MLSI, education nor physical activity were associated with SBP or DBP. Suggestive LOD scores were detected for SBP (LOD2.18) on 18q22 in the combined dataset and in AS, and for DBP (LOD=2.05) on 2p25 in AS.

About 16% of our sample was treated for hypertension and was excluded from our quantitative study. We are currently performing qualitative analysis of individuals with hypertension (or treated for hypertension) vs. non-hypertensive individuals. In addition, we are carrying out genome-wide bivariate linkage analysis for SBP and DBP.

On the analysis of copy-number variations (CNVs) in genome-wide association studies: A translation of the family-based association test (FBAT) approach. *I. Ionita-Laza[1], G.H. Perry[2,3], B.A. Raby[4], B. Klanderman[4], C. Lee[2,5], N.M. Laird[1], S.T. Weiss[4], C. Lange[1,4]* 1) Department of Biostatistics, Harvard University; 2) Department of Pathology, Brigham and Women's Hospital; 3) School of Human Evolution and Social Change, Arizona State University, Tempe, AZ; 4) Harvard Medical School, Channing Laboratory; 5) Harvard Medical School.

It has long been thought that human genetic variation is comprised primarily of single nucleotide polymorphisms (SNPs). However, recent studies have discovered an abundance of kilobase- to megabase-sized DNA segments that vary in copy number among human genomes. These copy number variants (CNVs) can influence levels of gene transcription and translation and therefore may be involved in human phenotypic variation including complex disease susceptibility. Given that copy number data will soon be available as part of many genome-wide association studies, we propose a direct approach to CNV-association testing in family-based association studies that bypasses the issue of uncertainty over CNV calls and genotyping. Instead of establishing associations between CNV calls and the phenotype, we advocate to directly use the raw intensity values that reflect copy number. By replacing the genotypes with the intensities, we are able to translate the family-based association testing (FBAT) approach with its numerous extensions to the analysis of CNVs. We show that, by appropriate conditioning on the intensities within families, the robustness against population admixture and stratification of the family-based approach is maintained and that testing strategies that are based on the idea of conditioning within-family can be applied in a straightforward manner. The power and robustness of the approach are evaluated in simulation studies using two different platforms: array-based comparative genomic hybridization data available for the HAPMAP samples, and Illumina 550K SNP data available for a disease dataset. An application to one of the first genome-wide association studies for CNVs highlights the potential of this approach. This research was partially supported by the following grants: U01 HL065899 and P01 HL083069.

Integrative genomics and genome-wide association using family-based designs. *J.H. Degnan[1], J.A. Lasky-Su[2,3], B.A. Raby[3], M. Xu[3], C.M. Molony[4], E.E. Schadt[4], C. Lange[1,3]* 1) Biostatistics, Harvard School of Public Health, Boston, MA; 2) Department of Psychiatry and Behavioral Sciences, SUNY Upstate Medical University, Syracuse, NY; 3) Harvard Medical School, Channing Laboratory, Boston, MA; 4) Genetics, Rosetta Inpharmatics, Seattle WA.

Expression QTL mapping by integrating genome-wide gene expression and genotype data is a promising approach for identifying functional genetic variation, but is hampered by the large number of multiple comparisons inherent to such studies. A novel approach for overcoming multiple testing problems in genome-wide family-based association studies is screening candidate markers using heritability or conditional power. We apply these methods for the setting in which microarray gene expression data are used as phenotypes, screening for SNPs near the expressed genes. We perform association analyses for phenotypes using a univariate approach using CEPH data. Simulations were also performed on trios with large numbers of causal SNPs to determine the optimal number of markers to use in a screen. We demonstrate that our family-based screening approach performs well in the analysis of integrative genomic datasets and that it was able to find several associations that were genome-wide significant after correction for multiple comparisons. We also find that screening using either by heritability or conditional power had similar performance, both in the simulation and in the analysis of the CEPH data.

Large-scale evaluation of polymorphisms in predicted microRNA binding sites reveal effect on mRNA expression levels. *M. Jain[1,3], F. Pettersson[1], J.M. Taylor[1], J.L. Min[1], J.C. Barrett[1], J. Broxholme[1], M.I. McCarthy[1,2], K.T. Zondervan[1], L.R. Cardon[1], C.M. Lindgren[1,2]* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK; 2) Oxford Centre for Diabetes, Endocrinology and Medicine, University of Oxford, Oxford, UK; 3) Medical Genetics Branch, NHGRI, Bethesda, MD.

MicroRNAs (miRNAs) are non-coding small RNAs that regulate mRNA by binding to *cis*-regulatory sites in 3 untranslated regions (UTR). They wield their influence by either targeting mRNA for cleavage or by repressing translation. Mutations in mRNA binding sites are known to result in a handful of diverse phenotypes emphasizing their functional importance. The effect of more common polymorphisms, however, remains unknown. We examined the role of miRNA on mRNA levels by performing an association analysis between SNPs in miRNA binding sites of *cis*-acting expression quantitative trait loci (eQTL) and mRNA expression data from the 4 HAPMAP populations. Results from 5,424 SNPs matched to 3,802 different transcripts in the HAPMAP CEU population indicate that 37 SNPs in different binding sites within 34 transcripts are associated with transcript level (empirical significance: $p<1x10^{-5}$). We substantiated the presence of seven miRNAs using probes for host mRNAs in the expression dataset. For all studied transcripts permutations validate an over-representation of associated miRNA binding SNPs compared to exon, intron, 5UTR and non-miRNA binding 3UTR SNPs (empirical significance: $p<1x10^{-4}$). Of the 37 associated SNPs in CEU, 22 replicate in CHB and JPT populations and 14 in the YRI population ($p<1x10^{-3}$). Nine eQTLs replicate in all three populations with seven leading to down-regulation of mRNA level. Of these, two, *ZNF230* and *ZNF584*, are purported transcription factors, one, *CRIPT*, is potentially functionally important in excitatory synapses and one, *AXIN1*, has been implicated in a variety of cancers. Our analyses show for the first time that miRNA binding site polymorphisms are associated with mRNA expression differences and suggest functional relevance for these variants and potential involvement in common, complex traits.

Characterization and replication of a novel locus for late-onset Parkinsons disease detected in a genome-wide association study in an isolated population. *Z. Bochdanovits[1,2], P. Rizzu[1,2], K. Rak[1,2], L. Pardo-Cortes[1,2], P. Heutink[1,2]* 1) Section Medical Genomics, Department of Clinical Genetics, VUMC, Amsterdam, the NetherlandsClinical Genetics, VU Medical Center, Amsterdam, Noord Holland, Netherlands; 2) Center for Neurogenomics and Cognitive Research, VU/VUMC, Amsterdam, the Netherlands.

Genetically isolated populations have two major advantages above general populations when conducting genome-wide association studies: 1- more extended LD allows for using less markers and 2- less genetic heterogeneity, hence a higher relative risk of individual susceptibility alleles. We have performed a genome-wide association study in a young genetic isolate in Turkey for late onset Parkinsons disease. This isolate exhibits increased prevalence of the disease relative to the general population suggesting that susceptibility alleles of relatively high risk are segregating in this homogeneous population. We used the Affymetrix 10K SNPChip to genotype 31 late-onset Parkinsons disease patients and 27 unrelated controls. Strong LD (r2>0.8) was commonly found up to approximately 150kb, hence the 10K SNPChip is sufficient to cover the entire genome in this isolate. Single SNP associations were carried out followed by a permutation test to determine the genome wide significance threshold in this dataset. One SNP, rs1492592, was found to be significantly associated with PD, with an empirical p-value of 4x10-6. Subsequently, 30 additional SNPs covering a 1.1 Mb region surrounding the initial SNP have been tested. Multiple SNPs from this panel confirmed the association. Within 1.5 Mb of the locus, several interesting candidate genes are located, most notably GRIN3A and PPP3R2. A known limitation of using genetic isolates is that the loci detected in one population might not be of relevance in other isolates or the general population. Therefore we screened two additional genetic isolates and the general Dutch population for association with tagging SNPs covering six candidate genes. We confirm our locus by showing that multiple tagging SNPs are significantly associated with late-onset Parkinsons disease in the additional isolates.

Comprehensive analysis of 331 candidate genes for orofacial clefting in a population-based infant-parent case-control study from Norway. *A. Jugessur[1], M. Shi[2], H. Gjessing[3], AJ. Wilcox[2], RT. Lie[1], CR. Weinberg[2], T. Nguyen Trung[1], AC. Lidral[4], AL. Boyles[2], K. Christensen[5], JC. Murray[4]* 1) University of Bergen, Norway; 2) NIEHS, Durham, NC; 3) Norwegian Institute of Public Health, Norway; 4) University of Iowa, IA; 5) University of Southern Denmark, Denmark.

Orofacial clefts rank among the most common birth defects in humans (1-2/1000 live births). The relative risk (RR) for recurrence in families is about 40, suggesting a partly genetic etiology. Identifying causative gene variants with adequate statistical power requires large and well-characterized datasets. The treatment of clefts is centralized in Norway, enabling a large population-based study of clefting with a high proportion of case-ascertainment. Moreover, Norway has an ethnically homogeneous population and one of the highest prevalence of cleft lip in the world (2/1000). The Norwegian dataset comprised 425 isolated case and 562 control infant-parent triads. We selected candidate genes based on linkage and association studies, studies of chromosomal rearrangements, and expression analyses in animal models. After CIDR genotyped a complete panel of 1536 SNPs in 357 genes, the genotypes for 1218 SNPs in 331 of the genes could be unambiguously assigned. We conducted single-marker and haplotype-based analyses using the program HAPLIN (Pubmed ID: 16674560) to estimate RRs when the infants carry one or two copies of a designated risk allele (or haplotype). We also identified risk-related haplotypes using TRIMM (Shi et al. AJHG, in press), which is a test that uses only the genotypes of affected members and their parents, does not require HWE, and circumvents the need to know or assign haplotypes and their phases. HAPLIN identified 24 genes for which the overall p-value was lower than 0.05, and TRIMM identified 26. The genes identified by both methods include ADH1B, APOA5, FOXE1, FZD2, HOXB6, IRF6, MSX1, RYK, UGT1A7, and VCL. Reassuringly, this list contains IRF6, FOXE1 and MSX1 that have repeatedly shown strong statistical associations with clefts in multiple diverse populations. Analyses on an independent set of 235 case-parent triads from a Danish cleft population is currently underway to confirm these findings.

Array Comparative Genomic Hybridization (a-CGH) in clinical practice: new syndromes identified, known syndromes redefined, variants and unknowns uncovered. *D.A.S. Batista[1,2], S. Morsey[1], J. Biscoe[1], E.C. Lisi[2], T. Wang[2], J. Hoover-Fong[2], A. Hamosh[2]* 1) Kennedy Krieger Inst, Baltimore, MD; 2) Johns Hopkins Univ, Baltimore, MD.

The use of a-CGH is expanding the phenotypic spectrums of known syndromes and allowing identification of new microdeletions and microduplications. We performed a-CGH with the BAC constitutional array from Spectral Genomics in 116 cases with a normal high-resolution karyotype (550 bands). A total of 7 abnormalities were detected by array (6%), all confirmed by FISH: two deletions of the Williams region on 7q11.23; an interstitial duplication at 10p15.3; a partial duplication of the Smith-Magenis region on 17p11.2; two deletions that included the NF1 gene on 17q11.2; and one duplication of the DiGeorge region at 22q11.2. Prior to a-CGH only one case of Williams syndrome and the cases with NF were suspected. The second patient with Williams had significant developmental delay, autistic behavior and no cardiac anomalies. Duplication 10p15.3 was seen in a boy with developmental delay, seizures, asymmetric face, prominent incisors and dysrhythmia with hx of supraventricular tachycardia; parental analysis to determine if this duplication is de novo is pending. The patient with partial duplication of the Smith-Magenis region had several brain anomalies, hypotonia and hypertelorism and the smallest duplication described for the dup 17p11.2 syndrome. Both patients with NF1 deletion were atypical: one patient had vascular ring and developmental delay more severe than expected; the other had pulmonic stenosis, segmental hyperpigmentation, vascular malformations and facial dysmorphic features. Dup 22q11.2 was found in a patient with failure to thrive, trigonocephaly, high arched palate and micrognathia. Several others copy number changes (n=12) were also detected, most within regions of known segmental duplication and in 3/3 cases tested were also present in a normal parent, thus possibly normal variants. In summary, using a-CGH we have observed unusual clinical presentations of known syndromes, described the smallest duplication in 17p11.2 thus far reported and discovered a possible new syndrome at 10p15.3.

Clinical feature of autosomal dominat spinocerebellar ataxia linked to 16q22.1. *Y. Ichikawa, S. Tsuji, J. Goto* Dept Neurology, Univ Tokyo, Tokyo, Japan.

Autosomal dominant cerebellar ataxias (ADCAs) are heterogeneous neurodegenerative diseases characterized by progressive cerebellar ataxia occasionally accompanied with other findings. A single nucleotide substitution (-16C>T) in the 5 UTR of the puratrophin-1 gene has recently been identified to be tightly associated with patients of families linked to chromosome 16q22.1 (16q-ADCA). In the 294 Japanese ADCA families analyzed in our laboratory on the referral basis, Machado-Joseph disease(MJD) / spinocerebellar ataxia type 3 (SCA3) was the most common ADCA, followed by dentatorubral-pallidoluysian atrophy (DRPLA) and SCA 6. We examined the possibility of 16q-ADCA about the 87 Japanese ADCA families excluded from SCA1, 2, 6, 7, 8, 12, 17, MJD/SCA3 and DRPLA. As a result, 16q-ADCA families comprised a substantial proportion (8.2%) among the Japanese ADCA families. Accordingly, 16q-ADCA was the fourth common Japanese ADCA. It has been reported that the characteristic clinical feature of the 16q-ADCA was slowly progressive pure cerebellar ataxia similarly to SCA6. We compared the clinical findings of 27 16q-ADCA patients whose clinical information was available with those of 46 SCA6 patients. The average onset age of 16q-ADCA patients was 56.37.4 years (40-68 years), which was higher than that of SCA6: 49.912.2 (23-76 years)(P =0.02 t-test). All the patients of 16q-ADCA showed ataxic gait or dysarthria as their initial symptoms (ataxia: 85.2%, dysarthria: 14.8%). Gaze nystagmus was more frequent in SCA6 patients (90.6%) than 16q-ADCA patients (65%). SCA6 patients showed higher percentage of hyperactive deep tendon reflexes than 16q-ADCA at 57.5% as opposed to 44% irrespective of the disease duration. Diplopia was observed in two 16q-ADCA patients, whose disease duration were 8 and 26 years. Subjective hearing impairment was observed in only one 16qADCA patient, and none in the SCA 6 patients irrespective of the disease duration. In summary, all 16q-ADCA patients showed cerebellar ataxia as to initial symptoms. The average onset age of 16q-ADCA was higher than that of SCA6, and the other neurological findings besides cerebellar ataxia tend to be fewer in 16qADCA than SCA6 patients.

Translational read-through of a nonsense mutation in ATP7A is associated with treatment responsiveness in Menkes disease. *A. Donsante[1], J. Tang[1], A. Yergey[2], P. Backlund[2], S.G. Kaler[1]* 1) Unit on Pediatric Genetics, NICHD, NIH, Bethesda, MD; 2) Lab. of Cellular and Molecular Biophysics, NICHD, NIH, Bethesda, MD.

Nonsense mutations usually lead to the termination of protein translation. However, functional stop codon read-through has been described in bacterial, viral, and yeast genes, mediated by ribosomal jumping or tRNA mispairing. We report read-through translation of a nonsense mutation in the human copper transport gene, ATP7A, associated with an excellent clinical response to early treatment in Menkes disease, an X-linked recessive disorder of copper metabolism. We previously proposed that internal initiation or translation re-initiation could mediate a favorable treatment response in the context of a premature stop signal in the 5 region of ATP7A (*Nature Genet* 13:21-22, 1996). *In vitro* evidence for re-initiation at this locus was reported recently (*Am J Hum Genet* 79:214-229, 2006). In a Menkes disease patient, we identified a novel C to T transition, changing codon 201 from CGA to UGA. In the context of his excellent neurologic outcome in response to therapy, we suspected that translation reinitiation downstream of R201X produced some truncated but partially functional copper transporter. However, Western analyses using antibodies against N- and C-terminal segments of ATP7A detected small amounts of the full-length (178 kDa) protein in patient fibroblasts, consistent with translational read-through of R201X. Sequencing of cDNA excluded RNA editing as an explanation. Immunohistochemistry and confocal microscopy detected trace amounts of a perinuclear, anti-ATP7A reacting material, consistent with normal trans-*Golgi* localization of ATP7A. In a yeast complementation assay, the R201X allele yielded 10% residual functional copper transport. We expressed peptides with the wild type or mutant sequence in 293 cells. We detected full length products from both by Western blot, with lower amounts in the mutant. Amino acid sequencing by MALDI mass spectroscopy confirmed 201R in the wild type; analysis of the mutant peptide is in progress. These findings are consistent with translational read-through and represent the first evidence of this phenomenon in mammals with a phenotypic effect.

Detailed analysis of the 17p11.2 region in 59 patients with Smith-Magenis syndrome. *M. Huizing[1], H. Edwards[1], C. Ciccone[1], M.P. Jones[1], S.C. Chandrasekharappa[1], C. Bendavid[2], J. Blancato[3], W.A. Gahl[1], A.C.M. Smith[1]* 1) NHGRI/NIH, Bethesda, MD; 2) Univ Rennes, France; 3) Georgetown Univ, Washington, DC.

Smith-Magenis syndrome (SMS) is characterized by distinct craniofacial and skeletal anomalies, speech/language delays, psychomotor and growth retardation, a striking neurobehavioral phenotype, and chronic sleep disorder related to an inverted circadian melatonin rhythm. Most cases are due to an interstitial deletion of 17p11.2; however, rare 'non-deletion' cases can be due to *RAI1* mutations. We performed a genotype-phenotype correlation on 59 SMS patients. Phenotype studies revealed some unique and variable clinical features, including hearing loss, low IgA levels, high cholesterol and skeletal features. We employed a dense map of 17p markers to determine the parent of origin of the deleted allele and found a slight skewing towards the maternal (63%) versus paternal (37%) allele, though this was not statistically significant. FISH analysis and quantitative real-time PCR (qPCR) were performed to determine the copy number of genes in the 17p11.2 area. qPCR assays for six genes of interest surrounding the SMS breakpoints were designed, including *RAI1* and *RASD1* (implicated in circadian rhythm), *MYO15A* (involved in hearing loss), *FLI1* (related to immune response), *PEMT* (functions in choline metabolism) and *TNFRSF13B* (implicated in IgA deficiency). The majority (56%) of patients had the common 17p11.2 deletion (3.5Mb), as expected. 11 patients (19%) had variable breakpoints, however, their clinical features could not be directly related to the copynumber of our 6 genes. 15 patients (25%) did not show a 17p11.2 deletion by FISH or qPCR, *RAI1* mutation analysis so far showed a novel mutation (P242L) in one of these patients. The non-deleted patients are being screened by whole genome CGH-array for possible novel chromosomal rearrangements. Our study emphasizes the value of a natural history study to recognize novel clinical features and outlier patients. We were unable to show a strong genotype-phenotype correlation. However, determination of exact breakpoints and the influence of genes outside the breakpoints on the resultant phenotype may shed more light on this.

Whole-genome association study identifies polymorphisms in the CERKL gene associated with QT prolongation during iloperidone treatment of patients with schizophrenia. *C. Heaton, K. Mack, S. Volpi, J. Hamilton, R. Lannan, C. Wolfgang, L. Licamele, M. Polymeropoulos, C. Lavedan* Vanda Pharmaceuticals, Inc., Rockville, MD.

Mutations in several genes can predispose to hereditary forms of long QT syndrome and to drug-induced prolongation of the QT interval of the electrocardiogram. Involvement of the *KCNH2* gene, which encodes the HERG potassium channel, has been well documented. Many drugs, including antipsychotics, have the potential to prolong the QT interval. We conducted a pharmacogenomic study to identify, among others, markers of QT prolongation during iloperidone treatment of schizophrenia. In a randomized, double-blind, placebo- and ziprasidone-controlled trial of iloperidone, an investigational atypical antipsychotic, patients were genotyped for approximately 500,000 SNPs. The change in QT interval from baseline to Day 14 was calculated based on Fridericia correction (QTcF), and a generalized linear model statistical analysis was performed. Two SNPs with highly significant associations are located on 2q31.3 in the *CERKL* gene, which encodes a ceramide kinase-like protein. Ceramide kinases convert the sphingolipid metabolite ceramide to ceramide-1-phosphate. Ceramide can decrease HERG currents and inhibit the basal turnover of HERG protein. The action of ceramide on ion channels is thought to be mediated mainly by kinase activity. Iloperidone-treated patients homozygous for an SNP were 6 times more likely than heterozygous patients to experience increased QTcF (>30 msec) by Day 14. The genotype of SNPs in the *CERKL* gene did not correlate with QT prolongation seen in ziprasidone-treated patients, even though ziprasidone showed a degree of QT prolongation similar to iloperidone. QT prolongation has been observed at therapeutic doses and at higher doses of other antipsychotic drugs, including risperidone, paliperidone, olanzapine, quetiapine, and aripripazole. Our results suggest that studying the involvement of *CERKL* and, more broadly, the ceramide pathway may lead to better understanding of the mechanism of QT prolongation induced by antipsychotic medications and other drugs known to affect the QT interval.

IL10 SNPs Modify the Effect of Dust Mite Exposure on Allergy and Asthma Exacerbations. *G.M. Hunninghake[1,4], M. Soto-Quiros[2], J. Lasky-Su[1,3], L. Avila[2], N. Ly[1,4], J. Sylvia[1], B. Klanderman[1,4], B. Raby[1,4], D. Gold[1,4], S. Weiss[1,4], J.C. Celedon[1,4]* 1) Channing Laboratory, Brigham and Women's Hospital, Boston, MA; 2) Hospital Nacional de Ninos, San Jose, Costa Rica; 3) Harvard School of Public Health, Boston, MA; 4) Harvard Medical School, Boston, MA.

Background: SNPs in IL10 (a candidate gene for asthma) may modify the effect of dust mite allergen on allergy and asthma exacerbations. Methods: We genotyped 11 SNPs in IL10 in 428 Costa Rican children with asthma and their parents; 6 of these SNPs were also genotyped in 483 families of 502 white children with asthma in CAMP. The family-based association test (FBAT) approach was used to test for interaction between IL10 SNPs and dust mite allergen on serum IgE to dust mite in Costa Rica (not measured in CAMP). We then assessed whether IL10 SNPs modify the effect of dust mite exposure on asthma exacerbations in both studies. Results: Parental genotypes were in HWE for all SNPs in both studies. Three SNPs in IL10 (rs1800896, rs3024492, and rs3024496) significantly modified the relation between dust mite exposure and IgE to dust mite in Costa Rica (P for interaction <0.0001 for SNP rs1800896). For each of these SNPs, homozygosity for the minor allele was associated with increased levels of IgE to dust mite with increased dust mite exposure. These results remained robust to bootstrapping using population-based regression methods. Using logistic and Poisson regression, we found that homozygosity for the minor allele of each of the three SNPs above was associated with increased risk for occurrence (~3-44 fold increase) and frequency (~25-36% increase) of asthma exacerbations among children exposed to >10 ug/g of dust mite allergen in Costa Rica. Similar results were obtained for two of these SNPs (rs1800896 and rs3024496)among children in CAMP. Conclusions: IL10 SNPs modify the effect of dust mite allergen levels on dust mite sensitization and asthma exacerbations. Our findings may help reconcile conflicting findings on dust mite exposure and asthma and allergies. This work was supported by grants HL66289, U01 HL065899, P01 HL083069 and F32HL083634 from the National Institutes of Health.

Folate metabolism genes and their associations with oral facial clefts. *A.L. Boyles[1], A.J. Wilcox[1], J.A. Taylor[1], M. Shi[2], C.R. Weinberg[2], K. Meyer[3], A. Fredriksen[3], P.M. Ueland[3], C.A. Drevon[4], K. Solvoll[4], J.C. Murray[5], A. Jugessur[6], R.T. Lie[6]* 1) Epidemiology Branch, NIEHS/NIH, Durham, NC; 2) Biostatistics Branch, NIEHS/NIH, Durham, NC; 3) Dept Pharmacology, Univ Bergen, Norway; 4) Dept Nutrition, Inst Basic Med Sciences, Univ Oslo, Norway; 5) Dept Pediatrics, Univ Iowa, Iowa City, IA; 6) Dept Public Health and Primary Health Care, Sect Epidemiology and Med Statistics, Univ Bergen, Norway.

Prenatal folic acid supplementation reduces the risk of neural tube defects and probably oral facial clefts as well. Folate pathway gene polymorphisms have been inconsistently associated with cleft risk in previous studies. In a Norwegian population-based study, 377 cleft lip with or without cleft palate (CL/P) families and 196 families with cleft palate only (CPO) were genotyped for 13 polymorphisms in 9 folate pathway genes using a MALDI-TOF MS multiplex method. We looked for associations of clefting with fetal polymorphisms, maternal polymorphisms, as well as parent-of-origin effects, using combined likelihood-ratio tests (LRT). We also stratified by maternal periconceptional intake of folic acid (400+g) to explore gene-exposure interactions.

There was a reduced risk of CL/P with mothers who carried the *CBS* C699T variant (rs234706); relative risk was 0.94 with one copy (95% CI 0.63-1.4) and 0.50 (95% CI 0.26-0.96) with two copies. The LRT had a p-value of 0.008. We found no evidence of interaction of this variant with folic acid status. There was no evidence of risk from the *MTHFR* C677T SNP (rs1801133) either overall or stratified by maternal folic acid. No associations were found between any of the folate polymorphisms and CPO. In a preliminary assessment of a large set of additional 331 gene assays, a subset of 86 haplotype-tagging SNPs in 26 folate metabolism genes showed no strong evidence of risk for combined orofacial clefts in unstratified haplotype-based analyses. Further exploration of these genes and their interaction with folate supplementation is needed.

Towards saturation mutagenesis of human *NIPBL* to evaluate its function in Cornelia de Lange Syndrome and sister chromatid cohesion. *M.A. Deardorff[1], M. Kaur[1], D. Yaeger[1], L.G. Jackson[2], I.D. Krantz[1]* 1) Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Drexel University School of Medicine, Philadelphia.

Cornelia de Lange Syndrome (CdLS; OMIM 122470) is a multisystem developmental disorder characterized by facial dysmorphia, hirsutism, growth and cognitive retardation, gastrointestinal abnormalities and limb deficiencies. In 2004, we demonstrated that mutations in human *NIPBL* cause CdLS. NIPBL orthologs in yeast (Scc2/Mis4) and Drosophila (Nipped-B) are required for sister chromatid cohesion and long-range transcriptional regulation. It is believed that NIPBL is required for the attachment of Cohesin to chromosomes. Subsequently mutations in other Cohesin complex members *SMC1* and *SMC3* have been identified in CdLS. Unlike data on SMC1A and SMC3, much less is understood about the function of NIPBL orthologs. Furthermore, despite several screens, few mutations have been reported in yeast and Drosophila NIPBL orthologs that serve to dissect functional units of this protein. We have collected a cohort of over 400 probands with a clinical suspicion of CdLS and have performed extensive screening of *NIPBL*, including sequencing of exons and adjacent intronic sequence, sequencing of evolutionarily conserved elements, and analysis for microdeletions. To date, we have found *NIPBL* mutations in 172 individuals comprising approximately 60% of patients with CdLS. In addition, 55 NIPBL mutations have been reported by others. Together, this includes more than 60 missense mutations, which represent key amino acids in understanding functional domains of this novel protein. Most of these mutations are unique, however several regions of human NIPBL appear to demonstrate clustering of mutations, particularly, the C-terminal HEAT repeat. Most of these missense mutations result in mild or moderate features of CdLS, however several are seen in patients with more severe disease, suggesting relative importance of these residues. This work is the most complete to date that serves to add insight to delineating the functional domains of NIPBL and the roles that each may play in causing CdLS or other Cohesinopathies.

Missing call bias in genome-wide association studies. *W. Fu[1], Y. Wang[1], L. Jin[1,2]* 1) Center for Anthropological Studies, School of Life Sciences, Fudan University, Shanghai, China; 2) CAS-MPG Partner Institute for Computational Biology, SIB, CAS, Shanghai, China.

The advent of high-throughput and cost-effective genotyping platforms have allowed genome-wide association studies a reality. While the primary focus has been invested upon the improvement of reducing genotyping error, the problems associated with missing calls are largely overlooked. To probe into the effect of missing calls on genome-wide association studies, we first show that missing call bias is a universal and important problem in genome-wide association studies using four technologies (Affymetrix 500K SNP array, SNPstream, Taqman, and Illumina Beadlab). We will show that missing call bias changes the allele frequency and leads to false conclusions. In particular, the influence of missing call bias is more serious than genotyping error, especially when alleles are relatively rare.

Human mitochondrial microarray (h-MitoArray) and gene expression analysis in patients with mitochondrial ATP synthase deficiency. *A. Cizkova[1, 2, 5], V. Stranecky[1, 2], R. Ivanek[1, 2, 4], H. Hartmannova[1, 2], L. Noskova[2], L. Piherova[1, 2], M. Tesarova[1, 3], H. Hansikova[1, 3], T. Honzik[1, 3], J. Zeman[1, 3], J. Paul[1, 5], J. Houstek[1, 5], S. Kmoch[1, 2]* 1) Center for Applied Genomics; 2) Institute of Inherited Metabolic Disorders; 3) Department of Pediatrics, 1st Faculty of Medicine, Charles University; 4) Institute of Molecular Genetics; 5) Institute of Physiology, Academy of Science, Prague, CR.

We constructed custom microarray and analyzed gene expression of 1632 human mitochondria-related genes in 9 control and 13 fibroblast cell lines from patients with ATP synthase deficiency (2 patients with mt9205TA microdeletion, MT group and 11 patients with not yet characterized nuclear defects, ND group). Principal component analysis and hierarchical clustering defined subgroup of patients with nuclear defect (ND1) which was together with (MT) group and rest of the patient (ND2) group considered in further analyses. ANOVA, functional annotation and gene enrichment analyses revealed in the ND1 group reduced expression of genes involved in cellular signaling (*FOS, NOV, CTSK, UPLC1, PIM1, NF2*), lysosomal metabolism (cathepsins, *NPC, CLN*), protein phosphorylation (*CDK5, PPAP2A*) and ROS metabolism (*GPX4, GPX5, PRDX5, SOD2*). The MT group showed reduced expression of mtDNA encoded ATPase subunits (*ATP6, ATP8*), nuclear encoded ATPase assembly factor 11, cytochrome c oxidase II and mitochondrial transcription factor B1 and elevated expression of nuclear respiratory factor 1. The ND2 group showed reduced expression of adenosin kinase, malate dehydrogenase and elevated expression of peroxisome proliferator-activated receptor gamma. Pathway analysis showed in the ND1 group elevated expression of complex I and reduced expression of complex IV and complex V subunit genes in OXPHOS system and reduced activity of several genes in MAP kinase and Jak-STAT signaling pathways. The MT group showed specific changes of genes involved in mitochondrial biogenesis regulation and retrograde signaling. No meaningful changes were detected in the ND2 group. Our analysis gave hints on potential disease causing genes and pathogenic mechanisms associated with ATPase deficiency.

Array-CGH reveals hidden gene dose changes in children with acute lymphoblastic leukemia and a normal or failed karyotype. *E. Kuchinskaya[1], M. Heyman[2], A. Nordgren[1], J. Schoumans[1], J. Staaf[4], S. Söderhäll[2], D. Grandér[3], A. Borg[4], M. Nordenskjöld[1], E. Blennow[1]* 1) Molecular Medicine and Surgery, Karolinska Institutet, Stockholm, Sweden; 2) Department of Woman and Child Health, Karolinska Institutet, Stockholm, Sweden; 3) Department of Oncology and Pathology, Karolinska Institutet, Stockholm, Sweden; 4) Department of Oncology, University Hospital, Lund, Sweden.

Cytogenetic alterations are of major prognostic importance in children with acute lymphoblastic leukemia. Failure to find cytogenetic abnormalities may therefore lead to diagnostic and therapeutic problems. We have used a 33K BAC array with the resolution of 100 kb to identify gene dose changes in 28 children with normal or failed karyotype using G-banding. Interphase FISH with labeled BAC clones from the sites of copy number alterations (CNA) was used to confirm the results. In 22 patients (79%), altogether 137 copy number alterations (CNA) were found, including 69 gains and 68 losses. In general, the losses were smaller than the gains. Array-CGH allowed us to revise the karyotype in 75% of the patients. According to the pattern of molecular cytogenetic and aCGH results, we divided the patients with B-precursor ALL into five groups: high hyperdiploidy (n=4), intrachromosomal amplification of 21q (n=5), ETV6/RUNX1 translocation (n=7), others (n=3), and no CNA (n=5). The aCGH results in patients with T-cell ALL (n=4) were analyzed separately. Tiling resolution aCGH revealed CNAs in almost 80% of the patients with a normal or failed karyotype. In addition to larger abnormalities, most of these patients showed copy number alterations that were below the resolution of G-banding. If aCGH was combined with interphase FISH for the most common, balanced rearrangements, aberrations were found in 90% of the patients. Important information regarding the frequency of genomic imbalances in children with ALL will be gained using this approach, and aCGH will in the future be an important tool to discover hidden and small imbalances that are of importance for the development and progression of ALL.

Genome-wide scan for malaria resistance and susceptibility genes in an Amazonian population. *R.G.M. Ferreira[1], R.C. Pagotto[2], M.J. Menezes[1], C.E. Kawamata[1], E.P. Camargo[1], H. Krieger[1]* 1) Dept Parasitology, University of Sao Paulo, Sao Paulo, SP, Sao Paulo, Brazil; 2) University of Rondonia, RO, Brazil.

The biochemical pathways involved in the pathogenesis of the parasite that causes malaria and the human host mechanisms of defense against the infection are not well know up to the present days. Epidemiologic studies, as well genetic studies, suggest the existence of genetic components related to the host innate resistance/susceptibility to malaria (Hill A.V.; Annu. Rev. Genet., 2006; 40:469-86.). To search for these genes, a genome-wide scan was conducted on a sample of 182 individuals, belonging to 34 nuclear families from Portuchuelo, Rondonia state, Brazil. Portuchuelo(8º37S, 63º49W) is a small riverine population with less then 200 individuals, located at the right bank of Madeira River, which is a hipo-endemic area for malaria (Ferreira R.G.M. *et al* Hum Biol., 2002 74(4):607-14).

The sample was genotyped using 108 STRs markers along 22 autossomes, with a mean distance of 24cM from each other. Those markers where obtained from Marshfield markers map (Broman K.W. *et al* Am. J. Hum. Genet. 1998 Apr 63:861-689). The software SimWalk2 (Sobel E. *et al*Am. J. Hum. Genet., 2002; 70:496-508) was used to check mendelian segregation of the alleles in families.

The reported number of malarial episodes, corrected by age and sex, was used as the affection phenotype. This phenotype showed expected association with Duffy- individuals (Ferreira *et al*, unpublished data) as well as biological driven inheritance, indicating its epidemiological importance. Linkage analysis were conducted using the software Solar 2 (Almasy L. *et al* Am. J. Hum. Genet. 1998 62:1198-1211).

Despite the small size of the sample, multipoint linkage analysis showed a peak of linkage at the short-arm of chromosome 4, between 0 and ~50cM with a lod-score suggestive of linkage (lod-score=2.1). (FAPESP, CNPq).

The relationship between congenital malformations and pediatric malignancies. *M. Akgul[1], O. Cogulu[2], S. Aksoylar[2], A. Alpman[1], B. Durmaz[2], C. Gunduz[3], G. Koturoglu[2], N. Cetingul[2], F. Ozkinay[2]* 1) Medical Genetics, Ege University, Izmir, Turkey; 2) Department of Pediatrics, Ege University, Izmir, Turkey; 3) Department of Medical Biology, Ege University, Izmir, Turkey.

Multipl environmental and genetic factors are responsible from the development of cancer. Common pathways may play a role in tumorogenesis and congenital malformations. Down syndrome is the most popular genetic syndrome associated with increased incidence of malignancy whereas central nervous system and urinary system abnormalities were reported as the highest risk group in regard to development of cancer. However the relationship between cancer formation and congenital malformations remains obscure. The aim of our study was to detect the distribution and incidence of congenital minor and/or major malformations in cases diagnosed with malignancies during childhood. A total of 64 pediatric cases diagnosed with different types of cancers and 60 age matched control group without any chronic disorders were enrolled in the study. Each patient was simultaneously subjected to dysmorphological examination by two clinical geneticists. Detected malformations, clinical and laboratory findings of the patients were recorded. Of the total cases, 28 had leukemia, 10 had lymphoma and 26 were diagnosed to have solid tissue tumors. The sex ratio was 1.0 and the average age was 9.845.77 in the patient group and 8.234.56 in the control group. Epicanthus was found in 32.81% of the patients and 13.33% of the controls (p=0.01), whereas blue sclera was recorded in 12.50% of the patients and 1.66% of the controls (p=0.03). High palate was observed in 65.62% of the patients and 23.33% of the control group (p0.01) and attached ear lobe was significantly higher in the patient group (28.12%) than the control group (5.00%) (p=0.0006). In conclusion, our results may support the idea that cancers and congenital minor anomalies share many common molecular pathways and factors, and, thus, further studies related to congenital anomalies may guide for the clarification of tumorigenesis in cancer.

Autosomal recessive malignant paraganglioma associated with mutations in the succinate dehydrogenase B gene.

C.A. Friedrich[1], S. Majumdar[2], C.A. Koch[3], G.W. Moll[4] 1) Dept Prev Med, Medical Gen, Univ Mississippi Medical Ctr, Jackson, MS; 2) Div Hem/Onc; 3) Div Endocrin; 4) Div Ped Endocrine, UMMC, Jackson, MS.

Paragangliomas are rare tumors and seldom cause endocrine hypertension. Germline mutations in the succinate dehydrogenase subunit B gene (SDHB) have been associated with autosomal dominant malignant paragangliomas. We here report a family with non-classic congenital adrenal hyperplasia (CAH), in whom one member suffered from metastatic paraganglioma. A 13 yo boy presented with delayed puberty, nocturnal enuresis, and headaches. Thyroid and adrenal tests were within normal limits. MRI of the brain showed a lesion in the diploic space in the frontal region. Head CT revealed a lytic bone lesion resembling a histiocytic eosinophilic granuloma. A bone scan showed another lytic lesion in the right proximal femur. Bone biopsy of the skull lesion identified a paraganglioma. Further imaging showed an 8x3x3 cm mass close to the vena cava and aorta. The patient was normotensive; 24 h urinary norepinephrine was slightly elevated. After surgical tumor removal, postoperative MIBG showed persistent uptake in the abdomen and right femur. His sister had been diagnosed with 3-beta-dehydrogenase deficiency; his maternal grandmother had a pituitary adenoma. Germline mutation analysis of the SDHB gene, located at 1p36.13, revealed a known missense mutation (C.418G>T) and a previously unreported splice donor region DNA sequence variation in intron 2 (C.200+7A>G). His sister and father were heterozygous for the splice donor variation, whereas his mother was heterozygous for the known missense mutation. Whole body imaging of the sister who suffered from nonclassical CAH was within normal limits. His parents had no known clinical manifestations to suggest a pheochromocytoma or paraganglioma. Autosomal dominant paragangliomas due to SDHB mutations have been reported, associated with loss of heterozygosity in tumor specimens. The combination of sequence variations in the SDHB gene in the same patient may have been necessary to trigger tumor growth of selected chromaffin cells. Autosomal recessive etiology of paraganglioma has not been reported previously.

Early infantile epileptic encephalopathy with suppression-burst (Ohtahara syndrome) is caused by a longer polyalanine expansion mutation in the ARX gene. *M. Kato[1], S. Saitoh[2], A. Kamei[3], H. Shiraishi[2], Y. Ueda[2], M. Akasaka[3], J. Tohyama[4], N. Akasaka[4], S. Kumada[5], M. Kubota[6], K. Nakamura[1], K. Hayasaka[1]* 1) Dept Pediatrics, Yamagata Univ Sch Medicine, Yamagata, Japan; 2) Hokkaido University Graduate School of Medicine, Sapporo, Japan; 3) Iwate Medical University, Morioka, Japan; 4) Nishi-Niigata Chuo National Hospital, Niigata, Japan; 5) Tokyo Metropolitan Neurological Hospital, Tokyo, Japan; 6) Tokyo Metropolitan Hachioji Childrens Hospital, Tokyo, Japan.

Early infantile epileptic encephalopathy with suppression-burst or Ohtahara syndrome (OS) is one of the most severe and earliest forms of epilepsy and often evolves to West syndrome (WS). The pathogenesis of OS remains unclear. *ARX* is a crucial gene for the development of interneurons in the fetal brain and polyalanine expansion mutations of *ARX* cause mental retardation or seizures including WS in male. Mutation analysis of *ARX* was performed for six sporadic male patients affected with OS by DHPLC and direct sequencing. We identified a hemizygous de novo 33 bp-duplication in exon 2, 298_330dupGCGGCA(GCG)9, which is thought to expand the original 16 alanine residues to 27 alanine residues (A110_A111insAAAAAAAAAAA) in the first polyalanine tract of the ARX protein, in two unrelated patients. Both patients started their seizures at the first day of life and had a small penis that was not seen in other patients. Their brain MRI showed the cerebral white matter changes, such as the dilatation of the lateral ventricles, thin corpus callosum, and delayed myelination. Although OS is mainly associated with brain malformations, *ARX* is the first responsible gene for idiopathic OS. The length of expansion in OS (11 alanine residues) was longer than that in WS (7 alanine residues) or non-syndromic mental retardation (1 to 3 alanine residues). Our observation that OS had longer polyalanine expansion than WS is consistent with the findings of earlier onset and more severe phenotypes in OS than in WS as observed in other polyalanine expansion or triplet repeat diseases. Hypogenitalism and white matter changes might be characteristic features for OS caused by the *ARX* mutation.

Characterization of SOX10 deletions in Waardenburg-Hirschsprung disease. *N. Bondurand[1], F. Dastot-Le Moal[1, 2], V. Baral[1], N. Collot[1, 2], I. Giurgea[1, 2], P. Sarda[3], A. Echaieb[4], R. Touraine[5], J. Amiel[6], M. Goossens[1, 2], V. Pingault[1, 2]* 1) Genetic department, INSERM U841, IMRB, creteil, France; 2) AP-HP, Groupe Henri Mondor-Albert Chenevier, biochimie et génétique, Créteil, France; 3) Department of Medical genetics, CHU Montpellier, France; 4) Chirurgie pediatrique, Hopital Pierre Zobda Quitman, Fort de France, France; 5) CHU-Hôpital Nord, Génétique, Saint Etienne, France; 6) INSERM U781 et département de Génétique, Hôpital Necker, Paris, France.

The SOX10 transcription factor is involved in development of neural crest derivatives including melanocytes, enteric nervous system and glial cells. Accordingly, SOX10 mutations have been found in patients presenting with intestinal aganglionosis, pigmentation anomalies and deafness, an association known as Waardenburg-Hirschsprung disease or WS4. Associated neurological signs have been reported in some cases leading to a syndrome called PCWH (Peripheral demyelinating neuropathy-Central dysmyelinating leukodystrophy-Waardenburg syndrome-Hirschsprung disease). The mutations identified so far include mostly truncating point mutations. Much evidence indicates that the more severe disease phenotype PCWH is realized only when the mutant mRNAs escape the nonsense mediated decay RNA surveillance pathway. Besides SOX10, mutations of EDN3 and EDNRB have been observed in WS4 patients. However, not all cases are explained at the molecular level, raising the possibility that other genes are involved or that some mutations within the known genes are not detected by commonly used genotyping methods. Here, we used semi-quantitative fluorescent multiplex PCR and Fluorescent in situ hybridization to search for SOX10 deletions. We identified the first 3 heterozygous deletions in patients presenting with WS4 or PCWH. Full characterization of the deletions revealed different events ranging from the deletion of a single exon to that of up to 220kb. Interestingly, one of the patients also carries a SOX10 Valine to Leucine substitution at the hemizygous state (V92L). Functional consequences of the V92L variation, and the influence of additional deleted genes on the phenotype severity will be discussed.

CYP1B1 variants are associated with prostate cancer in non-Hispanic and Hispanic Caucasians. *J. Beuten[1], J.J. Byrne[1], I. Balic[2], T.L. Johnson-Pais[3], I.M. Thompson[4], R.J. Leach[1,3,4]* 1) Department of Cellular & Structural Biology; 2) Department of Psychiatry; 3) Department of Pediatrics; 4) Department of Urology, UTHSCSA, San Antonio, TX.

Cytochrome P4501B1 (CYP1B1) is involved in the activation of many carcinogens and in the metabolism of steroid hormones. To test whether genetic polymorphisms within the CYP1B1 gene are associated with risk for prostate cancer (PCa) we compared allele, genotype, and haplotype frequencies of 7 single nucleotide polymorphisms (SNPs) within CYP1B1 among non-Hispanic Caucasians (482 cases, 501 controls) and Hispanic Caucasians (148 cases, 240 controls). When each of the SNPs were analyzed separately, significant differences were observed for allele frequencies between Hispanic Caucasian cases and controls for 366G/T(A119S) (p=0.026). In this group the TT genotype for 366G/T(A119S) increased the risk for PCa significantly (OR = 2.72, p = 0.004, 95%CI = 1.39-5.32). Moreover, a common G-C-C-C-G-G-A haplotype (frequency of 22.3%) for -1001C/T- -263G/A- -13C/T-142C/G(R48G)-355G/T(A119S)-4326C/G(L432V)-4390A/G(N453S) was found to occur more frequently in controls, as compared to cases in the Hispanic Caucasian samples (p = 0.04). Among non-Hispanic Caucasian men with more aggressive prostate cancer, variants -1001C/T, -263G/A, -13C/T, and 142C/G(R48G) were associated with the disease status: carrying one or both of the respective minor alleles at each variant resulted in a 1.7-3.2 fold increase among men with more aggressive PCa (p = 0.004-0.02). Furthermore, a common A-T-T-G-C-A haplotype (frequency of 27.6%) for -1001C/T- -263G/A- -13C/T-142C/G(R48G)-4326C/G(L432V)-4390A/G(N453S) was positively associated with high aggressive disease status (i.e., Gleason score greater than or equal to 7) among non-Hispanic Caucasian men (p = 0.0007). Our findings suggest that genetic polymorphisms in CYP1B1 may modify the risk for PCa and support the role of CYP1B1 as a candidate gene for prostate cancer.

Genetic Analysis of Syndromic X-Linked Microphthalmia. *J.J. Johnston[1], E. Hilton[2,3], V. Kimonis[4], C. Schwartz[5], G.C.M. Black[2,3], L.G. Biesecker[1]* 1) NHGRI, NIH, Bethesda, MD; 2) St. Mary's Hospital, Manchester, UK; 3) Manchester Royal Eye Hospital, Manchester, UK; 4) Harvard Medical School, Boston, MA; 5) Greenwood Genetics Center, Greenwood, SC.

Lenz microphthalmia is inherited in an X-linked pattern and comprises microphthalmia, mental retardation (MR), skeletal and other anomalies. This disorder has been mapped to two loci, MCOPS1 (microphthalmia with associated anomalies) at Xq27-q28 and MCOPS2 at Xp11.4. A single mutation in the BCL-6 interacting corepressor, BCOR, on chromosome Xp11.4, was identified in the family used to map the MCOPS2 locus. Mutations in BCOR have also been identified in Oculofaciocardiodental syndrome (OFCD). OFCD is inherited in an X-linked pattern with apparent male lethality and comprises microphthalmia, congenital cataracts, radiculomegaly, and cardiac and digital abnormalities. Initial studies show BCOR to be the major gene for OFCD. We have continued to screen additional patients with Lenz (2), OFCD (10), microphthalmia with or without MR (7), and X-linked MR with eye abnormalities (25) to better understand the contribution of BCOR mutations to these phenotypes, and in the case of Lenz syndrome, to identify families that map to the MCOPS1 locus. Nine out of ten patients with OFCD have had loss of function mutations in BCOR and no mutations have been identified in individuals with non-Lenz microphthalmia or in those with X-linked MR with eye anomalies. The identical substitution found in the original MCOPS2 family, p.P85L, was identified in the Lenz syndrome proband from a second family. The other proband with Lenz syndrome did not have a mutation in BCOR and the family is currently being evaluated for linkage to the MCOPS1 locus. We hypothesize that this family maps to Xq27-q28 and we will incorporate their data into our current efforts to refine the mapping of MCOPS1 in two previously reported families. In summary, loss of function mutations that affect BCOR cause OFCD as demonstrated by the mutations identified in affected individuals. Furthermore, it appears that while alterations in BCOR may contribute to Lenz syndrome, they do not appear to contribute to non-Lenz microphthalmia or X-linked MR.

Circadian rhythm abnormalities of melatonin in Smith-Magenis syndrome patients with *RAI1* point mutation.

D.X. Dang[1,4], D. Glaze[2,3,4], R.J. Reiter[5], D.X. Tan[5], J.R. Lupski[1,2,4], L. Potocki[1,4] 1) Molecular and Human Genetics, Baylor Col Medicine, Houston, TX; 2) Pediatrics, Baylor Col Medicine, Houston, TX; 3) Neurology, Baylor Col Medicine, Houston, TX; 4) Texas Children's Hospital, Houston; 5) Cellular and Structural Biology,Univ Texas Health Science Ctr., San Antonio, TX.

Smith-Magenis Syndrome (SMS) is a multiple congenital anomalies and mental retardation disorder in which neurobehavioral abnormalities and sleep disturbances are major features. Most persons with SMS harbor a 3.7 Mb microdeletion within 17p11.2; however, several non-deletion patients have been reported who have heterozygous point mutations of the retinoic acid induced 1 gene (*RAI1*) within the SMS critical region. The majority of persons with del(17)(p11.2p11.2) and those with *RAI1* point mutations are reported to have subjective sleep disturbances. However, whereas circadian rhythm abnormalities of melatonin have been established in deletion patients, this finding has not been reported previously in *RAI1* mutation patients. Herein we report abnormal melatonin levels in two SMS individuals harboring *RAI1* point mutations. Both patients underwent a 24-hour sleep study during which urinary samples were collected for analysis. Subjective sleep disturbances were present in each patient. Objective abnormalities of sleep were noted in the younger of the two patients (age 11y 3m), including decreased total sleep time, multiple nocturnal awakenings, and abnormal sleep-stage distribution (increased percentage of REM sleep). The other patient (age 27 years) had a normal sleep study. Urinary excretion of 6-sulphatoxymelatonin (aMT6s), the major metabolite of melatonin, revealed an inversion of the circadian rhythm of melatonin in both individuals, as is typical in SMS microdeletion patients. We also find that aMT6s levels are lower in older patients with either point mutation or deletion as compared to younger patients. Our results further implicate the dosage effect of *RAI1* in the clinical phenotype of Smith-Magenis Syndrome.

Prenatal diagnosis of a Roberts syndrome without prenatal cytogenetics characteristics findings. *C. de La Rochebrochard[1], J. Lucas[2], S. Blesson[3], P. Poulain[4], G. Le Bouar[4], L. Pasquier[1], C. Henry[2], J. Milon[4], C. Quelin[1], L. Loeuillet[5], A. Guichet[3], B. Laudier[3], H. Richard[6], G. Haddad[3], S. Odent[1]* 1) Department of Genetics, Rennes University Hospital; 2) Laboratory of Cytogenetics, Rennes University Hospital; 3) Department of Genetics, Tours University Hospital; 4) Department of Obstetrics and Gynaecology, Rennes University Hospital; 5) Department of Pathology, Rennes University Hospital; 6) Department of Obstetrics and Gynaecology, Fougeres Hospital.

The rare, autosomal recessive Roberts syndrome (RBS) is characterized by tetraphocomelia, profound prenatal growth deficiency, craniofacial anomalies, microcephaly and mental deficiency. RBS cells are characterized by heterochromatin repulsion (HR) or premature centromere separation (PCS). Recently mutations in ESCO2 gene have been reported in RBS. We report a non consanguineous couple referred to our centre for their second pregnancy. At 22 weeks of gestation of their first pregnancy, an ultrasonographic examination detected a severe tetraphocomelia with microcephaly and profound growth deficiency. RBS was suspected and confirmed on autopsy examination and cytogenetics analysis. The foetus exhibited Pierre Robin sequence and tetraphocomelia. RHG banded foetal chromosomes exhibited characteristic PCS on fibroblasts and amniocysts. The second pregnancy was monitoring by combined ultrasound examination with CVS foetal karyotype. RHG chromosome analysis concluded no PCS on 70 cytotrophoblastic cells. At 21 weeks of gestation, bilateral radial agenesis led us to evoke a RBS recurrence. Post-mortem autopsy at 22 SA confirmed moderate growth deficiency, craniofacial anomalies, bilateral radial and thumb agenesis. Interestingly, lower limbs, macroscopic and histological brain analysis were normal. Cytogenetics analysis on 5 more tissues revealed characteristic PCS in only 14 cells in lung and cord out of 213. ESCO2 gene screening is undergoing. RBS might be under diagnosed according to extreme cytogenetics findings variability. We emphasize the importance of ESCO2 mutation screening in suspected RBS, according to genetic counselling and reliable further precocious prenatal diagnosis.

The age, distribution, and molecular evolution of the MAPT inversion. *M.P. Donnelly, W.C. Speed, J.R. Kidd, A.J. Pakstis, K.K. Kidd* Department of Genetics, Yale University School of Medicine, New Haven CT, USA.

The 17q21 inversion, sometimes called the MAPT inversion, is a ~900 kb inversion found primarily in Europeans and Southwest Asians. There is no recombination between the H2 (inverted sequence) and H1 (non-inverted sequence). The H2 haplotype is found at frequencies of up to 35%. We have identified 20 SNPs that act as inversion markers. Using subsets of these markers, we are able to show that the inversion is found at the highest frequencies in Southwest Asia (frequencies of ~30%) with smaller frequencies in Eastern Europe, reaching as low as <5% in Finns, and rising again in Western Europe (frequencies of ~20%). The H2 inversion haplotype also occurs at low frequencies in Africa, Central Asia, India, East Asia, and the Americas, though the East Asian and American alleles are likely due to European admixture. We then used SNPs that were variable on either only one of the orientations or that were variable on both, in conjunction with the previous inversion marking SNPs, to trace the molecular evolution of the inversion. These SNPs can form haplotype networks that suggest the H2 haplotype may have originally arisen in Africa or Southwest Asia. Though reciprocal recombination between the H1 and H2 haplotypes is not seen (or expected) there is some evidence of gene conversion between the two alleles. With four STRPs and the method described by Stephens *et al.* (1998) we estimated the age of the inversion to 13,600-27,200 years. Though the H2 inversion has many fixed differences across the ~900 kb, the STRP data indicate the most recent common ancestor (MRCA) is very recent, much different from the 3 million year age estimated by Stefansson *et al.* (2005). Supported in part by NIH GM57672.

Autosomal Recessive Bestrophinopathy (ARB): a novel phenotype associated with *BEST1* mutations. *R. Burgess[1], I. Millar[2], B. Leroy[3], J. Urquhart[1], I. Fearon[2], P. Brown[2], A. Webster[4], G. Holder[4], F. Manson[1], G. Black[1]* 1) Medical Genetics, University of Manchester, Manchester, UK; 2) Life Sciences, University of Manchester, Manchester, UK; 3) Department of Ophthalmology, Ghent University Hospital, Ghent, Belgium; 4) Moorfields Eye Hospital, London, UK.

Autosomal dominant mutations in *BEST1* are associated with retinal phenotypic heterogeneity. Best disease is a macular dystrophy caused predominantly by missense mutations and the ocular developmental disorder, ADVIRC, is casued by splicing mutations.

We describe a novel recessive phenotype in 6 families caused by homozygous or compound heterozygous mutations in *BEST1*, which we term autosomal recessive bestrophinopathy (ARB). ARB is a panretinal disorder characterised by macular abnormalities, widespread punctate flecks and progressive photoreceptor dysfunction. Like Best disease, patients had a reduced EOG light rise but distinctly had reduced and delayed full-field ERG responses.

One family has a homozygous nonsense mutation in exon 5 which we predict would cause a null phenotype through nonsense mediated decay. This is the first report of a human null bestrophin, and given the phenotypic similarity between our families, we presume the other missense mutations associated with ARB also reflect a loss of protein function.

BEST1 encodes bestrophin-1, a chloride channel expressed exclusively in the retinal pigmented epithelium. We studied the Cl^-channel activity of wildtype and ARB mutated bestrophin-1 in transfected HEK293 cells using whole-cell patch-clamping. We found that ARB mutant bestrophin-1 had a reduced channel function compared with wildtype protein. Co-transfection with wildtype bestrophin-1 did not inhibit the wildtype channel activity, in contrast to experiments with Best disease mutant constructs. These data are consistent with the recessive nature of ARB. These findings have important implications for genetic testing and counseling, and helps in the understanding of the molecular mechanisms underlying the pathogenesis of *BEST1* associated disease.

No association of selected SNPs in *GALP, PCK1, SERPINA13* or *TNK1* with Alzheimers disease. *J.A. Figgins[1], S.T. DeKosky[2], R.L. Minster[1], M.I. Kamboh[1]* 1) Department of Human Genetics; 2) Department of Neurology, University of Pittsburgh, Pittsburgh, PA.

Alzheimers disease (AD) is a complex and multifactorial disease with the possible involvement of several genes. With the exception of the *APOE* gene as a susceptibility marker no other genes have been identified for late-onset AD (LOAD). A recent genome-wide association study of 17,343 gene-based putative functional single nucleotide polymorphisms (SNPs) found 19 significant variants in several genes showing association with LOAD in several population samples (Hum Mol Genet 2007;16:865-73). We have set out to replicate these significant associations in a large case-control cohort of American Whites. Thus far we have examined SNPs in four of the genes: *GALP*/*rs3745833* (c.216C>G p.I72M), *PCK1*/*rs8192708* (c.799A>G p.I267V), *SERPINA13*/*rs11622883* (c.*42980T>A), *TNK1*/*rs1554948* (c.81T>A). The four SNPs were genotyped in up to 1003 Caucasian Americans with late-onset Alzheimers disease and up to 868 age matched healthy Caucasian Americans. All four variants were genotyped using 5 nuclease assays. We did not observe a statistically significant association between the SNPs with the risk of AD, either individually or stratified by APOE. We are in the process of completing analysis on SNPs in 12 other genes noted in the paper. Our data suggest that the association of *GALP*/*rs3745833*, *PCK1*/*rs8192708*, *SERPINA13*/*rs11622883*, and *TNK1*/*rs1554948* with LOAD, if it exists, is not statistically significant in our population.

Sporadic Non-Immune Hydrops Fetalis Can Be Caused by *VEGFR3* Mutations. *A. Ghalamkarpour[1], C. Debauche[2], N. Van Regemorter[3], N. Revencu[1], Y. Gillerot[4], Y. Sznajer[5], D. Thomas[6], L.M. Boon[1,7], M. Vikkula[1]* 1) Human Molecular Genetics, de Duve Institute, Brussels, Belgium; 2) Department of Neonatology, Cliniques Universitaires Saint-Luc, Belgium; 3) Center de Génétique ULB, Hôpital Erasme, Belgium; 4) Center for Human Genetics, Cliniques Universitaires Saint-Luc, Belgium; 5) Unité de Génétique Clinique Pédiatrique, ULB, Belgium; 6) Unité Diagnostic Anténatal, Hôpitaux Iris Sud, Belgium; 7) Centre for Vascular Anomalies, Cliniques Universitaires Saint-Luc, Belgium.

Mutations in the vascular endothelial growth factor receptor 3 gene, *VEGFR3/FLT4*, have been identified in a subset of families with hereditary lymphedema type I or Milroy disease (MIM 153100). The classical clinical phenotype of the patients with a *VEGFR3* mutation is congenital lower limb lymphedema, which is usually bilateral and below the knees. We have shown that an inherited *VEGFR3* mutation can cause hydrops fetalis, indicating for a systemic lymphatic dysfunction. We hypothesized that sporadic non-immune hydrops fetalis may also result from an altered VEGFR3 signaling. Here, we report two such cases. The first patient presented *in utero* with severe generalized skin edema. The edema limited to the lower limbs after birth, yet in the presence of chylous ascites. We identified a heterozygous *VEGFR3* mutation in this patient, which was not present in either of the non-affected parents, and thus constituted a dominant *de novo* mutation. The second case was diagnosed *in utero* with thickening of subcutaneous tissues and chylous ascites. Similar to the first patient, the edema spontaneously limited to the lower limbs after birth. A heterozygous *VEGFR3* mutation was identified in this patient, however, we were unable to collect samples from his healthy parents and thus it is either a *de novo* or a non-penetrant familial mutation. Our data indicate that *VEGFR3* mutations can be the pathophysiological cause of non-immune hydrops fetalis in the patients with no family history of edema. This has implications for genetic counseling and a *VEGFR3* screening can be suggested in such individuals. (http://www.icp.ucl.ac.be/vikkula) (Miikka.Vikkula@uclouvain.be).

A recurrent mutation in the ARS gene in a Tunisian family with Mal de Meleda and congenital cataract. *M. BCHETNIA[1,2], C. CHARFEDDINE[1], S. KASSAR[3], M. MOKNI[2, 4], S. BOUBAKER[3], S. GHEDAMSI[4], A. DHAHRI-BEN OSMAN4[4], S. ABDELHAK[1]* 1) Molecular Investigation of Genetic Orphan Diseases Research Unit (MIGOD) UR 26/04, Institut Pasteur de Tunis, Tunisia; 2) Study of Hereditary Keratinization Disorders Research Unit (THK) UR 24/04, La Rabta Hospital, Tunis, Tunisia; 3) Anatomo-Pathology Department, Institut Pasteur de Tunis, Tunisia,; 4) Dermatology Department, La Rabta Hospital, Tunis, Tunisia.

Mal de Meleda (MDM) also referred to as keratosis palmoplantaris transgrediens of Siemens, is a rare autosomal recessive skin disorder with a prevalence in the general population of 1 in 100 000. The disease locus of MDM has been mapped to chromosome 8qter and in recent studies; homozygous mutations in the ARS (component B) gene have been identified in families with this disorder. The ARS gene encodes a secreted Ly-6/uPAR (lymphocyte antigen 6/urokinase-type plasminogen activator receptor) related protein 1 (SLURP-1). In this report, we performed mutational analysis of the ARS gene by direct sequencing in a large consanguineous family of Tunisian origin with MDM and hereditary congenital cataract. The mutation C99Y previously reported exclusively in Tunisian families was identified. This finding suggests that the ARS gene is likely to be responsible for MDM in this family and shows evidence of a founder effect in the Tunisian families sharing a common ancestral allele. The molecular exploration of the congenital cataract and its association with this type of palmoplantar keratoderma needs further investigations.

Highly mutable CCGCGG interruptions in expanded CTGCAG repeat tracts increase penetrance in SCA8 families. *Y. Ikeda[1], M.L. Moseley[1], J. Nielsen[2], L. Hasholt[2], A. Nørremølle[2], T. Bird[3], J.W. Day[1], L.P.W. Ranum[1]* 1) Inst. of Human Genet., Univ. of Minnesota, Minneapolis, MN; 2) Dept. of Cellular and Mol. Medicine, Univ. of Copenhagen, Denmark; 3) Dept. of Neurology, Univ. of Washington, Seattle, WA.

Spinocerebellar ataxia type 8 (SCA8) is a dominantly inherited neurodegenerative disorder caused by a CTGCAG repeat expansion bidirectionally expressed as both a polyglutamine protein and a non-coding CUG transcript. We have investigated interrupting trinucleotides within the repeat as modifiers that could explain the puzzling degree of reduced penetrance in SCA8. All expansion chromosomes in affected individuals (n=12) from a branch of the MN-A family, the largest SCA8 family known, contain variable numbers of CCGCGG interruptions within the CTGCAG tract. In contrast, all expansion chromosomes from a non-penetrant branch of the MN-A family have pure repeats, suggesting CCGCGG interruptions influence disease penetrance in this family. Analysis of an additional 31 SCA8 families show CCGCGG interruptions in 6 families including a three generation Danish family with 6 affected members. The number of CCGCGG interruptions within the repeat tract show dramatic variation between members of both the MN-A and Danish families (1-11 CCGCGGs). Additionally, CCGCGG interruptions were found at a higher frequency in families with multiple (6/13) versus single affected family members (1/19) (p=0.015). Analysis of additional relatives of the sporadic case with interruptions show that expansion alleles in the unaffected father and sibling had no interruptions. Additional studies in cells expressing interrupted vs. pure polyQ ATXN8 protein show that expression of ATXN8 with these arginine encoding interruptions in the polyQ tract changes the aggregation and solubility properties of the protein resulting in more 1C2 inclusions and shifted gel mobility. In summary, penetrance differences in humans indicate that CCGCGG interruptions increase the risk of developing ataxia and additional work is needed to determine if this effect is mediated by changes in the mutant protein or by changes in the toxicity of the mutant transcripts.

***GABRG1* and *GABRA2* Variation Associated with Alcohol Dependence in African American Population.** *C. Ittiwut[1,3,4], H.R. Kranzler[5], R. Anton[6], R. Hirunsatit[1,3,4], J. Covault[5], J. Gelernter[1,2,3]* 1) Dept Psychiatry, Yale Univ Sch. Medicine, New Haven, CT 06519, USA; 2) Genetics and Neurobiology, Yale Univ Sch. Medicine, New Haven, CT 06519, USA; 3) VA CT Healthcare System, West Haven, CT, USA; 4) Chulalongkorn Univ., Inter-Dept Program of Biomed Science, Bangkok, Thailand; 5) Dept Psychiatry, Univ CT Sch. Medicine, Farmington, CT, USA; 6) Medical Univ. of SC, Charleston, SC, USA.

GABRG1 and *GABRA2*, which encode the 1 and 2 subunits, respectively, of the GABA-A receptor, are located in a cluster on chromosome 4p. Although markers located at the 3 region of the *GABRA2* locus have been associated with alcohol dependence (AD), one recent study suggests the possibility that the signal may be attributable to the adjacent gene, *GABRG1*, located 90kb distant in the 3 direction. To elucidate the association with AD, we genotyped 13 single nucleotide polymorphisms (SNPs) that span *GABRG1* and *GABRA2* in 276 African-Americans (AAs) with AD and in 242 AA controls (some of whom were included in an earlier report). Six tag SNPs were identified using the htSNP approach in HAPLOVIEW. Individual SNP associations were tested by chi-square. Nominally significant allele frequency differences were identified for rs10938426, at *GABRG1* intron 1, with p=0.044. Significant differences in both genotype and allele frequency (p=0.008 and 0.007, respectively) were observed at rs279869, located at *GABRA2* intron 6. We performed haplotype association analysis by means of PHASE. Haplotypes combining six SNPs from both gene loci showed frequency differences between controls and AD subjects, p=0.0027, significant after Bonferroni correction. A two-SNP haplotype composed of rs10938426 and rs279869 showed greater significance (p=0.00013). Association analysis of haplotypes defined within each gene showed no other association between any other *GABRG1* or *GABRA2* haplotype and AD risk. This finding suggests that there is an interrelationship between these two genes and that each may contain risk loci. A two-SNP haplotype composed of one SNP from each gene is consistent with an interaction of these genes and supports the involvement of both in susceptibility to AD in AAs.

GALNS Gene Analysis and Expression profiles in Morquio A Patients Fibroblasts. *L. Carraresi[1], C. Filoni[1], A. Caciotti[1], R. Parini[2], M.A. Donati[1], S. Tomatsu[3], E. Zammarchi[4], R. Guerrini[1], A. Morrone[1]* 1) Metabolic and Muscular Unit, Clinic of Ped. Neurol., AOU Meyer, Florence, Italy; 2) Metabolic Unit, S. Gerardo Hospital, Monza; Milan; Italy; 3) Ped. Res. Inst., St. Louis University, St. Louis, USA; 4) Dept of Ped., University of Florence, Florence, Italy.

Mucopolysaccharidosis IVA (MPS IVA, Morquio A) is an autosomal recessive storage disorder caused by deficiency of lysosomal enzyme N-acetylgalactosamine-6-sulfate sulfatase (GALNS), required for degradation of keratan sulphate and condroitin-6-sulfate. MPS IVA patients show a broad spectrum of clinical severity with classical forms characterised by severe bone dysplasia and normal intelligence. Here we report the clinical, biochemical and molecular analysis of two classical MPS IVA patients. Direct sequencing of the patients GALNS gene identified in patient 1 the known splice-site mutation c.120+1GA at homozygous level and in patient 2 the new mutations p.K129X (nonsense mutation) and c.899-1GC (splice-site mutation). RT-PCR analysis on total RNA preparations from the patients fibroblasts showed that the splicing mutation c.899-1GC in patient 2 causes the skipping of exon 9, and results in a frameshift and a premature stop codon, while no transcript was detected in patient 1 with the known c.120+1GA mutation. In order to shed light on the molecular basis of pathophysiology of the mutation causing disease in MPS IVA patients here described and study the mutant mRNA stability, we used the high efficient and reproducible quantitative Real-Time RT-PCR. The analysis carried out on patients fibroblasts RNA confirmed the absence of GALNS mRNA in patient 1, harbouring c.120+1GA splice site mutation, demonstrating, instead, in patient 2 the presence of both mutated mRNA transcripts. This indicates that c.385AT (p.K129X) and c.899-1GC mutations produces mRNAs able to escape NMD pathway, according to the fact that PTC are 50nt upstream of the respective exon-exon junction. The absence in patient 1 and the presence in patient 2 of two mRNAs leading truncated inactive proteins enable us to make a genotype-phenotype correlation.

Molecular analysis of spinal muscular atrophy by gene dosage analysis of survival motor neuron genes in Korean population. *J.H. Kim[1], J.H. Lee[2,4], M.H. Lee[2,4], B.J. Kim[3,4], J.W. Kim[1,4], C.S. Ki[1,4]* 1) Departments of Laboratory Medicine, Samsung Medical Center; 2) Pediatrics, Samsung Medical Center; 3) Neurology, Samsung Medical Center; 4) Sungkyunkwan University School of Medicine, Seoul, Korea.

Purpose: Spinal muscular atrophy (SMA) is an neurodegenerative disorder mainly caused by homozygous deletion of survival motor neuron (SMN) genes. The causative gene is SMN1 gene, but the disease types and severity are influenced by SMN2 gene dosage and adjacent gene deletion. So we investigated SMN1, SMN2, and adjacent gene copy numbers to determine the gene dosage distributions in normal individuals and the patient groups. Methods: We investigated a total of 55 individuals (15 SMA patients, 6 carriers, and 34 controls) with a commercially available multiple ligation-dependent probe amplification (MLPA) kit. The 15 patients were tested for the homozygous deletion of SMN1 gene by PCR-RFLP and were composed of 9 patients with homozygous deletion of SMN1 gene and 6 patients with clinical diagnosis of SMA but without homozygous SMN1 gene deletion. Six carriers were parents of the SMA patients with homozygous SMN1 gene deletion. Direct sequencing of SMN1 gene was performed for a patient with a heterozygous SMN1 gene deletion. Results: The SMN1 gene dosage was 2 copies in all controls but the SMN2 gene dosage was variable: 1 copy in 10 individuals (30%) and 0 copy in one individual. In SMA patients showing homozygous SMN1 gene deletion, the SMN2 gene dosage was usually conserved. One patient, previously not detected with PCR-RFLP, was diagnosed as a compound heterozygote with a heterozygous SMN1 gene deletion and a frame shift mutation in the SMN1 gene. Three SMN2 gene copy numbers were seen in two patients of SMA type I and IV, respectively. Conclusion: The gene dosage analysis in SMA seems important for the detection of compound heterozygotes and carrier status. However, it is not clear the genotype-phenotype correlation between the copy numbers of SMN2 gene and disease severity. Further analysis for the patients with clinical SMA with neither heterozygous nor homozygous deletion of SMN1 gene are needed.

Extended identity of MHC SNP haplotypes is common and relates to type 1 diabetes risk. *E.E. Baschal, T.A. Aly, M.S. Fernando, M.M. Jahromi, S.R. Babu, M.J. Rewers, G.S. Eisenbarth* Barbara Davis Center for Childhood Diabetes, University of Colorado at Denver and Health Sciences Center, Aurora, CO.

The extensive linkage disequilibrium throughout the MHC both confounds and aids efforts to identify diabetes-associated MHC loci (with analysis of extended conserved haplotypes). We analyzed 165 families enrolled in the DAISY prospective study supplemented with 72 HBDI families using a custom Illumina SNP panel of an extended MHC region (364 SNPs, 10.7Mb) and 751 families from the Type 1 Diabetes Genetics Consortium (T1DGC, 2918 SNPs, 4.6Mb (limited to the MHC)). In the T1DGC data, 850 case and 390 control parental chromosomes (AFBAC) had typing for HLA-A, -B, -DR. Within this dataset, 782 chromosomes were represented by 43 haplotype groups, each containing at least 5 chromosomes with identical HLA-A, -B, -DR alleles. The most common HLA haplotypes were: A1 B8 DR3 (190), A2 B15 DR4 (80), A2 B44 DR4 (59), A2 B8 DR3 (34), A2 B40 DR4 (29), A3 B7 DR2 (23), and A30 B18 DR3 (22). Each of these haplotypes had at least two chromosomes with stretches of greater than 99% SNP identity (>3Mb). Of the 43 haplotype groups, 7 were over-represented in cases ($p=0.04$ to 10^{-7}) and 6 were under-represented ($p=0.04$ to 10^{-11}). Using a custom panel with SNPs extending 6Mb telomeric of the MHC, we found that the A1, B8, DR3 (8.1) extended haplotype exhibited greater than 99% identity for 3 to 9 million nucleotides. We identified a significant SNP (rs1233478, $p=10^{-6}$), 46kb telomeric of the UBD gene (telomeric of the MHC), using case-control AFBAC analysis. We replicated this finding in the T1DGC data ($p=10^{-15}$, genotype OR=4). A 5-SNP haplotype with rs1233478 was overtransmitted to cases ($p=10^{-13}$). In a combined analysis of only the 8.1 haplotypes in the DAISY/HBDI and T1DGC data (which fixes the entire MHC and all HLA alleles), rs1233478 was still significant ($p=0.01$). Additionally, rs1233478 was statistically significant with logistic regression using HLA-A, -B and -DR alleles as explanatory variables. This SNP analysis demonstrates the remarkable long-range identity of multiple MHC diabetes-associated haplotypes, and identifies a haplotype near the UBD gene associated with additional diabetes risk.

Semax and PGP affect the mRNA expression of neurotrophins and their receptors under the focal cerebral ischemia in rats. *V.G. Dmitrieva[1], L.V. Dergunova[1,2], I.V. Vlasova[1], O.V. Povarova[2], V.I. Skvortsova[2], S.A. Limborska[1,2]* 1) Human Molecular Genetics Dept, Institute of Molecular Genetics RAS, Moscow; 2) Institute of Stroke RSMU, Moscow, Russian Federation.

Neuroprotective polypeptide Semax is used for acute therapy of stroke. The effect of Semax and its C-terminal PGP tripeptide therapy on mRNA expression of neurotrophins Bdnf, Nt-3 and their receptors TrkB, TrkC after 3, 24, and 72 hours of cerebral ischemia was investigated. Focal cerebral ischemia was induced in male Wistar rats by permanent middle cerebral artery occlusion (MCAO). The intraperitoneal injections of either Semax or PGP were done at 15 min, 1, 4 and then after every 4 hour. Real-time RT-PCR has been used to measure changes in mRNA expression of genes investigated in the lesioned cortex of rat brains. Gapdh was used as the internal control. Compare with the increase of Bdnf mRNA expression observed in the ischemic tissue 24 h after MCAO, Semax promotes the increase of Bdnf mRNA level in the ischemic tissue as early as 3 h after occlusion and supports the high level of Bdnf mRNA to the point of 72 h after occlusion. PGP also increases Bdnf mRNA expression 3 h after ischemia but then Bdnf expression returned to control level. The analysis of TrkB mRNA expression in ischemic cortex of rats under the Semax treatment didnt reveal any significant difference compare to control. However under the treatment with PGP the level of TrkB mRNA was increased at 24 h after MCAO. In the damaged cortex the Nt-3 mRNA expression increases after 72 h of MCAO while under the Semax treatment the increase of the level of Nt-3 transcripts was detected at 24 h but then it returned to the control level. The Nt-3 mRNA expression in rat ischemic cortex didnt change under the PGP treatment compare to control. The changes in TrkC mRNA expression in ischemic cortex of rats under the Semax treatment were not observed. However under the treatment with PGP tripeptide the level of TrkC mRNA was increased during fist 24 h after MCAO. Thus in MCAO conditions used Semax increases the expression of neurotrophins Bdnf, Nt-3 whereas PGP mainly affect on the mRNA level of their receptors TrkB, TrkC.

Variants on 4q25 confer risk of atrial fibrillation. *D. Gudbjartsson[1], D. Arnar[2], A. Helgadottir[1], S. Gretarsdottir[1], G. Thorleifsson[1], G. Thorgeirsson[2], K. Kostulas[3], J. Hillert[3], R. Ma[4], M.C.Y. Ng[4], J. Rosand[5], P. Ellinor[6], H. Holm[1], J. Gulcher[1], U. Thorsteinsdottir[1], A. Kong[1], K. Stefansson[1]* 1) Statistics, deCODE Genetics, Reykjavik, Iceland; 2) Division of Cardiology, Department of Medicine, Landspitali University Hospital, Reykjavik, Iceland; 3) Department of Neurology, Karolinska Institutet at Karolinska University Hospital, Huddinge, Sweden; 4) Department of Medicine and Therapeutics, Prince of Wales Hospital, Chinese University of Hong Kong, Shatin, Hong Kong; 5) Department of Neurology, Massachusetts General Hospital Hospital and Harvard Medical School, Boston; 6) Cardiology Division and Cardiovascular Research Center, Massachusetts General Hospital and Harvard Medical School, Boston.

Atrial fibrillation (AF) is the most common sustained cardiac arrhythmia in man and is characterized by chaotic electrical activity of the atria. It affects one in ten individuals over eighty, causes significant morbidity, and is an independent predictor of mortality. We performed a genome-wide association scan on an Icelandic AF sample with 316,000 SNPs on an Illumina BeadChip. The genome-wide scan was followed by replication studies in European populations from Iceland, Sweden, the U.S. and Norway and a strong association between two sequence variants on chromosome 4q25 to AF was confirmed (P 10^{-40} and P 10^{-10}). Approximately 35% of individuals of European descent have at least one of the variants and the risk of AF increases by 1.72 and 1.39 per copy. We also tested the variants in a Chinese population from Hong Kong and replicated the association to the stronger variant. The stronger variant is carried by 75% of individuals in the Chinese sample and the risk of AF is increased by 1.42 per copy. A stronger association was observed in individuals with typical atrial flutter (AFl), individuals with lone AF and individuals with early onset of disease. The variants are in the same LD block, adjacent to PITX2, which is known to play a critical role in left-right asymmetry of the heart.

Using disease subtypes to reduce phenotypic heterogeneity: the example of TGFBR3 and pulmonary emphysema.
C.P. Hersh, F.L. Jacobson, R. Gill, A.A. Litonjua, J.J. Reilly, E.K. Silverman Brigham and Women's Hospital, Harvard Medical School, Boston, MA.

Background: Chronic obstructive pulmonary disease (COPD) is a heterogeneous syndrome, including emphysema, chronic bronchitis, and small airway disease. Using specific disease subtypes may avoid problems with phenotypic heterogeneity that have complicated many previous COPD genetics studies. **Methods:** Genome-wide linkage analysis was performed in 44 extended families of probands with severe, early-onset COPD and in a stratified analysis of 34 of these pedigrees with emphysema-predominant COPD probands. Emphysema was assessed by chest computed tomography scans. Emphysema candidate genes were selected in regions that showed stronger evidence for linkage in the stratified analysis. Association analysis of positional candidate genes was performed in 949 individuals from 127 extended pedigrees and in a case-control study, comparing 389 cases with severe emphysema to 472 control smokers without lung disease. **Results:** Genome-wide linkage analysis identified a region on chromosome 1p with suggestive evidence of linkage for lung function in families of emphysema-predominant probands (LOD score 2.89 in emphysema-predominant families vs. 1.85 in all families). Association testing of five positional candidate genes revealed replicated association with the transforming growth factor beta receptor-3 (TGFBR3) Ser15Phe SNP (p=0.01 in the family-based study, p=0.02 in the case-control study). **Conclusions:** Stratified linkage analysis followed by association testing has identified TGFBR3 as a potential susceptibility gene for the emphysema subtype of COPD. Published human microarray and murine linkage studies have also demonstrated the importance of TGFBR3 in emphysema and lung function, and our group and others have previously found association of COPD and related traits with TGFB1, a ligand for TGFBR3.

A Genome-Wide Search for Linkage to Chronic Kidney Disease (CKD) Phenotypes in a Community-based Sample. *N. Arar[1], S. Voruganti[2], S. Nath[1], F. Thameem[1], S. Cole[2], J. Blangero[2], J. MacCluer[2], C. Comuzzie[2], H. Abboud[1]* 1) Dept Medicine, Div Nephrology, Univ Texas Health Sci Ctr, San Antonio, TX; 2) Department of Genetics, Southwest Foundation for Biomedical Research, San Antonio, TX.

CKD phenotypes such as elevated urine albumin creatinine ratio (ACR), serum creatinine and/or decreased glomerular filtration rate (GFR) have been associated with several cardiovascular disease (CVD) risk factors. However, their role as independent risk factors for CVD in a community-based sample has not fully investigated. We conducted a genome-wide search to identify chromosomal regions linked to CKD phenotypes in Mexican Americans families enrolled in the San Antonio Family Heart Study (SAFHS). We used variance components decomposition, as implemented in the program SOLAR, to perform linkage analysis on 848 participants from 26 multiplex families of the SAFHS. A total of 417 microsatellite markers were genotyped at an average interval of 10 cM spanning 22 autosomal chromosomes. The mean age was 47.8 14.8 years, 37% male. 22 % of the subjects had T2DM, 52% were hypertensive. Mean urine ACR was 0.06 0.38 mg/mg, the mean serum creatinine was 0.85 0.72 mg/dl and the mean GFR was 99.18 25.69 ml/min. Urinary ACR showed suggestive linkage to chromosomes 20 (marker D20S107, LOD score of 2.93, p= 0.0020), 14 (marker D14S742, LOD score of 2.63, p = 0.00025), and 13 (marker D13S317, LOD score of 1.66, P= 0.0028). Serum creatinine showed suggestive linkage to chromosomes 9 (marker D9S922, LOD score of 2.61, p = 0.00026), 15 (marker D15S642, LOD score of 2.21, p = 0.00069), and 6 (marker D6S1056, LOD score of 2.19, p = 0.00073). GFR showed higher logarithm of odds (LOD) score than the other 2 phenotypes. Serum creatinine and GFR were both linked to chromosomes 9 and 15. Linkage to GFR was observed on chromosomes 9 (marker D9S1122, LOD score of 3.87, p = 0.00005), 15 (D15S642, LOD score of 1.61, p = 0.0018), and 2 (D2S1780, LOD score of 1.53, p =0.0092. Identifying gene(s) of complex diseases may lead to the development of novel therapeutic strategies targeted at high risk individuals.

Somatic partial chromosome 11 duplication in patients with Proteus Syndrome. *K. Duffy[1], D. Bick[1,2], P. vanTuinen[1], S. Dugan[2], A. Yilmaz[3], C. Schwartz[4], W. Foulkes[3], M. Olivier[1]* 1) Medical College of Wisconsin, Milwaukee, WI; 2) Children's Hospital of Wisconsin, Milwaukee, WI; 3) McGill University, Montreal, Canada; 4) J.C. Self Research Institute, Greenwood, SC.

Proteus syndrome (PS) is a rare sporadic disorder characterized by variable, progressive, asymmetric malformations and overgrowth in a variety of tissues. Here, we present evidence of a somatic duplication within chromosome band 11p15.2 as the cause of this disorder. We examined a fibroblast cell line derived from a surgically removed epidermal nevus from a 4-year old female patient diagnosed with PS. Copy number variant analysis using the Affymetrix GeneChip Human Mapping 100K Set identified a partial duplication of chromosome 11 unique to the cell line from the affected tissue. The duplication was localized to 11p15.2, resulting in a partial trisomy spanning over 800 kb. The duplicated region was verified using five quantitative PCR assays (TaqMan) from within the region when compared with two assays from locations outside the duplicated region identified as chromosomally normal. The same region was also duplicated in two additional DNA samples from fibroblast cell lines derived from affected tissue from two previously described PS patients, but not in DNA from blood of the initial PS patient, nor in DNA from the parents or other control DNA samples from unaffected individuals. The region duplicated in all cell lines contains seven known genes. RNA expression analysis was run in triplicate for each sample and revealed that only the gene expression of two of these seven genes, PDE3B and CALCB, was significantly up-regulated (p-values <0.0004) in all three PS cell lines when compared to four age- and gender-matched control fibroblast cell lines. These two genes have been implicated in the regulation of cell growth in a variety of tissues, and may explain the symptomatic overgrowth seen in adipose, epidermal, and bone tissue of patients with PS. This study, for the first time, identifies a somatic mutation in affected tissue from patients with PS and suggests that the effect of this partial chromosomal duplication is mediated through increased gene expression of individual genes.

Inference of population structure using arbitrarily linked multilocus genotype data. *L. Jin*[1,2], *Y. Wang*[1], *W. Fu*[1] 1) Center for Anthropological Studies, School of Life Sciences, Fudan University, Shanghai, China; 2) CAS-MPG Partner Institute for Computational Biology, SIBS, CAS, Shanghai, China.

STRUCTURE analysis plays an important role in revealing the genetic structure of populations. However, such analysis is only applicable to those markers that are not in strong linkage disequilibrium and therefore, the full amount of information from genome-wide scan can not be exploited. To overcome this obstacle, we describe a grade of membership models (GoM) clustering method using principle components (PC) to infer population structure and assign individuals to population. The population parameters and individuals admixture proportion to each population is simultaneously estimated. The principle component transformation allows our method to model arbitrarily linked genetic markers. The application of the method includes exposing hidden population structure in the sample, analyzing individuals admixture proportion, acting as the first step in structure association correction in case-control association study, determine the relation of nominal populations and so on. We test the software on three dataset and demonstrate the superiority of this method over the existing ones.

Gene-gender interactions in Systemic Lupus Erythematosus. *S. Han[1], I. Harley[1], A.L. Sestak[1], X. Kim-Howard[1], K.M. Kaufman[1,2,3], G. Bruner[1], J.M. Guthridge[1], G. Gilkeson[4], J.B. Harley[1,2,3], J.A. James[1,2], S.K. Nath[1]* 1) Oklahoma Medical Research Foundation; 2) VA Medical Center; 3) University of Oklahoma Health Sciences Center, Oklahoma City, OK,USA; 4) Medical University of South Carolina, USA.

Osteopontin (SPP1) gene polymorphisms have been shown to associate with SLE in small cohorts. This study tested association between SPP1 polymorphisms and SLE in a large, multi-ethnic cohort of 1488 unrelated SLE patients [707 European-American (EA), 549 African-American (AA), 232 Hispanics (HIS)], including 153 males, and 2321 unrelated controls (1309 EA, 834 AA, 178 HIS). To control for potential population stratification, admixture adjusted logistic regression, genomic control (GC), structured association (STRAT) and principle components analysis (PCA) were applied. Twelve SNPs out of 33 were in HWE and used for analysis. The pooled analysis of 3 ethnic groups revealed significant gene-gender interactions. Initially, 4 SNPs (SNP1, 6, 10, 12) showed significant association with SLE in males, but not in females. In accordance with the result, the interactions between the 4 SNPs and gender were also significant (P=0.02, 0.001, 0.005, 0.003, respectively). Further haplotype analysis of 3 SNPs (SNP10, 11, 12) demonstrated a significant association in males (P=0.0002) and interaction with gender (P=0.005). Subgroup analysis with single SNP and haplotype also identified the same pattern of gene-gender interactions in AA and EA. In AA males, 4 SNPs (SNP4, 6, 10, 12) demonstrated significant associations and a strong haplotype association (P=0.00004). In EA, 3 SNPs (SNP10, 11, 12) showed significant associations in males and a haplotype association (P=0.02). Additionally, haplotype interaction analysis with gender of the 3 SNPs was significant in AA and EA (P=0.006, 0.02, respectively). Although, for HIS, 2 SNPs (SNP2, 6) were associated with SLE, no gender effects were detected. All the associations remained consistent with GC, STRAT or PCA in subgroup analysis. Therefore, our data suggest SPP1 is associated with SLE in males. To our knowledge, this report serves as the first description of a human male lupus genetic risk.

A novel 3.4 Mb deletion at Xq22.2-Xq22.3 including PLP1 detected by oligonucleotide based array-CGH. *S.E. Im[1], E.J. Seo[1,2,3], J.O. Lee[3], K.J. Kim[3], T.S. Ko[4], J.K. Ko[4], H.W. Yoo[3,4], I.S. Park[3,4]* 1) Medical Genetics Clinic & Lab, Asan Medical Center, Seoul, Korea; 2) Dept. of Laboratory Medicine, University of Ulsan College of Medicine and Asan Medical Center; 3) Genome Research Center for Birth defects and Genetic disorders, Asan Medical Center; 4) Dept. of Pediatrics, University of Ulsan College of Medicine and Asan Medical Center, Seoul, Korea.

Duplication of the proteolipid protein gene (PLP1) located on Xq22.2 is a major mutation for Pelizaeus-Merzbacher disease (PMD). Whereas deletions of less than 0.5 Mb containing PLP1 have been observed infrequently in patients with dysmyelination and spasticity. An Xq22.3 duplication has been reported as a FGS5 locus for FG syndrome. We present a male infant with a de novo 3.4 Mb interstitial deletion of the long arm of chromosome X. The patient, a 5-month-old Korean boy, showed ventricular septal defect, pulmonary stenosis, dextrocardia, agenesis of the corpus callosum, blindness, micropenis, undescended testis and dysmorphism. Karyotype was found to be normal. The 244k oligonucleotide based array-CGH (Agilent) analysis could define a novel 3.4 Mb deletion at Xq22.2-Xq22.3 including RAB40A, TCEAL4, TCEAL1, MORF4L2, TMEM31, PLP1, RAB9B, MCART6, ESX1, IL1RAPL2, NRK, SERPINA7, MUM1L1, RNF128, CLDN2, and several open reading frames. Some genes located in the deleted region may be possible candidates for patients phenotype. ESX1 is involved in the embryonic development of head, thorax and abdomen. RAB40A, TCEAL1, PLP1, and RNF128 are highly expressed in brain, and NRK in heart predominantly. We now propose a new contiguous gene deletion syndrome in Xq22.2-Xq22.3 characterized by PMD, congenital heart defect, agenesis of corpus callosum and other anomalies.

Hereditary disorders of connective tissue may present with Chiari I malformation, occipitoatlantoaxial hypermobility, and functional cranial settling. *C. Francomano[1], T. Milhorat[2], P. Bolognese[2], M. Nishikawa[2], N. McDonnell[3]* 1) Greater Baltimore Med Ctr, Harvey Institute Human Genetics, Baltimore, MD; 2) The Chiari Institute, North Shore-Long Island Jewish Health System, Manhasset, NY; 3) National Institute on Aging, NIH, Baltimore, MD.

We report an association of hereditary disorders of connective tissue (HDCT) and Chiari malformation 1 (CM1), presenting with lower brain stem symptoms attributable to occipito-atlantoaxial hypermobility and functional cranial settling. The prevalence of hereditary disorders of connective tissue (HDCT) was determined in a prospectively collected cohort of 2,813 patients with CM1. All patients underwent a detailed medical and neuroradiological workup that included an assessment of articular mobility. Using reconstructed 3D-CT and plain x-ray images, osseus structures comprising the craniocervical junction were investigated morphometrically in 114 patients with HDCT/CM1 and compared to those in patients with CM1 alone (n = 55) and normal controls (n = 55). The diagnosis of Ehlers-Danlos syndrome (EDS) or other HDCT was made in 357 of 2,813 of patients with CM1 (12.7%). The clinical features of HDCT/CM1 were distinguished from those of CM1 alone by clinical stigmata of HDCT, a greater female preponderance (7:1 vs. 3:1), and a greater incidence of lower brain stem symptoms (0.43 vs. 0.05), retroodontoid pannus formation (0.71 vs. 0.16), and hypoplasia of the oropharynx (0.45 vs. 0.02). In patients with HDCT/CM1, upon sitting or standing there was reduction of the basal-dens interval (3.6 mm), enlargement of the basal-atlas interval (3.0 mm), and reduction of the clivus-axis angle(10.8^{o}), clivus-atlas angle (5.8^{o}), and atlas-axial angle (5.3^{o}). These changes were reducible by cervical traction or returning to the supine position. In normal controls and patients with CM1 alone, these measurements did not change with position.

Conclusions: The identification of HDCT in 12.7% of patients with CM1 establishes an association between these previously unrelated disorders. Patients with HDCT and symptoms suggestive of CM1 should be evaluated with brain MRIs in the supine and upright positions.

AAV mediated expression of myotubularin in muscle corrects the myotubular myopathy phenotype in a mouse model and suggests a function in membrane remodeling at the sarcolemma. *A. Buj-Bello[1,3], F. Fougerousse[2], Y. Schwab[1], N. Messaddeq[1], D. Spehner[1], P. Schultz[1], O. Danos[2], J. Laporte[1,3], A-M. Douar[2], J-L. Mandel[1,3]* 1) IGBMC, CNRS/INSERM/University of Strasbourg, 67404 Illkirch, France; 2) Genethon, CNRS UMR8115, 91000 Evry, France; 3) Genetique Humaine, College de France.

X-linked myotubular myopathy (XLMTM) is a severe congenital disease due to mutations affecting the phosphoinositide phosphatase myotubularin (MTM1 gene), and characterized by small skeletal muscle fibers with frequent occurence of central nuclei. The pathophysiology of the disease is still poorly understood and specific treatment is unavailable. We have constructed a recombinant serotype 1 adeno-associated virus (rAAV2/1) vector expressing myotubularin and injected it into skeletal muscle to analyze the subcellular localization of myotubularin in myofibers and test its therapeutic potential in a faithful XLMTM mouse model (Mtm1 conditional KO). We show that a substantial proportion of myotubularin associates to the sarcolemma and I band, including triads. Transgene expression in Mtm1 KO muscle halts the progression of the histological phenotype, leading to a large increase in muscle weight and myofiber area and to a decrease in the percentage of fibers with internal nuclei. Mislocalization of other organelles such as mitochondria was also corrected. A single injection in Mtm1 KO muscles leads to a full rescue of the contractile force in the injected muscle. Overexpression of myotubularin in wild-type muscle causes myofiber vacuolation and accumulation of packed membrane saccules (myelin-like) close to the sarcolemma. This suggests that myotubularin is involved in plasma membrane remodeling and/or homeostasis, like the two other known genes implicated in autosomal forms of centronuclear myopathy. Such a role fits also with the implication of MTM1 paralogs MTMR2 and MTMR13 in forms of recessive demyelinating CMT (CMT4B). This study has provided insights into the function of myotubularin in muscle and a proof of principle that viral-mediated MTM1 gene delivery may be an effective therapeutic approach for patients with myotubular myopathy.

A permutation test for estimating the number of subpopulations using whole-genome SNP data. *K. Bryc, H. Gao, C.D. Bustamante* Dept Biol Stats and Comp Biol, Cornell Univ, Ithaca, NY.

Population substructure is a potentially confounding factor in whole-genome association mapping. Many current approaches for correcting population stratification require knowledge as to the number of subpopulations, K, in the data (e.g., Yu 2006, Montana and Pritchard 2004). As the availability of large genome-wide marker data sets increases, the need for a computationally efficient method for estimating K grows. Recently, a principal component method, Eigenstrat, generated much interest due to its speed as well as accuracy (Patterson 2006). This algorithm approximates the p-value distribution used to identify the number of significant clusters in the data via the Tracy-Widom distribution. Using coalescent simulations under a litany of demographic scenarios (Hudson 2002), we find that the Tracy-Widom distribution may be a poor fit and result in spurious detection of substructure for a given nominal p-value. The problems potentially stem from two sources: (1) applying PCA analysis to correlated, non-symmetrical, and non-Gaussian data, and (2) general poor-performance of the sample variance-covariance matrices in finite samples. We show that the Eigenstrat algorithm performs as expected on clearly defined subpopulations (no admixture) only when extremely aggressive p-values are chosen. However, in certain population settings, choosing extremely small p-values will result in poor power to detect substructure. In short, our simulations indicate that the choice of a significance level alters Eigenstrats performance, which affects real world utility. We propose an empirical method for estimating K that does not make any assumptions about the distribution of the data. We replace the Tracy-Widom approximation with permutations of the original data, and find that the bias introduced by resampling is within an acceptable tolerance range. In our comparison of our method to Eigenstrat, we provide general insights into the advantages and limitations of principal component analysis for detecting population structure, as well as implications for association mapping.

Phenotypic spectrum of *STRA6* mutations: from Matthew-Wood syndrome to non-lethal syndromic microphthalmia. *C. Golzio[1,5], N. Chassaing[6], J. Martinovic-Bouriel[2], S. Thomas[1], S. Mougou-Zrelli[2], B. Bessières[3], S. Odent[7], M. Bonnière[2], S. Delahaye[4,5], P. Calvas[6], A. Munnich[1,2,5], F. Encha-Razavi[1,2,5], S. Lyonnet[1,2,5], M. Vekemans[1,2,5], T. Attie-Bitach[1,2,5], H.C. Etchevers[1,6]* 1) INSERM U781, Hôpital Necker-Enfants Malades, Paris, France; 2) Hôpital Necker-Enfants Malades, Paris, France; 3) Institut de Puériculture, Dept. of Fetal Pathology, Paris, France; 4) Hôpital Necker-Enfants Malades, Dept. of Obstetrics, Paris, France; 5) Université René Descartes-Paris 5, Hôpital Necker-Enfants Malades, France; 6) INSERM U563, Hôpital Purpan, Toulouse, France; 7) Hôpital Sud, Dept. of Genetics, Rennes, France.

STRA6 encodes an integral cell membrane protein that favors RA uptake from soluble retinol-binding protein (Kawaguchi et al. 2007). Subsequently, RA affects transcription of developmental genes such as members of the fibroblast growth factor family. One transcriptional target of RA is *STRA6* itself (Bouillet et al. 1997). Molecular analysis of *STRA6* was undertaken in two unrelated consanguineous human fetuses we have previously described with Matthew-Wood syndrome [MIM 601186]. Each fetus had homozygous truncating mutations predicting a premature stop codon in *STRA6* transcripts. A third Matthew-Wood fetus presented compound heterozygosity of a missense and splicing mutation in *STRA6*. Compound heterozygous missense mutations have also been found in a middle-aged patient with severe bilateral microphthalmia, tetralogy of Fallot, and mild mental retardation but no apparent pulmonary defects. This patient is a member of a non-consanguineous family in which there are two other affected siblings with divergent phenotypes, including spina bifida occulta and autism. Including other reported cases (Pasutto et al. 2007), no genotype-phenotype correlations can yet be drawn. We propose that pathogenic *STRA6* mutations reduce RA uptake from maternal blood, leading to the impairment of a set of essential target genes and possibly explaining phenotypic diversity through a combination of environmental and innate variations.

Bronchoscope-guided, targeted lobar aersolization of HDAd into nonhuman primate lungs results in uniform, high level pulmonary transduction, long-term transgene expression and negligible toxicity. *A. Beaudet[1], P. Hiatt[2], N. Brunetti-Pierri[1], R. McConnell[2], D. Palmer[1], R. Zuo[1], F. Vetrini[1], M. Finegold[3], P. Ng[1]* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Pulmonary Pediatrics, Baylor College of Medicine, Houston, TX; 3) Department of Pathology, Baylor College of Medicine, Houston, TX.

Uniform delivery of gene therapy vectors to all lung lobes is important for cystic fibrosis (CF) gene therapy. However, this important objective has not been achieved in large animals. To address this obstacle, we have developed an approach to deliver vector into all lung lobes. In this strategy, an intracorporeal nebulizing catheter is inserted into a bronchoscope to permit visual targeted aerosolization of vector specifically into each lung lobe. Using this approach, $1x10^{12}$ vp of HDAd-K18LacZ mixed with 0.1% LPC (to transiently open tight junctions) was sequentially aerosolized into each of the major lung lobes of a baboon. A very slight (2%), transient and fluctuating decrease in oxygen saturation that did not warrant supplemental oxygen was noted. The entire procedure was otherwise well tolerated and there were no changes in chest X-rays. X-gal staining of the lungs revealed extensive transduction of the epithelium in the large and small airways in all targeted lobes. Substantial expression from the K18 promoter was almost exclusively restricted to the airway epithelial cells and submucosal glands, the target cells for CF gene therapy. We also investigated the duration of pulmonary transgene expression. In these studies, we aerosolized a HDAd expressing the baboon -fetoprotein (bAFP) from the K18 promoter into the lungs of baboons. By measuring serum AFP levels, we found that pulmonary transgene expression from transduced airway epithelial cells can be detected for at least 177 days post-vector. These results demonstrate for the first time that exceedingly high levels of transduction of the airway epithelial cells and submucosal glands throughout all lung lobes in a large animal can be achieved with negligible toxicity resulting in long-term trangene expression. This should pave the way towards successful clinical CF gene therapy.

A Comparison of Single-Locus Measures of Association with Permutation Testing for Whole-Genome Association Studies. *W. Bush, S. Turner, T. Edwards, E. Torstenson, M. Ritchie* Ctr Human Genetics Research, Vanderbilt Univ, Nashville, TN.

Whole-genome association studies present several statistical challenges. When conducting single locus analysis, correlation structures among genotypes and other multiple testing issues make controlling the experiment-level false positive rate difficult. In addition to the well-known Bonferroni correction and methods that control the false discovery rate(FDR), permutation testing is a viable technique for assessing false positives. Permutation testing randomly reassigns the affection status of individuals in a dataset to create a distribution under the null hypothesis of no association. Permutation testing was used in a recent whole-genome study of type II diabetes by Sladek et al. to allow multiple genetic model considerations for Cochran-Armitage trend test analysis (Nature 445, 881 - 885). When using permutation testing, the distributional assumptions of the statistical test used become irrelevant. In this context, we do not use the theoretical distribution of a test statistic to assign a significance value; we instead define significance using the empirical distribution generated by the permutation testing procedure. As such, alternate measures of association with uncharacterized statistical properties may prove to have higher power than traditional test statistics. In this study, we examine the computational feasibility and statistical power of multiple basic single-locus association measures in the context of permutation testing. We simulated whole-genome case-control data containing patterns of linkage disequilibrium using genomeSIMLA software, and evaluate and compare the chi-square test of association, likelihood ratio test, normalized mutual information measures, odds ratio, and the Cochran-Armitage trend test under a variety of genetic models. We will show which approaches yield improved power for genome-wide association studies.

63 copy number variants (CNVs) identified in 400 autism spectrum disorder patients using a novel 19K whole genome tiling path BAC microarray. *S. Christian[1], C. Brune[2], J. Sudi[1], R. Kumar[1], J. Badner[3], J. Conroy[4], D. McQuaid[4], E. Hatchwell[5], S. KaraMohamed[1], C. Gilliam[1], N. Nowak[4], W. Dobyns[1], E. Cook[2]* 1) Dept Human Genetics, Univ Chicago, Chicago, IL; 2) Dept of Psychiatry, Univ of Illinois at Chicago, Chicago, IL; 3) Dept of Psychiatry, Univ of Chicago, Chicago, IL; 4) Roswell Park Cancer Institute, Dept of Cancer Genetics; 5) SUNY at Stony Brook, Stony Brook, New York.

Autism spectrum disorder (ASD) is a common neurodevelopmental disorder characterized by qualitative impairment of reciprocal social interaction and communicative development, restricted interests and repetitive behaviors. The prevalence of ASDs is ~1:160 with a 4:1 male to female ratio. One genetic mechanism that is associated with ASDs is chromosomal abnormalities. We have performed array comparative genomic hybridization (aCGH) on 400 ASD patients from the AGRE families using a novel 19K whole genome tiling path BAC microarray to identify copy number variants (CNVs) associated with ASD. 260 individuals from the NIMH Genetics Initiative control samples comprised of 160 Caucasians and 100 African-Americans were also analyzed to exclude common CNVs. We have identified 63 CNVs not present in the control samples in these 400 ASD patients using a threshold of 2 contiguous BACs to define a CNV. Currently, 38 CNVs have been confirmed using fluorescence in situ hybridization (FISH), microsatellite and/or quantitative PCR analyses. Four recurrent loci were identified at 11p11.2, 15q11-q13, 16p11 and 22q11. The other 49 CNVs were present in only a single patient. The sizes of the CNVs ranged from 185 kb to 6.1 Mb and included 0-45 Refseq genes. 18 loci overlapped regions with linkage to autism. These CNVs associated with ASDs will allow identification of recurrent chromosomal abnormalities, as well as, individual candidate genes that may either be causative or contributory to the ASD phenotype.

The Impact of Glucose Metabolism Genes on the Location of the Rostral Edge of Spinal Lesion in Patients with Spina Bifida Meningmylelocele. *T.M. King[1], C.M. Sullivan[1], C.M. Davidson[1], J.M. Fletcher[2], D.J. Francis[2], A.M. Walker[2], K.K. Stuebing[2], G.J. Cote[3], C.N. Singletary[1], K.S. Au[1], H. Northrup[1,4]* 1) Pediatrics, UT Houston Medical School, Houston, TX; 2) Psychology, University of Houston, Houston, TX; 3) Endocrine Neoplasia and Hormonal Disorders, MD Anderson Cancer Center, Houston, TX; 4) Shriners Hospital for Children, Houston, TX.

Derangements in maternal glucose metabolism may be causative in neural tube defect formation, including spina bifida meningomyelocele (SBMM). Evidence suggests that when a fetus is exposed to hyperglycemia, the ensuing malformations are not due to increased glucose, but rather a cascade of events starting with fetal hypoglycemia. This cascade leads to premature apoptosis and results in the malformation of various emerging organ structures. Our study involved 235 individuals with SBMM with detailed lesion descriptions who were genotyped for 12 glucose homeostasis genes: solute carrier family 2, member 1 (*GLUT1*) and member 4 (*GLUT4*), insulin (*INS*), insulin receptor (*INSR*), leptin (*LEP*), leptin receptor (*LEPR*), hexokinase 1 (*HK1*) and 2 (*HK2*), glyceraldehyde-3-phosphate dehydrogenase (*GAPDH*), tumor protein p53 (*TP53*), catalase (*CAT*), and superoxide dismutase 2 (*SOD2*). Our case population consisted 132 Caucasian (52.2%), 90 Hispanic (35.6%) and 31 other ethnicities (12.3%). Exact vertebral location of the rostral edge was available for all patients. Rostral edges were located in the T4-T12 region in 38 (15.0%) patients and in the L1-L5 in 215 (85.0%) patients. Our findings indicate that *LEPR* is significantly associated with the location of the rostral edge of the spinal lesion. The *LEPR* P1019 SNP altered rostral edge location in both Caucasians and Hispanics, while the N656K, R223Q and the S343 SNPs were significant in Hispanics. Two *LEPR* haplotypes (N656K-P1019 and R223Q-S343) were each significant in Hispanics. However, the full *LEPR* haplotype (N656K-P1019-R223Q-S343) was not significant. We found suggestive evidence of a gene-gene interaction between *GLUT1* and *SOD2*. In conclusion, our study shows that *LEPR* may play a role in modulating the location of the spinal lesion in SBMM.

Serotonin Transporter Polymorphism and Depression in Costa Rican Schizophrenic Patients. *J. Contreras[1,2], P. Quezada[2], A. Dassori[2], R. Medina[2], M. Escamilla[2], R. Salazar[1], H. Raventos[1]* 1) Centro de Investigacion y Biol, University of Costa Rica, San Jose, San Jose, Costa Rica; 2) University of Texas, Health Science Center at San Antonio, TX.

Context. Variation in serotonin transporter gene (5HTT) has been shown to influence depression in psychosis.

Objective. We tested the association between variation in the 5-HTTLPR promoter region (s/l variation) lifetime depression in Costa Rican schizophrenics.

Design. We tested if having an ss or sl genotype was associated with lifetime depression.

Setting. Subjects were originally recruited for a family based linkage disequilibrium study of schizophrenia and schizoaffective disorder. A best estimate consensus process was used to assign diagnoses and to determine major depressive syndrome in the patientslifetime.

Patients. For the 155 schizophrenic subjects we found Undifferentiated (68), Paranoid (48), Disorganized (22) and Residual Type (17). Of the total sample, 87 individuals (56.1%) had had at least one full episode or syndrome of major depression after the onset of schizophrenia.

Intervention. We genotyped each subject at the s/l promoter region polymorphic site.

Main Outcome Measure. Lifetime history of depressive syndrome (DSMIIIR).

Results. We found a significant association between the ss or sl genotype history of depression: X2=5.4 (p=0.02). Schizophrenic subjects with ss or sl genotype are 2.7 times more likely to develop depression: OR=2.7 (1.15-6.3) than those with the ll genotype.

Conclusions. This supports our previous finding that having an ss or sl genotype increases the risk of schizophrenic patients to develop depression.

Indian Genome Variation Initiative for Genotype to Phenotype correlations in complex diseases. *S.K. Brahmachari[1], Indian Genome Variation Consortium[1,2,3,4,5,6,7]* 1) Functional Genomics Unit, Institute of Genomics and Integrative Biology, Delhi, India; 2) Centre for Cellular and Molecular Biology, Uppal Road , Hyderabad, India; 3) Indian Institute of Chemical Biology, 4, Raja S. C. Mullick Road, Kolkata, India; 4) Central Drug Research Institute, Chattar Manzil Palace, Post Box No. 173 , Lucknow, India; 5) Industrial Toxicology Research Centre, Post Box No. 80, Mahatma Gandhi Marg, India; 6) Institute of Microbial Technology, Sector 39-A, Chandigarh, India; 7) Indian Statistical Institute, 203 Barrackpore Trunk Road, Kolkata, India.

Genetically isolated populations have assumed importance in dissecting complex diseases and mapping underlying genes with the availability of large number of polymorphic genetic markers. However, there has been limited success in SNP associations in complex disease possibly due to a nonlinear correlation of genome variations to phenotype. Genome information of an individual is stable while phenotype is a consequence of dynamic interactions. In the Indian Genome Variation Consortium we have undertaken a detailed genome variation analysis to decipher the various components of a set of complex disorders and drug response genes. Informative SNPs (5-8/gene) from nearly a thousand pathway based candidate genes have been genotyped on Indian populations of diverse linguistic, geographical and ethnic origins. In the 1st phase, SNPs from 72 disease candidates/drug responsive genes and two disease associated genomic regions (6Mb) were analyzed in 2,014 individuals from 55 contrasting endogamous populations. This study revealed (1) large genetically related clusters that correlate with linguistic and ethnic histories (2) genes influenced by natural selection (3) population stratification issues (4) extent of portability of HAPMAP data and (5) Indian populations represent entire world population. Based on Phase 1 inferences we identified 23 reference populations on which variation analysis of over a thousand genes, genome wide neutral markers and CNV regions has been completed. This data would serve as a rich resource and guide for disease gene mapping, pooling populations and cohort validation studies.

Integrating Genomics into Public Health Practice: Views of Stakeholders in Tobacco Control. *M. Dingel[1], A. Hicks[2], M. Robinson[2], B. Koenig[2]* 1) North Dakota State University, Fargo, ND; 2) Mayo Clinic, Rochester, MN.

For well over a decade genomic research, or more properly, the promise of genomic research, has dominated the scientific landscape. Scientists and others have begun to predict how genomic research might contribute generalizable knowledge that would improve human health at the population level, a major goal of public health. However, public health and genetics hold different priorities, research techniques, worldviews, and requirements for evidence. The genetics of nicotine addiction serves as an illustrative case study for the issues in combining these two fields because of the scope of the problem - the World Health Organization estimates that a billion people will die of tobacco-related disease in this century. It is also an area in which both traditional public health measures, like increased taxes and indoor smoking bans, and pharmaceuticals, like nicotine replacement therapy, have had some success. In order to gauge how key constituents in the public policy debate on tobacco control perceived the tensions and promises of integrating genetics into public health programs, our team conducted 86 interviews between Jan 2004 and Aug 2006 with stakeholders in tobacco control (19 clinicians, 20 scientists, 25 prevention workers, 11 pharmaceutical employees, and 11 health payers). These interviews reveal both hopes and concerns of combining these fields. While there is strong support for traditional public health programs among all stakeholders, these individuals also recognize that public health programs struggle to combat the powerful forces of the tobacco industry while dealing with the individual needs of those most at risk. Stakeholders recognize that alternatives to current tobacco control initiatives are needed, but problems of acquiring adequate funding for both traditional and new genetic approaches remain. These concerns mirror contentious debates in Science and JAMA about the efficacy and cost-effectiveness of genetic approaches to tobacco control. For genomic approaches to integrate into public health practice there must be honest evaluation of the strengths and weaknesses of each approach and a reckoning of what counts as evidence of efficacy.

genomeSIMLA: a data simulation package to explore the human genome. *T.L. Edwards, W.S. Bush, S.D. Turner, E.S. Torstenson, S.M. Dudek, M.D. Ritchie* Ctr Human Genetic Res, Vanderbilt Univ, Nashville, TN.

In the quest for disease susceptibility loci, many novel statistical and computational methods are in development. Data simulation is necessary to evaluate the performance of these methods before their utility can be demonstrated in real data applications. However, it is difficult to emulate the properties of genetic data in human populations which are the result of complex demographic history. Explicitly modeling all linkage disequilibrium (LD) parameters observed in real data with many variables is computationally infeasible; additionally, synthetic models often lack the complexity of real data. Rather than modeling human population history or LD characteristics, we use a forward-time population simulator that uses random mating, genetic drift, recombination and population growth to allow a population to naturally obtain LD features. We have developed a software package, genomeSIMLA, that uses these properties to simulate data on a genome-wide scale for both case-control and family-based study designs with linkage disequilibrium patterns that resemble those observed in human populations. Positions of real human markers can be used to estimate the expected frequency of recombinant gametes under the Haldane or Kosambi models which can be applied to simulations to emulate patterns of LD observed in human populations. After a pool of chromosomes has developed suitable LD, datasets can be drawn by randomly sampling chromosomes with replacement. Disease-susceptibility effects of multiple genetic variables with any mode of inheritance as well as interactions between them may be modeled using a prospective logistic regression model. In contrast, purely epistatic interaction models can also be simulated. genomeSIMLA provides a robust data simulation package for creating whole-genome data to evaluate novel analysis approaches in a realistic context on a scale relevant to modern genetic epidemiology. A graphical user interface is provided for ease of use. Additionally, a website is available where pools of chromosomes using human markers with similar LD to the HapMap data may be downloaded to draw datasets from or increment further generations for new LD.

A duplication at chromosome 11q12.2 is associated with spinocerebellar ataxia type 20 (SCA20). *M.A. Knight[1], D. Hernandez[2], I. Rafferty[2], S.M. Forrest[3], R.J.M. Gardner[4, 5], E. Storey[5, 6], A. Dutra[7], E. Pak[7], K.H. Fischbeck[1], A.B. Singleton[2]* 1) Neurogenetics Branch, NINDS/NIH, Bethesda, MD, USA; 2) Molecular Genetics Unit, Laboratory of Neurogenetics, NIA/NIH, Bethesda, MD, USA; 3) Australian Genome Research Facility, Walter and Eliza Hall Institute of Medical Research, Melbourne, VIC, Australia; 4) Genetic Health Services Victoria, Melbourne, VIC, Australia; 5) Murdoch Childrens Research Institute, Royal Children's Hospital, Melbourne, VIC, Australia; 6) Department of Medicine (Neurosciences), Alfred Hospital Campus of Monash University, Melbourne, VIC, Australia; 7) Genetic Diseases Research Branch, Cytogenetic and Microscopy Core, NHGRI/NIH, Bethesda, MD, USA.

SCA20 is an autosomal dominant cerebellar ataxia that is clinically distinct from the other SCAs. It is characterized phenotypically by a slowly progressive ataxia with the additional clinical features of dysphonia and palatal tremor, and the unique observation on neuroradiology of calcification of the dentate nucleus of the cerebellum. SCA20 is linked to chromosome 11. The locus overlaps the SCA5 disease locus, but after discovery of the SCA5 gene, -III spectrin (*SPTBN2*), it was found that SCA5 and SCA20 were not allelic. Since SCA20 is a separate entity, we studied the structure of the genomic DNA, using Illumina 550 SNP genotyping chips. The results indicated a 2.6Mb duplication within the previously linked region. The duplication was shown to be present in all affected individuals in the single reported SCA20 pedigree. We are currently doing fluorescent *in situ* hybridization analysis on metaphase chromosome spreads to confirm the duplication and determine its orientation. We are also investigating twelve known genes within the duplicated region to determine which, if any, are expressed in the cerebellar Purkinje cells and the dentate nucleus, which we presume to be the neural substrate predominantly affected in SCA20. We are seeking to determine whether the disease is caused by increased dosage of one or more of the genes within the duplicated region, or by a breakpoint in one of the genes resulting in a novel gene product.

Comprehensive evaluation of the Bardet-Biedl syndrome type 1 (BBS1) M390R mouse model. *R.E. Davis[1], K. Rahmouni[1], K. Agassandian[1], R. Swiderski[1,2], R.F. Mullins[1], A.R. Philp[1,2], C.C. Searby[1,2], D.Y. Nishimura[1,2], M.P. Andrews[1,2], B. Yang[1], M.D. Cassell[1], E.M. Stone[1,2], V.C. Sheffield[1,2]* 1) University of Iowa, Iowa City, IA; 2) Howard Hughes Medical Institute, Iowa City, IA.

Bardet-Biedl syndrome (BBS) is an autosomal recessive disorder resulting in obesity, retinopathy, polydactyly, cognitive impairment, congenital heart defects, as well as renal and reproductive tract abnormalities. Patients with this disorder exhibit variable expressivity. Twelve BBS genes have been identified to date. The most frequent BBS variation, the *BBS1* M390R missense mutation, is implicated in ~20% of cases. Our laboratory has developed a *Bbs1* M390R knock-in mouse model. *Bbs1*$^{M390R/M390R}$ mice manifest cardinal features of the human phenotype including photoreceptor cell death, male infertility and obesity. Here we demonstrate additional aspects of the *Bbs1*$^{M390R/M390R}$ mouse phenotype including olfactory deficits, social dominance defects and ventriculomegaly. We found that obesity in *Bbs1*$^{M390R/M390R}$ mice is associated with hyperphagia, decreased locomotor activity and high circulating levels of the adipocyte-derived hormone leptin. To assess the relative contributions of hyperphagia and decreased energy expenditure to the obesity associated with the *Bbs1* M390R mutation, we performed a pair-feeding study and found that hyperphagia contributes significantly to the obesity of *Bbs1*$^{M390R/M390R}$ mice. We also found that the hyperleptinemia observed in *Bbs1*$^{M390R/M390R}$ mice is associated with leptin resistance, as systemic and direct central neural injection of leptin failed to decrease body weight and food intake in *Bbs1*$^{M390R/M390R}$ mice. Furthermore, evaluation of *Bbs1*$^{M390R/M390R}$ brains using transmission electron microscopy shows abnormalities in ependymal cell motile (9+2) cilia and primary (9+0) cilia of the hypothalamus. These data verify the efficacy of the *Bbs1*$^{M390R/M390R}$ knock-in mouse model for further elucidation of the BBS obesity phenotype and suggest a connection between obesity and cilia abnormalities in the brain.

Influence of FCGR3A-V212F and TNFRSF1B-M196R genotypes in patients with rhumatoid arthritis treated by Infliximab therapy. *B. Arveiler[1], C. Rooryck[1], T. Barnetche[1,2], C. Richez[2], A. Laleye[1], T. Schaeverbeke[2]* 1) Human Genetics Laboratory, Université Victor Segalen Bordeaux 2, Bordeaux, France; 2) Department of Rheumatology, University Hospital Pellegrin, Bordeaux, France.

Rheumatoid arthritis (RA) is a complex, polygenic disease of unknown aetiology, with prevalence estimates of 0.25 to 0.5% in French population. Anti-TNF therapies are widely used in rheumatoid arthritis (RA) patients. Despite their efficacy has been clearly proven, some discrepancies were observed in the treatment response with still 40% of non-responders patients. The aim of this study is to determine whether two functional single-nucleotide polymorphisms: V212F in the FCGR3A, and M196R in the TNFRSF1B genes correlate with rheumatoid arthritis susceptibility and response to anti-TNF therapy. The population study included a French cohort of 78 RA patients and 70 healthy controls. Allele and genotype frequencies were compared between patients and controls, according to their response to infliximab therapy, using the American College of Rheumatology response criteria (OR=4.58, IC95%= [1.67-12,8], p=7.10-4). No association was found between these two SNPs and RA susceptibility. However, a significant correlation was found between 196R allele carriers and low response to infliximab therapy. This is the first report of a statistically significant association between the TNFRSF1B-M196R SNP and response to infliximab in a French cohort. Larger studies are needed to confirm the relevance of this association.

Significant correction of disease after postnatal administration of recombinant EDA in canine X-linked ectodermal dysplasia. *M.L. Casal[1], J.R. Lewis[1], E.A. Mauldin[1], A. Tardivel[2], K. Ingolde[2], M. Favre[3], F. Paradies[3], S. Demotz[3], O. Gaide[4], P. Schneider[2]* 1) School of Veterinary Medicine, Univ of Pennsylvania, Philadelphia, PA; 2) Department of Biochemistry, Univ of Lausanne, Switzerland; 3) Apoxis, SA, Switzerland; 4) Department of Dermatology and Venerology, Univ of Geneva, Switzerland.

X-linked hypohidrotic ectodermal dysplasia (XLHED) in man (MIM #305100; defect in ED1), developmental defect, is characterized by sparse or absent hair, missing and/or malformed teeth, and hypoplastic eccrine glands. There is significant morbidity and mortality in affected children due to hyperthermia caused by their inability to sweat and an increased risk of respiratory tract infection. Tooth abnormalities include delayed primary and secondary dentition and poor occlusion, conical tooth crowns (peg teeth), and oligodontia, which lead to difficulties with mastication, growth retardation, and speech impairment. The canine model of XLHED was used to study the developmental impact of EDA on secondary dentition, since the dog has an entirely brachyodont, diphyodont dentition similar to humans, and as opposed to mice that only have permanent teeth (monophyodont dentition). Also, clinical signs in XLHED humans and dogs are virtually identical, whereas several are missing in the murine equivalent. In our model, the genetically missing EDA was compensated for by post-natal intravenous administration of soluble recombinant EDA. Shirmer tear testing was used to measure lacrimation; mucociliary clearance was examined to assess pulmonary function; and a modified iodine-starch test was used to evaluate sweating. Untreated XLHED dogs have an incomplete set of conically shaped teeth similar to those seen in human patients with XLHED. After treatment with EDA, significant normalization of adult teeth was achieved in 4 of 5 XLHED dogs. Moreover, treatment restored normal lacrimation and resistance to eye and airways infections, and improved sweating ability. These results not only provide a proof of concept for a potential treatment of this orphan disease, but also demonstrate an essential role of EDA in the development of secondary dentition.

Proteomic analysis to identify candidate genes influencing high-density lipoprotein particle size in obese individuals. *L.A. Collins[1], S.P. Mirza[1], L. Martin[2], A.H. Kissebah[1], M. Olivier[1]* 1) Medical College of Wisconsin, Milwaukee, WI; 2) Childrens Hospital, Cincinnati, OH.

Obesity is associated with a significant risk for cardiovascular co-morbidities. This effect is primarily mediated by an atherogenic dyslipidemic profile, specifically a preponderance of small, dense high-density lipoprotein (HDL) particles. However, the molecular basis for the altered HDL particle size distribution in obesity is poorly understood. A genetic analysis in a family-based cohort of 2207 individuals identified strong quantitative trait locus (QTL) (LOD = 3.15) for HDL median particle diameter on human chromosome 12. The interval contains 213 annotated genes, none of which have a known role in cholesterol or lipid metabolism.

Here, we describe a proteomic analysis using tandem mass spectrometry in conjunction with an enzymatic peptide labeling technique to identify differentially expressed proteins in HDL particles. Recent research suggests that the HDL proteome is altered in dense HDL particles.

We isolated HDL fractions from plasma samples using non-denaturing fast protein liquid chromatography, with the use of a single Superose 6 30/100 GL column. A chloroform extraction procedure allows for the efficient isolation of lipid-embedded or associated proteins from HDL particles compatible with subsequent mass spectrometric analysis. Preliminary data will be presented on quantitative profiling of the HDL proteome. Using proteomic data, in conjunction with pathway and protein interaction analyses, we will highlight connections between alterations in protein expression and genes in the QTL region on human chromosome 12.

Role of DNA-protein interactions in central nervous system signaling: the interaction between serotonergic and glucocorticoid signaling systems in HPA axis regulation. *V.R. Falkenberg, S.D. Vernon, E. Aslakson, M.S. Rajeevan*
Centers for Disease Control and Prevention, Atlanta, GA USA 30333.

The central nervous system (CNS) functions through coordinated interaction between several signaling systems. Serotonergic and glucocorticoid signaling systems play pivotal roles in regulation of the hypothalamic pituitary adrenal (HPA) axis with negative feedback regulation exerted by glucocorticoid receptor (GR). Computational models indicate an influence of pituitary GR expression on HPA axis homeostatic set points. The HPA axis is also regulated by serotonin (5-hydroxytryptamine [5-HT]) through complex and unclear interactions. In this study, experimental and bioinformatic approaches are used to determine if DNA-protein interactions provide a molecular link for the interaction between various CNS signaling systems. Glucocorticoid responsive elements (GREs) are identified in the promoters of a number of 5-HT receptor genes. These GREs include sites for GR, the progesterone receptor (PR), and the androgen receptor (AR). 5-HT receptors with putative GREs specific for the GR include *HTR1D, HTR1F, HTR3A* and *HTR6*, and those 5-HT receptors containing GREs with slightly higher affinities for AR or PR include *HTR1D, HTR1F, HTR6* and *HTR2A*. A number of 5-HT receptors (*HTR1A, HTR1B, HTR2B, HTR2C, HTR3D, HTR3E, HTR4, HTR5A*, and *HTR7*) do not contain any putative GREs. EMSA is used to experimentally verify the predicted DNA-protein interactions. GRE binding (GR, AR, or PR) was verified for *HTR1D, HTR1F, HTR6* and *HTR2A* demonstrating that DNA-protein interactions exist between the serotonergic and glucocorticoid signaling systems. Computational models of the HPA axis are being generated to reflect this molecular connection and to determine the impact on HPA axis homeostasis. Studies are in progress to characterize the functional significance of these interactions in the transcriptional control of genes involved in the regulation of the HPA axis. Identification of these molecular links is important for modeling systemic feed-forward and feed-back mechanisms between the systems. These results are indispensable to understanding the functioning of inaccessible organs like the human brain.

***Hox* Genes and Idiopathic Talipes Equinovarus.** *A.R. Ester[1], D. Ma[2], A. Scott[3], S.H. Blanton[2], J.T. Hecht[1,3]* 1) Univ Texas Medical Sch, Houston, TX; 2) University of Miami Miller School of Medicine, Miami, FL; 3) Shriners Hospital for Children, Houston, TX.

Idiopathic talipes equinovarus (ITEV, clubfoot) is a common birth defect, occurring 1/1000 live births, with over 135,000 cases born around the world each year. Talipes equinovarus (TEV) is characterized by forefoot adductus, midfoot cavus, hindfoot adductus, and hindfoot equines, and ITEV is applied to clubfoot that is not associated with any other anomaly. Segregation analyses suggest that multigenic inheritance with environmental effects contribute to the development of ITEV. Among children that had clubfoot along with other anomalies, six overlapping chromosomal deletion regions were identified, which may contain genes that contribute to ITEV. One of these regions, 2q31-33, contains the *HoxD* gene cluster, which has been shown to be involved in limb development. Mutations in this cluster have been associated with synpolydactyly and congenital vertical talus in humans, and a knockout mouse shows rotational limb defects as well as fusion of the vertebrae. A mutation in *HoxD10* (M319K) has been associated with congenital vertical talus (CVT) and was also seen in an individual with CVT in one foot and TEV in the other. The M319K mutation was postulated to play a role in the development of ITEV in the previous study. This study interrogated the *HoxA* and *HoxD* gene clusters on chromosomes 4 and 7, using SNP genotyping including the M319K polymorphism. The population consisted of 76 Caucasian and 152 Hispanic simplex trios and 93 Caucasian and 52 Hispanic multiplex families. The M319K mutation was not present in any cases or controls. Minimally positive p values were found for one SNP in *HoxD4* (rs1867863) and two SNPs in *HoxA11* (rs3779456 and rs1859164) in the Caucasian population. These results indicate that the M319K mutation does not play a role in ITEV and suggests that variation in these *Hox* genes does not significantly contribute to the isolated clubfoot phenotype.

Custom design and validation of an oligonucleotide microarray combining whole genome and targeted strategies for clinical cytogenetics. *E.L. Baldwin, J. Lee, D. Blake, B. Bunke, C. Alexander, A. Kogan, J. Hauenstein, D.H. Ledbetter, C.L. Martin* Dept Human Genetics, Emory Univ, Atlanta, GA.

Array Comparative Genomic Hybridization (aCGH) has rapidly become an integral part of cytogenetic diagnostics. We report the design, validation, and clinical utility of a custom oligonucleotide array which combines whole-genome coverage at a high-resolution (equivalent to a 6,000 band karyotype) with enhanced coverage at clinically relevant regions, including telomeres, centromeres and the common microdeletion/duplication regions. Individual probes were placed every 75 kb across the entire euchromatic genome to establish a chromosomal backbone. Although the 75 kb spacing allows detection of imbalances of ~300 kb, we have chosen a limit of 500 kb to decrease the identification of benign copy number variants, ~95% of which are 500 kb in size. Thirty patient samples were tested on the array as part of the validation study. These cases included normal samples and cases with trisomy 21, sex chromosome abnormalities, telomere imbalances, unbalanced translocations, microdeletions and duplications. For all 30 samples, the array results were consistent with previous FISH and/or karyotype findings, validating the array for clinical detection of copy number imbalances greater than 500 kb. In addition, we have carried out prospective clinical analysis of 75 samples using this custom array. Of these 75 cases, 61 were found to have normal array results, while 14 contained various abnormalities. Nine of the abnormal cases were submitted for array studies to further define an abnormality originally detected by G-banding. Five of the abnormal samples, however, had previously been reported as normal by G-banding. Three of these cases (two deletions of 15q11-13 and a 4.4 Mb 21q telomere deletion) would have also been detected with targeted arrays which have limited coverage for certain regions of the genome. However, two imbalances, a ~3 Mb 2p interstitial deletion and a ~9 Mb 2q interstitial duplication, would only be identified with whole-genome coverage. Our early results highlight the diagnostic utility of this custom array design for detecting clinically relevant cytogenetic imbalances.

Ribosomal fameshifting on expanded *ATXN3* transcripts: a *Drosophila* model. *C. Gaspar[1], S. Stochmanski[1], J. Laganiereè[1], D. Rochefort[1], M. Therrien[1], P. Dion[1], F. Blondeau[1], D. Van Meyel[2], G.A. Rouleau[1]* 1) Center for the Study of Brain Diseases, CHUM Research Center, Montreal, QC, Canada; 2) Center for Research in Neuroscience, MGH Research Institute, Montreal, QC, Canada.

Rationale: Spinocerebellar ataxia type 3 (SCA3) is caused by the expansion of a coding CAG repeat in the *ATXN3* gene. We have previously shown that the expanded CAG repeat in SCA3 is prone to -1 ribosomal frameshifting, leading to the production and aggregation of proteins containing polyalanine stretches. These frameshifted molecules confer increased toxicity to cells when compared to constructs containing expanded CAA repeats, which code for polyglutamine in the main frame but lack the ability to frameshift into an alanine frame. Anisomycin (a ribosome interacting antibiotic that reduces -1 frameshifting) decreases frameshifting in expanded CAG tracts and ameliorates the cellular toxic phenotype. **Aims:** To model expCAG repeat -1 frameshifting *in vivo*; to assess the contribution of -1 frameshifting to expCAG toxicity in *Drosophila*. **Methods:** Full-length *ATXN3 Drosophila* transgenic lines carrying either wtCAG, expCAG or expCAA constructs containing epitope tags in the three possible reading frames were generated and comparatively analysed. **Results:** We show that: (1) transgenic expression of expCAG *ATXN3* constructs is deleterious in the fly; (2) transgenic expression of expCAA *ATXN3* constructs, despite adequate levels of protein expression, is not toxic; (3) -1 frameshifting occurs in *Drosophila* and is restricted to the expanded CAG transgenic lines. **Conclusions:** We propose that -1 ribosomal frameshifting is a major contributor to the toxicity observed in expanded CAG repeat diseases. This novel pathological mechanism may open new therapeutic opportunities for these diseases.

A Grid-based web service for the analysis of genome-wide association data. *A. Herrmann[1,2], A. Franke[1], S. Buch[1,2], M. Nothnagel[3], T. Steinke[4], S. Schreiber[1], M. Krawczak[3], J. Hampe[2]* 1) Institute for Clinical Molecular Biology, Christian-Albrechts University, Kiel, Germany; 2) Department of General Internal Medicine, University Hospital Schleswig-Holstein Campus Kiel, Kiel, Germany; 3) Institute of Medical Statistics and Biometry, Christian-Albrechts University, Kiel, Germany; 4) Zuse Institute Berlin, Berlin, Germany.

Genome-wide association analysis has been shown to be a successful approach to the identification of susceptibility factors for complex human disorders. The timely handling and analysis of genome-wide association data poses logistic and computational challenges. A typical experiment involving thousands of individuals will usually generate in excess of a billion genotypes. The Grid implementation may allow a faster administration and analysis of large amounts of disease association data. We have therefore ported and extended the Genomizer stand-alone software (www.ikmb.uni-kiel.de/genomizer) as a Grid application within the MediGRID project framework, which is part of the German e-Science initiative D-Grid. User friendly access is realised by GridSphere Java Portlet technology. To accses the distributed and shared Grid resources use OGSA-DAI, SRB and GLOBUS technologies. Certificate management secures critical data which contains patient information. Currently implemented analysis cover the workflow of an association experiment, including data management, single-point and haplotype analysis, lead definition, and data visualization.

Metabolic pathway profiling in C. elegans mitochondrial respiratory chain mutants. *M.J. Falk[1], Z. Zheng[1], J.R. Rosenjack[2], E. Daikhin[1], I. Nissim[1], O. Horyn[1], M.M. Sedensky[2], M. Yudkoff[1], P.G. Morgan[2]* 1) Divisions of Human Genetics, Biomedical Informatics, & Metabolism, The Children's Hospital of Philadelphia & Univ of Pennsylvania, Philadelphia, PA; 2) Departments of Anesthesiology, Genetics, & Pharmacology, Univ Hospitals of Cleveland & CASE, Cleveland, OH.

C. elegans affords a model of mitochondrial dysfunction that allows insight into cellular adaptations that occur consequent to genetic alterations associated with human disease. We characterized genome-wide expression profiles of hypomorphic C. elegans mutants in various nuclear-encoded subunits of respiratory chain complexes I, II, and III. Our goal was to detect concordant changes of clusters of genes that comprise a defined metabolic pathway utilizing gene set enrichment analysis. Results indicate that respiratory chain mutants significantly upregulate a variety of basic cell metabolism pathways involved in carbohydrate, amino acid, and fatty acid metabolism, as well as cellular defense pathways such as the P450 system and the -glutamyl pathway of glutathione synthesis. Initial results were confirmed in an independent data set. In addition, metabolomic profiling at the protein level in C. elegans mitochondrial mutants confirms and extends expression analysis findings. Detection of consistent changes in nuclear gene expression patterns in a translational genetic model of mitochondrial dysfunction provides insight into disease mechanisms. Furthermore, our results provide novel evidence for an increase in transamination reactions occurring in primary mitochondrial mutants caused by their failure to oxidize ketoacids. This approach may permit exploration of the complex pathogenesis underlying primary mitochondrial disease. To this end, further metabolomic profiling of these mutants is underway using stable isotopic/mass spectrometric studies of precursor-product relationships as well as measurements of flux through specific biochemical pathways. These studies in a simple genetic model of mitochondrial disease will form the basis for developing screening tools for mitochondrial dysfunction in humans based upon pathway expression patterns and metabolomic profiling.

Functional analysis of a nonsynonymous coding variant (R325W) in the pancreatic -cell specific zinc transporter, *SLC30A8*, associated with type 2 diabetes. *M.R. Erdos[1], L. Qin[2], L.L. Bonnycastle[1], A.J. Swift[1], A.G. Sprau[1], A.U. Jackson[3], C.W. Willer[3], C.L. Yang[4], S. Humphreys[4], D.H. Ellison[4], J. Tuomilehto[5], R.N. Bergman[6], M. Boehnke[3], K.L. Mohlke[2], F.S. Collins[1]* 1) GTB, NHGRI, NIH, Bethesda, MD; 2) UNC, Chapel Hill, NC; 3) U Mich, Ann Arbor, MI; 4) OHSU, Portland, OR; 5) National Public Health institute, Helsinki, Finland; 6) USC, Los Angeles, CA.

Genome wide association studies have identified several novel susceptibility genes for type 2 diabetes (T2D) including *SLC30A8*, a pancreatic -cell specific zinc transporter. Type 2 diabetes association with the SNP (rs13266634) that marks a non-synonymous coding substitution (R325W) in *SLC30A8* achieves genome wide significance (OR= 1.12, $p= 5.3x10^{-8}$) in the combined analysis of three major studies (DGI, UKT2D, and FUSION). We now report that quantitative trait analyses in ~2380 FUSION individuals also suggest association with systolic blood pressure (p= .028), pulse pressure (p= .004), triglycerides (p= .036, p=.009 in controls), fasting free fatty acids (p= .024) and BMI-related traits (BMI, waist, whr; p= .033-.05). In db/db diabetic mice, dietary zinc supplementation has been shown to attenuate hyperglycemia and hyperinsulinemia. In a pilot study, normal glucose tolerant Finns homozygous for the risk allele (C, n=16) had modestly lower, but not statistically different, plasma zinc levels (72.6 ug/dl, SD= 15.0) than those homozygous for the non-risk allele (T, n=19; 75.9 ug/dl, SD= 11.5). We have synthesized both alleles of the full length SLC30A8 cDNA and transfected these into HeLa cells. We observed similar expression levels and cellular localization for each allele, and we are now examining zinc uptake with each allele using the cell permeable zinc fluorophore, Fluozin-3. In a second model system, we are injecting *Xenopus laevis* oocytes with *in vitro* transcribed cRNA for each allele of *SLC30A8* in the presence of $^{65}Zn^{+2}$ supplemented media, and monitoring the zinc transporter activity by radioactivity uptake. These studies may define the mechanism for this newly discovered risk factor for type 2 diabetes, with the potential for future therapeutic insights.

Searching for Master Regulatory Variants of Gene Expression. *J. Ding, G.R. Abecasis* Department of Biostatistics and Center for Statistical Genetics, University of Michigan, Ann Arbor, MI.

Gene transcript levels can serve as an intermediate phenotype which bridges genotypes and more complex organismal phenotypes. Although many examples of cis-regulators of expression have now been mapped, identifying trans-regulators of expression has proved more challenging. Within the framework of genome-wide association studies of gene expression, we develop a method to search for single nucleotide polymorphisms (SNPs) that are associated with mRNA expression levels for multiple genes (master regulatory SNPs). Our approach should increase power to identify regulatory variants that influence gene expression for multiple genes.

While conventional methods assess significance of association for individual SNP-gene pairs by p-values and then highlight SNPs that are significantly associated with large numbers of gene transcript levels, our method proposes a new statistic to summarize all p-values for each SNP. It results in a summary statistic that takes into account both significance levels and the number of association signals simultaneously. In a genome-wide scan, we rank SNPs based on this summary statistic and determine significance by a permutation test. As an example, we apply our method to the gene expression and genotypic data of HapMap subjects (Stranger *et al., Science* **315**, 848 (2007).). We show that our method has advantages over conventional methods. In addition, we find common master regulatory SNPs of gene expression among four study populations. Our study can potentially shed light on the global regulation of gene expression by genetic variants.

Dissecting the genetics of Crohns disease using the Wellcome Trust Case Control Consortium data. *C.A. Anderson[1], J.C. Barrett[1], M. Tremelling[2], N.J. Prescott[3], S.A. Fisher[3], D.P. Jewell[4], J. Satsangi[5], J.C. Mansfield[6], C.G. Mathew[3], M. Parkes[2], L.R. Cardon[1]* 1) Wellcome Trust Centre for Human Genetics, Oxford, UK; 2) Addenbrooks Hospital, Cambridge, UK; 3) Guy's Hospital, London, UK; 4) Radcliffe Infirmary, Oxford, UK; 5) Western General Hospital, Edinburgh, UK; 6) Royal Victoria Infirmary, Newcastle, UK.

As part of a groundbreaking study, the Wellcome Trust Case Control Consortium (WTCCC) recently published a genome-wide association scan for Crohns disease (CD). Using 1748 cases and 2938 controls genotyped with the Affymetrix 500K chip, they reported four novel CD risk loci and confirmed associations to five previously known CD risk loci. The four novel CD loci were replicated in a follow-up study of 1182 CD cases and 2024 controls. Given the large number of cases, the high density of markers and the extensive subphenotype information available for each CD case, the WTCCC data represents a rich resource for further investigation of the loci underlying CD. We conducted sub-phenotype analyses of the WTCCC data, fitted interaction models to assess the possibility of epistasis and explored the extent to which further undetected loci are likely to exist for CD. For epistasis assessments, we carried out pair-wise interaction analyses of all known risk loci using the WTCCC main scan data. After accounting for multiple tests only one apparent interaction ($P = 1.9 \times 10^{-3}$) was observed between rs12037853 (1q24) and rs4958847 (*IRGM*). However, this finding failed to replicate in our replication samples ($P = 0.55$), suggesting that the CD genes known to-date act in a statistically independent manner. This finding is in keeping with those from previous gene-gene interaction studies of CD and other complex diseases. Moreover, that further loci exist is without question because we were unable to distinguish between CD cases and controls in the main WTCCC data after calculating the average identity-by-state at the known risk variants. This observation is consistent with the small proportion of phenotypic variance explained by the known risk loci, and highlights the potential for further identification of new CD variants.

Osteoporosis: a new feature of Bardet Biedl syndrome. *E. Heon[1, 4], W. Cole[2, 4], A. Daneman[3], J. Bin[4], G. Billingsley[4], E. Sochett[5]* 1) Ophthalmology and Vision Scien, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Orthopedic Surgery, Surgery, The Hospital for Sick Children, Toronto, Ontario, Canada; 3) Diagnostic Imaging, The Hospital for Sick Children, Toronto, Ontario, Canada; 4) Genetics and Genomics Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 5) Endocrinology, Pediatrics, The Hospital for Sick Children, Toronto, Ontario, Canada.

Bardet-Biedl syndrome (BBS: OMIM 209900) is a genetically heterogeneous disorder characterized by the primary features of progressive retinal dystrophy, obesity, polydactyly, renal malformations, cognitive impairment and hypogenitalism. 12 BBS genes have been identified to date. Identification of 2 BBS patients with severe, early-onset osteoporosis led us to explore the incidence of this finding in a cohort of Canadian patients affected with BBS. Forty patients affected with Bardet-Biedl syndrome were studied including 16 males, 24 females. Investigations included: thoracic and lumbar spine X rays, bone mineral density assessment, documentation of the following parameters: BMI, height, genotype, serum creatinine, PO4, ALP, PTH, Calcium, Vit D and electrolytes. Data was interpretable in 37 cases. Only one child (8 yrs) had normal x-rays. The others showed a variable combination of findings including: Osteoporosis, degenerative changes and vertebral deformity. Osteoporosis was observed in all cases (age range 3.4-40 yrs), degenerative changes were seen in 14/37 patients while vertebral deformities such as kypho scoliosis was seen in 23/37 patients. History of fracture was documented in 4 cases (age range 9-15 yrs) while a history of bone pain was present in 15 cases. There was no significant correlation with the genotype, gender, weight, height, or biochemical anomalies. However, the incidence and severity of the changes observed correlated with age. In summary, impairment of the function of BBS proteins appears to predispose patients to develop osteoporosis and to interfere with bone health. Documentation of this clinical feature in BBS will be important to optimize patient management and improve our understanding of the molecular pathways involved.

Update on the NIH Study on ARPKD/CHF and other Ciliopathies. *M. Gunay-Aygun[1,2], E. Font-Montgomery[1], M. Parisi[3], D. Adams[1], H. Edwards[1], L. Lukose[1], P. Choyke[4], R. Fischer[1], I. Bernardini[1], J. Bryant[1], B. Gochuico[1], L. Guay-Woodford[5], H. Heller[6], P. Mohan[7], K. Daryanani[8], W. Gahl[1,2]* 1) MGB, NIH/ NHGRI, Bethesda, MD; 2) Intramural Office of Rare Diseases, NIH; 3) University of Washington, Seattle, WA; 4) NCI, NIH; 5) University of Alabama, Birmingham AL; 6) NIDDK, NIH; 7) CNMC, Washington, DC; 8) NIH Clinical Center.

Human ciliopathies are a group of distinct syndromes with overlapping features caused by defects of the cilia or its basal body/centriole. These include the autosomal dominant (ADPKD) and recessive (ARPKD) polycystic kidney diseases, nephronophthisis (NP), Joubert (JS) and related cerebello-oculo-renal syndromes (CORS), and Bardet-Biedl (BBS), Meckel-Gruber (MGS), Oral-Facial-Digital (OFD), and Alstrom syndromes (AS). ARPKD, the most common pediatric ciliopathy, is characterized by progressive renal insufficiency and congenital hepatic fibrosis (CHF). Although a subset of the patients with JS/CORS, BBS, OFD, and AS are known to have kidney and liver involvement, the nature of kidney and liver disease in these syndromes is poorly defined, largely because pertinent data are limited and retrospective. We have recently expanded the ongoing NIH natural history study on ARPKD/CHF (www.clinicaltrials.gov, trial NCT00068224) to include other ciliopathies. Here we present MRI and high resolution ultrasound (HR-US) results, correlated with liver and kidney function data, on 88 patients with 95 admissions (60 ARPKD/CHF, 6 JS/CORS, 8 ADPKD/CHF and 14 unknown type of PKD/CHF). In ARPKD/CHF, kidney size and extent of cyst involvement on imaging did not correlate with creatinine clearance, except for the very mild patients. MR cholangiogram and HR-US were the most useful imaging modalities for biliary abnormalities and mild kidney involvement, respectively. Three JS/CORS patients had enlarged kidneys with diffuse cystic changes diagnosed perinatally, indistinguishable from ARPKD. We continue to enroll patients to this study to define the full phenotypic spectrum of ciliopathies and to produce comprehensive longitudinal data to provide the groundwork for more focused studies and future therapeutic interventions.

Tooth enamel thickness and adaptive evolution of *enamelin* in Humans and among Primates. *J.L. Kelley, W.J. Swanson* Genome Sciences, University of Washington, Seattle, WA.

Scans of the human genome have identified many loci as potential targets of recent selection, but exploration of these candidates is required to verify the accuracy of genome-wide scans and clarify the importance of adaptive evolution in recent human history. We present analyses of one such candidate, *enamelin*, whose protein product operates in tooth enamel formation. *enamelin* sequences of 100 individuals from 10 populations show lower than expected levels of nucleotide polymorphism. Evidence of a recent selective sweep at this locus confirms the signal of selection found by genome-wide scans. Patterns of polymorphism in *enamelin* correspond with population-level differences in tooth enamel thickness, and selection on enamel thickness may drive adaptive *enamelin* evolution in human populations. Sequences of exons from 12 primate species show evidence of historical selection on *enamelin*. In primates enamel thickness correlates with diet, and bursts of adaptive *enamelin* evolution occur on primate lineages with dietary changes and evolved differences in enamel thickness. Our hypothesis is that among human populations, and among primate species, evolution of tooth enamel thickness is associated with the adaptive evolution of *enamelin*.

Limited evidence of association to type 2 diabetes in African Americans with WGA diabetes SNPs. *D.W. Bowden, J.P. Lewis, N.D. Palmer, M.M. Sale, B.I. Freedman* Wake Forest University School of Medicine, Winston-Salem, NC.

Recently, several genome-wide association (WGA) studies have reported identification of multiple type 2 diabetes mellitus (T2DM) susceptibility genes in various Caucasian populations. However, little or no investigation of these loci has been reported in African Americans (AA). Striking differences between these populations suggest they may not share identical genetic risk factors. Previously we have shown that common genetic variants in *TCF7L2* contribute to T2DM in AAs (Sale et al., submitted). Our objective was to examine the influence of genes recently identified in WGA studies in a large AA case-control population. We genotyped 17 SNPs in 11 T2DM loci previously associated in Caucasians including *HHEX*, *SLC30A8*, *CDKAL1*, *PKN2*, *IGF2BP2*, *FLJ39370*, *EXT2*/*ALX4*, *FTO*, and LOC387761 in a sample of 1048 T2DM AA cases enriched for diabetic nephropathy and 1128 AA controls. In contrast to prior reports of association, our analysis of SNP data provided little evidence of association with T2DM. However, a SNP in intron 5 of *CDKAL1* (rs10946398) was marginally associated with T2DM in this population (2df P=0.0394, OR 0.88). In addition, rs7480010 located in LOC387761 also reached statistical significance (2df P=0.0036, OR 0.77) but was inconsistent with Hardy-Weinberg proportions (P=0.0035). All other SNPs investigated were not associated with T2DM with 2df P-values ranging from 0.06-0.97. Interestingly, 4 of the SNPs are nonpolymorphic in the Yoruba population of the HAPMAP project but were polymorphic in AAs. This may represent true allele frequency differences within different African-derived populations or may be a consequence of admixture. Overall, despite the highly significant evidence of association of these genes in Caucasian samples, this study suggests these variants do not contribute in a major way to diabetes susceptibility in the AA populations. These results also suggest genes contributing to T2DM in African Americans are, at least in part, different from those in Caucasians.

Representing genomic variation: a hierarchical database structure. *E. Bruford[1], T. Sneddon[1], M. Lush[1], M. Wright[1], S. Povey[2], E. Birney[1]* 1) HUGO Gene Nomenclature Committee, European Bioinformatics Institute, Hinxton CB10 1SA, UK; 2) Dept of Biology, University College London, Wolfson House, London NW1 2HE, UK.

The HUGO Gene Nomenclature Committee (HGNC) has to date approved over 24,000 unique symbols and names, the majority of which are for genes, i.e. genomic segments that are transcribed and translated into functional proteins. However, an increasing number of genes that were initially thought to be single copy in the human genome have been shown to be copy number variant (CNV) between individuals. This is especially true for genes encoding secreted, olfactory and immunity-related proteins, such as the amylase and defensin gene families. As individual copies of CNV genes are being discussed in the literature, and represented in the databases by alternative haplotypes (e.g. c5_H2 and c22_H2 in Build 36.1), there is an increasing need for a meaningful and systematic nomenclature system for them. Therefore the HGNC, in consultation with the scientific community and using data from the Database of Genomic Variants (http://projects.tcag.ca/variation/), has recently implemented a hierarchical structure in our gene nomenclature database (www.genenames.org). This facility allows for an approved gene record to contain sub-entries for each copy number variant e.g. the DEFB103 gene record links to DEFB103A and DEFB103B sub-entries. Examples of copy number variant genes that have been incorporated into our hierarchical database structure will be presented. We welcome requests from the research community to incorporate other experimentally verified CNV genes into our database. In addition to copy number variants, this new hierarchical database structure will also allow us to capture and represent information concerning other types of genomic variation, such as the complex gene loci encoding immunoglobulins, T cell receptors and protocadherins, and read-through/chimeric transcripts. We have recently relocated to the European Bioinformatics Institute EMBL Outstation at Hinxton, near Cambridge in the UK. For further information please email us at nome@ebi.ac.uk, or go to our new website, http://www.genenames.org. The work of the HGNC is supported by the NHGRI and the Wellcome Trust.

High frequency of uroporphyrinogen decarboxylase gene mutations in sporadic porphyria cutanea tarda patients. *K.H. Astrin[1], I. Nazarenko[1], E. Gehrie[1], K.E. Anderson[2], C. Lee[2], M. Yasuda[1], R.J. Desnick[1]* 1) Genetics & Genomic Sciences, Mount Sinai School of Medicine, New York, NY; 2) Preventive Medicine & Community Health, University of Texas Medical Branch, Galveston, TX.

Porphyria cutanea tarda (PCT), the most common disorder of heme biosynthesis, presents with characteristic light-induced blistering skin lesions. Familial PCT (F-PCT) is an austosomal dominant disorder with low penetrance and all heterozygotes have uroporphyrinogen decarboxylase (URO-D) mutations and half-normal erythrocyte URO-D activities. In contrast, sporadic PCT (S-PCT) patients have normal URO-D genes and erythrocyte URO-D activities. Both have decreased hepatic URO-D activities when symptomatic presumably due to the specific inhibition of the hepatic enzyme. S- and F-PCT are precipitated by multiple factors including alcohol, iron overload, and viral infections. S- and F-PCT are diagnosed biochemically by markedly elevated urinary uroporphyrin and heptacarboxylate porphyrin levels. The erythrocyte URO-D activities are problematic for identifying F-PCT patients, due to the overlap of mutation-positive patient and normal activities. Also, urinary porphyrins are not diagnostically increased in asymptomatic F-PCT patients. To determine if PCT patients with no family history had URO-D mutations, the entire ~3.5 kb gene and 1000 bases upstream and downstream were sequenced in 27 biochemically documented patients and 16 patients referred with only a clinical diagnosis. URO-D mutations were identified in 6 of the 27 (22.2%) biochemically diagnosed patients (Q9H, P44L, A80S, G210D, H220P, and 648insT) and in 4 of the 16 (25%) clinically diagnosed patients (R142X, G281V, H331R, and g645del1053ins10). Overall 10/43 or 23.3% of the PCT patients without a family history had URO-D mutations. Five of the 10 URO-D mutations were novel (Q9H, P44L, G210D, H331R and 648insT). These findings indicate that 20-25% of PCT patients without a family history actually have F-PCT, Therefore, it is recommended that all PCT patients be screened by mutation analysis, that members of F-PCT families have diagnostic mutation testing, and that heterozygotes be counseled about their risk and PCT precipitating factors.

Dilated aortic root: a previously unrecognized complication of mitochondrial diseases. *N. Fouladi[1], N. Brunetti-Pierri[1], J. Towbin[2], J.L. Jefferies[2], V.R. Sutton[1], J. Belmont[1], W. Craigen[1], L.-J. Wong[1], F. Scaglia[1]* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Pediatric Cardiology, Baylor College of Medicine, Houston, TX.

Mitochondrial cytopathies are a genetically, biochemically, and clinically heterogeneous group of disorders associated with abnormalities of oxidative phosphorylation. The heart is highly energy dependent and particularly vulnerable to energy production defects. Hyperthrophic and dilated cardiomyopathy and left ventricular noncompaction are among the main cardiac manifestations in mitochondrial cytopathies. Dilated aortic root is typically found in connective tissue disorders, such as Marfan and Ehlers-Danlos syndrome and has not been previously reported in mitochondrial disorders. We found aortic root dilation in seven patients with mitochondrial cytopathies. The aortic root dilation was mild to moderate with a z-score ranging from +2.9 to +4.0. In at least two cases the aortic root dilation was progressive requiring treatment with -blockers. We then investigated the aortic root diameter in a series of 45 patients followed in our Center with a diagnosis of mitochondrial disorder based on the modified Walker criteria. Interestingly, we found a statistically significant increase in aortic root diameter with the mean z-score being +0.961.14 (CI 95% +0.63 to +1.3), which is significantly increased compared to normal controls ($p<0.001$). The screening and follow-up of more patients with mitochondrial cytopathies are necessary to define the natural history of this newly recognized complication of mitochondrial diseases. The pathomechanism(s) leading to aortic root dilation in mitochondrial disorders is unknown. Mitochondrial dysfunction may lead to nitric oxide (NO) dysregulation and increased generation of reactive oxygen species triggering a signaling cascade of apoptosis. Therefore, we propose the increased endothelial and/or smooth muscle cell apoptosis induced by nonfunctioning mitochondria as a potential mechanism for the observed finding.

Resolving the Power of Multifactor Dimensionality Reduction in the Presence of Many Noise Variables or Genetic Heterogeneity. *S.M. Dudek, T.L. Edwards, M.D. Ritchie* Ctr for Human Genetics Res, Vanderbilt University Medical Center, Nashville, TN.

In human genetic studies of common, complex disease, an important consideration is the detection of joint effects at several variables. The search space to find such multi-locus associations is very large relative to the number of single locus effects. Conventional parametric approaches such as logistic regression, which were not designed to screen these spaces, suffer from low power due to multiple comparisons and subsequent corrections. The Multifactor Dimensionality Reduction (MDR) algorithm searches these large spaces with an exhaustive approach and has been shown to have good power to detect interactive effects. Prior to this study, the performance of MDR for the detection of gene-gene interaction effects given large numbers of noise variables or varying degrees of genetic heterogeneity was unknown. A variety of 2-locus and 3 locus purely epistatic genetic models with a range of effect sizes were simulated. We explored increasing numbers of SNPs (100, 500, 1,000, 5,000, and 10,000) in datasets consisting of 500 cases and 500 controls. The results show that MDR has power to detect these interactive effects in datasets that exceed the largest candidate gene studies when heritability and effect sizes are moderate to large. Three levels of heterogeneity and four sample sizes were also simulated. The results indicate that selection of a good study population, where heritability and effect size estimates are reasonable, is more relevant to the performance of MDR than sample size. This property of MDR is analogous to a parametric statistic where the power to detect an association is larger when the effect size is doubled rather than the sample size doubled. These results also demonstrate that MDR is robust to locus heterogeneity, regardless of the degree, when the definition of power is liberal. Thus, our results provide additional evidence that MDR is a powerful approach for the detection of gene-gene interactions in the study of common, complex disease.

Genetic Studies in a Colombian Family with Familial Exudative Vitreoretinopathy or Criswick-Schepens Disease. *N. Gelvez[1], J. Montoya[1], C. Varón[2], M. Gómez[2], J. Gómez[2], M. Jaramillo[2], M.L. Tamayo[1]* 1) Inst Genetica Humana, Univ Javeriana, Bogota, 1, Colombia; 2) Fundación Oftalmológica de Santander, Clínica Ardila Lulle (FOSCAL). Bucaramanga, Santander. Colombia.

The Familiar exudative vitreoretinopaty (FEVR) or Criswcick-Schepens Disease is a genetic disorder of retinal vessel. The features of the disease can be variable even within the same family. It is bilateral, asymmetric and progressive with variable inheritance, being the Autosomal Dominant the most common. A complete ocular examination was practiced on 32 individuals belonging to a family with diagnosis of FEVR. After informed consent, DNA sample was taken for DNA extraction and the coding region of FZD4 gene was sequenced. Eleven individuals were defined as affected and the other 21 as non-affected. Autosomal Dominant inheritance was confirmed and the 1501delCT mutation in the FZD4 gene was identified in all affected individuals. We confirmed the hypothesis that some non-affected relatives did not present partial manifestations of the disease. The findings of Angiography, Optical Coherent Tomography (OCT) and ocular ecography showed the peripheral retinal avascularization. We defined an Autosomal Dominant inheritance and the causal mutation in the FZD4 gene in this family. The molecular characterization of this family allows us to practice a complete genetic counseling in all evaluated individuals.

Association between polymorphisms in catechol-O-methyltransferase (*COMT*) and cocaine-induced paranoia in European-American and African-American populations. *R. Hirunsatit[1,4,5], H.R. Kranzler[6], C. Ittiwut[1,4,5], R. Weiss[7], K. Brady[8], V. Hesselbrock[6], B. Rounsaville[1,4], L.A. Farrer[9], J. Gelernter[1,2,3,4]* 1) Yale Univ. Sch. Medicine, Dept Psychiatry; 2) Genetics; 3) Neurobiology, New Haven, CT; 4) VA CT Healthcare System, West Haven, CT; 5) Chulalongkon Univ. Thailand; 6) Univ. CT Sch. Medicine, Farmington, CT; 7) Harvard Medical Sch., Boston, MA; 8) Medical Univ. of SC, Charleston, SC; 9) Boston Univ Sch. Medicine and Public Health, Boston, MA.

COMT (genetic locus,*COMT*) is a major enzyme involved in catecholamine metabolism that has been reported to be associated to numerous psychiatric phenotypes and endophenotypes. We studied the association of 17 *COMT* SNPs with cocaine-induced paranoia (CIP) in 319 African-American (AA) and 302 European-American (EA) nuclear families ascertained for cocaine or opioid dependence, using family-based association methods (FBAT/HBAT). SNP rs737865 was nominally associated with CIP in AA families (p=0.05 in additive and p=0.03 in dominant and recessive models). In EA families, rs737866 was significantly associated with CIP in dominant and recessive models (p=0.02). SNP rs174696 also showed significance in all models (p=0.02 additive, p=0.004 dominant and recessive). The best-known marker, rs4680 (Val158Met), was nominally significant in all models (p=0.03 additive, p=0.005 dominant and recessive). Haplotype analysis including rs737866, rs4680, and rs174696 revealed an association of haplotype A-A-T with increased CIP risk in EA families (p=0.0044) and an association of haplotype G-G-T with decreased risk of CIP in AA families (p=0.0014) after Bonferroni correction [corrected p0.008 for significance] for testing of six major haplotypes in both populations. We conclude that COMT is associated with cocaine-induced paranoia in both AAs and EAs. Different haplotypes composed of the same SNPs were associated in the two populations, which suggests that the actual risk variant (or variants) were introduced on different chromosomal backgrounds in the different populations. COMT is the second enzyme involved in dopamine metabolism (after DBH) that has been shown to be associated with CIP.

Microrearrangements could be the major molecular mechanism in isolated holoprosencephaly: array CGH detects gains and/or losses in 24% of the patients. *C. Bendavid[1, 2], J. Seguin[1], C. Dubourg[1,2], I. Gicquel[1], L. Pasquier[1, 4], M.R. Durou[2], S. Jaillard[1, 3], C. Henry[3], J. Mosser[1], S. Odent[1, 4], V. David[1, 2]* 1) UMR 6061 CNRS, Univ de Rennes1, Rennes, France; 2) Molecular Genetics, CHU Pontchaillou, Rennes, France; 3) Cytogenetics, CHU Pontchaillou, Rennes, France; 4) Medical Genetics, Hopital Sud, Rennes, France.

Holoprosencephaly (HPE) is the most common developmental brain anomaly in humans, usually associated with facial features. Our group focuses on patients with HPE and normal karyotype. Genetics of holoprosencephaly is complex: in our experience, mutations (18%) or deletions (8%) in the four main genes (SHH, ZIC2, SIX3 and TGIF) can explain about 26% of HPE cases. MLPA subtelomeric screening revealed 4% of additional complex rearrangements. In order to identify new candidate loci and thus novel candidate genes, we decided to screen HPE patients using Agilent CGH-array technology. 74 samples (47 fetuses and 27 live-borns children), with no karyotype alterations, were tested using a unique male or female DNA as control. Out of these 74 samples, 18 presented with new rearrangements involving known or new potential HPE loci located on different chromosomes but with poor redundancy. We observed 11 isolated deletions, 5 isolated duplications and 2 associated genomic losses and gains, the latters suggesting an unbalanced translocation from parental origin. Detected alterations ranged from less than 100 kb to 16 Mb and were not further considered if they involved less than 3 consecutive spots on the array. None of these regions matched against copy number variations described in databases (TCAG database). The few observed redundancies encompassed chromosomal regions on 21q and 20p. Frequencies of alterations were higher in foetuses (32%) than in live-borns (11%), but no correlations could be made between the size of the defects and the severity of the phenotypes. Added to the previous microdeletion findings in known HPE genes and subtelomeres, our data show that microrearrangements could be the major molecular mechanism in HPE and strongly reinforce the multigenic origin in this developmental disorder.

Fine-mapping of an Asthma Susceptibility Locus on Chromosome 3p14. *T.D. Howard[1], E.R. Bleecker[1], E.A. Ampleford[1], G.H. Koppelman[2], D.S. Postma[3], D.A. Meyers[1]* 1) Ctr Human Genomics, Wake Forest Univ Sch Med, Winston-Salem, NC; 2) Dept of Pediatric Pulmonology, Beatrix Children's Hospital, University Medical Center Groningen, University of Groningen, The Netherlands; 3) Dept of Pulmonology, University Medical Center Groningen, University of Groningen, The Netherlands.

Asthma is an increasingly common disease caused by bronchial inflammation and characterized by bronchial hyperresponsiveness (BHR) and intermittent airways obstruction. In an effort to delineate the genetic susceptibility to asthma, we have previously performed a genome-wide screen in a Dutch population of 200 families ascertained by a proband with asthma. The two genomic regions with the strongest evidence for linkage with BHR and asthma (determined by an algorithm incorporating BHR and other components) were located on chromosomes 3p14-p21 and 5q31. On chromosome 3p, the peak lod score after fine-mapping with 36 additional microsatellite markers was 3.4 for asthma and 3.9 for BHR, between the markers D3S1514 and D3S2452. Using BHR, the lod - 1 support interval extends from 102cM to 105.5cM, between markers D3S3588 and D3S1547. We have recently constructed a high-density SNP map of this ~4Mb region in the Dutch population, utilizing LD data available from the International HapMap Project. A total of 776 SNPs were genotyped with minor allele frequencies of >0.01 in this Dutch population. Two of these significantly deviated (<0.001) from Hardy-Weinberg Equilibrium, while an additional 27 SNPs showed modest deviation (<0.05). Both FBAT and parenTDT (as implemented in HaploView) analyses were performed with BHR (defined as a 20% drop in forced expiratory volume in 1 second with <32mg/ml histamine) and asthma. Forty-six SNPs were significant with either BHR or asthma with either analytical method (p = 0.0001 - 0.01). Several SNPs are located in potential candidate genes, including CAST and IL17RD, while others are in intergenic regions. Additional work is in progress to replicate and confirm these findings in independent multi-ethnic populations and to determine the overall relevance of these SNPs in asthma susceptibility.

Association between Neuregulin 1 and Schizophrenia in the PAARNTERS Study. *M.R. Dickson, H. Wiener, R. Perry, Z. Chen, R.C.P. Go, on behalf of The PAARTNERS Study Group* Epidemiology, UAB, Birmingham, AL.

Neuregulins are essential for neuronal development. Neuregulin 1 (*NRG1*), located at 8p13, is a candidate gene for schizophrenia (SCZ) first identified by linkage studies with replication in different populations. Association studies have shown specific polymorphisms in *NRG1* to be associated with development of SCZ. The PAARTNERS study is a familial study of SCZ liability among African Americans. For this initial study, DNA samples were available for 486 families with 1 proband with SCZ. Eight SNPs within the *NRG1* gene, that were examined in previous studies, were genotyped and tested for association using FBAT. We performed two analyses, first using as affected only those determined to have SCZ (DSM-IV code 295.xx excluding 295.7), and second including those with schizoaffective disorder (including DSM-IV code 295.7). When an underlying additive effect of SNP genotype on risk of development of SCZ was assumed, allele G of SNP rs6988339, located in the 3 region, was observed to be transmitted to cases more frequently than expected by chance in both analyses (p=.028 with 77 informational families in the first, p=.033 with 79 informational families in the second). The assumption of a dominant model yielded an association with the same SNP in the first analysis (p=.043 with 75 informational families) with allele G, again, being the one transmitted more frequently. In the second analysis, two SNPs were seen to be associated under a dominant model: rs6988339 (p=.049 with 77 informational families), and rs6994992, located within the 5 region, (p=.047 with 116 informational families) with the T allele at this locus being transmitted more frequently than its C allele. Using the full genotype model available in FBAT, which does not impose a simpler a priori genetic model between genotype and phenotype, confirmed what was seen in the simpler models above. *NRG1* haplotype association with neurocognition in the PAARNTERS set will also be presented. Variation within the *NRG1* gene provides preliminary evidence of modest association with SCZ liability, and awaits confirmation in a larger PAARTNERS set and replication in other African American populations.

Optimized methylated DNA analysis of formalin fixed paraffin embedded tissue samples by bisulfite sequencing.
V. Boyd, M. Barker Applied Biosystems, Foster City, CA.

The tissue preservation process compromises genomic DNA from formalin fixed paraffin embedded (FFPE) samples. However, FFPE samples remain the most abundant tissue available to researchers and are extremely valuable due to the associated clinical records. A workflow enabling researchers to reliably extract the gDNA, perform bisulfite conversion and obtain sequence information that provides clues to the methylation status of a FFPE sample would be a unique contribution to the field of epigenetics. There are multiple steps that have been optimized and consolidated to achieve this goal. Genomic DNA extracted using a commercially available kit that provides DNA suitable for the bisulfite conversion by thoroughly removing protein associated with the DNA. Residual protein associated with the DNA reportedly impairs bisulfite conversion. A mild bisulfite conversion with a commercially available bisulfite conversion kit limits fragmentation of the already fragmented gDNA from FFPE samples by avoiding temperatures in excess of 50 degrees. Our recent results include a time-course study showing efficient bisulfite conversion occurs within three hours. The bisulfite converted gDNA, present as fragments due both to FFPE preservation and bisulfite treatment, is readily purified without bias or sample loss using a spin centrifugation device. All fragments and methylation states are recovered using this unique purification protocol based on size-cutoff and provides accurate representation of the methylation states present. A percentage of functionality test can be performed on the extracted DNA prior to bisulfite conversion which provides an indication of DNA quality, and correlates well with the expected success of analyzing the same sample after bisulfite conversion. PCR conditions have been optimized prior to bisulfite sequencing using tailed primers and a two-tiered thermal cycling program. A new commercially available sequencing clean-up matrix provides both ease of use and sensitivity.

EURExpress, a web-based transcriptome atlas of the developing mouse embryo. *G. Diez-Roux, The EURExpress consortium* Telethon Institute of Genetics & Medicine, Naples, Italy.

Genome-wide expression analyses have a crucial role in functional genomics. RNA in situ hybridization (ISH) provides an accurate spatio-temporal description of the distribution of transcripts at cellular resolution. The EU-funded EURExpress consortium is generating a transcriptome-wide acquisition of expression patterns by means of ISH with non-radioactive probes and using this data to establish a web-linked, interactive digital transcriptome atlas (www.eurexpress.org). The goal of EURExpress is to generate the expression data of > 20,000 genes on sagittal sections from E14.5 wild type murine embryos. To date we generated over 9000 expression patterns, which have been thoroughly annotated using a special interface for high-throughput annotation. This interface includes 1420 anatomical structures and correlative trees regarding ontological (embryological) and topological relations allowing advanced queries. The analysis of the data produced so far has determined that 45-50% of genes show a specific/restricted pattern of expression at E14.5. Over 20% of these are unknown genes of which a large percentage show restricted expression patterns in organs such as the central nervous system, ear, eye, skin, liver, skeletal muscle, mesenchyme and salivary glands, indicating that this database represents a unique resource to identify novel molecular markers. The potential impact on these data on the study of human development and disease is enormous allowing to identify tissue specific markers to characterize disease phenotype, to evaluate disease prognosis, to measure therapeutic benefits and to help identifying genes whose mutations lead to disease phenotypes. In addition, the data has allowed also performing detail molecular characterization of the CNS and has identified, for example, novel molecular regionalization of the thalamus, diencephalon and the telencephalic pallium. Analysis are being performed to find relationships between gene expression and gene ontology and to characterize the mouse genome based on the expression patterns of genes.

Estimation of allelic frequencies and inbreeding coefficient. *R. He, R. Chakraborty, M. Rao* Center for Genome Information, University of Cincinnati, Cincinnati, OH.

Estimating allele frequencies and inbreeding coefficient in the case of a bi-allelic gene is simple and fairly routine. When we move away from the bi-allelic case to multi-allelic case, formidable problems crop up. In this presentation, we will outline how a multi-allelic problem can be solved by focusing on solving a series of associated bi-allelic problems. Special emphasis will be placed on the tri-allelic case. Tests are developed that the inbreeding coefficient model is valid for the problem on hand.

A farnesyltransferase inhibitor prevents cardiovascular disease in a progeria mouse model. *B.C. Capell[1], M. Olive[1], M.R. Erdos[1], K. Cao[1], D.A. Faddah[1], K.N. Conneely[2], H. San[1], X. Qu[1], H. Avallone[3], F. Kolodgie[3], R. Virmani[3], E.G. Nabel[1, 4], F.S. Collins[1]* 1) NHGRI, NIH, Bethesda, MD; 2) University of Michigan School of Public Health, Ann Arbor, MI; 3) CVPath, Gaithersburg, MD; 4) NHLBI, NIH, Bethesda, MD.

Hutchinson-Gilford progeria syndrome (HGPS) is the most dramatic form of human premature aging. Death occurs at a mean age of 13, usually from heart attack or stroke. HGPS is almost always caused by a *de novo* point mutation in the *LMNA* gene that results in production of a mutant lamin A protein, termed progerin, that is permanently modified by a lipid farnesyl group. It is hypothesized that progerin remains associated with the nuclear membrane due to its farnesyl-anchor, thus acting as a dominant negative, disrupting the lamina, leading to the blebbed nuclei that are the cellular hallmark of the disease. Treatment with farnesyltransferase inhibitors (FTIs) has been shown to prevent and even reverse this nuclear abnormality in cultured HGPS fibroblasts. In a study extending over a year, we show that the dose-dependent administration of the FTI, tipifarnib (R115777, Zarnestra) to a transgenic mouse model of HGPS can ameliorate a cardiovascular phenotype (loss of vascular smooth muscle cells (VSMC) in the media of the large arteries) that is strikingly similar to the cardiovascular disease seen in HGPS. Twenty-eight mice were randomly assigned to receive oral administration of 450 mg/kg/d, 150 mg/kg/d, or vehicle-only beginning at one month of age. Following sacrifice at 9-12 months of age, five blinded observers scored pathology levels examining both VSMC loss and proteoglycan accumulation. Using levels of the biomarker non-farnesylated HDJ-2 as a measure of *in vivo* FTI activity, we found a highly significant association between FTI activity and the prevention of the cardiovascular phenotype. Experiments currently underway will determine whether this FTI can also reverse this cardiovascular disease in HGPS mice that are allowed to reach 6 months or 9 months of age before treatment is started. Our results provide encouraging evidence in support of a clinical trial of FTIs for this rare and devastating disease.

RAPP-HODGKIN SYNDROME.CASE REPORT. *G. Garcia-Sanchez[1], C.F. Martínez-Cruz[2,3], M.C. Mata-Rivera[4], L. Hernandez-Gomez[4]* 1) Servicio de Genética.Direccion de Investigacion.Instituto Nacional de Rehabilitación, México, D.F; 2) Servicio de Comunicacion Humana.Depto de Seguimiento Pediatrico.Instituto Nacional de Perinatologia. México D.F; 3) Servicio de Pediatría Instituto Mexicano del Seguro Social.HGZ 53. México, D.F. email. guillegs@yahoo.com.mx; 4) Servicio de Audiologia.Instituto Nacional de Rehabilitación, México, D.F.

Rapp-Hodgkin syndrome (RHS), was first described over 30 years ago in an affected mother, son, and daughter with a combination of anhidrotic ectodermal dysplasia, cleft lip, and cleft palate (Rapp and Hodgkin, 1968). The clinical syndrome is comprised of a characteristic facies (narrow nose and small mouth), wiry, slow-growing, and uncombable hair, sparse eyelashes and eyebrows, obstructed lacrimal puncta/epiphora, bilateral stenosis of external auditory canals, microsomia, hypodontia, cone-shaped incisors, enamel hypoplasia, dystrophic nails, and cleft lip/cleft palate. Approximately 45 cases of this developmental disorder, usually with autosomal-dominant inheritance, have been reported. Several ectodermal dysplasia syndromes, including Rapp-Hodgkin, syndromes, are known to result from mutations in the p63 gene. A 7-year-old Mexican boy was seen in The Department of Genetics. Instituto Nacional de Rehabilitación. The proposito was the first child of nonconsanguineous Mexican parents. The pregnancy was uncomplicated with no known exposure to teratogens. The child was born at term with a birth weight of 3,600 g. His clinical findings included characteristic facies, sparse hair, eyebrows and eyelashes. Obstructed right lacrimal puncta and epiphora. Repaired right cleft lip and cleft palate, multiple caries, unerupted upper central incisors. The skin was dry. Hands with some hyperpigmented areas. Diffuse dermatitis of the scalp and face was present. All fingernails and toenails were dystrophic. He had hearing loss. Bilateral ear discharge at 3 and 6 years old. No other family member is affected. The clinical presentation of ectodermal dysplasia with cleft palate was consistent with Rapp-Hodgkin syndrome, which is one of several allelic diseases associated with mutations in the TP63 gene. sweating.

Polymorphisms in the AMPA receptor 1 gene region are associated with psychotic symptoms in bipolar disorder.
B. Kerner, A. Jasinska, J. DeYoung, M. Almonte, O.-W. Cho, N.B. Freimer Ctr Neurobehavioral Genetics, Univ California, Los Angeles, Los Angeles, CA.

Bipolar disorder with psychotic symptoms has been linked to a region on chromosome 5q31-33 in several studies by us and others. We report here the fine-mapping of this region in 56 nuclear families (299 individuals) from the National Institute of Mental Health Bipolar Genetics Initiative (NIMH-BPGI) data sets. 1134 single nucleotide polymorphism (SNP) markers were genotyped in those families that contributed to the original linkage finding on chromosome 5q across a 9.4 Mb region under the linkage peak, as well as in a replication sample. Family based association in the presence of linkage was then tested with the computer software package FBAT. Twenty-nine SNPs were significantly associated with the phenotype (empirical p-value <.05) in the initial sample. One of those SNPs was also marginally associated with psychotic bipolar disorder in the replication sample (p-value=0.06). These SNPs were located in the first and second intron of the -amino-3-hydroxy-5-methyl-4-isoxasole proprionic acid (AMPA) subunit 1 receptor gene (GRIA1) (rs472792, rs524905), in the first intron of the IL2-inducible T-cell kinase (ITK) (rs452223), and in intron 6 of the Early B cell factor 1 gene (EBF1) (rs4244438). One SNP (rs2421050) was located in a gene poor region without known significance. The AMPA1 receptor has been shown to influence cognitive functions, such as working memory and reward learning. Variations in this gene have been implemented in the pathogenesis of schizophrenia (SZ). Our findings suggest that variations in this receptor may contribute to the pathophysiology of bipolar disorder with psychotic features.

A genome-wide autism association study identifies a common variant with sex-dependent effects at the neurexin-superfamily member *CNTNAP2*. *D.E. Arking[1], D.J. Cutler[1], C.W. Brune[2], T.M. Teslovich[1], K. West[1], M. Ikeda[1], A. Rea[1], M. Guy[1], S. Lin[1], E.H. Cook Jr.[2], A. Chakravarti[1]* 1) Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Institute for Juvenile Research, University of Illinois at Chicago, Chicago, IL.

Autism is a common childhood neuropsychiatric disorder that, despite high heritability, has largely eluded efforts to identify genetic variants underlying its etiology. We performed a two-stage genetic study, in which genome-wide mapping was validated by replication in an independent sample. In stage I, we screened 72 multiplex families, corresponding to 78 sib-pairs and 145 parent-child trios, using Affymetrix 500K arrays. Genome-wide linkage analysis revealed a single significant peak at 7q35 (lod = 3.4). A parallel genome-wide association analysis using TDT was performed for both single SNPs and haplotypes; however, no genome-wide significant results were observed. In contrast, TDT under the chromosome 7q35 linkage peak revealed a single SNP significantly associated with autism after correcting for the number of SNPs tested under the linkage peak by permutation (P 0.006). This SNP is common (MAF = 0.36) and resides in an intron of the contactin-associated protein-like 2 (*CNTNAP2*) gene, which encodes a member of the neurexin family. To validate this initial finding, we genotyped an independent sample of 1,295 parent-child trios, and again observed over-transmission with the same allele (P 0.005). Given the marked sex-difference in the incidence of autism, we examined transmission stratified by parental gender and by offspring gender. The overall transmission frequency (0.55) is significantly greater from mothers (0.61) than from fathers (0.53) in the combined sample and this parent-of-origin difference is significant (P 0.001). This genetic effect is largely observed in affected males, although the rarity of affected females implies that this may be due to reduced power in females. In summary, we identified a common polymorphism in *CNTNAP2* that is significantly associated with autism susceptibility, and displays a parent-of-origin and gender effect recapitulating the inheritance of autism.

Autosomal Recessive Polycystic Kidney Disease/Congenital Hepatic Fibrosis (ARPKD/CHF) Associated with Congenital Anomalies. *E. Font-Montgomery[1], H. Edwards[1], D. Adams[1], P. Held[1], P. Choyke[2], L. Guay-Woodford[3], T. Heller[4], P. Mohan[5], K. Daryanani[6], W. Gahl[1,7], M. Gunay-Aygun[1,7]* 1) MGB, NHGRI/NIH, Bethesda, MD; 2) NCI, NIH; 3) University of Alabama, Birmingham AL; 4) NIDDK, NIH; 5) CNMC, Washington, DC; 6) NIH CC; 7) Intramural Office of Rare Diseases, NIH.

ARPKD/CHF, the most common childhood ciliopathy, is characterized by dilated renal collecting ducts resulting in renal insufficiency and ductal plate malformation of the biliary system resulting in CHF. It is caused by mutations in PKHD1, which encodes fibrocystin, a protein located on the primary cilia-basal body/centriole. Other ciliopathies, commonly associated with overlapping features, include Joubert Syndrome (JS) and related cerebello-oculo-renal syndromes (CORS), Bardet-Biedl (BBS), Meckel-Gruber (MGS) and Oral-Facial-Digital-1 (OFD1) syndromes and potentially other, yet-to-be-discovered disorders. Although many ciliopathy genes have been identified, for most of these disorders the processes of gene identification and phenotype delineation remain incomplete. The current consensus clinical diagnostic criteria for ARPKD/CHF require characteristic kidney and liver involvement, family history consistent with autosomal recessive inheritance, and absence of congenital anomalies. In the ongoing NIH natural history study on ARPKD/CHF and other ciliopathies (www.clinicaltrials.gov, trial NCT00068224), we have evaluated 88 patients, 72 of whom were referred with a diagnosis of ARPKD/CHF. NIH evaluations including high resolution ultrasound, MRI and sequencing of the PKHD1 gene confirmed ARPKD/CHF in 59 of the 72 patients. Here we present 5 of the 72 patients who had congenital abnormalities in addition to the typical kidney and liver disease of ARPKD/CHF. These include a patient with tetralogy of Fallot and another with unilateral cleft lip/palate, both of whom have two pathogenic mutations in PKHD1. PKHD1 sequencing was negative in the other 3 patients, one of whom had craniofacial dysmorphism associated with enlarged basilar cisterns. We continue enrolling patients to better delineate the phenotypic spectrum and improve diagnostic accuracy of these disorders.

Interlaboratory validation of High Resolution Melting (HRM) for BRCA1 and BRCA2 on the LightCycler 480.

T. Janssens[1], N. van der Stoep[2], R. Buser[3], G. Michils[1], A. Corveleyn[1], P. Maillet[3], E. Bakker[2], G. Matthijs[1] 1) Center for Human Genetics, Leuven, Belgium; 2) Center for Human and Clinical Genetics, Leiden, The Netherlands; 3) Laboratory of Oncogenetics, Geneva, Switzerland.

EuroGentest is a network funded by the European Commission that aims to improve and harmonize the overall quality of genetic services throughout Europe. The validation of new technologies is one of many contributions to accomplish this. High Resolution Melting (HRM) was selected as one of the technologies for which a thorough validation would be very timely. In a collaborative study, we extensively tested HRM on the LightCycler 480 (Roche Applied Science). HRM is a fast, simple and cost effective high-throughput scanning method to detect sequence variations. PCR is performed in the presence of a saturating fluorescent dsDNA binding dye. Single-base variations in the amplicon result in altered melting behavior after heteroduplex formation, which affects the curve shapes in HRM plots. The LightCycler 480 performs both PCR and HRM in a single multistep run. BRCA1 and BRCA2 were chosen as target genes, because their size and mutation spectrum represent a challenge in molecular diagnostics. The current methods, like e.g. dHPLC and DGGE, despite their good performance, are limited by their throughput or labour-intensity. HRM is potentially useful for solving these problems. However, it needs to be shown that the sensitivity and the ease of use are at least as good as the current state of the art. Therefore, an extensive validation was set up in parallel in 3 labs. The first objective was to design a complete primer set for BRCA1 and BRCA2, which was derived from the dHPLC and sequencing primers, but optimized for HRM. Indeed, the performance of HRM is largely depending on the quality of the PCR. Critical criteria were specific banding patterns after gel electrophoresis, nice sigmoid curves on the real-time PCR plots and no more than 2 melting domains per amplicon. For the final validation, at least 150 known variations will be tested in a blinded way. This will allow us to determine whether HRM reaches a sensitivity close to 98%, which would make it a suitable new method for diagnostic use.

Genetic Screening of Usher Syndrome in Children. *W.J. Kimberling[1], R.J.H. Smith[2], E.M. Stone[2], R.G. Weleber[3], C. Moller[4], C. Carney[1], M. Jensen[1], K. Trzupek[3]* 1) Boys Town Hospital, Omaha, NE; 2) Univ. Iowa, Iowa City, IA; 3) Oregon Health Sciences Center, Portland, OR; 4) Swedish Institute for Disability Research, Orebro, Sweden.

Past estimates of the frequency of Usher syndrome (US) in children relied on clinical diagnosis of the associated retinitis pigmentosa (RP) and generally reported that 5% of deaf children manifested Usher syndrome. Population studies yielded frequencies in the range of 1 in 25,000. New molecular testing offers a more accurate and less expensive alternative. We conducted two pilot studies designed to determine the frequency of US. The first involved high school children from the state of Oregon who are in the special education program for the deaf and hard of hearing (D/HOH). DNA samples were collected by mail using a Genotek saliva collection kit (dnagenotek.com) and genotyped using the an US chip (asperophthalmics.com). Out of 78 children who were genotyped, eight (10.5%) had at least one pathologic mutation. Mutations were observed in CDH23(3), MYO7A(2), or USH2A(3). A second study was carried out on children who had received cochlear implants at the University of Iowa. Fifty-five children were genotyped using the US chip. GJB2 positive children were eliminated from the Usher genotyping. Of these, 7 (12.7%) were observed to have mutations in MYO7A, CDH23, USH1C, or USH2A. Adjusting for the elimination of GJB2 positive children yielded an estimate of the frequency of US at 8.2%. Both pediatric populations gave similar estimates of US frequency and a similar distribution of the genetic subtypes. Assuming that the US chip has a 50% sensitivity, between 15 and 21% of D/HOH children have or will develop RP. Assuming also that the frequency of childhood Deafness is 1/1000, the population frequency of US is between 1/5000 and 1/10000 births, a value much greater than previously believed. Further, this study shows that molecular screening for US is a cost effective and accurate means for early diagnosis. Early diagnosis is particularly relevant since recent research suggests several possibilities of intervention, all of which would be expected to more effective if instituted early.

Optimization of whole genome amplification from FTA cards for genetic epidemiology studies. *I. Dimulescu, A.K. Smith, E.R. Unger, S.D. Vernon, M.S. Rajeevan* Centers for Disease Control, Atlanta, GA.

Sample collection, processing, extraction and amplification of nucleic acids are key elements in bio-banking and conducting large-scale, multi-center genetic studies of public health importance. While blood dried on FTA cards offers a number of advantages, current methods recover low amounts of DNA which limits the number of genetic markers that can be tested. In this study, we evaluate the ability of different whole-genome amplification (WGA) protocols to generate a representative and renewable source of DNA from FTA cards. Peripheral blood was obtained from 33 anonymous volunteers in the CDC blood bank. Reference genomic DNA was extracted from whole blood or from PBMCs of each subject. Each sample was also used to prepare replicate FTA cards. Dried blood spots were extracted using the FTA, GenVault, and Qiagen lysate protocols, or used directly in the WGA. Two different WGA protocols were evaluated: Qiagens REPLI-g kit based on phi 29 DNA polymerase mediated isothermal amplification and Sigmas GenomePlex kit based upon random fragmentation of the genome and amplification by PCR. A total of 80 single nucleotide polymorphisms were genotyped using either Applied Biosystems TaqMan allelic discrimination assay or the Sequenom iPLEX Gold assay. Performance of the WGA assays on each template source was determined based on the call rate and the concordance of genotype calls compared to gDNA. Based on the initial 130 genotypes determined by TaqMan, DNA extracted using FTA and GenVault protocols and amplified with REPLI-g had a call rate of 100% with concordance rates of 94.6% and 100%, respectively. In another set of 1180 genotypes derived from the iPLEX platform, DNA extracted from FTA lysate and amplified with REPLI-g resulted in 97.8% call rate and 99.9% concordance. DNA amplified with GenomePlex directly from FTA paper discs generated the highest call rate, 99.0% and were 100% concordant. Preparation of DNA template from stored FTA paper and selection of WGA protocol can influence call rate and allele drop-out. Studies are in progress to validate these pilot study results with FTA samples collected as part of a population-based genetic epidemiology study.

Arterial Tortuosity Syndrome: clinical and molecular findings in 12 newly identified families. *B. Callewaert, A. Willaert, J. De Backer, B. Loeys, P.J. Coucke, A. De Paepe* Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium.

Background: Arterial tortuosity syndrome (ATS) is a rare autosomal recessive connective tissue disease, characterized by widespread arterial involvement with elongation, tortuosity and aneurysms of the large and middle-sized arteries. Recently, mutations in SLC2A10 were identified in this condition. This gene encodes the facilitative glucose transporter GLUT10 and was previously suggested as a candidate gene for diabetes mellitus type 2. Methods: Twelve newly identified ATS families with 16 affected individuals were clinically and molecularly characterized. In addition, extensive cardiovascular imaging and glucose tolerance tests were performed in both patients and heterozygous carriers. Results and conclusions: All 16 patients harbor bi-allelic SLC2A10 mutations and haplotype analysis suggests founder effects for all 5 recurrent mutations. Facial resemblance was obvious and all patients had involvement of the skin and skeleton. Remarkably, patients were significantly older than those previously reported in literature ($p=0.04$) and only one affected relative died, most likely of an unrelated cause. Although the natural history of ATS in this series was less severe than previously reported, it does indicate a risk for ischemic events. Two patients initially presented with stroke, respectively at age 8 months and 23 years. Tortuosity of the aorta or large arteries was invariably present. Two adult probands (aged 23 and 35 years) had aortic root dilation, 7 patients had localized arterial stenoses and 5 had long stenotic stretches of the aorta. Heterozygous carriers did not show any vascular anomalies. HbA1c levels and glucose tolerance tests were normal in 6 patients and 8 heterozygous individuals of 5 families. As such, overt diabetes is not related to SLC2A10 mutations associated with ATS.

Genome wide association analysis identifies SNPs near *MMP1* and *MMP3* as being strongly associated with matrix metalloproteinase-1 (MMP1) levels: The Amish Heredity and Phenotype Intervention (HAPI) Heart Study. *Y. Cheng[1], W.H.L. Kao[1], A.R. Shuldiner[2], B.D. Mitchell[2], P.F. McArdle[2], H. Shen[2], K. Ryan[2], T.I. Pollin[2]* 1) Johns Hopkins University, Baltimore, MD; 2) University of Maryland, Baltimore, MD.

Background MMP1 may play a role in cardiovascular disease (CVD) susceptibility by influencing plaque rupture via its ability to degrade extracellular collagens. **Methods** We performed a genome wide SNP scan of *ln*-transformed MMP1 levels using the Affymetrix GeneChip Human Mapping 500K Array Set to identify genetic determinants of serum MMP1 levels in a cohort of 585 healthy Amish adults who were part of the HAPI Heart Study. SNPs with minor allele frequencies (MAF) 2%, Hardy-Weinberg Equilibrium p 0.001 and genotype call rates 90% were included in the analysis (361,981 SNPs). Age- and sex-adjusted *ln*-MMP1 residuals were initially screened for association with SNPs using ANOVA as implemented in HelixTree v5.3. SNPs with p-values in the lowest 1% were re-analyzed assuming an additive genetic model using variance components as implemented in SOLAR to account for familial relationships. **Results** Median MMP1 level was 2.79ng/mL (inter-quartile range: 1.74 - 4.62ng/mL) with an estimated heritability of 84.7% (p0.0001). Seventy-nine SNPs showed associations with MMP1 levels with genome wide significance (p $9.1x10^{-8}$), all residing in 11q22. The top 3 SNPs (rs603050, rs495366 and rs650108) each had p $1.4x10^{-19}$ for association with MMP1 levels; their MAF were 0.35-0.36 and they were in high linkage disequilibrium with each other ($r^2$0.97) in the Amish. Rs603050 and rs495366 are in the intergenic region between *MMP1* and *MMP3* and rs650108 is within *MMP3*. Each SNP could explain 14.5-16.2% of the variation in MMP1 level. The difference in MMP1 levels between the two homozygous groups of rs603050 was 2.66ng/mL. **Conclusions** We provide strong evidence that serum MMP1 level is highly heritable and that SNPs near *MMP1* and *MMP3* explain a significant portion of the variation in MMP1 levels in the Amish. Identification of the functional SNP(s) that influence MMP1 levels may provide insights into genetic mechanisms of CVD.

The molecular basis of Gaucher disease in black South African patients. *S. Arndt[1,2], M. Ramsay[1,2]* 1) Division of Human Genetics, National Health Laboratory Service; 2) University of the Witwatersrand, School of Pathology, Johannesburg, South Africa.

Gaucher disease (GD) is the most common lysosomal storage disease and it is caused by defects in the human glucocerebrosidase gene (GBA). The gene is located in a gene rich region on chromosome1q21,harboring 18 genes in its 200kb genomic surroundings. Two immediate neighboring genes downstream to GBA are pseudogenes resulting in this region to be prone to recombination events. GD is characterized by a high degree of heterogeneity with 266 disease causing mutations recorded in the Human Genome Mutation Database to date. The disease is panethnic in its distribution and occurs at a particularly high frequency in people of Ashkenazi Jewish descent. We studied twenty unrelated black GD patients and identified 39/40 disease causing mutations. Deletion c.222-224delTAC in exon 3 (delta T36) was found in 17/40 (0.425) alleles and 8/40 (0.2) alleles were identified as the recombinant allele RecNciI. The remaining 14/40 disease causing mutations were missense and nonsense mutations of which three are novel. Interestingly, 7/20 (0.35) black patients were compound heterozygotes for deltaT36/RecNciI, thus suggesting low genotypic heterogeneity among black South African GD patients. 66 random population-matched individuals were screened for the delta T36 mutation and a carrier frequency of 1/66 (2/132 alleles) was obtained for this variant. Haplotype studies are in progress for seven SNP markers spanning 200kb upstream and 35kb downstream of the GBA gene. Results for five SNP markers upstream of GBA (rs9628662, rs2242577, rs2361543, rs932972, rs11264372) show complete LD with the frequently observed c.222-224delTAC mutation, supporting a founder hypothesis for this allele. Ethics approval for this research project has been obtained (M030201).

Mapping the Location of Acetylated H3 Histones as a Method to Identify Transcriptional Regulatory Elements in Risk Genes: Application to Reading Disabilities. *C. Barr[1,2,3], I. Livne-Bar[1], Z. Xu[1], T. Cate-Carter[2], R. Tannock[2], E. Kerr[2], M. Lovett[2], R. Bremner[1], J. Couto[1,2,3]* 1) Genetics and Development, Toronto Western Hosp, UHN, Toronto, ON, Canada; 2) Program in Neurosciences and Mental Health, Hospital for Sick Children, Toronto, Canada; 3) Institute of Medical Sciences, University of Toronto, Toronto, Canada.

Introduction: Specific histone modifications (e.g. H3 and H4 acetylation, methylation) mark transcription regulatory elements (e.g. promoters, enhancers) and this property of histones has recently been used as a means for identifying regulatory regions across large genomic regions. Evidence for linkage/association to reading disabilities (RD) on chromosome 6p22 has been supported by multiple studies with recent studies pointing to DCDC2 and KIAA0319 as the most likely candidate. Further, a correlation with reduced gene expression and a KIAA0319 risk haplotype has been reported, indicating a change in gene expression as contributing to risk. Methods: To identify gene regulatory elements for these genes, we used chromatin immunoprecipitation to acetylated histone 3 (H3ac) coupled with genomic tiling arrays (ChIP-chip) to identify regions marked by acetylated histones across a 500 kb genomic region in mouse, syntenic to the region on 6p22. Results: We identified a region marked by H3ac spanning the first untranslated exon of KIAA0319. Five markers previously associated with RD in independent studies were located within this acetylated region. An additional 4 polymorphisms associated to RD, including the most significant marker in our families, were located within a 22 kb haplotype block that encompassed the acetylated region. Conclusions: These results support this putative regulatory region as the likely site of genetic variation contributing to RD on 6p and narrowing the region necessary to screen for the susceptibility alleles. This study is the first to use the position of modified histones as a method for identifying gene regulatory regions as the site of DNA variation contributing to a genetic trait.

Methods of Educating the Next Generation in Genetics and Genomics Science. *S.E. Harding, V.L. Bonham, C.L. Easter, D.H. Lea, J. Witherly* Education and Community Involv, National Human Genome Research Institute/NIH, Bethesda, MD.

The overall goal of this presentation is to describe two genomic science education programs developed by the National Human Genome Research Institute (NHGRI) for students and faculty. The NHGRI Education and Community Involvement Branch (ECIB), created in 2003, serves as a liaison between NHGRI and the public to inform the public of the latest advances in genomics. One of ECIBs main strategies is to reach out to high school and college faculty who have shown an interest in genetics and genomics but who have not yet integrated these topics into their curricula, as well as high school and college students who have shown an interest in science and genetics but have not yet determined their career path. To that end NHGRI established a Current Topics in Genomic Research Short Course in 1997 to engage students and faculty from underrepresented minority institutions to incorporate genomics into the curriculum and to expose students to genomic research careers. Over the past 10 years, 300 faculty and students from underrepresented minority and rural institutions have participated in the Short Course. ECIB also reaches out to students across the country with National DNA Day, a nationally recognized science education program aimed at high school students. NHGRI partners with ASHG, the Genetic Alliance and the National Society of Genetic Counselors to connect genetics professionals with science classrooms around the country. Through the use of educational materials, online resources and speakers, students learn about the latest advances in genetics, as well as ways they might get involved in the field. Beginning in 2005, high school students across the nation have been invited to take part in a live, on-line Chatroom staffed by NHGRI. In 2007 NHGRI staff received a 52 percent increase in questions from 2006 and responded to a total of 648 questions answered in the 10 hour period. In this presentation, the two programs will be described including the number of students and faculty reached; the number and type of institutions participating; results of evaluations indicating how information has been used by participants; and how these programs can be adapted.

Genetic mechanisms of trinucleotide repeat instability in Drosophila. *J. Jung*[1], *N.M. Bonini*[1, 2] 1) Department of Biology, University of Pennsylvania, Philadelphia, PA; 2) Howard Hughes Medical Institute.

Expansion of trinucleotide repeat sequences is responsible for over 20 human diseases, including polyglutamine (polyQ) diseases caused by CAG repeat expansions and Fragile X syndromes or Myotonic Dystrophy caused by CGG or CTG repeat expansions in the non-coding part of respective genes. Disease phenotype and the age of disease onset are strongly affected by repeat expansions. However, mechanisms of repeat expansions in vivo remain poorly understood. Previously, we have reported the development of a Drosophila model of germline trinucleotide repeat instability, which recapitulates key features of human repeat instability. Utilizing the model, we uncovered two novel modifiers of repeat instability, nucleotide excision repair (NER) and CREB-binding protein (CBP). Moreover, through genetic or pharmacological treatments targeting NER or CBP, we were able to suppress trinucleotide repeat expansions, presenting a potential therapeutic opportunity to suppress repeat instability. Currently, We are conducting a genome-wide genetic screen to identify additional modifiers of repeat instability. We will report the progress in our modifier screen during the meeting.

Genome-Wide Association Study of Major Depression. *S.P. Hamilton[1], J.B. Kraft[1], E.J. Peters[1], H.A. Garriock[1], G.D. Jenkins[2], M.S. Reinalda[2], P.J. McGrath[3], S.L. Slager[2]* 1) Department of Psychiatry and Institute for Human Genetics, University of California, San Francisco, CA; 2) Division of Biostatistics, Mayo Clinic College of Medicine, Rochester, MN; 3) New York State Psychiatric Institute and Columbia University, New York City, NY.

Background: Major Depressive Disorder (MDD) is a common and disabling psychiatric illness determined to be influenced by genetic factors. Candidate gene approaches to identifying risk genes for depression have not provided meaningful findings. We have thus undertaken a genome-wide association study to look for novel genetic determinants of susceptibility to MDD. Methods: We used a subset of 780 MDD cases who are enrolled in the antidepressant trial Sequenced Treatment Alternatives to Relieve Depression (STAR*D). We used 895 controls from the NIMH Center for Collaborative Genetic Studies on Mental Disorders who did not meet lifetime criteria for MDD. All subjects were genotyped on 500K Affymetrix mapping arrays. Filtering of SNP genotype data was carried out by call rate and Hardy-Weinberg equilibrium. Single locus association tests were performed using the Armitage trend test. Results: Preliminary analyses indicate a greater than expected number of associations meeting genome-wide levels of statistical significance. We are determining the empirical significance of our association findings. Assessments of population structure differences between the STAR*D cases and NIMH Controls demonstrates that the populations are largely similar. Conclusions: Our initial results suggest promising novel genes and chromosomal regions that are associated with MDD. However, these results from our first stage of the study will need to be confirmed in our validation stage.

Detection sensitivity of DNA methylation status using high resolution melting on the LightScanner. *C. Hough, J. McKinney, L. Cutler, D. Teng* Idaho Technology, Inc. 390 Wakara Way, Salt Lake City, Utah 84108.

DNA methylation is a frequent epigenetic modification of CpG dinucleotides. Aberrant DNA methylation patterns within CpG islands of many gene promoters have been associated with increased cancer risk. CpG island hypermethylation results in stable gene silencing as noted in cancer and aging as well as in normal development, imprinting, and X-chromosome inactivation. In contrast, global genomic CpG hypomethylation has been demonstrated in aging and early neoplasia. Traditional methods for determining methylation status include bisulfite conversion of all unmethylated cytosines to uracil followed by PCR amplification and direct sequencing. Methylated cytosines remain unconverted and can be easily identified by sequencing. We sought to systematically evaluate whether the methylation status of DNA could be reliably detected by high resolution melting using the LightScanner instrument. Such pre-sequencing detection could allow for a decreased sequencing effort if methylation detection using Hi-Res melting is robust and sensitive. To create methylation status controls, untreated and SssI-treated pBluescript II plasmid were bisufite converted using the Qiagen EpiTect kit. Sequencing of a representative region confirmed complete methylation and bisulfite conversion of the samples. Primers were designed to amplify 7 different fragments with a size range of 79-216 bp and 1-8 CpG sites interspersed throughout. The 100 percent methylated and unmethylated samples were run straight and mixed at the following percentage of methylated sample: 50, 40, 30, 20, 15, 10, 5, and 2 percents. The 100 percent methylated and unmethylated samples were easily distinguishable. When the two samples were mixed at the above ratios, the melting profiles showed a reproducible dose-response type relationship, with the 50 percent mix having the greatest deviation from the unmethylated standard. Hi-Res melting was sensitive enough to detect methylation status down to 2 percent in certain fragments. Hi-Res melting appears to be a sensitive method for pre-sequencing detection of methylation status.

Comprehensive genetic analyses using a modified whole genome amplification protocol and microarrays to identify genetic disorders and determine embryo implantation from single cells. *W.G. Kearns[1], R. Pen[1], A. Benner[1], E. Widra[2], R. Leach[1]* 1) Shady Grove Center for Preimplantation Genetics, Rockville, MD; 2) Shady Grove Fertility Reproductive Science Center, Rockville, MD.

Purpose: To optimize molecular genetic experimental techniques to successfully amplify DNA from single cells and perform a complex genetic analysis from preimplantation embryos using microarrays.

Design: Prospective study

Methods: A modified whole genome amplification protocol was performed on 185 single cells (3pns, 2pns, white blood cells (wbcs) and cell lines) to optimize DNA extraction and amplification protocols from single cells. We used invariant DNA genomic loci for each chromosome arm to ensure the entire genome was amplified and TaqMan PCR to ensure heterozygous allele amplification. A modified microarray analysis using single nucleotide polymorphisms (snps) was employed to determine total numerical chromosome abnormalities, structural chromosome aberrations, to identify what partner provided the extra aneuploid chromosome, to determine what embryo implanted, to identify epigenetic changes, and to identify single gene or mitochondrial disorders.

Results: Our initial results showed a genomic coverage > 75% with heterozygous allele detection in 60% of cells. The detection rate ranged from 63.9% to 78.1% and a genotype call rate from 42.2% to 48%. Experimental modifications on wbcs and 2pns increased our genomic coverage to > 98% with heterozygous allele detections > 90%. Our detection rate ranged from 95% to 98.1% and a genotype call rate of 95% to 96%.

Conclusion: Using an optimized whole genome amplification protocol and DNA microarrays, we can successfully provide a comprehensive genetic analysis on single cells.

Detecting unusual genotypic patterns in a single subject. *S-A. Bacanu, M.R. Nelson, E. Foot, M. Ehm, A. Slater*
GlaxoSmithKline, Res Triangle Park, NC.

Many adverse drug reactions (ADRs) are rare, and may only be observed in a small number of cases. Consequently, the limited number of cases for pharmacogenetic studies presents a challenge for analysis and inference using traditional methods. Under certain circumstances, we may even wish to make inferences about possible genetic causes within a single case. Even for larger case sample sizes, if we suspect the ADRs are genetically heterogeneous, it may be more appropriate to attempt case-specific genetic inferences. In such instances, instead of aggregating the information at each marker (usually single nucleotide polymorphisms, or SNPs) among cases, we choose to aggregate the genotypic information among different adjacent markers for each case and obtain a statistic capturing the likelihood of those patterns against a reference control set. The distribution of this statistic under the null hypothesis is estimated by computing the same statistic for each control relative to the pattern found in the remaining controls. An appropriate p-value comparing the case statistics relative to controls statistics is obtained using a newly developed method for bounding tail probabilities for a large class of distributions. Using this method we estimate the power to detect genetic aberrations such as deletions, loss-of-heterozygosity (LOH), translocations and inversions as a function of the number of SNPs spanning the aberrations and the linkage disequilibrium among SNPs. We apply this method to investigate if any such unusual genotypic patterns occur in a study involving one ADR case suspected of having LOH in a drug-modifying gene.

A neurological examination score for the assessment of spinocerebellar ataxia. *L. Jardim[1,3], C.R.M. Rieder[2], A. Chaves[1], C.R. Cecchin[1], T.L. Monte[2], R. Giugliani[1,4], C. Kieling[1]* 1) Medical Genetics Service, Hospital de Clinicas, Porto Alegre, RS, Brazil; 2) Neurology Service, Hospital de Clinicas, Porto Alegre, RS, Brazil; 3) Department of Internal Medicine, UFRGS, RS, Brazil; 4) Department of Genetics, UFRGS, RS, Brazil.

Objective: Spinocerebellar ataxias are a group of autosomal dominant disorders characterized by a highly heterogeneous set of genetic and clinical manifestations. The purpose of this work was to assess the neurological features of spinocerebellar ataxias, and to describe and test the feasibility, reliability and validity of a comprehensive neurological examination score (NESSCA). Methods: The NESSCA was administered to patients who were molecularly diagnosed with spinocerebellar ataxia type 3 (SCA3) at an outpatient neurogenetics clinic. The scale, based on the standardized neurological examination, consisted of 18 items that yielded a total score ranging from 0 to 40. The instruments interrater reliability and internal consistency were investigated, and a principal components analysis and correlation with external measures were performed. Results: Ninety-nine individuals from 58 families were evaluated. Interrater reliability ranged from 0.8 to 1 across individual items ($p<0.001$); internal consistency, indicated by Cronbachs alpha, was 0.77. NESSCA scores were significantly correlated with objective measures of disease severity: disease stage ($rho=0.76$, $p<0.001$), duration ($rho=0.56$, $p<0.001$), and length of CAG tract ($rho=0.30$, $p<0.05$). Discussion: The NESSCA is a reliable instrument for the assessment of distinct neurological deficits in SCA3 patients. Global scores correlated with all external variables tested, showing the NESSCA to be a comprehensive measure of disease severity that is both clinically useful and scientifically valid. Further studies are required to evaluate its correlation with recently developed ataxia rating scales, as well as its suitability for rating other SCA.

A Fine-Mapping analysis of the MHC region in IgA Deficiency. *R.C. Ferreira[1,4], W. Ortmann[1,4], P.K. Gregersen[2], L. Hammarström[3], T.W. Behrens[1,4]* 1) University of Minnesota, Minneapolis, MN, USA; 2) Feinstein Institute for Medical Research, Manhasset, NY, USA; 3) Karolinska University Hospital Huddinge, Stockholm, Sweden; 4) Current address: Genentech, Inc., South San Francisco, CA, USA.

IgA Deficiency (IgAD) is the most common primary immune deficiency in humans, with an estimated prevalence of approximately 1/500 in Caucasians. Although the genetic basis of IgAD is well established, the characterization of the susceptibility loci is still an ongoing process. Previous studies have shown association of major histocompatibility complex (MHC) haplotypes with IgAD, and we have recently shown that *MSH5*, located in the central MHC region, is a strong candidate gene for IgAD.

The MHC, located in human chromosome 6, contains a high density of genes expressed in the immune system, and is characterized by a high level of linkage disequilibrium (LD). In order to identify all the genetic variation contributing to the MHC signal in IgAD, the International MHC Autoimmunity Genetics Network (IMAGEN) initiated a fine mapping effort of the MHC in IgAD, using a 1,230 SNP panel spanning the entire MHC region. These SNPs were chosen to tag all common European haplotypes across the MHC.

Here we report the results from the fine mapping effort of the MHC in a cohort of 264 Swedish IgAD patients and 657 matched controls. We found a very high level of association across the MHC, with the main peak of association being located at SNP rs3134942, located between the MHC class II and class III regions ($P = 2.1 \times 10^{-16}$). In total, 116 SNPs showed P values $< 10^{-8}$. Haplotype analysis showed that the strongest signals derived from an extended HLA-A1-B8-DR3 haplotype. Conditional regression analysis was then used to characterize DR3-independent SNP variation contributing susceptibility to IgAD. This analysis identified SNPs that tag for the ancestral DR2 haplotype as strongly protective for IgAD. These data identify common risk and protective MHC haplotypes for IgAD in Swedish cases, and are consistent with the hypothesis that several genes in the MHC, including *MSH5*, contribute to IgAD risk.

Novel combinatorial optimisation methods to partition large pedigrees for genetic analysis. *D. Brocklebank, J. Gayán, L.R. Cardon* Dept. Statistical Genetics, WTCHG, University of Oxford, UK.

Large multigenerational pedigrees are powerful resources for the identification of genetic loci influencing traits. However, there are computational limitations to the analysis of these large families, despite the substantial advances which have been incorporated in pedigree analysis software packages. Methods for genetic analysis impose varying constraints on the complexity of the inheritance information they can analyze. The identification of computationally feasible pedigree structures for genetic analysis has emerged as a crucial factor for detecting loci influencing disease traits. Our aim here is to maximally exploit the information contained in large pedigree resources while allowing for tractable statistical analyses. We have developed two new combinatorial optimisation methods, based on simulated annealing and genetic algorithms. The algorithms search over the space of possible sub-pedigrees that conform to a given constraint imposed by a statistical test. An important feature of the methods is that they optimise the pedigree structures for information retained for analysis with direct control over the complexity of the simplified output pedigree, so that, for example, one can extract the largest sub-pedigrees that still permit practical analyses in Merlin, Allegro or SimWalk2. We apply the methods to real extended and inbred human and animal pedigrees, and show that the complexity of the pedigree structures identified by the methods strongly influences the power for linkage analysis. Maximal exploitation of the information contained in large pedigree resources, and their success, is thus expected to rely substantially on analyzing the most highly complex pedigrees that are tractable for a given analysis. Our methods aim to provide a systematic approach to extract maximum information for analysis and to advance the effective use of complex pedigree structures.

Glucagon is a Thrifty Gene in Mexican Americans. *C.S. Carlson[1], M.O. Goodarzi[2], A. Reiner[3], X. Guo[2], L.J. Raffel[2], A. Xiang[4], T.A. Buchanan[4], W.A. Hsueh[5], D. Siskovick[3], J.I. Rotter[2], M.J. Rieder[3], D.A. Nickerson[3]* 1) Fred Hutchinson Cancer Research Center, Seattle, WA; 2) Cedars-Sinai Medical Center, Los Angeles, CA; 3) University of Washington, Seattle, WA; 4) USC Keck School of Medicine, Los Angeles, CA; 5) David Geffen School of Medicine at UCLA, Los Angeles, CA.

The glucagon gene (GCG) encodes several hormones that play important roles in glucose homeostasis: GCG, GLP1 and GLP2. On the basis of genomic re-sequencing data, patterns of sequence diversity at GCG in European Americans (EA) are consistent with a recent positive selective sweep, while patterns in Mexican Americans (MA) suggest positive selection for a second, highly divergent haplotype in the Americas. This MA haplotype is tagged by the G allele of an A/G SNP (rs6732914). We used a GEE approach to assess the association between the G allele and fasting glucose in the Mexican American Coronary Artery Disease study, a population of adult offspring of CAD patients, and observed a mean increase in fasting blood glucose of 2.4 mg/dl in G allele carriers as compared to AA homozygotes ($p=0.045$). This association was robust to adjustment for population stratification using 145 microsatellite genotypes. We confirmed this association in the Mexican American Hypertension and Insulin Resistance study, in which the families of hypertensive probands had glucose phenotypes available, where QTDT analysis demonstrated a significant increase in fasting glucose for G allele carriers ($p=0.016$).

In vitro tests of the A/G polymorphism in a GFP expression system show significantly reduced mRNA expression from the G allele. The SNP alters the poly-A cleavage site, so the decreased expression is likely attributable to altered mRNA turnover. The G allele is common in Mexican Americans and African Americans (populations at high risk of diabetes) but rare in European Americans and Asian Americans, providing support to the 44 year-old hypothesis that glucagon is a thrifty gene. This polymorphism may have important consequences for the utility of glucagon-derived therapeutics.

Combining SNP genotype data and hybridization intensity to simultaneously detect and test deletions for disease association. *J.R. Kohler, D.J. Cutler* Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD.

Elucidating the role of copy number variation in complex disease has proven difficult. Showing association between any variant and complex disease requires large study designs and accurate estimates of frequency for the variant. Our program, *microdel*, is the first tool capable of using trio-based SNP genotype data to both detect deletions at high power and assign accurate estimates of the deletion frequency, thereby facilitating association testing. In realistic simulations using 100 trios with 1 SNP per 6 kb, *microdel* can detect deletions as small as 20 kb or as rare as 5% frequency with greater than 80% power. Using this approach on the HapMap 16c data, we report 693 deletions with 253 validated by previous studies.

Our improved version, *microdel v2*, is the first tool capable of combining both genotype data and hybridization intensity to detect deletions in SNP genotyping studies. *Microdel v2* handles inherent error in the methods used to call copy number from hybridization intensity, effectively increasing power to detect real deletions while eliminating false positives as our false positive deletion detection rate is ~10^{-6} per SNP. Using 1000 trios, *microdel v2* is limited only by SNP density and deletion frequency and in realistic simulations has ~100% power if a SNP falls within the deletion and the deletion has frequency > 0.5%.

Genotyping studies may or may not have family data. Thus, it is important to develop tools capable of analyzing both family-based and unrelated sample data. *Microdel v2* facilitates analysis of unrelated individuals, alone or in combination with family data. To accomplish the former, prior information concerning error rates and missing data rates at each SNP must be available, easily derived from previous applications of *microdel v2* to familial samples or perhaps from clustering characteristics of hybridization intensities. Thus, these tools incorporate all information from SNP arrays into a single framework and enable simultaneous discovery and testing of deletions for disease association using both family-based and unrelated sample designs.

Genome-wide analysis of RUNX/AML target genes. *L. Cao, Y. Liu, J. Paschal, A.M. Bowcock* Dept Genetics, Washington Univ, St Louis, MO.

RUNX1 is a member of the RUNX family of transcription factors and is involved in the development of hematopoietic cells. Recent genetic association studies have revealed a potential role for RUNX targets in the development of some inflammatory diseases including systemic lupus erythematosus, rheumatoid arthritis and psoriasis. In these instances, an associated SNP allele lies within a RUNX binding site, and leads to an increase in inflammation when compared to the effects of the other allele. RUNX1, 2 and 3 recognize the same target sequences and a RUNX3 knockout mouse has an inflammatory phenotype that includes asthma and inflammatory bowel disease. This provides further evidence that genes regulated by these transcription factors are important in the pathogenesis of inflammatory diseases. To identify RUNX targets that may play important roles in the prevention of autoimmune and inflammatory diseases we have performed chromatin immunoprecipitations (CHIP) from Jurkat T cells, using a RUNX1 antibody. RUNX1 pulldown DNA was either sequenced following conventional cloning and transformation, or after sequencing with 454 technology. With conventional cloning approaches we identified 61 potential RUNX1 targets that were pulled down more than twice. A search for RUNX1 transcription factor binding sites revealed that each of these 61 genes/regions contains at least 2 AML-1 binding sites. Four RUNX1 targets (CANX, ASCC1, SPINK5 and a novel gene) were further confirmed as being RUNX1 targets with electrophoretic mobility shift assays. SPINK5 (serine peptidase inhibitor, Kazal type 5) alterations are associated with the inflammatory skin disease Netherton syndrome and the common inflammatory skin disease, atopic dermatitis, and CANX (calnexin) is a major histocompatibility complex class I antigen-binding protein. Sequencing of RUNX pull down DNA fragments with 454 technology has permitted an analysis of over 24,000 potential RUNX targets and revealed a powerful method for the identification of additional targets that does not involve the bias created by conventional cloning and transormation methodologies.

New approaches to understand the genetic differences between classic Rett syndrome and Preserved Speech Variant. *F. Ariani[1], E. Scala[1], R. Caselli[1], F. Papa[1], R. Artuso[1], MA. Mencarelli[1], I. Meloni[1], F. Mari[1], M. Zappella[2], G. Hayek[2], DH. Yasui[3], JM. LaSalle[3], A. Renieri[1]* 1) Medical Genetics, Dept Molecular Biol, Univ Siena, Siena, Italy; 2) Child Neuropsychiatry, Univ Siena, Siena, Italy; 3) Medical Microbiology and Immunology, Rowe Program in Human Genetics, School of Medicine, University of California, Davis, CA.

In classic Rett (RTT), the III stage is characterized by mild improvement of eye contact. At the same stage, the Preserved Speech Variants (PSV) recover the ability to speak and to use hands. Both phenotypes are due to similar or identical de novo mutations in MECP2 (http://www.biobank.unisi.it and Sampieri, Hum Mut 2007). In order to understand the genetic differences between the two phenotypes, we have: i) searched for statistically significant differences in allele frequencies of polymorphisms in genes associated to a similar phenotype (CDKL5) or target genes (BDNF); ii) analyzed differences in genomic variations by array-CGH in two sisters with discordant phenotype, balanced XCI, and the same MECP2 partial deletion absent in parents. We have established that the p.Q791P CDKL5 polymorphism is not involved in the modulation of epilepsy in RTT (p=0.373). Array-CGH analysis on the above described RTT sisters showed a duplication of 390 Kb on chromosome 16 in the classic RTT girl inherited from the healthy father and absent in the PSV sister. The duplication includes 10 genes. Two are disease-genes: one related to a known myopathy and the other to a CNS disease. Chromatin immunoprecipitation promoter array (ChIP-chip) analysis identified three potential MeCP2 target genes within the duplicated region. Real Time RT-PCR experiments are ongoing to analyze the combined effect of MECP2 defect and 16p duplication on the expression of these three genes. Understanding the genetic differences between classic RTT and PSV will help in designing therapeutic strategies.

Identification of ancestrally informative regions in Latinos using whole genome SNP data. *S. Kim[1], R. Jiang[2], C. Shtir[2], R. Varma[2,3], P. Marjoram[2], J. Wall[1]* 1) Institute of Human Genetics, UC San Francisco, San Francisco, CA; 2) Department of Preventive Medicine, Keck School of Medicine, USC, Los Angeles, CA; 3) Doheny Eye Institute and Department of Ophthalmology, Keck School of Medicine, USC, Los Angeles, CA.

Standard admixture mapping requires the identification of ancestrally informative markers (AIM), which often incur additional experimental costs in genome-wide association studies. Having a method for conducting admixture mapping that does not require AIMs would be both easier and cheaper than the current protocols. Here we explore the feasibility of using new methods for estimating genetic ancestry directly from whole genome SNP sets, such as the Affymetrix 500K. We identified regions suggestive of high Native American ancestry in our sample of Latinos from the Los Angeles Latino Eye Study. These regions may serve as candidate regions that may harbor susceptibility genes for traits with higher incidence rates in Native Americans compared to Europeans.

Study of evolutionary conserved regions on the vicinity of COL18A1 reveals putative functional sequences. *E. Kague[1], S. Fisher[2], S.L. Bessling[2], M.R. Passos-Bueno[1]* 1) Department of Genetic and Evolutive Biology, Universidade de Sao Paulo, Sao Paulo, Brazil; 2) Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, USA.

COL18A1 has 43 exons that transcribe three isoforms from two different promoters. The three isoforms display complex patterns of tissue-specific expression, including in kidney, lung, brain, and retina. Mutations in COL18A1 lead to Knobloch Syndrome, an autosomal recessive disease characterized by vitreoretinal and macular degeneration and occipital encephalocele. We analyzed the promoter of COL18A1 short isoform with luciferase assays and transfections in HEK293T cells of 5` COL18A1 deletion constructs. It revealed a core promoter between -103 and -270bp from the transcription start site, and two other important regions between -540 and -750, and -919 and -1030. We also evaluated non-coding sequences associated with COL18A1 for transcriptional regulatory activity using in vivo assay in transgenic zebrafish. Sequences were selected based on evolutionary conservation using VISTA (>100pb and >75% identity with mouse) and PhastCons programs, resulting in 21 regions. These regions and 4 promoter constructs were assayed for their ability to drive EGFP expression in mosaic injected embryos. For comparison, whole embryo in situ hybridizations were carried out to evaluate endogenous col18a1 expression in zebrafish embryos. None of the human promoter constructs leads to expression in zebrafish embryos. However, 9/21 conserved non-coding regions drove expression consistent with endogenous zebrafish col18a1. Four constructs drove EGFP expression in pronephic duct at 1 dpf, a prominent site of col18a1 expression. Additional tissues where expression was observed included notochord, cartilage, retina, forebrain, otic vesicle, pectoral fin, cranial blood vessels and connective tissue of the fin. The regions selected with VISTA program were also analyzed by transfections in cells with high (HEK293T) and low (HeLa) endogenous expression of COL18A1. 9/13 increased luciferase expression at least 4 fold, and there were no difference between transfections in HEK293T and Hela cells.

The MSH2 sequence variant p.Gly322Asp (c.965GA) is a benign polymorphism. *T.B. Bradley[1], N. Williams[1], D. Reinhardt[1], N. Andrew[2], D.U. Baty[2], H.R. Davidson[3], Z. Miedzybrodzka[4], M.G. Dunlop[5], M.E. Porteous[1], J.P. Warner[1]*
1) Molecular Genetics Service, Western General Hospital, Edinburgh, UK; 2) Molecular Genetics Laboratory, Ninewells Hospital, Dundee, UK; 3) Duncan Guthrie Institute of Medical Genetics, Yorkhill Hospital, Glasgow, UK; 4) Department of Medical Genetics, University of Aberdeen, UK; 5) MRC Human Genetics Unit, WGH, Edinburgh, UK.

Variations in the mismatch repair genes contribute to the pathogenesis of hereditary non-polyposis colorectal cancer (HNPCC). In Scotland, MLH1, MSH2 and MSH6 gene analysis, using bidirectional sequencing and Multiplex Ligation-dependent Probe Amplification (MLPA), is carried out for Amsterdam positive families. If tumor specimens are available, microsatellite instability studies (MSI) and immunohistochemical (IHC) staining are performed. Medium risk families are pre-screened and only patients with tumors showing loss of staining or MSI are selected for gene analysis. The confirmation that sequence variants identified by gene analysis are pathogenic and causative is critically important as misleading predictive test results could lead to inappropriate withdrawal of routine surveillance. The MSH2 missense variant p.Gly322Asp (c.965GA) has been reported both as a pathogenic and a benign variant. DNA from 630 affected patients from high and medium risk HNPCC families was tested and this variant was present in 14 (2%). In a control cohort of 400 DNAs from individuals with no known family history of colorectal cancer it was seen in 16 (4%). Typical p.Gly322Asp pedigrees from our colorectal patient panel are illustrated. A family with an individual homozygous for p.Gly322Asp, who developed colorectal cancer aged 60 and a second family with p.Gly322Asp in combination with an MSH6 exon 5-6 deletion are shown. All tumors analysed, where the variant p.Gly322Asp was seen were MSI low. SIFT analysis (http://blocks.fhcrc.org/sift/SIFT.html) using a panel of representative proteins shows that this position is unlikely to be critical to MSH2 protein function. These data provide conclusive evidence that the variant p.Gly322Asp is a benign polymorphism.

Strong Evidence for a Genetic Component to Multiple Myeloma and Pleiotropy with Other Hematologic Malignancies. *N.J. Camp, T.L. Werner, L.A. Cannon-Albright* University of Utah School of Medicine, USA.

A familial component of Multiple Myeloma (MM) has been suggested. However, only 1st degree familial relative risks (FRRs) have so far been reported. Analyzing beyond 1st degree is important because shared environment decreases for distant relatives and familiality can more readily be interpreted as evidence for a genetic component. Here we have performed FRRs for 1st, 2nd and 3rd degree relatives and genealogical index of familiality (GIF) analyses using data on all relatives. We investigated subgroups of MM based on sex, diagnosis age and survival to identify highly familial subtypes, and also the relationship between MM and other hematological and solid cancers to identify potential overlapping etiologies (pleiotropy). We used the Utah Population Database (UPDB) for our analyses. The UPDB is a unique resource, including genealogical data and Utah Cancer Registry data for all cancers diagnosed in Utah since 1966. We used UPDB data for the approximately 2 million individuals with genealogical data (3-10 generations) available. Strong evidence for familiality was found for MM, with significant excess risk apparent from both the GIF analysis ($p<0.001$) and in the FRR analyses out to 3rd degree relatives (FRR 2.69, 1.51 and 1.21 for 1st, 2nd and 3rd, respectively). No evidence for highly familial MM subtypes was found. Investigating other hematologic malignancies, chronic lymphocytic leukemia (CLL) was found in significant excess in the 1st and 2nd degree relatives of MM, and Non-Hodgkin Lymphoma (particularly B cell type, NHLB) in 1st. In complement, MM was found in excess in the 1st degree relatives of individuals with CLL and NHLB. Further, CLL was in excess in the relatives of NHLB. For solid cancers, prostate cancer and melanoma were significantly increased in 1st, 2nd and 3rd degree relatives of MM and in the cases themselves. Prostate cancer was observed in excess in NHLB and CLL, too. It is of note that characteristics such as diagnosis age, gender distribution and survival are also similar for these three malignancies. Our results indicate a strong genetic component to MM and suggest a potential for pleiotropic genes involved in MM, CLL and NHLB.

A Practical Approach: Multiplex Ligation-Dependent Probe Amplification (MLPA) Analysis of Deletions/Duplications in CFTR Gene Using Whole Genome Amplification (WGA). *L. Chou[1], K. Sumner[1], E. Lyon[1,2]* 1) Institute for Clinical and Experimental Pathology, ARUP Laboratories, Salt Lake City UT 84108-1221, USA; 2) Department of Pathology, University of Utah School of Medicine, Salt Lake City, UT 84132, USA.

In clinical diagnostic laboratories, a common challenge in validating a genetic test is the lack of positive controls. Positive controls are hard to obtain, because they are rare and/or have limited amounts (e.g. prenatal samples). Such samples are inadequate for reproducibility studies or as controls in routine testing. Copy number variations (CNV) techniques such as array CGH usually require large quantities of initial DNA input. There are reports describing the success of using whole genome amplified (WGA) samples with array CGH. However, there is no study regarding the use of WGA samples with MLPA, a small scale, high-resolution technique to detect CNV. Here, we first report the results of using WGA with MLPA, with the CFTR gene as a disease model. After initial optimization, we found exonic deletions could be reliably identified by MLPA using WGA samples. However, we observed consistent failures of one chromosomal control probe and one target specific probe. The reason of this failure is unknown; possible explanations include unexpected biased amplification affecting the quantitative analysis. In order to obtain reproducible results, three parameters need to be considered and optimized: DNA extraction method, post WGA purification, and initial DNA input for MLPA (>200 ng/uL). Based on these initial data, we conclude that it is possible to use WGA samples with MLPA technique.

Incorporating Quantitative Covariates into Multipoint Linkage Mapping Using Affected Relative Pairs. *Y. Chiu*[1], *J. Chiou*[2], *C. Lee*[1] 1) Biostatistics & Bioinformatics, National Health Research Inst, Zhunan, Miaoli, Taiwan; 2) Institute of Statistical Science, Academia Sinica, Taiwan, R.O.C.

Many dichotomous traits for complex diseases are often associated with quantitative covariates or traits. Incorporating these quantitative variables into linkage mapping could greatly improve the efficiency and precision in disease locus localization. Previously, we proposed a robust multipoint Identity-by-Descent (IBD) approach to estimate a disease locus using affected sib pairs with incorporation of a quantitative covariate (Chiou et al., 2005). In the present study, we studied the relative efficiency of estimating a disease locus with and without incorporating a quantitative covariate through a systematic simulation study. The quantitative covariate could be a quantitative trait associated with the disease through different genetic mechanisms. The information about the relative efficiency under different genetic models is also helpful to elucidate the relationship between a quantitative trait and the disease. We examined the relative efficiency of estimating a disease locus under a variety of pleiotropy and co-incident models of a quantitative trait. Further, we extended this approach to different types of affected relative pairs (ARPs). This extension allows us to account for heterogeneity in risk ratios for different ARPs when conducting linkage mapping. Different types of ARPs may provide some insight to the underlying genetic model of a disease. The collaborative study on the genetics of alcoholism (COGA) data released for GAW14 was used to illustrate the application of this extended method. We showed the efficiency was enhanced by using affected relative pairs than using affected sib pairs after incorporating the quantitative variable "maximum number of drinks in a 24 hour period" into the linkage mapping. This approach could also be applied to incorporate an additional categorical covariate using affected relative pairs. By applying this method to the same data set, we demonstrated the efficiency improvement in estimating the disease locus by incorporating "smoking status" into the linkage mapping using affected relative pairs.

DNA-repair genetic polymorphisms and breast cancer risk among Cypriot women. *A. Hadjisavvas[1], M. Loizidou[1], S. Malas[3], Y. Marcou[2], K. Kyriacou[1]* 1) Department of EM/Molecular Pathology, The Cyprus Institute of Neurology & Genetics, Nicosia, Cyprus; 2) Bank of Cyprus Oncology Centre, Nicosia, Cyprus; 3) Department of Oncology, Limassol General Hospital, Limassol, Cyprus.

Genetic factors are important in breast cancer but less than 20% are attributable to the inheritance of mutations in genes such as BRCA1 and BRCA2. The polygenic model of breast cancer suggests that there are multiple low-penetrance alleles which have a small effect on breast cancer risk. In an attempt to identify genetic variants which modify breast cancer risk we are contacting a case-control genetic epidemiology study using a cohort of 2286 Cypriot women (1109 patients and 1177 healthy controls). In the present study we genotyped 6 single nucleotide polymorphisms (SNPs) in genes which are involved in the DNA repair pathway: BRCA2 N991D, OGG1 S326C, RAD51 135G/C and 172G/C and p53 P72R. The prevalence of the 6 SNPs was compared between cases and controls. Odds ratios were generated from 2x2 tables, and statistical significance was assessed using the Pearson Chi-Square test.BRCA2 N991D was found at a significantly higher frequency in the population-based series of breast cancer patients (142/1086, 12.9%, odds ratio [OR] =1.42, 95% confidence interval [CI]= 1.09-1.85, p=0.01) than among population controls (112/1177, 9.5%). Furthermore, a marginally significant association between the p53 P72R variant and breast cancer was observed ([OR] (PP vs. PR+RR) =1.18, 95% CI (1.0-1.39), p=0.05). In addition, our results show that the effect of RAD51 135 C allele may be protective indicating that women who harbour this allele have a reduced risk of breast cancer compared with women who carry the G allele. These results suggest that a proportion of the SNPs under study are modifying breast cancer risk, but the effects of individual SNPs are likely to be small. Large numbers of samples will be needed to verify our results in other populations. We are currently expanding our analysis to include a greater number of SNPs and to evaluate potential underlying gene-gene or gene-environment interactions, in order to advance our knowledge on the effect of genetic polymorphisms on breast cancer susceptibility.

The fragile X protein controls GFP transgene expression in mouse neurons. *C. Dobkin[1], D. Ziemnicka[1], G. LaFauci[1], X. Ding[1], W.T. Brown[1], A. El Idrissi[2]* 1) Department of Human Genetics, NYS Institute for Basic Research, Staten Island, NY; 2) Department of Biology and Center for Developmental Neuroscience and Developmental Disabilities. College of Staten Island, CUNY, Staten Island, NY.

We analyzed Fmr1 protein (Fmrp) and enhanced green fluorescent protein (EGFP) expression in adult female mice that carried the Fmr1 knock out mutation on one X chromosome and the EGFP transgene on the other X. As expected, confocal fluorescent microscopy showed that, due to X inactivation, approximately 50% of brain cells were negative for both Fmrp and EGFP. Surprisingly we found that Fmrp immunoreactivity was discordant with EGFP fluorescence, even though both the functional Fmr1 gene and the EGFP transgene were located on the same X chromosome. Cells that were strongly immunopositive for Fmrp showed little or no EGFP fluorescence. In vitro analysis of cerebellar granule cells from male mice carrying this X-linked EGFP transgene also showed substantial discordance between EGFP fluorescence and Fmrp immunoreactivity. Activation of glutamate receptors increased EGFP fluorescence, as has been observed in other systems (Job & Eberwine, 2001) and also appeared to increase the coincidence of EGFP fluorescence and Fmrp immunoreactivity. These observations suggest that Fmrp represses translation of the EGFP message and that the repression may be relieved by glutamate receptor activation. Translation repression by Fmrp is thought to be relieved through a signal cascade initiated by metabotropic glutamate receptor activation (Baer, Huber & Warren, 2004). It is possible that the EGFP transgene can serve as an indicator of Fmrp activity and possibly of the mGluR signaling cascade. To illustrate the potential linkage between mGluR activation, Fmrp and EGFP expression, we will show the effects of translation inhibitors, mGluR receptor agonists and antagonists on EGFP fluorescence in cerebellar granule cells in vitro.

Survival in Machado-Joseph Disease (SCA3). *C. Kieling[1], P.R. Prestes[2], R. Giugliani[1,2], M.L.S. Pereira[1,3], L.B. Jardim[1,4]* 1) Medical Genetics Service, Hospital de Clinicas, Porto Alegre, RS, Brazil; 2) Department of Genetics, UFRGS, Porto Alegre, RS, Brazil; 3) Department of Biochemistry, UFRGS, Porto Alegre, RS, Brazil; 4) Departmento of Internal Medicine, UFRGS, Porto Alegre, RS, Brazil.

Machado-Joseph disease, one of the most prevalent autosomal dominant cerebellar ataxias, is a neurodegenerative disease that starts during adulthood, with patients presenting difficulties in gait, and later becoming bedridden. There is scarce data quantifying disease impact on patient survival. We then investigated the overall survival of a large series of MJD patients and compared it with the survival of their asymptomatic relatives. 412 affected and 413 unaffected individuals were ascertained from a consecutive sample of 82 families with a molecular diagnosis of MJD. Estimated mean survival time was 63.96 (95% CI, 62.09-65.83) and 78.61 years (95% CI, 74.75-82.47) for the affected and unaffected group, respectively ($p<.001$). Each additional year of birth increased the HR by 1.03. Mean age at onset was 36.37 years (95% CI, 35.21-37.53). Mean survival after disease onset was 27 years. Early onset and large CAG length predicted a shorter survival time. Therefore, MJD reduced survival, and this phenomenon was related to CAG length, age at onset, and year of birth.

***ATP1B1*, a hypertension candidate gene, has a conserved and polymorphic 3UTR element that regulates the selective polyadenylation of its mature mRNA.** *K. Bhalla[1], Z. Pan[2], A. Chakravarti[3], A.R. Shuldiner[1], B. Tian[2], Y-P.C. Chang[1]* 1) Division of Endocrinology, Diabetes and Nutrition, University of Maryland, Baltimore, MD; 2) Department of Biochemistry and Molecular Biology, New Jersey Medical School, Newark, NJ; 3) Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD.

Essential Hypertension, defined as chronically elevated blood pressure (BP) with no identifiable cause, is a significant risk factor for coronary heart disease, stroke, and renal disease. A previous genome-wide linkage scan for BP-related QTLs, followed by candidate gene association studies, identified several SNPs associated with BP levels in *ATP1B1*. This gene encodes the regulatory subunit of Na,K-ATPase, a key enzyme in maintaining renal sodium reabsorption and vascular smooth muscle tone. The most significant association signals came from 2 SNPs located in the highly conserved 3UTR of *ATP1B1*. This 3UTR contains multiple potential polyadenylation sites and adenylate/uridylate-rich elements (AREs) that reduce mRNA stability. Hence, the selective use of one poly(A) site over another can lead to mRNAs that differ in length, stability, and translation efficiency. By sequencing *ATP1B1* 3' UTR, we have identified a polymorphic and highly conserved T-rich track that is a putative downstream regulatory element important for cleavage and polyadenylation of mRNA. Alleles of this T-rich element can be grouped into 2 categories: $T_{21\text{-}24}$ and $T_{11\text{-}12}GT_3GT_6$. Using lymphocyte mRNA, we found that the ratio of *ATP1B1* mRNAs using the 5 versus 3 poly(A) signal depends on the genotype of this T-rich element (13.2 and 2.3 for $T_{21\text{-}24}$ homozygotes and $T_{21\text{-}24}/T_{11\text{-}12}GT_3GT_6$ heterozygotes, respectively). *In vitro* polyadenylation assays also showed that the $T_{21\text{-}24}$ motif has a lower polyadenylation activity than elements with $T_{11\text{-}12}GT_3GT_6$ (3.2 fold). In summary, we have identified a novel polymorphic element that regulates the expression of *ATP1B1*. However, whether variants in this T-rich element are directly responsible for the association between 3UTR SNPs with BP levels is unclear and requires additional studies.

Significant linkage on chromosome 5q35 for the disorganization dimension of schizophrenia revealed by quantitative trait linkage analysis. *D. Avramopoulos[1,2], J. Mcgrath[1], M. Mohseni[2], V.K. Lasseter[1], P. Wolyniec[1], M.D. Fallin[3], K.Y. Liang[3], D. Valle[2], G. Nestadt[1], A.E. Pulver[1]* 1) Dept. Psychiatry, Johns Hopkins Univ, Baltimore, MD; 2) Institute of Genetic Medicine, Johns Hopkins Univ, Baltimore, MD; 3) Bloomberg School of Public Health, Johns Hopkins Univ, Baltimore, MD.

Schizophrenia is a frequent heritable brain disorder with a peak onset between 18 and 35 years. Many linkage scans, two of which from our group, have attempted to locate genes for schizophrenia using varying research strategies. Apparent lack of consistency among scans may reflect the underlying genetic heterogeneity of schizophrenia, also likely reflected in its phenotypic heterogeneity. Latent structure analytic methods have been used to characterize this phenotypic heterogeneity, and the resulting latent classes or factors are considered more homogeneous aspects of the schizophrenia phenotype. We hypothesized that such factor scores might better reflect the individual's genetic makeup than the schizophrenia diagnosis alone, factors showing higher heritability presumably being more influenced by genes and thus more appropriate for linkage analysis. Using 73 items available for our collection of 1199 schizophrenia patients we performed a principal components factor analysis and developed a statistically supported nine factor model consistent to a large extent with previous reports. We used scores on factors with heritability > 0.3 as quantitative traits for a genome scan on 116 multiplex Caucasian pedigrees. We obtained a LOD score of 4.1 on chromosome 5q35 for the disorganization factor. This is a region previously reported by multiple linkage studies, in which however there was no significant linkage to the binary disease phenotype in our pedigrees. Our approach successfully reduced genetic heterogeneity providing significant linkage in a replicated region. Inconsistency in linkage findings might be in part due to studying less specific phenotypes.

Ancestral reconstruction of segmental duplications reveals punctuated cores of human genome evolution. *Z. Jiang[1], H. Tang[2], M. Ventura[3], M.F. Cardone[3], R. Hubley[4], A. Smit[4], X. She[1], P.A. Pevzner[5], E.E. Eichler[1,6]* 1) Department of Genome Sciences, University of Washington, Seattle, WA 98195; 2) School of Informatics and Center for Genomics and Bioinformatics, Indiana University,Bloomington, IN 47408; 3) Department of Genetics and Microbiology, University of Bari, 70126 Bari, Italy; 4) Institute for Systems Biology, Seattle WA, 98103; 5) Department of Computer Science and Engineering, UCSD, La Jolla, CA 92093; 6) Howard Hughes Medical Institute.

Human segmental duplications are hotspots for non-allelic homologous recombination leading to genomic disorders, copy-number polymorphisms and gene/transcript innovations. The complex structure and history of these regions has precluded a global evolutionary analysis. Combining a modified A-Bruijn graph algorithm with comparative genome sequence data, we identify the origin of 4,692 ancestral duplication loci/ and use these to cluster 437 complex duplication blocks into 24 distinct groups. The sequence divergence data between donor-acceptors pairs and a comparison with the chimpanzee and macaque genome support a punctuated model of evolution whereby at least 18 regions were formed by bursts of multiple independent duplication events. Our analysis reveals that human segmental duplications are frequently organized around core duplicons which are enriched for transcripts and associated with genes undergoing positive selection. We hypothesize that the rapid expansion and fixation of some intrachromosomal segmental duplications during great-ape evolution has been due to the selective advantage conferred by these genes/transcripts embedded within these core duplications. Using these data, we have developed a new program package called DupMasker which can be used to analyze the mosaic structure of duplication blocks in newly sequenced primate genomes.

Chromosome copy-number detection through methylation-sensitive DNA amplification and microarray analysis.

S. Brown[1], G. Brown[2], L.Y. Brown[1] 1) Dept OB/GYN, Univ Vermont, Burlington, VT; 2) Columbus Regional Hospital, Columbus IN.

Fetal DNA, most likely of trophoblast origin, is present in both the blood and cervical mucus of pregnant women and provides a potential basis for non-invasive fetal diagnostic tests. However, fetal DNA from both sources is generally highly contaminated with maternal DNA, and this contamination is the main technical challenge in trying to accomplish non-invasive detection of fetal chromosome abnormalities. Existing methods for the selective amplification of fetal DNA have generally relied on specific sequence differences between the mother and fetus. As an alternative, we have developed a method for selective amplification of fetal DNA that makes use of observation that trophoblast DNA is globally hypomethylated in comparison with DNA from other sources. In this method, a DNA mixture is first digested with a methylation sensitive restriction enzyme and then amplified by linker-mediated PCR. After an initial amplification, a second isothermal rolling circle amplification is performed. This procedure results in the differential amplification of short, relatively hypomethylated fragments. After amplification, the resulting representations are comparatively hybridized to a microarray consisting of oligonucleotides that correspond to restriction fragments generated by the initial digest. Copy number differences are then detected through statistical analysis of array addresses that have been previously shown to exhibit trophoblast-specific amplification. To test the feasibility of this method for detecting aneuploidy, we have prepared mixtures of peripheral blood DNA and first trimester trophoblast DNA from either normal or aneuploid samples. We present data showing that aneuploidy can be detected even when 90% of the starting DNA sample was derived from a euploid source and only 10% was from an aneuploid trophoblast sample. Future work will focus on testing whether our approach can be used for non-invasive prenatal diagnosis.

Felix the Double Helix: Teaching Elementary Students about DNA. *H.D. Edwards[1], W.J. Introne[1], A.M. Garcia[1], T.C. Markello[1], H.M. Dorward[1], M.A. Kayser[1], D.M. Krasnewich[1], G.A. Gahl[1,2], M.A. Merideth[1,2]* 1) NHGRI, NIH, Bethesda, MD; 2) Intramural ORD, NIH, Bethesda, MD.

Recent evidence supports the theory that early science education in children improves their natural scientific and math abilities (1). Given the paucity of curriculum material for genetics education of elementary-age children, we have designed an interactive educational project to teach kindergarten through second grade students about DNA through the use of a life-size costume: Felix the Double Helix. The main goals of this community outreach project are to introduce elementary students to science in action, and promote an interest in science The presentation, which lasts 30 minutes, incorporates the use of songs, a game and audience participation to meet 4 main teaching objectives: 1) What is DNA? 2) Where can we find DNA? 3) Why does Felix the Double Helix look the way he does? 4) How can we protect our DNA? The presentation is given in both English and Spanish to meet the needs of the primarily Spanish-speaking student population. Ultraviolet light beaded bracelets are distributed at the end of the program to reinforce the message about protecting DNA from sun damage by using sunscreen. Evaluation forms are given to the teachers and reviewed by the team to adjust the presentation based on their feedback . Continued development of curriculum to educate elementary school children will assist in meeting the goal of promoting science and math. Future plans for this project include finding optimal tools to assess the comprehension level of the children and expanding the program presentation materials to higher elementary school grade learning levels. 1) Gallenstein, NL. Engaging young children in science and mathematics. Journal of Elementary Science Education, 9/22/05.

Extreme sampling may improve power of admixture mapping for quantitative traits. *D. Hu, E. Ziv* Dept Medicine, Univ California, San Francisco, San Francisco, CA.

Admixture mapping can be used to map regions for complex traits in populations of mixed ancestry. Admixed populations consist of 2 or more ancestral populations which have mixed recently. The advantage of admixture mapping is that the recent admixture creates long range linkage disequilibrium between markers that have allele frequency differences in the ancestral populations. The main limitation of admixture mapping is that power depends strongly on the allele frequency difference of the causative variant(s). Admixture mapping has no power if the allele frequency of the causative variant(s) is identical in the ancestral populations. For quantitative traits, the power to detect a locus by association mapping may be enhanced by sampling the extremes of the distribution. We evaluate the power to detect a quantitative trait locus by admixture mapping using an extreme sampling approach (eg sampling from the top and bottom deciles of a distribution). We find that power remains considerably high even for loci with relatively modest allele frequency differences (0.15 - 0.2). In addition, this design is relatively immune to variation in the contribution of ancestral populations. Furthermore, in some cases, the power is greater for less common alleles with the same effect size and the same allele frequency difference. For example, assuming a marker with an allele frequency of 0.4 and 0.5 in 2 ancestral populations (allele freq difference 0.1) and an additive effect of 0.67/SD, with a sample size of 500/group sampled from the top and bottom deciles, we expect ~31% power to detect an effect with alpha 0.00005. Using the same assumptions about effect size, sample size, alpha and sampling scheme, we expect ~76% power to detect a marker with an allele frequency of 0.025 and 0.125 in 2 ancestral populations (allele freq difference 0.1). Thus, we conclude that admixture mapping for quantitative trait loci may benefit substantially from extreme sampling. Since many variants with allele frequency <0.15 in one population are often absent in other populations, this design may be an efficient approach to detecting such variants.

Repetitive Behaviors in Children with Autism and Maternal Prenatal Problems. *R.K. Abramson[1], A.V. Hall[2], S.A. Ravan[2], M.L. Cuccaro[3], J. Gilbert[3], M. Pericak-Vance[3], H.H. Wright[1]* 1) Dept Neuropsychiatry Univ South Carolina Sch. Med, Columbia, SC; 2) Dept Communication Sciences, Univ. South Carolina Sch. Public Health, Columbia, SC; 3) Univ Miami Inst Hum Gen, Miami, FL.

Leonard, 2006, in a population study identified common prenatal problems that increase risk for Autistic Disorder(AD). Little is known how specific prenatal factors affect expression of AD. This study will examine whether maternal prenatal problems are associated with specific behaviors in the child with AD. Subjects (n=149) were from the Duke/USC molecular study of AD. The ADI-R, Pregnancy Assessment Monitoring System (PRAMS), the Aberrant Behavior Checklist (ABC), and the Repetitive Behavior Scale-Revised (RBS) were completed for each child. Four prenatal factors were identified: infectious illness, F1; bleeding/early loss, F2; hypertension-edema- preeclampsia, F3; and diabetes, F4. One-way multivariate ANOVA revealed no significant results for the dependent variables of the ADI-R Q19 -Speech, the Insistence on Sameness Factor (Shao, 2003), or the ABC scores. There were significant results for F1 and RBS subscales Compulsive Behavior -CB, $F(1,149)=9.143$, $p=.003$; Ritualistic Behavior- RB, $F(1,149)=4.465$, $p=.036$; and Sameness Behavior- SAB, $F(1,149)=13.584$, $p=.000$. There were significant results for F3 and RBS subscales Stereotyped Behavior- SB, $F(1,148)=11.09$, $p=.001$ and Restricted Behavior- REB, $F(1,148)=8.707$, $p=.004$, and for F4 and SB, $F(1,148)=26.757$, $p=.000$; CB, $F(1,148)=8.703$, $p=.004$; and REB, $F(1,148)=21.414$, $p=.000$. There was a significant interaction between F3 and F4 for SB, $F(1,148)=19.358$, $p=.000$ and REB, $F(1,148)=9.951$, $p=.002$. Pearson correlations were significant between F1 and CB, $r=.197$, $p=.016$; RB, $r=.206$, $p=.012$; and SAB, $r=.273$, p=0.00l; between F4 and SB, $r=.270$, p=.00l; CB, $r=.202$, $p=.014$; and REB, $r=.277$, p=.00l; between F1 and ABC-irritability, $r=.149$, $p=.035$; and ABC-hyperactivity, $r=.148$, $p=.036$ and between F2 and ABC hyperactivity, $r=.141$, $p=.045$. Thus, there may be a relationship between certain prenatal problems and repetitive behaviors and prenatal infectious illness, an environmental factor, may affect the expression of repetitive behaviors in AD.

Role of the polyproline region in aggregate size and subcellular localization of mutant huntingtin. *J.W. Bradford[1,2], J.Y. Shin[3], S.H. Li[1], X.J. Li[1]* 1) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA 30322; 2) Graduate Program in Genetics and Molecular Biology, Emory University School of Medicine; 3) Department of Neurology, UCSF, San Francisco, CA 94158.

Huntingtons disease is the most common disease in a family of dominantly inherited neurodegenerative disorders caused by an expanded CAG/glutamine tract. An expansion of over 37 glutamines in the disease protein huntingtin results in the late onset of Huntington disease symptoms, including movement disorders, cognitive deficits, and eventually death. Polyglutamine expansion also causes huntingtin to misfold, aggregate, and abnormally accumulate in the nucleus. Following the polyglutamine tract in the N-terminus of huntingtin are two polymorphic polyproline regions. Polyproline regions have been characterized in many proteins. Proteins containing SH3 domains are found to interact with repeated proline regions. Thus, it is interesting to know whether the polyproline stretches play a role in the function of huntingtin. We have generated transfection vectors that express normal (23Q) and expanded (103Q) N-terminal human huntingtin with and without the polyproline regions. Upon transient transfection of HEK 293, PC12, and primary neuronal cell lines, we see a dramatic difference in aggregate size and subcellular localization between huntingtin with and without the proline regions. This finding suggests that the polyproline region may regulate huntingtin conformation to influence its aggregation and subcellular localization. Supported by NIH grants NS045016 and NS41669.

Unsupervised clustering of individuals into HLA genetic clusters using Hardy-Weinberg Deviation. *L. Gragert*[1], *M. Maiers*[1], *W. Klitz*[2] 1) Bioinformatics, National Marrow Donor Program, Minneapolis, MN; 2) Public Health Institute, Oakland and University of California, Berkeley, CA.

The Hardy-Weinberg equilibrium (HWE) of genotypes describes the random combination of male and female gametes in a randomly mating population. In HLA studies deviation from HWE has been used to infer typing inaccuracies, possible selection and population stratification. Here we show that in large and consistently typed samples of bone marrow donor registries, HWE deviations can be used to demonstrate not just the existence of stratification among major world populations but to actually identify population subgroups. We have created a novel distance measure for clustering human populations using distortions of genotypic proportions from HWE. The individuals are grouped without using any prior knowledge of population haplotype frequency or self-described race/ethnicity of the genotypes. This method is applied in the case of the HLA system, which exhibits both extremely high polymorphism and privacy of HLA haplotypes to specific ancestral populations. A cohort of 880,000 individuals typed using consistent methods for the HLA-A, B, and DRB1 loci from several racial/ethnic backgrounds represented in the National Marrow Donor Program (NMDP) adult donor registry was analyzed. To illustrate the effectiveness of the algorithm, the top 200 haplotypes from an equally mixed sample of European-Americans and African-Americans were clustered with 97.5% accuracy based on comparisons with haplotype frequency distributions from known populations. This clustering method can be used for labeling donors who do not supply race/ethnicity information, identifying and analyzing subpopulations within broader race/ethnic classifications, and estimating the level of admixture between populations.

Integration of novel statistical and biological methods identifies a causal SNP for schizophrenia in NOS1AP. *L. Brzustowicz[1], N.S. Wratten[1], H. Memoli[1], Y. Huang[3], M.A. Azaro[1], J. Messenger[1], J.E. Hayter[1], E.W.C. Chow[4], A.S. Bassett[4], S. Buyske[1,2], V.J. Vieland[3]* 1) Depts of Genetics and; 2) Statistics, Rutgers Univ, Piscataway, NJ; 3) Center for Quantitative and Computational Biology, Columbus Childrens Research Institute, Columbus, OH; 4) Clinical Genetics Research Program, CAMH and Dept of Psychiatry, Univ of Toronto, ON.

We have previously shown linkage between 1q23 and schizophrenia and linkage disequilibrium (LD) with markers in NOS1AP in a set of European-Canadian families. We have also reported increased expression in schizophrenia of NOS1AP in postmortem samples from BA46, suggesting a regulatory mutation. Here we apply novel statistical methods and additional experiments to isolate at least one causal allele within the gene. Using the Posterior Probability of Linkage Disequilibrium (PPLD) to measure both the probability that a SNP is in LD with schizophrenia in these families as well as to estimate the extent of trait-marker LD, we are evaluating >130 SNPs (tagSNPs and additional SNPs from conserved regions) from the 300 kb genomic extent of the gene and flanking 5' and 3' regions. We have completed genotyping and analysis of 60 SNPs. Since causative mutations should show trait-marker D'=1, we prioritized all SNPs from this set with evidence of LD (PPLD >5%) and D' estimates of 1. This left just 4 of the 60 SNPs for functional testing. These 4 SNPs show strong LD with one another (all pairwise D' values >0.8). Three of these SNPs have been tested to date for regulatory function with a luciferase reporter assay, cloning the allelic variants into a vector with a luciferase gene and a NOS1AP promoter and transfecting into two neuronal cell lines with confirmed native NOS1AP expression. rs12742393 (PPLD=43%, D'=1) demonstrated significant allelic expression differences in both SK-N-MC (p=.0002) and PFSK-1 (p<.0001). The allele associated with higher expression in this assay is also associated with higher expression in postmortem brain tissue and with schizophrenia in our family sample, implicating this allele in NOS1AP misexpression in schizophrenia. These studies bring us a step closer to understanding the causal genetic variants for schizophrenia.

An effect of bone marrow transplantation for a 15-year-old patient with Mucopolysaccharidosis (MPS) IVA in Japan. *Y. Chinen[1], Y. Higa[1], T. Higa[1], N. Hyakuna[1,2], T. Ohta[1]* 1) Dept Pediatrics, Univ Ryukyus Sch Medicine, Okinawa, Japan; 2) Dept Pediatrics, Okinawa Prefectural South Medical Center, Okinawa, Japan.

Mucopolysaccharidosis IVA (MPS IVA; Morquio A disease) is an autosomal recessive lysosomal storage disorder that is caused by defective N-acetylgalactosamine-6-sulfate sulfatase (GALNS). A progressive skeletal dysplasia is commonly observed among the MPS IVA patients. We describe a patient with MPS IVA diagnosed at 14 years of age. At 8 years of age he had odontoid dysplasia with atlanto-axial subluxation and underwent the surgical operation of atlanto-axial fixation. He had twice correction osteotomy for valgus knee. He had mild corneal clouding, glaucoma, mild tricuspid insufficiency, snoring loudly and moving with a wheelchair. At 15 years 8 months of age he received related-donor bone marrow transplantation (BMT). After BMT, the enzyme activity of GALNS in white blood cells increased to 73.6 nmol/mg protein/17hr from 2.8, bone mineral density at L2-4 to 0.539 g/cm2 from 0.374, the concentration of uronic acid in urine decreased to 23.5 mg/g creatinine from 34.6. He could walk for100 meters after correction osteotomy for valgus knee. Glaucoma and snoring loudly disappeared, but the shape of vertebral deformity and hypermobility of joints were unchanged three years after BMT.

Risk of age-related macular degeneration is determined by genes and smoking. *A. Hughes, N. Orr, C. Patterson, H. Esfandiary, R. Hogg, V. McConnell, G. Silvestri, U. Chakravarthy* Queen's Univ Belfast, Belfast, United Kingdom.

Age-related macular degeneration (AMD) is the major cause of blindness in the elderly. Those with the neovascular end-stage of disease have irreversible loss of central vision. AMD is a complex disorder in which genetic and environmental factors play a role. Polymorphisms in the complement factor H gene (*CFH*), *LOC387715* and the *HTRA1* promoter are strongly associated with AMD and smoking also contributes to the etiology.

We genotyped polymorphisms in *CFH*, *LOC387715* and the promoter of *HTRA1* in 401 patients with neovascular AMD and 266 controls without signs of disease, and collated genetic risk scores at these loci with risk from smoking history.

We scored risk haplotypes within *CFH* and *LOC387715*/*HTRA1* and smoking status. Each was found to exert a large effect on overall susceptibility, enabling risk scores to be generated with appropriate weighting of these three factors. Patients with severe macular degeneration had considerably higher scores than those without disease, and risk of blinding AMD rose to more than 14% in the tenth of the population with highest predicted risk.

Transformation Efficiency of B Cells by Epstein Bar Virus in the NINDS Human Genetics DNA and Cell Line Repository. *J.L. Andrews*[*1], C.M. Ziccardi*[*1], M.A. Keller[1], C.M. Beiswanger[1], K.A. Gwinn[2], R.A. Corriveau[1]* 1) Coriell Institute for Medical Research, Camden, NJ 08103; 2) NINDS-NIH NINDS/NIH Bethesda, MD 20817.

The NINDS Human Genetics DNA and Cell Line Repository, established in 2002, has banked over 16,000 unique samples from subjects representing cerebrovascular disease, epilepsy, motor neuron disease, Parkinsonism, and controls. The goal of the Repository is to accelerate research in the genetics of nervous system disorders. An important part of this endeavor is to use Epstein-Barr virus (EBV) to create cell lines by transforming B cells from peripheral blood. These cell lines serve as a renewable resource of genomic DNA from banked samples. Here we evaluate the efficiency of transformation of B cells from peripheral blood by EBV. Variables include the age of subject, volume of blood submitted, time between blood collection and processing, and neurological disorder. Preliminary analysis shows that blood with volumes less than 4 ml and in transit more than eight days have a decreased incidence of transformation. Additionally, samples submitted from younger subjects are more likely to transform successfully than from an older population, with the exception of the very oldest subjects (over 90 years old) that display transformation efficiencies comparable to subjects aged 46 to 50 years (~94%). Lastly, samples from subjects with the neurological diseases banked by the NINDS Repository do not appear to differ in their transformation efficiency as compared to control subjects. Further studies will consider what factors may contribute to the overall decrease in transformation efficiency associated with increased age of the donor.

Intraspecific *Cis*-Regulatory Variation Underlying Functional Differences in *PDYN* Expression. *C.C. Babbitt[1], J.S. Silverman[2], R. Haygood[2], M.V. Rockman[2], G.A. Wray[1,2]* 1) Institute of Genome Science and Policy, Duke University, Durham, NC; 2) Department of Biology, Duke University, Durham, NC.

Previous work has shown that the regulatory region of *prodynorphin* (*PDYN*) has been under selection in modern and ancient human populations, indicating that there may be segregating variation in populations that is responsible for differences in phenotype. We present a functional analysis of 11 polymorphisms in the *cis*-regulatory region of *PDYN*, an endogenous opioid precursor known to play a role in cognitive function and disease. To address the functional consequences of the polymorphisms we transiently transfected 19 naturally occurring *PDYN cis*-regulatory haplotypes into 2 neuroblastoma cell lines. This approach was chosen in order to explore all of the known *cis*-regulatory polymorphisms and also *trans* factors that influence expression in the many brain regions *PDYN* is found in. For each cell line, we performed a cross-validated regression tree analysis, which identified the polymorphisms most strongly associated with variation in expression level among the haplotypes. Regression tree analyses find the variants that statistically best explain expression differences and to partition out the separate affects of epistatic interactions that may be occurring between different parts of the *cis*-regulatory region. Expression results supports cell-type dependent effects and overall implicated 4 of the polymorphisms as explanatory genetic polymorphisms for differences in expression. These polymorphisms were a previously identified 68-bp tandem repeat, two microsatellites and a SNP. Despite the extensive work on *PDYN*, this is the first study to characterize the standing functional haplotype variation that exists in human populations. Our study helps to bridge the gap between knowledge of the phenotypic consequences of changes in *PDYN* expression and the *cis*-regulatory variation that causes these changes. The results of this study provide new candidate regions that will allow future clinical studies to further elucidate the genotype/phenotype relationship of *PDYN*.

Molecular cytogenetic characterization of an interstitial de novo 13q deletion in a 3-month-old with severe pediatric gastroesophageal reflux. *N.L. Champaigne[1], N. Laird[1], J.K. Northup[2], G. Velagaleti[1,2]* 1) Dept Pediatrics, Univ Texas Medical Branch, Galveston, TX; 2) Dept Pathology, Univ Texas Medical Branch, Galveston, TX.

Gastroesophageal reflux (GER) occurs when gastric contents travel back into the esophagus through the esophageal sphincter. GER is very common in infants with most growing out of it, but some continue to have chronic symptoms throughout childhood and adulthood. Previous linkage analysis identified a gene, GERD1, responsible for severe pediatric GER. GERD1 has been mapped to 13q14. We report here a de novo interstitial deletion of chromosome 13 in a 3-month-old biracial male who presented with severe GER and failure to thrive. His height, weight, and OFC were all below the 3rd percentile. On physical examination, he was noted to have hypotonia and multiple dysmorphic features including large eyes with downslanted palpebral fissures, a very short frenulum, absent uvula, small mandible, a short neck with extra nuchal folds and coronal hypospadias. Chromosome analysis from cultured peripheral blood lymphocytes showed an interstitial deletion of chromosome 13, with the karyotype 46, XY, del(13)(q12.3q14.1). FISH analysis with several BAC probes localized to the 13q12.2-q14.3 region showed the proximal breakpoint to be between RP11-203D17 (13q12.3) and RP11-90M5 (13q12.3). Similarly, the distal breakpoint is between RP11-13I8 (13q14.11) and RP11-160G19 (13q14.11). Based on the BAC-FISH analysis, the deletion appears to encompass at least 12.3 Mb and does involve the GERD1 locus. The GERD1 locus has been mapped to a 9-cM interval located between the markers CAGR1 and D13S263, both of which we have shown to be deleted in our patient. Further FISH analysis with overlapping BAC clones localized to the breakpoint regions is in progress to more precisely determine the extent of the deletion. We propose that the GER phenotype in our patient is due to a haploinsufficiency for GERD1.

Splicing defects associated with unclassified variants of *BRCA1* and *BRCA2* detected using a novel reverse transcription-PCR design and a DNA-based *ex vivo* splicing assay. *C. Bonnet[1], S. Krieger[2], A. Rousselin[2], M. Vézain[1], I. Tournier[1], A. Martins[1], T. Frébourg[1], M. Tosi[1], A. Hardouin[2]* 1) Inserm U614, Faculty of Medicine and Department of Genetics, University Hospital, Institute for Biomedical Research, Rouen, France France, France; 2) Laboratory of Clinical and Oncological Biology, Centre François Baclesse, Caen, France.

Many unclassified variants (UV) of *BRCA1* or *BRCA2* may have an effect on pre-mRNA splicing by altering degenerate positions of splice site sequences or by inducing cryptic splice site activation. Moreover, exonic variants may be pathogenic by affecting splicing regulatory sequences such as exonic splicing enhancers (ESE). We have developed a strategy that combines the analysis of RNA extracted from peripheral blood of patients and the characterization of each variant in an *ex vivo* splicing assay. On one hand, we have optimized the conditions for RT-PCR analysis of BRCA1 and BRCA2 mRNAs. On the other hand, we have PCR-amplified from patient DNA exons and flanking sequences that carry UVs and inserted the PCR products into a splicing reporter minigene. After transfection into HeLa cells, the effects of variants on splicing were evaluated by RT-PCR. We have presently examined with both methods 20 variants: 16 were intronic, at positions different form the conserved GT or AG dinucleotides at the intron boundaries and 4 were exonic. Results obtained from RT-PCR analysis of patient RNA and from the *ex vivo* splicing assay were fully concordant. Six of the intronic variants examined induced a splicing alteration: 3 by inducing partial or total exon skipping, 2 by activating cryptic splice sites and 1 by modifying the balance of an alternative splicing towards stronger exon inclusion. Two exonic variants generated or activated new donor splice sites and one affected a novel putative exonic splicing enhancer. This work reveals an important fraction of splicing defects among unclassified variants. Moreover we show that functional analysis of splicing using a reporter minigene is reliable and is of particular value in many cases in which patient blood samples suitable for RNA extraction are not available.

Identification of compounds with ability to induce read-through of nonsense mutations by high throughput screening. *L. Du[1], R. Damoiseaux[2], J. Goldstine[3], J.M. Pollard[1], H. Feng[1], C.H. Lai[1], M. Ambrose[1], R.A. Gatti[1,3]* 1) Department of Pathology and Laboratory Medicine, The David Geffen School of Medicine at UCLA,CA,90095; 2) Molecular Shared Screening Resources, Department of Pharmacology, UCLA, CA,90095; 3) Department of Human Genetics, The David Geffen School of Medicine at UCLA, CA,90095.

A large number of common genetic diseases result from nonsense mutations which introduce premature termination codons (PTCs) into coding sequences and cause the formation of either no protein or truncated non-functional protein. It has been known that certain compounds can influence the fidelity of stop-codon recognition and induce read-through of PTCs mutations, which allows translation of a full-length normal protein. In many cases, the read-through-induced protein might be at least partially functional, even if it contains a wrongly-incorporated amino acid. Considering that large numbers of genetic disorders are caused by PTC mutations, the read-through of PTCs might be exploited as a potential treatment strategy. In this study, we successfully developed a high throughput PTT-ELISA screening assay (HTS) for identifying novel PTC read-through compounds using Ataxia-telangiectasia (A-T) as a genetic disease model. This PTT-ELISA assay is based on a coupled transcription/translation reaction (PTT) that uses plasmid templates containing prototypic Ataxia-telangiectasia mutated (ATM) mutations, patterned after disease-causing mutations in A-T patients. The PTT-ELISA assay has been validated for a fully-automated 384-well robotic platform and is adaptable for large-scale screening of chemical libraries. As proof of principle, we screened ~37500 compounds and identified several low-molecular-weight compounds with potential PTC read-through activity in vitro; these compounds were subsequently confirmed by manual testing. Ex vivo ELISA experiment showed that one compound could induce ATM protein in ATM deficient cells containing PTC mutation.

The HIV Elite Controller Study: a genome-wide association study to identify variants involved in HIV viral control and disease progression. *P.I.W. de Bakker[1], F. Pereyra[2], L. Davies[1], A. Rothchild[2], L. Gianniny[1], B. Block[2], B. Baker[2], N.P. Burtt[1], R.R. Graham[1], R.M. Plenge[1], B.D. Walker[2], HIV CONTROLLER CONSORTIUM* 1) Broad Institute of Harvard and MIT, Cambridge, MA; 2) Partners AIDS Research Center, Massachusetts General Hospital, Boston, MA.

The HIV ELITE CONTROLLER STUDY (www.elitecontrollers.org) is a collaborative effort between academia and the community to study untreated HIV infected people who are able to maintain viral load (VL) at or below the limits of detection. The goal of this collaboration is to identify the key viral, host genetic and immunologic contributions to this extraordinary outcome of infection. While the vast majority of untreated HIV infected individuals exhibit evidence of progressive viral replication and CD4+ T-cell depletion, approximately 1 patient in 300 is able to control replication at low levels without the need for antiretroviral (ARV) medications. These so-called elite controllers have VL50 copies/mL, and represent the extreme tail of an otherwise normal distribution of viral load in the HIV infected population. To test the hypothesis that host genetic factors influence innate and adaptive immunity and durable suppression of HIV infection, we are conducting a genome-wide association study in 300 elite and 300 viremic controllers (2000 copies/mL) as cases and 900 individuals with high VL (in the absence of ARV, ultimately requiring therapy) selected from a cohort of the AIDS Clinical Trial Group as controls. We are genotyping these individuals using the Illumina HumanHap650Y platform. We present the results of the association analysis and highlight analytical strategies we have taken to correct for population stratification and admixture. Although this initial scan has good power to detect common alleles of large effect (odds ratio 2.0; as seen for HLA risk alleles in autoimmune diseases), power is limited to detect more modest effects (OR1.5; as seen for complex traits such as type 2 diabetes). Efforts are underway to recruit the estimated 2000 or more persons in the US that fit the HIV controller criteria, with additional international collaborations adding to the numbers, to improve power.

Whole Genome 500K SNP Microarray Analysis for Evaluation of Patients with Mental Retardation, Developmental Delay, Autistic Spectrum Disorder and/or Multiple Congenital Malformations. *M. Ito[1,2], J.M. Milunsky[1,2,3], T.A. Maher[1], A. Milunsky[1,2]* 1) Center for Human Genetics; 2) Department of Pediatrics; 3) Department of Genetics and Genomics, Boston University School of Medicine, Boston, MA.

Whole genome SNP (Single Nucleotide Polymorphism) microarray copy number analysis is a powerful tool for detection of cryptic unbalanced chromosomal abnormalities, providing detailed insights of chromosomal aberrations such as small duplications and deletions, and defining breakpoints of unbalanced rearrangements often not detected by standard cytogenetic analyses. We have utilized the previously validated 500K Affymetrix SNP microarray (combination of 250K NspI and 250K StyI chips) with Copy Number Analysis Tool (CNAT) software. The average distance between one SNP to another is approximate 5.8kb in these chips. The average call rates were greater than 97%. Abnormal findings from the first array were confirmed and further refined with the second array and FISH studies. In 115 patients with mental retardation (MR), developmental delay (DD) and autistic spectrum disorder (ASD), and/or multiple congenital anomalies (MCA), after normal karyotype with or without CGH or subtelomeric FISH analyses, we have found ten patients with clinically significant structural chromosomal aberrations by this analysis (8%; nine deletions and one duplication). The average size of such aberrations is approximate 2Mb, ranging from 0.8Mb to 3.8Mb. In addition, approximately 30% of patients have smaller aberrations less than 0.4Mb. Two thirds of them are reported variants found in normal individuals, however, others require parental samples to clarify the pathogenicity of such aberrations. Caution is necessary in reporting these results. Since resolution is much finer, we propose using actual physical positions in conjunction with cytogenetic banding terminology to indicate exact locations of aberrations to avoid confusion. This experience underwrites the value of copy number analysis using the 500K SNP microarray which clearly is a powerful tool for identifying chromosomal aberrations and should routinely be included in the genetic analysis of those with MR, DD, ASD, and/or MCA.

Reduction of measurement noise in a pooling-based GWA study using multimarker analysis of SNPs in linkage disequilibrium. *N. Homer[1], W. Tembe[2], S. Szelinger[2], M. Josephson[2], J. Pearson[2], D. Stephan[2], S. Nelson[1], D. Craig[2]*
1) University of California - Los Angeles, 5554 Gonda, 695 Young Drive South, David Geffen School of Medicine at the University of California - Los Angeles, Los Angeles, CA 90095-7088; 2) The Translational Genomics Research Institute, 445 N. Fifth Street Phoenix, AZ 85004.

Recently emerged Genome-wide association (GWA) studies utilizing hundreds of thousands of single nucleotide polymorphisms (SNPs) have the potential to revolutionize our ability to identify the common genetic influences of complex traits and diseases. Additionally, numerous pooling-based studies have found associations for complex diseases such as Diabetes, Supra Nuclear Palsy, and Memory Loss. Pooling-based GWA studies are cost effective and have the power to detect significant associations. Nevertheless, the inherent difficulties of pooling-based studies are to correctly predict allelic frequency and more importantly to reduce measurement noise. In this vein, multi-marker statistics can leverage SNP linkage disequilibrium to increase resolution. Using known linkage disequilibrium from the HapMap project, we are able to improve our test of significance for each SNP and thus increase our power to detect associations. We evaluate numerous methods to combine correlated tests of significance and develop our own tests based on the underlying error model. Using pooled samples from a subset of the HapMap population we are able to assess these methods against the traditional single marker analysis and known individual genotype data and conclude an increase in power when using the multi-marker methods.

The CanMap Project: Population Genetics and Whole Genome Association Mapping of Morphological and Behavioral Differences among Domestic Dog (Canis familiaris) Breeds. *C.D. Bustamante[1], T. Spady[2], H.G. Parker[2], B. vonHoldt[2,3], K. Bryc[1], M.H. Wright[1], N.B. Sutter[2], A. Reynolds[1], A.R. Boyko[1], M. Castelhano[1], E. Wang[4], K. Zhao[1,5], G. Johnson[6], M. Nordborg[5], R.K. Wayne[3], M. Cargill[4], E.A. Ostrander[2]* 1) Cornell University, Ithaca, NY; 2) NHGRI/NIH, Bethesda, MD; 3) UCLA, Los Angeles, CA; 4) Affymetrix, Santa Clara, CA; 5) U. Southern California, Los Angeles, CA; 6) U. of Missouri, Columbia, MO.

Domestic dog breeds exhibit great variation in behavior and morphology among breeds and low phenotypic and genetic diversity within breeds, making the dog an excellent genetic system for mapping traits of interest. Here, we present population genetic analyses and preliminary results for simultaneous whole-genome association mapping of morphological and behavioral trait differences among breeds using a panel of 1,000 dogs from 80 breeds genotyped on the Affymetrix Canine Array v.2.0 (~100,000 SNP). Population genetic analyses reveal clear genetic clustering of dogs into breeds with well defined boundaries, and shallow clustering of breeds into higher order groups. We use fine-scale recombination rate estimates across the genome to identify regions of unusually high linkage-disequilibrium within a breed, which may identify recent targets of selection during breed formation. We also estimate the domestication bottleneck size for dog as well as breed-specific bottleneck and inbreeding rates which account for dramatic differences in effective population size among popular breeds. Using a mapping strategy that accounts for expected high genetic relatedness within a breed, we aim to identify regions of the dog genome associated with skeletal conformation, hair pigmentation and texture, and behavioral trait differences including: body size, foreshortened limbs, foreshortened face, compact face and cranimum, proportional dwarfism, wire hair, curly hair, corded coat, face mask color, and prey drive. For several traits, overlying peaks of association with signatures of selection allows us to refine our signals to a just a few candidate genes. The approach we employ replicates previously identifies gene-trait association, including the link between IGF1 and body size.

Startle disorder, Hyperekplexia, is primarily a recessive disorder. *S. Chung[1], A. Robertson[1], C. Hammond[1], R.J. Harvey[2], M.I. Rees[1]* 1) Neuroscience, University of Wales Swansea, Swansea, United Kingdom; 2) 2Department of Pharmacology, The 2Department of Pharmacology, The School of Pharmacy, 29-39 Brunswick Square, London, UK.

Glycinergic neurotransmission is a major inhibitory system in the central nervous system (CNS) and defects in glycinergic genes are associated with a startle disorder, hyperekplexia. This rare, but potentially fatal, neurological disorder is primarily a hereditary disorder, typically associated with dominant mutations in the glycine receptor 1 subunit, GLRA1. As part of an ongoing 10-year screening program, we have analysed the entire coding regions of GLRA1 within 56 sporadic patients. Of the 21 hyperekplexia mutations identified in this study, 16 were inherited in a recessive mode or part of compound heterozygosity. Consistent with previous studies, all deletion and nonsense mutations were associated with recessive onset of phenotype, where as missense mutations could exert an effect either as dominant or recessive traits depending on the position of the mutation in the polypeptide. This study indicates, that on a population basis, recessive hyperekplexia is more common than expected and that the previous label and reference towards a dominant disorder was an ascertainment bias on familial presentation and founder linkage analysis cohorts. The discovery of mutations in the glycine transporter-2 gene in hyperekplexia in 2006 also displays predominantly recessive inheritance and compound heterozygosity. In contrast to other diseases caused by dysfunction of ion channels or murine hyperekplexia models, patients with recessive mutations/null hyperekplexia mutations in GLRA1 were not particularly associated with severe cases of hyperekplexia. The explanation for tolerance of null GLRA1 gene function in humans is likely due to a compensatory mechanism by other neuro-inhibitory mechanisms. The discovery of hyperekplexia associated mutations and biophysical studies of the mutations will provide invaluable opportunities to study the pathophysiology of this neuromotor disorder.

Promoter regions of many neural- and nutrition-related genes have experienced positive selection during human evolution. *O. Fedrigo[1,2,3], R. Haygood[1,3], C.C. Babbitt[2,3], T. Severson[2], S. Morrow[2], G.A. Wray[1,2]* 1) Biology Department, Duke University, Durham, NC; 2) Institute for Genome Sciences and Policy, Duke University, Durham, NC; 3) These authors contributed equally to this work.

Surveys of protein-coding sequences for signatures of positive selection in humans and chimpanzees resulted only in a few genes involved in neural or nutritional processes, despite the pronounced differences between humans and chimpanzees in behavior, cognition, and diet. It is likely that most phenotypic differences between human and other primates are due to gene regulation rather than protein structure. We performed a genome-wide scan for signatures of positive selection on promoter (5'-flanking) regions unique to the human lineage compared to macaque and chimpanzee. We adapted and used a lineage specific Random Effect Likelihood model comparison to test for faster evolution along the human lineage in a promoter region relative to a putative neutral region picked from nearby intronic sequences. A Bayes Empirical Bayes method has been applied to detect particular sites under lineage specific selection. We were able to analyze 6,280 promoter regions from which 46 showed a signal of positive selection after correction for multiple comparisons. We examined the biological trend of the top scoring genes using PANTHER and GO ontology classifications. Our results indicate that positive selection has targeted the regulation of many genes known to be involved in neural development and function, both in the brain and elsewhere in the nervous system, and in nutrition, particularly glucose metabolism. We empirically validated select top scoring genes by performing in-vitro reporter assays showing significant difference in transcriptional inducibility.

Haplotype-based population tree for 45 human population samples. *K.K. Kidd, A.J. Pakstis, W.C. Speed, S. Gu, N. Mukherjee, M.P. Donnelly, J.R. Kidd* Dept Genetics, Yale U. Sch Med, New Haven, CT.

While enormous SNP and STRP datasets are emerging for a handful of human populations, studies of genetic relationships of human populations from around the world to date have used the HGDP-CEPH panel of ~1,000 individuals. Our study of 2,345 individuals from 45 populations includes supersets for 15 of the 51 HGDP-CEPH groups. Our larger sample sizes per population allow more accurate estimation of haplotype frequencies. Geographic regions represented include: Africa(10 pops), S.W. Asia(4), Europe(9), N. Asia/Siberia(3), E. Asia(9), Pacific Is.(2), N.America(4), S. America(4). We analyzed 506 multi-SNP haplotyped loci from 2,556 SNPs distributed across 17 autosomes (~6.2 million genotypes). Regions with multiple SNPs were analyzed for LD (HAPLOT3) to identify relatively independent SNP clusters with strong inter-SNP LD. Haplotype frequencies were calculated via EM algorithm(HAPLO). The use of frequencies of multi-SNP haplotypes helps overcome the diverse ascertainment biases associated with individual SNPs. Avg heterozygosities for 506 haplotypes range from .4 to .7 among the groups studied with Africans highest (avg ~0.65) and groups farther from Africa trending lower; S.American groups avg ~0.48. The first 3 PCA factors account for ~90% of the genetic variation; pop. samples cluster in clear geographical patterns. Over 500 alternative trees were evaluated with the Least Squares search program (LSSEARCH) to find the best tree. PHYLIP programs were used to generate 1,000 replicate data sets and generate bootstrap values for the consensus tree. Bootstrap values of 100% occur 11 times for various population groupings with the African branch accounting for 6 while the rest either divide major tree segments separating continental groupings or particular population clusters. Several boostrap values in the 90-99% range were found for groupings within continental regions. While major improvements in the robustness of various population groupings were achieved compared to earlier studies with smaller marker sets, larger datasets are needed to get high bootstrap values within continental groupings where populations are closely related. Supported by NIH GM57672.

Therapeutic potential of a generalized stress response. *R. Deering[1], S. Purvis[1], G. Dong[1], J. Keefer[1], K.D. Smith[1,2]*
1) Dept of Human Genetics, Johns Hopkins Univ, Baltimore, MD; 2) Kennedy Krieger Institute, Baltimore, MD.

In response to various stresses, cells mount several evolutionarily conserved pathways, comprising the generalized stress response (GSR), that enhance cell survival and homeostasis. Histone deacetylase inhibitors (HDACi) have been used to alleviate the symptoms of a variety of diverse Mendelian and complex disorders. It seems unlikely that non-specific HDACi activity would elicit specific responses related to each specific genetic abnormality. Also, similar responses are induced by several non-HDACi. We hypothesize that both HDACi and non-HDACi activate a GSR to enhance cell survival and homeostasis. We investigated HDACi 4-phenylbutyrate and trichostatin A and non-HDACi hydroxyurea and sulforaphane (confirmed by HDAC activity assays) in sickle cell disease (SCD) and X-linked adrenoleukodystrophy (XALD). In SCD, symptoms are due to mutations in -globin and are lessened by increased levels of HbF. XALD is associated with increased levels of very long chain fatty acids (VLCFA). Beneficial downstream drug responses (HbF levels increase in SCD and VLCFA decrease in XALD) were observed with both HDACi and non-HDACi and were dependent on drug-induced mitochondrial biogenesis, a common stress response. The evolutionarily conserved GSR involves transcriptional upregulation of genes that regulate reactive oxygen species, sense and repair DNA damage, are molecular chaperones, degrade proteins, and regulate fatty acid, lipid, and energy metabolism. The drugs tested increased transcription levels of genes involved in the major stress response systems: unfolded protein response, heat shock response, MAPK cascades, mitochondrial biogenesis, and antioxidant response. Inhibiting stress activated protein kinases blocked drug-induced mitochondrial biogenesis. These data support the hypothesis that triggering a GSR is a universal response to these drugs. Thus, enhanced cell survival and improved cellular homeostasis, rather than specific changes in gene expression responsive to each distinct disorder, may provide protection in a variety of genetic disorders. These drugs may have therapeutic potential for a spectrum of disorders with mild cellular phenotypes.

Fine mapping of a chromosome 16 locus associated with low high-density lipoprotein cholesterol level (HDL-C) in French Canadians. *Z. Dastani[1,2], M. Marcil[2], J.C. Lee[3], P. Pajukanta[3], D. Gaudet[4], J. Genest[1,2], J.C. Engert[1,2]* 1) Dept. of Human Genetics, McGill Univ., Montreal; 2) Cardiovascular Genetics Laboratory, McGill Univ. Health Centre, Montréal; 3) Dept of Human Genetics, David Geffen School of Medicine, Univ. of California, Los Angeles; 4) Dyslipidemia, Diabetes and Atherosclerosis Group and Community Genomics, Chicoutimi.

Low HDL-C is an independent risk factor for coronary heart disease. We previously performed quantitative linkage analysis in two independent studies in French Canadians: a Quebec-wide study (QUE) consisting of 362 individuals families and 410 individuals from the Saguanay-Lac St-Jean region (SLSJ) and showed linkage to 16q23-24 in both studies. This locus was implicated in multiple previous linkage scans for HDL-C in different populations and resulted in linkage peaks that are less than 12 cM far from our peak. We performed SNP fine mapping using family based association and case-control association analysis. Using families from the QUE study, defining HDL-C < 5th% (age/gender-matched) as cases, the region was narrowed from 25 cM to 18.1 cM. Affected from four families share a 2 microsatellite haplotype. SNP genotypes narrowed the shared haplotype to 4Mb. A SLSJ case-control study identified several significant SNPs, one located in the same region as the shared haplotype from the QUE families. A haplotype containing this SNP and another increased the evidence for association (p = 0.016 to 0.0097). The CHST6 gene, found within this region, was previously associated with macular corneal dystrophy. Because of the presence of occular manifestations with other genes associated with low HDL-C (e.g. LCAT, ApoA1), we sequenced the CHST6 gene and its nearby homologue CHST5, and found two missense variants. The variant in the CHST5 gene did not segregate with low HDL. However, a variant in the CHST6 gene showed strong segregation in the 4 families sharing the microsatellite haplotype. This same variant also demonstrated an odds ratio >2 in the case/control sample, but this was not significant due to the small sample size. Our data present strong evidence for a HDL-C gene on chromosome 16q23-24 that may be related to the CHST6 or CHST5 loci.

Cooperative role of tfap2a and tfap2g in zebrafish neural crest induction. *T. Hoffman, T. Schilling* Cell and Developmental Biology, University of California, Irvine, Irvine, CA.

Transcription factor AP2 (Tfap2) genes play essential roles in development of the epidermis and migratory cells of the neural crest in vertebrate embryos. These transcriptional activators are among the earliest genes expressed in the ectoderm and specify fates within the epidermis/crest through both direct and indirect mechanisms. The Tfap2 family arose from a single ancestral gene in a chordate ancestor that underwent gene duplication to give up to five family members in living vertebrates. This coincided with the acquisition of important roles in neural crest development by Tfap2 genes suggesting that this gene family was important in ectodermal evolution and possibly in the origin of neural crest. Here, we show that a zebrafish tfap2g is expressed in the non-neural ectoderm during early development and functions redundantly with tfap2a in neural crest specification. In zebrafish embryos depleted of both tfap2a and tfap2g, neural crest cells are virtually eliminated. Cell transplantation experiments indicate that tfap2g functions cell-autonomously in NC specification. Cells of the enveloping layer, which forms a temporary skin layer surrounding the ectoderm, also fail to differentiate or to express appropriate keratins in tfap2g deficient-embryos. The role of Tfap2 genes in epidermal and neural crest development is considered here in the broader context of ectodermal evolution. Distinct, tissue-specific functions for Tfap2 genes in different vertebrates may reflect subfunctionalisation of an ancestral gene that consequently led to the gain of novel roles for different subfamilies in patterning the epidermis and neural crest.

Frequency of m1 polymorphism (CYP1A1) in adult Mexican patients with acute lymphoblastic leukemia. *C. Batista, M.P. Gallegos, G.M. Zúñiga* Medicina Molecular, CIBO, Instituto Mexicano del Seguro Social, Guadalajara, Guadalajara, Mexico.

The etiology of most types of leukemia remains unknown. Acute lymphoblastic leukemia (ALL) is a heterogeneous disease characterized by the predominance of lymphoblasts or immature haematopoietic precursors, in which the malignant cells express diverse phenotypes with variable response to chemotherapy. Polymorphisms in genes encoding (activate procarcinogens and detoxify carcinogens) metabolism enzymes may be relevant for susceptibility to acute lymphoblastic leukaemia. We evaluated the distribution of CYP1A1 (m1) genotype in peripheral blood DNA samples from 227 healthy controls and 96 adult patients with ALL. The frequency of CYP1A1 (m1) wild type genotype was 53% (120 of 227) for controls and 29% (15 of 51) for ALL patients; heterozygote genotype was 39% (89 of 227) and 45% (23 of 51); and polymorphic genotype was 8% (18 of 227) and 26% (13 of 51) respectively with odds ratio of 4.0; 95% CI, 1.6-9.3 and $p<0.05$. Our observations suggest a possible interactions of CYP1A1 (m1) polymorphism to the risk of developing ALL in adults Mexican patients.

Whole Genome Association Study Identifies Novel Risk Alleles for Multiple Sclerosis. *J.L. Haines for The International Multiple Sclerosis Genetics Consortium* Ctr Human Genetics Research, Vanderbilt Univ Medical Ctr, Nashville, TN.

Background: Multiple sclerosis (MS) is an autoimmune disease with significant heritability. We present the first large scale, replicated whole genome association scan to identify risk alleles associated with MS.

Methods: The Affymetrix GeneChip Human Mapping 500K array was used to examine common genetic variation in ~1,000 MS affected offspring, their ~2,000 parents and 2,431 independent controls. A strict quality control analysis in which SNPs and DNA samples with low genotyping rates, excessive Mendelian errors or low minor allele frequencies were removed from further analysis resulted in a final screening data set of 931 trios genotyped for 334,923 SNPs. In the second stage, 110 SNPs were genotyped in an additional 609 trios, 2,322 cases, and 2,987 controls. The overall combined sample sizes were 1,540 trios, 2,322 independent cases and 5,418 controls (total 12,360 individuals) and final P values were calculated.

Results: After extensive quality control, a transmission disequilibrium test analysis of the initial data revealed 49 SNPs with P values <1 x 10-4, 38 of which were selected for the second stage analysis. The case-control analysis identified an additional (non-overlapping) 32 SNPs with P values <1 x 10-3. A further 40 SNPs with less stringent P-values (at least <0.01) but supported from other, a priori sources were also selected. The strongest replicated results for MS susceptibility came from two SNPs within the CD25 gene encoding the IL-R2 chain (P = 2.96 x 10-8). A non-synonymous SNP in the IL-7R chain gene was also strongly associated with MS susceptibility (P = 2.94 x 10-7). As expected, the HLA-DR locus was unequivocally associated with disease susceptibility (P = 8.94 x 10-81).

Conclusions: The combined results from this first whole genome association scan in MS have unequivocally confirmed non-MHC genetic variants associated with MS susceptibility and strongly implicate cytokine pathways.

Autosomal Dominant Small intestinal atresia/stenosis - Case Report. *P. Kim[1], J. Jessen[2], S. Koenen[2], D. Chitayat[1,2]*
1) Hospital for Sick Children, Dept. of Pediatric Surgery (PK), Clinical and Metabolic Genetics (DC); 2) Mount Sinai Hospital,Dept. of Obstetrics and Gynecology (SK), Prenatal Diagnosis and Medical Genetics (JJ,DC) Toronto, Ontario, Canada.

Intestinal atresia (IA)caused by intramural web is an uncommon variant of congenital IA, typically reported neonatally or in childhood and occasionally remaining asymptomatic throughout the entire life span. Type I [mucosal web (Martin and Zerella, 1976)] jejunoileal atresia (JA) is generally thought to be a sporadic event with hereditary types believed to be uncommon although familial cases with autosomal recessive mode of inheritance have been reported. We report a mother with JA and her son with duodenal atresia (DA), both due to web, suggestive of an autosomal dominant mode of inheritance. Case Report: The pregnancy was conceived via IVF following 3 years of infertility. The mother was of Ashkenazi-Jewish Russian descent, the father of Polish descent. The couple was non-consanguineous. The mother was born with intestinal obstruction and on surgery was found to have JA due to a web. The mother's maternal great aunt had a son with reportedly DA and this son has a son with the same condition. The pregnancy was initially uncomlicated, and FTS was done and showed a nuchal translucency of 0.9 mm with an adjusted risk for Down syndrome of 1:724. Mother presented due to rupture of membrane at 30 weeks gestation, fetal ultrasound showed severe oligohydramnios, distended stomach and loop of proximal small bowel, likely duodenum. Emergency cesarean section was performed at 33 weeks gestation. Duodenal obstruction was confirmed postnatally. At the time of surgery, baby was found to have a duodenal web. Duodenojejunostomy was done. The baby is doing well at 6 months follow up. There are 2 theories regarding the etiology of IA. The first proposed a lack of recanalization during the embryological solid cord stage of intestinal development. The second is that IA is caused by an embryological vascular accident resulting in necrosis of the affected segment. To the best of our knowledge this is the first report of a mother and son affected, suggestive of autosomal dominant mode of inheritance.

TopoIII, a Member of the BRAFT Complex, functions in the Fanconi anemia pathway. *A. Hemphill, S. Philip, M. Al-Dhalimy, S. Olson, R. Moses* Dept Molecular & Medical Gen, Oregon Health & Science Univ, Portland, OR.

Fanconi anemia (FA) is a recessive disorder characterized by an increased cellular sensitivity to interstrand crosslinks (ICLs), manifest at the cytogenetic level by the formation of chromosomal radials. FA is caused by a defect in any of at least 13 known genes. Following ICL damage, a core complex of at least 8 FA proteins (A, B, C, E, F, G, L, M) forms in the nucleus, resulting in the mono-ubiquitination of FANCD2. A number of these core complex proteins have also been shown to form a complex with Bloom protein (BLM), replication protein A (RPA), and TopoIII, known as the BRAFT complex. We have previously presented data showing that BLM is functionally epistatic to the FA core complex for the repair of ICLs. We have now used siRNA depletion of TopoIII to study its role after ICL damage. Depletion of TopoIII in a normal human fibroblast cell line results in decreased survival following exposure to ICLs, as well as increased formation of radials. To study the role of TopoIII in the FA pathway, we then depleted TopoIII in several FA cell lines. Unlike in normal fibroblasts, depletion of TopoIII did not result in an increased sensitivity to ICLs in the FA cell lines. Thus, as we have reported for BLM, TopoIII appears to be epistatic to the FA pathway for ICL repair. This indicates that the BRAFT complex is a functional complex for ICL repair.

Low correlation among association tests for quantitative traits. *J.E. Herrera-Galeano[1,2], R.A. Mathias[2], H. Sung[2], N. Faraday[1], D.M. Becker[1], L.C. Becker[1], A.F. Wilson[2]* 1) Dept of Medicine, Johns Hopkins Medical Institutions, Baltimore, MD; 2) Genometrics Section, NHGRI, NIH, Baltimore, MD.

Background: Recently, there has been a dramatic increase in the amount of genotyping data available for testing for association with quantitative traits. Several different methods of testing for associations are available; these methods use different kinds of information and have different strengths and weaknesses with respect to their statistical properties. **Objective:** To determine the pair-wise correlations among the following methods: ASSOC (SAGE v4.6.1), FBAT v1.7.3, GEE (SAS v8.0) and ROMP v0.2. **Methods:** Levels of 24 traits related to platelet aggregation were measured before and after 2 weeks of daily doses of 81 mgs of aspirin (ASA) in 541 African Americans and 955 Caucasians, in 155 and 264 families, respectively. Genotypes were determined for 2638 SNPs in 191 candidate genes using the Illumina Golden Gate platform. Tests of association were performed with each of the 4 methods in each ethnic group for each trait (506,496 total tests). Pair-wise Pearson product moment correlations were calculated, as were McNemar chi-squares categorizing p-values as significant (p 0.001) or not significant. **Results:** Pair-wise correlations between the methods were evaluated only on those tests that returned a result for all four methods (57,018). The Pearson correlations were <0.14 for all pair-wise comparisons of these four methods. Furthermore, the pair-wise comparisons of the methods with the McNemar chi square tests were significant p 0.001 for all pairs except ROMP-FBAT. **Conclusions:** Our results indicate that there is little correlation between the four tests of association for quantitative traits. In the absence of a consensus across association methods, the method that uses the most information should be given the greatest weight. In this case, a test of association in two and three generation family data, ASSOC, a likelihood based method that includes phenotype and genotyping information on all family members makes the fullest use of the available information.

A case of pure, non-mosaic trisomy 8q with multiple cardiac defects and congenital anomalies. *N. Cohen, S. Pardo, N.B. Kardon, L. Edelmann* Dept Genetics and Genomic Sciences Mt Sinai Sch Med, New York, NY.

We report on an infant born at 38 weeks of gestational age with multiple cardiac and congenital anomalies, resembling a severe form of mosaic trisomy 8 syndrome. Conventional cytogenetic analysis by high resolution GTG-banding revealed an abnormal male karyotype with a de-novo, non-mosaic, partial trisomy of chromosome 8q designated 46,XY,add(8)(p23). Upon physical examination, the infant was noted to be severely dysmorphic with facial features that included frontal bossing, downslanting long palpebral fissures, low set dysplastic ears, wide/broad nasal bridge, short smooth philtrum and micrognathia. Additional findings included a webbed neck, hypoplastic and wide spaced nipples, bilateral cryptorchidism, anteriorly placed anus and deep sacral crease. Multiple hand and foot anomalies were noted, including overlapping digits, 2-3rd toe syndactyly and deep sole creases. Neurological exam showed diffuse hypertonicity with limited range of motion of all joints and bilateral wrist contractures. Echocardiogram revealed multiple cardiac defects, including patent ductus arteriosis, critical coarctation of the aorta and ventricular septal defect. Fluorescence In Situ Hybridization (FISH) analysis with a whole chromosome 8 paint (WCP 8, Vysis) verified that the additional material at 8p was derived from chromosome 8. Telvysion FISH with probes for 8p and 8q (Vysis) indicated that the 8p subtelomere was intact and that the duplicated segment extended to include the 8q subtelomere. The revised karyotype was designated as 46,XY,add(8)(p23).ish der(8)dup(8)(qter>q13::pter)(8ptel+,8qtel++). Oligonucleotide array CGH analysis (Agilent) confirmed that the proximal breakpoint of the duplicated segment was within 8q13 and that the whole p-arm of chromosome 8 was intact. To date, all cases of partial trisomy 8q reported in the literature involved the segments from 8q22-8q24 to 8qter. To our knowledge, this is the first report of a pure partial trisomy of 8q involving 8q13 to 8qter in a patient. In summary, the non-mosaic nature and size of the duplicated segment of 8q contributed to the severe phenotypic presentation of trisomy 8 syndrome in this patient.

Neonatal Screening for Pompe Disease: A Two-tier Screening Strategy. *J. Keutzer[1], Y.H. Chien[2], S.C. Chiang[2], X.K. Zhang[1], N.C. Lee[2], W.L. Hwu[2]* 1) Scientific Affairs, Genzyme Corp, Cambridge, MA; 2) Department of Pediatrics and Medical Genetics, National Taiwan University Hospital, Taipei, Taiwan.

Pompe disease is caused by the deficiency of acid alpha-glucosidase (GAA). Recombinant human GAA has been used to treat infantile-onset Pompe disease (IOPD), resulting in prolonged survival, reversal of cardiomyopathy, and growth and in a subgroup of patients, the achievement of independent ambulation. Best motor outcomes are reached when recombinant human GAA treatment is initiated early. A neonatal screening pilot program for Pompe disease was started in October 2005 at National Taiwan University Hospital (NTUH). Blood spot GAA activities were measured on the dry blood cards collected from babies for routine neonatal screening three days after birth. The methods employed 4-MU-glucoside as the substrate, and acarbose as an inhibitor of maltase-glucoamylase. A two-tier screening strategy was used. In the first tier, assay GAA activity was measured. In the second tier, GAA activity and neutral maltase activity were measured. A second sample was requested from babies with low GAA activity and a high ratio of neutral maltase to GAA. Currently, more than 130,000 newborns have been screened and 4 cases of IOPD have been confirmed. No false negative results have been encountered. The results from this pilot program, which is ongoing, suggest that neonatal screening for Pompe disease is feasible.

Methods for comparative sequence analysis using mass spectrometry. *C. Honisch, Y. Chen, T. Shi, D. van den Boom*
Molecular Applications, Sequenom, Inc, San Diego, CA.

Mass spectrometry has become a standard tool for automatic identification of proteins and mapping of proteomes using peptide mass fingerprinting and pattern matching against established databases. We recently developed new algorithms and software tools for nucleic acid mass fingerprinting that enable automated, high-throughput comparative sequence analysis by MALDI-TOF mass spectrometry including the detection of single nucleotide changes. Large-scale genome DNA-sequencing projects provide a rapidly increasing number of reference sequences for the approach. As part of our comparative sequencing method, reference patterns are simulated based on the imported sets of reference sequences and mass spectra are acquired after PCR, in vitro transcription and base specific-cleavage of 500-800 bp genomic regions. In theory, samples can be identified by finding the best match of the detected peak pattern with the simulated pattern of the references, but missing and additional peaks due to deviations between the sample and the best match, contaminating adduct peaks, intensity variations and the overall spectra quality required the implementation of an iterative identification process and the development of a quality scoring scheme. Using these new algorithmic approaches, we developed analysis routines reporting on sequence identification results, confidence levels and single nucleotide changes. Normalization and scaling of acquired data allow for cluster analysis and grouping of samples based on their specific patterns. Sample mixtures are reflected in the data and can be analyzed. We will present data on the successful application of the algorithms to comparative sequence analysis for mutation detection, haplotyping, mixed population analysis and microbial typing.

.

Pre-mutation alleles in myotonic dystrophy type 2. *L.L. Bachinski[1], T. Czernuszewicz[1], L.S. Ramagli[1], T. Suominen[3], C.A. Thornton[2], B. Udd[3], M.J. Siciliano[1], R. Krahe[1]* 1) Dept. of Cancer Genetics,Univ.of Texas MD.Anderson Cancer Center, Houston,TX; 2) Dept. of Neurology,Univ.of Rochester Medical Center, Rochester,NY; 3) Dept. of Neurology, Tampere Univ. Hospital, Finland.

Myotonic Dystrophy types 1 and 2 are neuromuscular disorders with multi-system involvement, caused by expansion of microsatellite repeats. For DM1 there is a reservoir of pre-mutation alleles in the population. However, there have been no reports of pre-mutation alleles for DM2 and the minimum size of a pathogenic expansion is not known. The DM2 expansion is part of the complex polymorphic motif (TG)12-26_(TCTG)7-12_(CCTG)3-9_(G/TCTG)0-4_(CCTG)4-15. Expansions are as large as 40 kb with the CCTG motif uninterrupted. Reported normal alleles have repeat track lengths of up to 176 bp or 26 CCTG motifs with one or more interruptions. The smallest reported DM2 expansion had an uninterrupted (CCTG)75. Because of their large size, PCR across DM2 expansions is not possible and few disease alleles have been sequenced. To address questions of the presence of pre-mutation alleles in the population, the smallest pathogenic allele size, and the possible role of the DM2 repeat as a modifier in other neuromuscular diseases, we cloned and sequenced a number of unusually large alleles, along with typical ones, from both normal and disease populations. We identified one DM2 patient whose expanded allele contained an uninterrupted (CCTG) track of only 55 repeats. We found one patient with diagnosis of DM2 and a large expansion by Southern in addition to two consistently amplifiable alleles, differing by 4 bp (possibly mosaic). For him we genotyped 276 clones and saw 45 different alleles, suggesting instability. All of the 16 clones sequenced had uninterrupted CCTG tracks and, except for the length of the CCTG motif, appeared identical. Small-pool PCR found 45% novel alleles, confirming this instability (p=3.99 E-07). A number of other large alleles with track lengths of 170 - 222 bp were also sequenced with up to (CCTG)32 and 1-4 interruptions. We conclude that large unstable alleles exist and may represent a pre-mutation allele pool. Also, the minimum pathogenic allele can contain as few as 55 (CCTG) motifs.

Identification of Sequence Variants in Glutamate Receptor and Interacting Protein Genes in Patients with Mental Retardation Using High-throughput CE-SSCP. *A. Adamczyk[1], S. Bhat[1], A.K. Srivastava[2], C.E. Schwartz[2], D. Valle[1], T. Wang[1]* 1) Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) Greenwood Genetic Center, Greenwood, SC.

Mental retardation (MR) is a common cause of severe handicap in children and young adults, affecting 2-3% of the general population. Genetic defects account for >50% of the identifiable causes of MR. L-glutamate is the predominant excitatory neurotransmitter in CNS via the activation of ionotropic and metabotropic receptors. Glutamate signaling is essential for the induction and maintenance of long-term potentiation (LTP) and long-term depression (LTD), two cellular models of learning and memory. To determine the nature and spectrum of genetic defects in glutamate-signaling that cause MR, we initiated a study on a large cohort (n=1,200) of patients with MR of unknown cause to identify pathological sequence variants (SV) in coding and key regulatory regions of genes that encode glutamate receptors (n=25) and direct interacting proteins using a high-throughput capillary electrophoresis single strand conformation polymorphism (CE-SSCP) screen. We conducted a proof of principle study using DNA samples from 29 patients, each with a different and sequence confirmed mutation, in the ornithine-?-aminotransferense (*OAT*) gene and identified aberrant SSCP tracings in 25 of the 29 (86%;) samples. In a pilot screen of *GRIA1, GRIA2* and *GRIP1* in 768 samples, we found 6 nonsynonymous coding variants (CV) that involve highly conserved functional domains and are absent in SNP database in 8 patients and 6 synonymous CV in 9 patients. in vitro functional studies on these CV are ongoing. We conclude that CE-SSCP is a powerful method to achieve a high-throughput, low cost, and reliable screen to identify potentially pathological SVs in genes that are essential in glutamate signaling in patients with MR.

LDOrbits: Feature Definition in Genome Wide Association Studies. *P. Croteau, J. Segal, Q. Nguyen-Huu, T. Keith, J. Raelson, P. Van Eerdewegh* Genizon BioSciences, St-Laurent, QC, Canada.

In GWAS, where typically more than 300,000 SNPs are analyzed, two issues become critical: 1) distinguishing between truly independent signals (and their respective ranking across the genome) and signals that are correlated due to linkage disequilibrium (LD) and 2) the challenging problem of multiple testing. To reduce the problem of multiple testing and increase the power to detect real signals we have developed a method, LDOrbits, that defines sets of SNPs or orbits. An orbit consists of the SNP with the highest signal and all genotyped SNPs that are in high LD. Various thresholds for LD, as measured by r^2, can be considered. In turn, we identify the highest signal among the remaining SNPs that are not part of any orbits and proceed recursively to define all orbits in the genome. This methodology ensures that two orbits are not correlated, up to the chosen r^2 threshold. We then test for genome wide significance of these p-values by random permutations of case-control status. Although disjoint in the LD space, orbits often consist of non-contiguous sets of SNPs and several such orbits can be interlaced. We therefore compared it to the Asymmetric Running Average (ARA), which is implicitly based on LD but creates disjoint sets of contiguous SNPs. The ARA is based on the single SNP nominal p-values and determines separately the left and right boundaries of the signal where the mean $-\log_{10}$ p-values falls below a set threshold. To measure the advantage of defining orbits or ARA features before testing for genome wide significance, rather than considering each SNP separately, we compare the threshold for significance by each method based on the distribution of order statistics, in a scan of 370,000 markers. Considering first order statistics would lead to identical results among methods, but since true signals will not necessarily rank the highest, it is important to consider lower ranks as well. Using the second order statistic and its 95^{th} percentile, LDOrbits with an r^2 value of 0.2 and ARA increase the threshold for significance for p-values from 9.2×10^{-7} to 1.25×10^{-6}. Similar effects are observed for lower order statistics.

The fibroblast growth factor gene FGF19 is regulated by both FOXC1 and FOXC2. *L. Huang[1], Y. Tamimi[2], M.A. Walter[1]* 1) Medical Genetics, University of Alberta, Edmonton, AB, Canada; 2) Oncology, University of Alberta.

FOXC1 and FOXC2 are related members of the Forkhead Box transcription factor family. Mutations in *FOXC1* cause Axenfeld-Rieger malformations. Mutations in *FOXC2* cause hereditary lymphedema with distichiasis. During eye development, *Foxc1* and *Foxc2* have overlapping expression patterns, and *Foxc2*+/- mice and *Foxc1*+/- mice display very similar eye phenotypes. *Foxc1*+/- and *Foxc2*+/- double heterozygous mice present more severe ocular defects than in either single heterozygote, suggesting overlapping function of FOXC1 and FOXC2 in the developing eye. We hypothesize that FOXC1 and FOXC2 co-regulate some downstream target genes. Recent work revealed that FOXC1 directly regulates *FGF19* expression in cell culture and zebrafish embryos. This study aimed to test if FOXC2 also regulates the expression of *FGF19*.

Luciferase assays were used to test if FOXC2 can activate transcription from *FGF19* regulatory elements in non-pigmented ciliary epithelium cells (NPCEs). A 354bp amplicon (FGF19RE) of the FGF19-5UPE containing FOX binding site was cloned into the pGL3TK luciferase vector. Luciferase activities were monitored after cotransfecting NPCEs with FGF19RE-pGL3TK luciferase reporter vectors, and FOXC2 or FOXC1 expression vectors. Both FOXC2 and FOXC1 significantly activated FGF19RE luciferase reporter. Consistent with this result, chromatin-immunoprecipitation experiments in NPCEs revealed that both endogenous FOXC2 and FOXC1 bind to the *FGF19* promoter *in vivo*. The fragment of the *FGF19* promoter sequence containing a FOX binding site was PCR amplified from sonicated chromatin purified by antibodies to FOXC1, or to FOXC2. These results indicate that *FGF19* is a shared downstream target gene of both FOXC1 and FOXC2, supporting the hypothesis that both of these transcription factors are key regulators in overlapping ocular genetic pathways. Our finding that FOXC1 and FOXC2 independently regulate *FGF19* expression provides an explanation for the similar phenotypes of heterozygous *Foxc2*+/- mice and *Foxc1*+/- mice.

The Generic Genetic Studies Database: A Data Management System for Large Scale Genetic Studies. *A. Day*
Dept Human Genetics, Univ California, Los Angeles, Los Angeles, CA.

Continuing advances in genotyping technology are fundamentally changing the way researchers investigate disease. These new technologies are allowing researchers to assay genetic variation at hundreds of thousands of markers across the entire genome simultaneously. Unfortunately, this progress in genotype data generation has not been matched with advances in the sophistication and capabilities of data management tools. The trend toward highly collaborative projects and the number of subjects, markers, and phenotypes being investigated in each project simply overwhelms the traditional ways of managing data with flat files.

The Generic Genetic Studies Database (GGSD) is an open-source data management software package for large scale genetic studies. GGSD is a web-integrated, relational database driven system that stores and appropriately links: (1)pedigree/individual information; (2)genotype data for both SNPs and microsatellites; (3)phenotype data for both quantitative and qualitative traits; and (4)disease definitions and individuals status for those diseases. GGSD allows researchers to store and manage several projects all through a single interface, and manages the users of the system to track the project(s) each user has access to and their type of access (e.g. upload/delete/update or search/download). GGSD is an extremely flexible system. For example, it allows batch entry of data via file uploads, manual entry and editing of data through web forms, entity-centric web forms for complex querying of any table in the database, pedigree drawing, Hardy-Weinberg equilibrium determination for markers, data download in tab-delimited or linkage format, and sends emails to registered users when data is added/edited/deleted.

The GGSD system was designed around the LAMP and LAPP stack paradigm of constructing dynamic, interactive web-based applications. The entire system was designed and programmed using JavaScript, Perl, PHP, and ANSI SQL. Utilizing this open-source software design framework makes GGSD extremely versatile, portable, and economical.

Genome-wide analysis of transcript isoform variation in humans. *T. Kwan, D. Benovoy, C. Dias, S. Gurd, C. Provencher, T.J. Hudson, R. Sladek, J. Majewski* Human Genetics, McGill University, Montreal, Quebec, Canada.

We conducted a genome-wide association analysis of variation in transcript isoform structures among individuals from the CEU HapMap population using a comprehensive exon-tiling microarray, the Affymetrix Human Exon 1.0 ST Array. Significant genetic associations of cis-acting SNPs with splicing variants (cassette exon skipping, alternate splice site usage, intron retention), differential 5 UTR (initiation of transcription) and 3 UTR (alternative polyadenylation) usage, and differential transcript expression levels were observed. Many of the confirmed splicing events within coding exons are predicted to affect protein structure, while variations in the UTRs are predicted to have transcriptional and translational effects through the addition or removal of important regulatory sequences. Our method has identified the putative causative SNP responsible for the variations in isoform structure in several cases, such as *CAST*, where the associated SNP disrupts a consensus splice site. Several of the transcript isoform variants, such as *OAS1* (cryptic splice site usage) and *IRF5* (differential polyadenylation), have been associated with disease phenotypes, indicating the potential of our analysis method for discovering disease-associated isoform variants. Previous genome-wide association studies have linked genetic variations with changes in gene expression levels, however we now find that a large number of these are in fact transcript isoform variations with differences mainly at the 3 end. Our results show that the variation of gene expression in humans is qualitatively different than previously believed, and illustrates the value and importance of using exon-tiling microarrays for identifying variations in overall gene structure and shedding new light on the detailed effects of cis-acting genetic variants. Under this new paradigm, the functional consequences of future and many previously identified changes need to be re-evaluated.

Replication of association to ATG16L1 and IL23R in a Norwegian population repesentative cohort with inflammatory bowel disease (IBD), but no association with primary sclerosing cholangitis (PSC). *A. Franke[1], M.B. Kirsten[2], T.H. Karlsen[2], T. Balschun[1], A. Bergquist[4], C. Solberg[3], E. Schrumpf[2], M.H. Vatn[2], S. Schreiber[1]* 1) IKMB, Christian-Albrechts University, Germany; 2) Medical Department, Rikshospitalet-Radiumhospitalet Medical Center, Norway; 3) Ullevaal University Hospital, Norway; 4) Department of Gastroenterology and Hepatology, Karolinska University Hospital, Sweden.

Crohn disease (CD) and ulcerative colitis (UC) are the 2 major forms of IBD. Recently, variants in the IL23R and ATG16L1 gene were identified to be associated with IBD and CD, respectively. We previously showed that NOD2 is only weakly associated with CD in Norway. We now replicated ATG16L1 and IL23R in a 10 year incidence cohort from Southern Norway (IBSEN I study). As Norway has very high incidences of PSC, a disease associated with IBD, a large PSC patient panel was tested in a 2nd experiment for ATG16L1 and IL23R. 368 controls, 145 CD, 327 UC, and 365 PSC patients were investigated for the ATG16L1 variant T300A and the IL23R variant Arg381Gln. T300A was significantly associated with CD (p=0.008; OR=1.89, 95% CI [1.10-3.23]), but not with UC. The Il23R variant Arg381Gln was replicated in both the CD and the UC panel (IBD: p=0.005; OR=0.49, 95% CI [0.29-0.82]). However, no significant association between the two tested variants and PSC was detected. Subphenotype analyses for CD revealed an association between ATG16L1 predisposition and smoking status, as well as with disease localization. We replicated associations between IBD and the susceptibility genes ATG16L1 and IL23R in the Norwegian population. Since other reported IBD genes previously failed to replicate or gave only weak signals, ATG16L1 and IL23R are the first *bona fide* susceptibility genes in the Norwegian population. However, both variants do not play a role in the genetic predisposition to PSC. Associations of ATG16L1 with smoking status and ileal localization were identified in subanalyses and need to be confirmed in future studies.

Genome-wide screen for Aicardi-Goutieres-like microcephaly syndrome suggests a molecular etiology distinct from Aicardi-Goutieres syndrome. *K.A. Aldinger[1], A. Rajab[3], M.E. Ross[4], W.B. Dobyns[2]* 1) Committee on Neurobiology and; 2) Departments of Human Genetics, Neurology and Pediatrics, The University of Chicago, Chicago, IL; 3) Genetic Unit, DGHA, Ministry of Health, Muscat, Sultanate of Oman; 4) Department of Neurology and Neuroscience, Weill Medical College of Cornell University, New York, NY.

Background: Several autosomal recessive syndromes with intracranial calcifications in children are known including Aicardi-Goutieres (AGS), Cree encephalitis, Coats-plus and pseudo-TORCH syndromes. All four share early onset leukoencephalopathy, basal ganglia and white matter calcifications, and brain atrophy mimicking a CNS infection. Four AGS loci have previously been identified on 3p21 (AGS1), 13q14-21 (AGS2), 11q13 (AGS3), and 19p13 (AGS4), with Cree encephalitis allelic to AGS1. We have identified an AGS-like microcephaly syndrome (AGSMIC) that consists of microcephaly, short stature, variable mental retardation, and progressive motor deterioration in late childhood. Testing found diffuse basal ganglia and white matter calcifications, osteoporosis, normal fundi and normal TORCH titers; CSF has not been examined. **Objective:** To test the hypothesis that AGSMIC and AGS share similar genetic etiologies. **Methods:** We performed a genome-wide screen in a three-generation Omani family with a consanguineous first cousin marriage and four children affected with AGSMIC using the Affymetrix 50K XbaI SNP chip, followed by homozygosity mapping. We used WebQTL to determine whether expression of AGS-causative genes (*Trex1, Rnaseh2a, Rnaseh2c*) in mouse whole brain and striatum correlates with expression of genes within our 2q locus. Finally, we sequenced candidate genes to identify causative mutations. **Results:** Our results demonstrate the most significant evidence for linkage under an autosomal recessive model for AGSMIC on chromosome 2q35-36.3 (LOD = 3.01 at 215-229 cM), and moderate evidence for linkage at a second locus on 12q15-21.3 (LOD = 2.02 at 90-91 cM). Homozygosity mapping restricted the 2q locus to 9.5 Mb containing 93 known genes, and the 12q locus to 14 Mb containing 38 known genes. The AGS1-4 loci were excluded. Using WebQTL we identified 5 genes on 2q with correlated expression level of AGS-causative genes, but no causative coding mutations were found. **Conclusion:** We report a novel AGS-like phenotype and the first evidence for linkage suggesting that this disorder is genetically distinct from AGS.

Admixture and Hormone Receptor Status of Breast Cancer among African Americans. *L. Fejerman[1], E. John[2], C. Ambrosone[3], A. Whittemore[6], S. Neuhauser[7], K. Amend[4], W. Davis[5], D. Bovberg[4], S. Huntsman[1], D. Hu[1], W. Lorizio[1], E. Ziv[1]* 1) Medicine, UCSF, San Francisco, CA; 2) Northern California Cancer Center, Union City, CA; 3) Epidemiology, Roswell Cancer Center, Buffalo, NY; 4) Oncological Sciences, Mount Sinai School of Medicine, New York, NY; 5) Cancer Prevention and Population Sciences, Roswell Cancer Center, Buffalo, NY; 6) Health Services Research, Stanford University, Palo Alto, CA; 7) Epidemiology, UCIrvine, Irvine, CA.

African American women present more commonly with estrogen receptor (ER-) and progesterone receptor negative (PR-) breast cancer compared with Caucasian women. We hypothesized that this difference in incidence of PR/ER- tumors is due to the difference in the frequency of predisposing alleles between the ancestral populations (European and African). We used an admixture mapping approach to search for loci that may underlie this difference. Methods: Samples are from African American women newly diagnosed with first primary invasive breast cancer (N=333). 1,491 ancestry informative markers were successfully genotyped. Ancestry estimates were calculated with the program STRUCTURE1.2. We tested the association between locus specific ancestry and ER/PR status using logistic regression, including individual ancestry as a covariate. We used a permutation test to evaluate for genome wide significance. Results: Our results suggest an association between lack of expression of hormone receptor and African ancestry ($p=0.03$ for PR and $p=0.059$ for ER). Examining locus specific ancestry differences among PR- vs. PR+ and ER- vs. ER+, we found nine regions with a nominally significant ($p<0.05$) difference in ancestry. One region on chromosome 15q- was strongly associated with PR status ($p=0.00006$) and was significant at the genome-wide level ($p=0.017$). At this locus, individuals with PR- tumors tend to have higher African ancestry, and individuals with PR+ tumors higher European ancestry. Conclusion: Breast cancer hormone receptor status risk is associated with ancestry among African American women. At least some of this difference may be determined by a locus on chromosome 15.

How good is whole-genome amplified DNA for genome-wide association studies? *N. Akula[1], S. Cichon[2], M. Noethen[2], F. McMahon[1]* 1) Genetic Basis of Mood and Anxiety Disorders, National Institutes of Mental Health/National Institutes of Health, Bethesda, MD; 2) Department of Genomics, Life & Brain Center, University of Bonn, Germany.

The quality and quantity of available DNA samples remains a limiting factor for genome-wide association studies. This issue becomes even more critical if cell lines are not available or samples were collected under sub-optimal conditions. Whole-genome amplification is a cost-effective solution, but the performance of whole-genome amplified DNA on genome-wide single-nucleotide polymorphism chips is not well established. We genotyped four unrelated DNA samples derived from whole blood on the Illumina HumanHap550 genotyping chip both before and after whole-genome amplification, and compared the results. The genotype discrepancy rate between genomic DNA and whole-genome amplified DNA was less than 0.02% in all samples we tested. One SNP in an inter-genic region on chromosome 2p was discrepant in all 4 samples between the genomic and whole-genome amplified DNA. Call rates for genomic DNA samples were all greater than 99%, whereas call rates for the corresponding whole-genome amplified samples were 95%-96%. This study demonstrates that whole-genome amplified DNA performs well on a widely-used genome-wide genotyping platform.

Complete skewed X-inactivation pattern in a patient carrying a Xq28 deletion. *R. Della Casa[1], R. Taurisano[1], D. Melis[1], F. DElia[1], C. Figliuolo[2], R. Genesio[2], A. Conti[2], F. Fabbrini[2], L. Nitsch[2], G. Sebastio[1], G. Andria[1]* 1) Dept Pediatrics, Federico II Univ, Naples, Italy; 2) Dept Biology and Cellular and Molecular Pathologye, Federico II Univ, Naples, Italy.

We describe a patient carrying a duplication of Xp22.3 and a deletion of Xq28 band in one of two X chromosomes. The patient, a female, was born at term by cesarean section. Intrauterine growth retardation was registered during pregnancy and microcephaly was observed at birth. When the patient was 5 year-old, the phenotype included: short stature, microcephaly, dysmorphic features (small forehead, slightly deep-set eyes, apparent hypotelorism, relatively large ears, a prominent nasal bridge, prognathism), small hands and feet, proximal implant of thumbs bilaterally. Brain Magnetic Resonance Imaging showed thinning of corpus callosum; Psychometric tests demonstrated an IQ of 60; ABR, ophthalmology examination, abdominal ultrasound showed no abnormalities. Karyotype analysis was normal. The study of sub-telomeric regions revealed a de novo duplication of Xp22.3 and a deletion of Xq28 band in one of two X chromosomes. The duplication and the deletion interested whole par1 and par2 regions, respectively. The study of chromosome X inactivation pattern showed a complete (100% analyzed lymphocytes) skewed X inactivation of the chromosome carrying the alteration. The present case confirm the hypothesis, already reported in the literature, that genes, involved in the regulation of skewed X inactivation, map in Xq28.

Functional Assessment of Variants of the Copper Transporter, ATP7B, in Wilson Disease. *S.M. Kenney, C.N. de Leeuw, L.M. Luoma, G. Macintyre, L. Prat Davies, D.W. Cox* Medical Genetics, Univ of Alberta, Edmonton, AB, Canada.

Wilson Disease is a recessive disorder of copper transport resulting in copper accumulation in, and damage to, liver, kidney and brain. The age of onset of symptoms varies from 3 to almost 70 years, and the diagnosis for this treatable disorder is easily missed. The defective gene encodes a copper transporting membrane P-type ATPase. We have entered all reported mutations in *ATP7B* in the HUGO/HGVS Wilson Disease Database, which includes more than 500 variants (probable disease-causing and the remainder possible normal variants) from populations worldwide (www.medicalgenetics.med.ualberta.ca/wilson/index.php). Of 380 suspected disease-causing mutations in the database, 199 are missense, 114 insertions and deletions, 34 nonsense and 33 splice site mutations. A major issue to address is discrimination between disease-causing and rare normal variants. We use a transport assay in yeast, and cytotoxicity and trafficking assays in Chinese Hamster Ovary (CHO) cells, and homology modeling for functional assessment. Ccc2p, a yeast homologue of ATP7B, supplies copper to Fet3p that imports iron into yeast. *ccc2* mutant yeast do not transport copper to Fet3p, and cannot grow on iron deficient medium (IDM). Human *ATP7B* complements the *ccc2* mutant yeast defect and supports growth on IDM, mutants do not complement. We tested the copper transport ability, in yeast, of 9 ATP7B variants identified in patients. We identified 6 ATP7B variants with a severe impairment in copper transport. Three of the tested variants, and 5 additional variants were assessed in a copper cytotoxicity assay. CHO cells do not express *ATP7B* and are sensitive to copper. *ATP7B* confers protection against copper. Variants defective in trafficking are not protective. 3 variants had similar results in both assays, one severe and two mild. Of five untested variants, 4 had severe defects and were copper-sensitive. A SIFT (Sorting Intolerant From Tolerant) analysis did not distinguish normal from disease variants in 23% of cases. Identification of mutations that contribute to Wilson disease in patients will expand our understanding of the function of this copper transporter and aid in molecular diagnosis.

Physical mapping of human chromosome 21p. *J. Doering[1], R. Ennesser[1], Z. Flener[1], E. Miller[1], S. Bracken[1], M. Cummings[2]* 1) Loyola University Chicago; 2) University of Illinois, Chicago.

While 10-15% of the human genome is composed of heterochromatic DNAs, these regions are not included in the completed sequence. We are creating a detailed physical map of the centromere and p arm of HC21 as a model for the organization of such regions. Our previous work demonstrated that the proximal short arm of HC21 contains a copy of the chAB4 duplicon that is actually part of a larger duplicon ~200kb in size. Copies of this duplicon are highly conserved on HC21, Y, 17 and 22. Further sequence analysis now reveals that there is a 47kb inverted repeat within this duplicon as well as poorly conserved copies of rDNA spacer sequences and acrocentric chromosome subtelomeric sequences. This duplicon on proximal 21p is located in the midst of the 21-II region, which contains multiple clusters of monomeric alphoid DNA more than 2Mb away from the centromere. Such an organization of alphoid sequences has not been found on other chromosomes to date. We have identified an HC21p BAC containing the 9kb subtelomeric repeat known to be on distal 21p13 and have constructed a nearly 400kb contig including that BAC by identifying sequences in the database that had not been previously placed in the overall genome map. This region contains complex rearrangements of portions of the same duplicon found in the proximal area of 21p. We have also constructed an overall physical map for most of 21p13. It contains a single 0.8Mb cluster of satellite I, adjacent to one major satellite III cluster of 0.5Mb, which in turn is adjacent to a small cluster of satellite. Regions between these clusters appear to be composed of low copy number sequences. The overall organization of HC21p appears to be much more complex than originally proposed, and it indicates that extensive sequence rearrangements have been involved in the evolution of this chromosomal region.

Aortic root dilatation is highly prevalent in male patients affected with Fabry disease and correlates with the presence of a megadolicho-ectatic basilar artery. *D.P. Germain[1], B. Diebold[2], S. Peyrard[3], A.I. Martin-Mista[1], K. Benistan[1]* 1) Centre de reference de la maladie de Fabry et des maladies hereditaires du tissu conjonctif. Deparment of Genetics, Hopital Raymond Poincare, Garches, France; 2) Department of Cardiology, HEGP, Paris, France; 3) URC, HEGP, Paris, France.

Background : Fabry disease (FD, OMIM 301500) is an X-linked metabolic storage disorder due to the deficiency of lysosomal alpha galactosidase A, and the subsequent accumulation of glycosphingolipids throughout the body. While FD pathophysiology basically results from multifocal small-vessel involvement, little is known about the involvement of large vessels with the exception of the classically described ectatic vertebral and basilar arteries. Methods: Using echocardiography, we prospectively investigated aortic root diameter in 71 consecutive hemizygous males (mean age : 40 years, range 16-66 years) and 67 heterozygous women with a (mean age : 41 years, range 15-67 years)affected with classic FD. Cranial MRI was also simultaneously performed in all patients (n=138). Results: The mean aortic diameter was 33.2 mm (SD = 5.8) in males and 32.9 mm (SD = 5.7) in females. Of 71 male patients, 17 (24 percent) had an aortic root dilation (diameter > 40 mm). In contrast, only one heterozygote had aortic root diameter > 40 mm. Out of the 17 hemizygotes with aortic dilatation, 9 had a megadolicho-ectatic basilar artery on cranial MRI. Out of the remaining 54 hemizygotes, 7 additional cases of ectatic basilar artery were found. Discussion : This is the first study demonstrating that, in addition to its microvascular involvement, FD is associated to an increased risk of developing aortic root dilatation in male patients. Aortic root dilation was detected in 24 percent (n=17) of our 71 hemizygous male patients. Aortic root dilatation was statistically associated with the presence of a dolicho-ectatic basilar artery (corrected Chi square, P=0.004). We recommend to search for aortic root dilatation and dilative arteriopathy of the vertebrobasilar circulation in male patients affected with FD.

The diverse phenotypic spectrum associated with fibulin-4 mutations. *A. De Paepe[1], L. Ades[2], M. Renard[1], K. Wettinck[1], B. Callewaert[1], P. Coucke[1], B. Loeys[1]* 1) Medical Genetics, Univ Hosp Gent, Belgium; 2) University of Sidney, Australia.

Heritable diseases of elastic fiber formation affect multiple organ systems and are associated with several genes coding for elastin (ELN), fibrillin-1 and -2 (FBN1/2), fibulin-5 (FBLN5), GLUT10 (SLC2A10), TGFbeta receptor 1 or 2 (TGFBR1/2). Recently, fibulin-4 (FBLN4) was linked to autosomal recessive cutis laxa. In one patient presenting with cutis laxa, multiple fractures, hernias, emphysema, generalized tortuosity with aneurysms and joint hypermobility a homozygous FBLN4 missense mutation (p.E57K) was identified. In this study, we characterize the clinical and molecular spectrum associated with FBLN4. We performed direct sequencing of FBLN4 in two cohorts of patients: group I of 15 patients with cutis laxa (negative for ELN and FBLN5) and group II of 38 patients with arterial tortuosity, stenosis and aneurysms (negative for SLC2A10, FBN1 and TGFBR). In group I, no FBLN4 mutations were found but in group II, three homozygous FBLN4 missense mutations were identified. The first mutation replaces the exact same glutamine from the EGF consensus sequence as the previously reported p.E57K but in a different cbEGF domain, whereas the others affect amino acids in the first cbEGF domain and the fibulin-type module. The latter mutations were absent in 200 control chromosomes. All patients present with a vascular phenotype but quite diverse in nature. The first proband has a history of extreme arterial tortuosity and massive aneurysms of the aorta, pulmonary artery and major abdominal arteries necessitating surgery at young age (2.5 m). She did have a smooth, velvety skin but no cutis laxa. The second patient presented with premature coronary disease at age 46, necessitating bypass surgery. At that time, a thickened aortic wall was noticed. Her history is otherwise significant for atrophic scars and keloid formation. The last patient presented with joint hypermobility, ascending aortic aneurysm and tortuosity. No other skin, lung or bone abnormalities were seen. Histology of aortic biopsies showed disrupted elastic fibers and increased deposition of glycosaminoglycans.

Disease InfoSearch includes a Portal to National Library of Medicine Databases. *H. Ferguson[1], K. Puchir[1], K. White[1], J. Ostell[2], S. McDaniel[2], J. Coleman[2], L. Forman Neall[2], C. Falco[1], A. Krokosky[1], H. Travers[1], S.F. Terry[1]* 1) Genetic Alliance, Washington, DC; 2) NCBI, NLM, Bethesda, MD.

Accessing accurate information about genetic conditions has become increasingly difficult. Patients and their families are often unfamiliar with medical terminology and scientific literature. It may be difficult to ascertain what constitutes genetic disease-specific expertise. Healthcare providers may find medical and scientific information lacking reliability, either because it is based on out-dated information or because the available case studies do not conform to the higher ARHQ standards of evidence. Further, time constraints limit the abilities of healthcare providers to do extensive searches. Genetic Alliances Disease InfoSearch (DIS)is an online search tool providing links to clinical information for many genetic conditions. Each entry includes detailed information about advocacy and support groups and provides updates on management and treatment when available. All of the information is deposited into DIS by the condition-specific advocacy organization. Aggregating information vetted by their professional advisory boards creates links to accurate information. These experts review the literature for their condition and recommend the most current quality information. In collaboration with the National Center for Biotechnology Information (NCBI), Genetic Alliance expanded DIS to include a portal to the National Library of Medicine (NLM) databases. A customized search targeting the users condition directly from DIS uses backend filters to display NLM resources on a portal page. This portal organizes information so that a broad spectrum of users can drill directly into the NLM databases at the most appropriate level. A feature, MyNCBI, which allows users to track emerging information over time through a notification system, is highlighted for DIS users on the portal. The combined expertise of Genetic Alliances advocacy organizations members and NCBIs staff make DIS an invaluable source of information for newly diagnosed individuals, their caregivers, and healthcare professionals, thereby improving the lives of those with genetic disorders.

Focusing on linked pedigrees for localizing disease genes: the sumLINK statistic applied to general and aggressive prostate cancer linkage data from the ICPCG. *G.B. Christensen, N.J. Camp, ICPCG* Dept Biomedical Informatics, Univ Utah, Salt Lake City, UT.

We propose a new genomewide linkage-based statistic, sumLINK, to identify disease-susceptibility loci. Our approach focuses only on linked pedigrees (pedigree-specific LOD0.588; p0.05) to identify regions of extreme consistency across pedigrees. The sumLINK statistic is simply the sum of multipoint LOD scores for linked pedigrees at a given point in the genome. The significance of the sumLINK is assessed by a unique shuffling method that simulates the expected consistency of linked pedigrees. For each pedigree, we calculate multipoint LOD values at 1-cM intervals across the genome. All chromosomes are connected to create a loop, then the loop is broken at a random position to create a null genomewide scan for the pedigree. This procedure maintains each pedigrees potential for linkage signals across the genome, but randomizes consistency across pedigrees. For each null simulation, all pedigrees are realigned to their new starting points and the sumLINK is calculated for each cM position. The process is repeated 1000 times to determine the empirical distribution of the sumLINK for the pedigree resource. We applied the sumLINK approach to autosomal data for 1,232 pedigrees with prostate cancer (PCa) from the International Consortium for Prostate Cancer Genetics (ICPCG), and 190 ICPCG aggressive PCa pedigrees. Peaks were considered significant if exceeded fewer than 0.05 times per genome in the simulations, and suggestive if exceeded less than once per simulated genome. In the general PCa analysis, two genomewide significant regions (5p, 22q) and eleven suggestive regions were identified. In the aggressive PCa pedigrees, two significant (11p, 20q) and one suggestive (2p) loci were found. Some loci found here were also seen using standard HLOD analyses, but several have not previously been identified. An advantage of loci identified with the sumLINK approach is that they have good potential for subsequent gene localization using statistical recombinant mapping, as, by definition, there exist multiple linked pedigrees contributing to each peak.

Systematic review and meta-analyses of preterm birth genetic association studies. *S.M. Dolan[1], M. Merialdi[2], A. Pilar[2], T. Allen[2], B.K. Lin[3], J. Eckardt[9], M.J. Khoury[4], J.P. Ioannidis[5], L. Bertram[6], M. Hollegaard[7], D.R. Velez[8], R. Menon[9]* 1) Albert Einstein College of Medicine; 2) World Health Organization; 3) March of Dimes; 4) Centers for Disease Control and Prevention; 5) University of Ioannina School of Medicine; 6) MassGeneral Institute for Neurodegenerative Disease; 7) Statens Serum Institut; 8) Vanderbilt University; 9) The Perinatal Research Center.

Preterm birth (PB) is a major public health concern with rates over 12% and rising in many parts of the world. Studies reporting associations between single gene variants and PB have been hampered by varying definitions of PB, small sample sizes and population admixture. The challenge of identifying robust associations between genetic variation and susceptibility to PB is enormous. A systematic review and continually updated online field synopsis will provide the cumulative evidence on genetic associations with PB. Such associations can be deemed more robust if they are based on large-scale evidence, extensively replicated, and free of bias. Many criticisms of studies of complex diseases can be avoided if systematic review allows pooling of data and meta-analysis that can reveal true associations. In conjunction with the Human Genome Epidemiology Network (HuGENet), members of the Preterm Birth International Collaborative (PREBIC) conducted a systematic review of the literature on genetic associations in PB. Medline and Embase were searched using a sensitive search strategy to identify all appropriate studies published since 1/1/90. 5421 titles were identified and abstracts reviewed according to a set of inclusion and exclusion criteria. We selected 88 abstracts and obtained full text articles, thereby cataloging all genetic association studies published in the field of PB to date. Where sufficient data exist, we will conduct meta-analyses on specific gene variants. Concurrent with the research, an online summary of the data will be placed online to allow continued updating of data. This work will facilitate research in PB and, like *AlzGene* (www.alzgene.org), can be a model for other fields to integrate cumulative evidence on genetic association studies.

Whole Genome Study of Idiopathic Talipes Equinovarus (Clubfoot) Families. *J.T. Hecht[1,2], A.R. Ester[1], X. Tang[1], F.R. Dietz[3], M.S. Bray[4], A. Scott[2], Y. Bradford[5], S.H. Blanton[6]* 1) Dept Pediatrics, University of Texas Medical School, Houston, TX; 2) Shriners Hospital for Children, Houston, TX; 3) University of Iowa, Iowa City, IA; 4) Baylor College of Medicine, Houston, TX; 5) Vanderbilt University, Nashville, TN; 6) University of Miami Miller School of Medicine, Miami, FL.

Idiopathic talipes equinovarus (ITEV), or isolated clubfoot, is a common birth defect with a prevalence of 1/1000 live births. Males are affected twice as often as females; half of the cases are bilateral, with the majority of the unilateral occurrences in the right foot. ITEV is defined by four characteristics: forefoot adductus, midfoot cavus, hindfoot adductus and hindfoot equinus. Segregation studies of ITEV show that it is a complex disorder caused by multiple genes and environmental exposures. Few gene identification studies have been performed in ITEV. The focus of this study is to identify the genes contributing to the ITEV phenotype. We conducted a genome scan using ten of our largest multiplex ITEV families and the Linkage IV genotyping panel (Illumina, Inc., San Diego, CA), which contains 6,008 single nucleotide polymorphisms (SNPs). The resulting data was analyzed using parametric and nonparametric linkage analyses (Fastlink and Allegro) and disequilibrium analysis (PDT). Multipoint linkage analysis identified four chromosomal regions with a LOD score above 1.5: 4p13-14 (LODmax=1.89), 17q22-24.1 (LODmax=2.17), 19q13.32-13.42 (LODmax=1.66) and 20q13.11-13.13 (LODmax=1.71). Interestingly, the 4p13-14 region overlaps with a previously identified chromosomal deletion region found in children with clubfoot and other anomalies. The overlapping deletion region contains several candidate genes of particular interest including WDR19 and HIP2 which reportedly suppress apoptosis. Apoptosis has been associated with ITEV. These regions provide a starting point to begin to dissect the complex etiology of ITEV.

TUNA (Testing UNtyped Alleles) reveals new associations with type 2 diabetes in Mexican Americans. *M.G. Hayes[1], W. Wen[2], Y. Sun[3], A. Pluzhnikov[1], C.L. Hanis[4], N.J. Cox[1,3], D. Nicolae[1,2]* 1) Medicine; 2) Statistics; 3) Human Genetics, The University of Chicago, Chicago, IL; 4) Human Genetics Center, The University of Texas Health Sciences Center, Houston, TX.

Initial investigations (Hayes et al., 2007, *Diabetes*) in our genomewide association study (GWAS) identified several susceptibility genes for type 2 diabetes (T2D) in Mexican Americans (MA) from Starr County, Texas. Although the Affymetrix 100K mapping array directly interrogates only ~95K SNPs in the MA sample, given a reference database like the HapMap and the knowledge of the LD patterns in it, it is possible to use the SNPs genotyped on the array to conduct association tests in the remainder of the untyped variation in the human genome. Using the TUNA (Testing UNtyped Alleles) statistical framework (Nicolae, 2006, *Genetic Epidemiology*) for this procedure, we estimated unobserved allele frequencies as a linear combination of observed haplotype frequencies. The set of untyped variants to be tested is found using a multi-locus measure of LD, M_D, and haplotype frequencies from the European (CEU) and Asian (ASN) HapMap samples (we independently considered the LD patterns in these two populations due to the admixed nature of the MA population) to yield $_1^2$ distributed statistics under the null hypothesis of no association. TUNA is relatively quick (hours to overnight), and increased the number of SNPs examined from ~95K SNPs passing quality control thresholds to 800K SNPs. Interrogating the imputed SNPs reveals several new associations with T2D not detected among the SNPs typed on the 100K array. For example, *MAGI2*, shows marginal evidence of association using the typed SNPs on the 100K array (best $_1^2$=7.274), but yielded $_1^2$20 with imputed SNPs regardless of which HapMap population (CEU or ASN) is used in the calculations. This gene is of particular interest since it shows evidence of replication in the Broad/Lund/Novartis Diabetes Genetics Initiative GWAS. We are currently genotyping these imputed SNPs and others identified as highly associated with T2D in the MA for confirmation and proof of principle of this approach.

Bayesian choice of optimal number of subpopulations from multilocus genotype data. *H. Gao, K. Bryc, C.D. Bustamante* Dept.Bio.Stat.& Comp. Bio. , Cornell University, Ithaca, NY.

Strong population stratification is a known factor that inflates the false positive rates substantially in association mapping tests. The popular software STRUCTURE performs Bayesian classification of individuals into subpopulations conditional on the input of the number of clusters. We present a Bayesian model selection criterion--Deviance Information Criterion (DIC)--to determine the number of the clusters underlying a given sample, which fits the Bayesian clustering algorithm of STRUCTURE well and can be easily integrated into the Markov Chain Monte Carlo framework. We also performed extensive coalescent simulations under various genetic contexts (e.g. population differentiation with migration or partial self-fertilization, hierarchical population stratification) to evaluate the accuracy and robustness of the DIC approach vs. several other methods, such as the likelihood approximation method implemented in STRUCTURE, the K method and the EIGENSTRAT approach. It turns out the DIC outperforms the rest methods in most genetic scenarios, with its percentage of correct hittings of true number of subpopulations always close to 100%, which implies it can facilitate correcting for the confounding effect caused by population structure in the whole-genome association studies.

New insights into the understanding of premature suture closure: increased plasticity of cranial periosteal cells harboring Apert p.Ser252Trp FGFR2 mutation. *R. Fanganiello[1], A.L. Sertié[1], E. Yeh[1], D.F. Bueno[1], M.T. Martins[2], I. Kerkis[3], M.R.S. Passos-Bueno[1]* 1) Dept Genetics & Evolution, Biosciences Inst, Sao Paulo, Brazil; 2) Department of Pathology, School of Dentistry, São Paulo, Brazil; 3) Instituto Butantã, Sao Paulo, Brazil.

Apert syndrome (AS), a severe form of craniosynostosis, is caused by dominant gain-of-function mutations in FGFR2. Accelerated suture fusion during development and after surgery has been attributed to an increased osteogenic potential of the osteoblasts. However, as we have shown in a previous report (Fanganiello et al, 2007, in press), it is possible that the FGFR2 mutant periosteal cells also contribute to the accelerated process of suture fusion. In order to better understand the function of this tissue in AS cranial pathophysiology we compared the proportion of mesenchymal surface markers and the differentiation potential of the coronal suture periosteum cells from 3 AS patients (p.Ser252Trp mutation) to wild type periosteal fibroblasts from 3 controls. In flow-cytometry experiments, we observed that both AS and control cells stained positively (95%) for mesenchymal stem cell (MSC) markers (SH2, SH3, CD29, CD90) but negative for hematopoietic (CD45, CD117) or endothelial SC markers (CD31), indicating a highly homogeneous population (95-98%) of mesenchymal cells. Under in vitro differentiation conditions AS periosteal cells had a strikingly higher differentiation potential towards osteoblast and adipocytes when compared to non-mutated control cells. This was verified by cell/tissue specific staining techniques (von Kossa and Oil-Red) and confirmed by quantitative real-time PCR of tissue specific gene expression (Osteopontin and COL1A1 for osteoblasts and LPL for adipocytes, p0.05). We are currently evaluating the in vivo ability of these cells to reconstruct large-sized cranial bone defects in rats with a model previously established in our lab. Our findings suggest that the mutant periosteal cells might play an important role in the suture ossification of AS patients as well as in the recurrent suture closure after surgery due to its increased osteogenic potential. FAPESP, CNPq.

Nucleosome Exclusion Regions across the Human Genome. *S. Khuri[1], A. Radwan[2], P. Luykx[3], A. Younis[3]* 1) Miami Institute for Human Genomics, University of Miami Miller School of Medicine; 2) Dept. Electical and Computer Engineering, University of Miami; 3) Dept. Biology, University of Miami.

Nucleosomes are DNA-protein complexes that are the building blocks of eukaryotic chromatin. They are involved in genome condensation, and play a significant role in transcriptional regulation. Each nucleosome comprises eight histone proteins that together form a compact unit that accommodates 147 nucleotides wound around it. There are certain DNA sequence patterns that are unlikely to be involved in nucleosome binding, due to a lack of flexibility inherent in their double helical structure. These sequence patterns include GC-rich motifs, as well as poly-A and poly-T tracts. Previously we developed a webtool (NXSensor) that was able to predict these nucleosome exclusion motifs. Using a pilot grid computing architecture, we developed an updated version of NXSensor and implemented it on the whole human genome (build hg18), where we observed three main trends. First, we were able to predict the location of Nucleosome Exclusion Regions on all chromosomes, and found that these were correlated with gene density. Second, we calculated Nucleosome Exclusion Scores (NXScores) for the promoter regions (-1500 to +500 bp) of all known genes, and found that there was a strong signal for nucleosome exclusion around the transcriptional start site. In addition, the high NXScores persisted on average 250 nucleotides into the gene, presumably to allow the transcription machinery to gain momentum, or to give leeway for alternative transcriptional start sites. Third, we correlated promoter-region NXScores with gene expression and tissue specificity. We found the more tissue specific a gene is, the more likely it is to have nucleosomes positioned along its promoter. Furthermore, gene expression was positively correlated with a high NXScore such that genes with median expression levels also had high NXScores, but expression level drops with very high NXScores. This may be a reflection of the slower movement of the transcriptional machinery through regions of a high GC content. These results provide further insights into the relationships between the human nucleosome landscape and gene regulation.

Association of polymorphisms in folate pathway genes (MTHFR, CBS, MTRR and GCPII) and risk for neural tube defects in the State of Yucatan, Mexico. *L. Gonzalez-Herrera, I. Castillo-Zapata, M.G. Garcia-Escalante, D. Pinto-Escalante 1., T. Canto-de Cetina* Dept Genetica, Univ Autonoma de Yucatan, Meridal, Yucatan, Yucatan, Mexico.

Neural tube defects (NTD) are prevalent congenital malformations in the state of Yucatan, Mexico (22.31 per 10,000 births). Several candidate genes have been derived from the folate pathway including MTHFR, MTRR, CBS and GCPII, since their allelic variants might increase the risk for NTD. Frequency of polymorphisms C677T and A128C in MTHFR, ins68bp in CBS, A66G in MTRR and C1561T in GCPII, was evaluated for an association with the risk for NTD in the State of Yucatan, Mexico. 96 newborn patients with non-syndromic NTD, as well 82 of their mothers and 52 of their fathers were analysed and compared with an ethnically matched control group of 115 healthy volunteers. Genotypification was performed by PCR-RFLPs. Allelic and genotypic frequencies were compared between cases and controls for gender and phenotype stratification in EpiInfo software (OR, IC 95%;). Genotypic frequencies in control group for the five polymorphisms were according to Hardy-Weinberg expectations (p> 0.33). Polymorphisms C677T-MTHFR, ins68bp in CBS, and C1561T in GCPII did not show significant differences between cases and control (p>.05), suggesting that these variants are not associated risk factors for NTD in Yucatan. Frequency of polymorphism A66G-MTRR were significantly higher in controls (50.8%;) than in cases (8.4%;) (p< 0.0001), suggesting that this allele might be associated as a protection factor in the population (OR: 0.10, IC 0.05-0.17). The variant A1298C-MTHFR showed a gender specific distribution and its frequency was significantly higher in male (p= 0.017). A1298C-MTHFR was associated with NTD in female affected newborns (OR= 2.62 IC: 0.92-7.62) and with mothers of NTD (OR 3.01, IC: 1.18-9.75). According to phenotype stratification, mothers of anencephaly offspring showed the strongest association for the allele A1298C (OR= 4.33 IC:1.23-15.29), suggesting that this polymorphism is an associated risk factor in female for both to develop an NTD and for having offspring with anencephaly in the Yucatan population.

Testing models of human aneuploidy: age-related variation in recombination in trisomic meioses. *H. Hall[1], U. Surti[2], T. Hassold[1]* 1) School of Molecular Biosciences and Center for Reproductive Biology, Washington State University, Pullman, WA; 2) Magee-Womens Research Institute, Pittsburgh, PA, 15213.

Trisomy affects about 4% of clinically recognized pregnancies. To date, only two factors have been linked to the origin of trisomy, recombination and maternal age. We have been interested in testing models that explain the relationship between these two predisposing factors. In the course of these studies, we have examined the parental/meiotic origin and recombination status of over 300 new cases of trisomies 13, 16, and 22. Combined with previous studies of trisomy, our results suggest three types of nondisjunctional mechanisms: those shared by all chromosomes, those by groups of chromosomes, and those specific to individual chromosomes. As a test of the relationship between recombination and maternal age, we evaluated recombination levels in maternal meiosis I derived trisomies for our new data set and for previously published data on trisomies 15, 18, 21, and sex chromosome trisomies. We tested these data against two popular models of human nondisjunction: the production line model and the two-hit hypothesis. The production line model predicts declining recombination levels with maternal age in both normal and trisomy-generating meioses. We found no evidence of this for any of the trisomies we examined; thus, this model is unlikely to explain the maternal age effect. The results for the two hit model were more complicated. This model proposes that nondisjunction-prone chiasmata configurations (the first hit) occur in a proportion of fetal oocytes and with age, these become more likely to nondisjoin due to degradation of meiotic processes (the second hit). Thus, in its simplest form, this model predicts similar levels of susceptible configurations in trisomies involving younger and older women. Our results indicate this is the case for some, but not all trisomies; for most trisomies, we observed a decrease in susceptible events with maternal age. Thus, it seems unlikely that either of the models satisfactorily explains the maternal age effect, suggesting a more complicated, and likely chromosome-specific, relationship between age, recombination, and nondisjunction.

Autosomal Dominant Duodenal Atresia - Report of two families. *J. Jessen[1], K. Chong[1,2], D. Chitayat[1,2]* 1) Mount Sinai Hospital, Dept. Prenatal Diagnosis and Medical Genetics; 2) Hospital for Sick Children, Division of Clinical and Metabolic Genetics, Toronto, Ontario, Canada.

Duodenal atresia (DA) is the result of a lack of epithelial apoptosis and recanalization of the duodenum at 8-10 weeks' gestation. Recent mouse model research suggests that some forms of atresia may be hereditary and result from deregulation of proliferation and apoptosis of the developing intestine through the fibroblast growth factor pathways indicating a critical role for the Fgf10 -Fgfr2b signaling pathway (Fairbanks, 2006). We report on two families with parent and child affected with duodenal atresia/stenosis (DS). Case 1: The couple presented with fetal ultrasound findings of double bubble at 27 weeks gestation, suggestive of DA. The mother was of Polish/Ukrainian and the father of Scottish/English descent. The couple was non-consanguineous. The father was born with duodenal stenosis (DS), which was confirmed during surgery shortly after birth. The pregnancy was conceived via IVF and was otherwise uncomplicated. Amniocentesis was done at 36 weeks gestation for polyhydramnios management and the karyotype was 47, XXY. The baby was born at 41 weeks gestation and the diagnosis of DA was confirmed at the corrective surgery. Case 2: The couple was seen regarding their first pregnancy which was complicated with fetal ultrasound findings of double bubble. Amniocentesis was declined. The pregnacy was uncomplicated and the diagnosis of DA was confirmed at corrective surgery shortly after birth. The mother was of Italian/Polish/Ukrainian and the father of Scottish/English descent. The couple was non-consanguineous. The mother was born with DA corrected surgically and is otherwise healthy. Their second pregnancy was uncomplicated and the newborn is well. DA is a rare condition and has an incidence of 1:5,000-10,000 live births. Most cases are sporadic and 1/3 of the cases are associated with trisomy 21. Investigations of familial cases of duodenal atresia suggest an autosomal recessive inheritance in these individuals (Fonkalsrud, 1969; Mishalany, 1971). To the best of our knowledge these are the first two families suggestive of autosomal dominant inheritance.

Report of a prenatally detected XX/XY chimera with true hermaphroditism. *T.L. Gillan[1], R.L. Sparkes[2,3], J.L. Lauzon[2,3], A.M. Innes[2,3], S. Shetty[1,2], P.J. Bridge[2,4], J.E. Chernos[1,2]* 1) Cytogenetics Laboratory, Alberta Children's Hosp, Calgary, AB, Canada; 2) Department of Medical Genetics, University of Calgary; 3) Clinical Genetics Unit, Alberta Childrens Hospital; 4) Molecular Diagnostic Laboratory, Alberta Childrens Hospital.

We report a case of an XX/XY chimera, first ascertained prenatally following chromosome analysis for a positive first trimester screen. On chorionic villus sampling (CVS) four distinct cell lines were identified: two predominant diploid cell lines (46,XX and 46,XY), seen with a frequency of 70% and 30% respectively, and a smaller proportion of tetraploid cells (92,XXXX and 92,XXYY). Subsequent amniocentesis demonstrated the presence of both 46,XX and 46,XY cell lines in a ratio similar to that in CVS. Second trimester ultrasonography and echocardiography were normal. Postnatally, the infant showed ambiguous genitalia: prominent labioscrotal folds, 2 cm phallus with a single opening at the base, left inguinal hernia and the absence of palpable gonads. Further investigations confirmed that both Mullerian and Wolffian structures were present. Pathology on the single gonad showed distinct regions of both ovarian and testicular tissue, consistent with an ovotestis. Interphase FISH on blood lymphocytes confirmed the presence of XX and XY cell lines in a ratio similar to that detected prenatally. Molecular analysis of 15 polymorphic markers in all tissues revealed a single maternal allelic contribution at all loci and two paternal contributions at some loci. The establishment of individual XX and XY clones to determine if one or both cell populations have biparental contributions is currently underway. Molecular studies of these cell lines will provide evidence as to the mechanism underlying true hermaphroditism in this individual. True hermaphroditism in humans is a rare condition phenotypically characterized by the presence of both testicular and ovarian tissues in the same individual often resulting in the formation of ambiguous genitalia. Approximately 10% of hermaphroditic individuals are mosaic for a 46,XX/46,XY karyotype. Several proposed mechanisms to explain chimerism for 46,XX/46,XY will be discussed.

***APITD1*, a tumor suppressor candidate gene with transcriptional inactivation and growth suppressive properties in the neuroblastoma deletion region on 1p36.2.** *C. Krona, H. Kryh, K. Ejeskär, L. Olsson, H. Carén, R-M. Sjöberg, T. Martinsson* Dept Clinical Genetics, Gothenburg University, Gothenburg, Sweden.

High-risk neuroblastoma tumors are often characterized by amplification of the *MYCN* oncogene and deletion of a distal part of chromosome 1p, indicating the presence of one or more tumor suppressor genes which are inactivated on the remaining chromosomal allele. Recently, a novel gene denoted *APITD1* was identified in the region of common deletion on 1p36.22. Although ubiquitous expression levels of this gene was observed in samples derived from normal fetal and adult tissues, a significant down-regulation of *APITD1* was found in high-risk tumors when compared to low-risk tumors. Cell growth was reduced in neuroblastoma cells transfected by different amounts of in vitro transcribed *APITD1* mRNA compared to control cells transfected by the same amounts of *EGFP* mRNA and a large proportion of the *APITD1* transfected cells entered apoptosis. Western blot using antibodies towards peptides from the encoded *APITD1* sequence against nuclear and cytoplasmic cell fractions show that the protein is preferably located in the nucleus. Studies of interaction partners of the APITD1 protein performed both by a yeast two-hybrid screening and immunoprecipitation followed by MALDI-TOF mass spectrometry indicate that *APITD1* encodes a chromatin binding protein involved in cell cycle regulation or maintenance of cellular integrity. Based on its cytogenetic location, 1p36.2, and its biological features in neuroblastoma tumors, *APITD1* therefore presents as a candidate tumor suppressor gene. Further functional studies of *APITD1* in vitro and in vivo are ongoing.

Utility of the targeted Array-based Comparative Genomic Hybridization (aCGH) in detection of copy number changes in conjunction with traditional cytogenetic analysis-Experience at Pittsburgh Cytogenetics Laboratory using 670 clinical samples. *L. Gole[1], S. Madan-Khetarpal[2], N. Powell[2], R. Avron[2], K. Schmidt[2], J. Hu[1], S. Mann[1], U. Surti[1]* 1) Reproductive Genetics, Magee Womens Hospital and University of Pittsburgh, Pittsburgh, PA; 2) Department of Medical Genetics, Children's Hospital of Pittsburgh, 3520 Fifth Avenue, Pittsburgh, PA.

We present a retrospective analysis of targeted aCGH and traditional cytogenetic analysis performed from May, 2006 to June, 2007 on 670 mostly pediatric samples with abnormal phenotype and/or developmental delay and mental retardation. Majority of the samples showed a normal karyotype and were subsequently processed for aCGH at Signature Genomic Laboratory using 1887 BAC clones representing 622 loci. Eighty six cases gave abnormal aCGH results (12.8%). These included 11 *de novo* deletions, 6 *de novo* duplications, 4 familial abnormalities, 23 polymorphic variants and 42 cases that are awaiting parental investigation. Four balanced chromosome abnormalities and 3 cytogenetic abnormalities from the regions not represented on the array resulted in normal microarray results as expected. At present we process the sample for traditional cytogenetics before considering microarray analysis. This technology has almost replaced laborious all telomere FISH testing in our laboratory and quick turn around time is a distinct advantage. In addition to the targeted aCGH analysis, 4 cases with known complex structural abnormalities involving chromosomes 8, 15, 20 and X were analyzed using the GeneDX 44K oligo-array to refine the breakpoints. Our experience with microarray testing - the advantages and drawbacks - has been an ongoing learning process enabling us to evaluate the needs of each patient and order an appropriate test platform which would yield maximum useful information and minimize complications due to structural variants.

Delineation of a *de novo* chromosome 19(p13.1p13.2) duplication using comparative genomic hybridization (CGH). *A. Iglesias[1], M.J. Macera[2], J. Breshin[2], F. Cohen[2], A. Babu[2]* 1) Dept Pediatrics, Div Genetics, Beth Israel Medical Ctr, New York, NY; 2) Dept Medicine, Div Molecular Medicine & Genetics, Wyckoff Heights Medical Center, Brooklyn, NY.

An eight day old male with a history of polyhydramnios and neonatal hypotonia was seen because of feeding difficulties and arthrogryposis. The proband was born full term via cesarean delivery to a 27 year-old mother. He weighed 3015 g with a length of 51 cm and HC 34 (AGA). His apgar scores were 9/9. He had a rounded face with horizontal palpebral fissures, depressed nasal bridge, inverted V-shaped upper lip, a cupped right ear with a normal palate. Hip dysplasia was noted with distal arthrogryposis in his hands and talipes equinovarus (club foot). A neurological exam showed axial hypotonia and milder, but positive distal hypotonia. The suck/swallowing coordination was assessed as poor.

Chromosome analysis using GTG banding revealed one derivative chromosome 19 with additional material on the p arm. FISH using wcp19 painting probe and 19ptel telomere probe (Vysis) confirmed that the additional material originated from 19 and established the presence of a single19 p telomere on the der(19). The karyotype was 46,XY,? dup(19)(p13.1p13.2).ish dup(19)(?p13.1p13.2)(19ptel+,wcp19+). CGH analysis established the proximal breakpoint of the duplicated material at the middle of band p13.1 and the other at the distal end of band p13.2. This direct duplication occurred *de novo*, as both parents had normal karyotypes. The final karyotype was 46,XY,dup(19)(?p13.1p13.2).ish cgh dup(19)(p13.1p13.2). The proband is making good progress and is due for a follow up visit.

Duplications of chromosome 19p are rare as less than ten cases have been reported in the literature. The phenotypes are similar to those reported for trisomy 19 syndrome, however, not as severe. It is interesting to note that club feet, associated with trisomy 19, was observed in our proband and one of the dup(19)p cases. The use of CGH in such cases will help to improve the correlation of segmental imbalances and clinical manifestations.

Siblings with static encephalopathy and a microdeletion at 14q12 that includes the FOXG1B gene. *K. Herman[1], J. Pinter[2], M. Lipson[3], A. Patel[4], A. Pursley[4], S. Yang[1]* 1) Medical Genetics, University of California at Davis Medical Center, M.I.N.D. Institute, Sacramento, CA; 2) Child Neurology, University of California at Davis Medical Center, M.I.N.D. Institute, Sacramento, CA; 3) Medical Genetics, Kaiser Permanente Medical Group, Sacramento, CA; 4) Kleberg Cytogenetics Laboratory, Baylor College of Medicine, Houston, TX.

We are reporting two siblings with severe to profound mental retardation, congenital microcephaly, and static encephalopathy that were found to have a 0.7Mb deletion at 14q12 by chromosomal microarray analysis (RP11-96617->RP11-260G13). The mother of these children has mild to moderate mental retardation, but has not yet been tested to confirm presence of this deletion.

This deletion includes the FOXG1B gene, which is a highly conserved DNA-binding domain with expression in the developing brain restricted to telencephalic neurons (OMIM #164874). To our knowledge there have been no previous clinical reports of individuals with mutations or deletions of this gene. These cases represent the first report of microcephaly and mental retardation due to deletion of this gene and demonstrate the need for further research into the clinical phenotype associated with the FOXG1B gene.

Trisomy 5qter (Hunter-McAlpine syndrome) and monosomy 10qter syndrome occurring simultaneously as a result of inheritance of a der(10)t(5;10)(q35.3;q26.1). *P.L. Crotwell, B.M. Hannan, P.R. Delk, W. Torres-Martinez, D.D. Weaver, V.C. Thurston, G.H. Vance* Department of Medical & Molecular Genetics, Indiana University School of Medicine, Indianapolis, IN 46202.

The proband is a 9-month-old female referred to our clinic for counseling and evaluation of an abnormal karyotype of 46,XX,der(10)t(5;10)(q35.3;q26.1), which was discovered via conventional cytogenetics and subtelomeric FISH analysis, and confirmed by CGH. She presented with speech and developmental delay, and dysmorphic features including upslanting palpebral fissures, posteriorly rotated ears, micrognathia, a short nose, and genital hypoplasia. Cytogenetic and CGH results obtained on the probands parents showed that the mother carries a balanced t(5;10) translocation. A family history disclosed that the probands maternal uncle has mental retardation and dysmorphic features. By CGH analysis, this latter individual has the same unbalanced rearrangement as the proband. We conclude that the dysmorphic features and developmental delay and mental retardation of the proband and her uncle, respectively, are a result of their partial monosomy of 10q26.1-qter and partial trisomy 5q35.3-qter. Monosomy 10qter syndrome and trisomy 5qter (Hunter-McAlpine syndrome) each have been described in the literature, but to our knowledge, have not been described as occurring simultaneously in the same individual. The syndromes have overlapping features including microcephaly, congenital heart defects, strabismus, and mental retardation (1,2). Our proband has microcephaly and developmental delay and her uncle has microcephaly, strabismus, and mental retardation, but neither has had a congenital heart defect. Further analysis will be performed and a summary of the clinical and laboratory findings will be presented. [1. Hunter et al., 2005. Clin Genet 67:53-60. 2. Leonard et al., 1999. AJMG 86:115-7.].

Mouse Mutants as Models for Human Developmental Malformations: The Extra-Toes Spotting (Xs^J) Mouse.

D.E. Gildea[1,2], S.K. Loftus[1], Y. Yang[1], W.J. Pavan[1], L.G. Biesecker[1] 1) GDRB, NHGRI, NIH, Bethesda, MD; 2) Genetics, The George Washington University, Washington, DC.

Greig cephalopolysyndactyly syndrome (GCPS) is a malformation syndrome that includes limb anomalies, specifically polydactyly and syndactyly. GCPS is caused by mutations in the Glioma-associated oncogene-3 (GLI3), which plays a role in Sonic hedgehog (SHH) signaling. The GLI3/SHH pathway regulates many developmental processes, including limb patterning. Dysregulation of this pathway due to mutations in GLI3 can result in limb malformation. The Extra-toes ($Gli3^{XtJ}$) mouse is an excellent animal model for GCPS. Like the human phenotype, $Gli3^{XtJ}$ mice exhibit preaxial polydactyly. Another mouse model for polydactyly, Extra-toes spotting (Xs^J), shares a similar phenotype with the $Gli3^{XtJ}$ mouse. Xs^J mice exhibit preaxial polydactyly and/or belly spotting. Both the $Gli3^{XtJ}$ and the Xs^J phenotypes are inherited semidominantly. Previous linkage mapping has excluded mouse *Gli3* as the Xs^J gene, and the gene and Xs^J mutation remain unknown. To identify the gene, we are performing recombination mapping in Xs^J mice. To map the locus, we needed to outbreed our Xs^J animals to castaneus mice to introduce a distinct chromosomal background, as we encountered substantial homozygosity in the candidate interval. Offspring from this outcross do not exhibit the Xs^J phenotype. When breeding carriers from the outcross to B6C3FeF1/J mice, we experienced a penetrance of 36%. These data show variable penetrance of the Xs^J phenotype that is greatly dependent upon mouse genetic background. We have mapped the Xs^J locus to a 322 kb region on mouse chromosome 7 and are currently evaluating candidate genes. Since $Gli3^{XtJ}$ and Xs^J mice overlap phenotypically, we hypothesize that the gene mutated in the Xs^J mice is a gene in the Gli3/Shh pathway. To test this hypothesis, we are evaluating by *in situ* hybridization the expression of *Shh*, *Gli3*, and other members of the Gli3/Shh pathway in Xs^J embryos. Preliminary data show no change in *Shh* expression in Xs^J embryos. Here we present our genetic analysis strategy, our phenotypic characterization, the mapping data, and our plan for developmental analysis of the animals.

Assessing the Use and Impact of Information Sheets and Patient Letters Given Prior to and Post Genetic Counseling. *S. Armel, A. Buchanan, K. Rajamanikkom, R. Demsky, B. Rosen* Familial Breast and Ovarian Cancer Clinic, Princess Margaret Hospital, Toronto, ON, Canada.

Many patients overestimate their personal risk of developing breast and ovarian cancer prior to genetic counseling. Similarly, there may be confusion concerning genetic counseling and the basis for the referral. In this study we address this issue by evaluating the effectiveness of providing patients with written information before and after genetic counseling. At the Familial Breast and Ovarian Cancer Clinic (FBOCC) at Princess Margaret Hospital in Toronto, Canada, patients are sent an information sheet prior to their appointment outlining basic cancer genetics, risks, genetic testing, and screening methods. Patients are also sent a summary letter 1-2 weeks after counseling outlining decisions and recommendations made during the appointment. 182 patients who underwent genetic counseling at the FBOCC in 2006 were recruited immediately following counseling to complete a questionnaire pertaining to the information sheet. A second questionnaire was sent 1-2 weeks after the summary letter to evaluate its effectiveness. Of 182 patients participating, 118 completed the second questionnaire. 99% of patients found the information sheet helpful, specifically in obtaining general information about cancer (70%), information about genetic counseling and genetic testing (42%), understanding the nature of the appointment (51%), and in answering questions (53%). The majority of patients (99%) agreed we should continue to provide the information sheet, and do so prior to the appointment (91%). Results for the summary letter were similar, with 99% appreciating the letter and 98% agreeing we should continue to provide it. Between the information sheet and the summary letter 92% preferred to receive both. The results were fairly consistent among patients who sought counseling based on a familial mutation, patients with cancer, and patients without cancer. The results from this study illustrate the benefit of providing written information to patients prior to genetic counseling in addition to providing a summary letter of their session 1-2 weeks following.

Population stratification in a case-control study of brain arteriovenous malformation (BAVM) among Hispanics.
H. Kim, P.G. Hysi, L. Pawlikowska, C.E. McCulloch, S. Choudhry, P.-Y. Kwok, E.G. Burchard, W.L. Young University of California-San Francisco, San Francisco, CA.

Genetic association studies conducted in recently admixed populations, such as Hispanics, may be confounded by population stratification. Two major statistical approaches have been developed (genomic control and structured association), both of which use unlinked genetic markers to identify and correct for population stratification. We genotyped 83 ancestry informative markers (AIMs) in a case-control study of 79 BAVM cases and 215 healthy controls of self-reported Hispanic race/ethnicity. Individual ancestry estimates (IAE) were obtained using Structure, assuming three underlying populations. Average group admixture estimates were 47% Native American, 45% Caucasian, and 8% African ancestry, with dramatic heterogeneity observed between individuals. The summary ^{2} test comparing genotype frequency of AIMs between Hispanic cases and controls was significant (^{2} = 204.40, df=163, P=0.015), suggesting population stratification. We further investigated the effect of stratification on the association between BAVM and a promoter variant in the IL6 gene (-174G>C), which was previously associated with hemorrhagic presentation in BAVM patients. IL6-174 G and C alleles are equally common in Caucasians, whereas the C allele is rare (<5% frequency) among Africans and Asians genotyped in HapMap. Among Hispanics, IAE were associated with IL6-174G>C genotypes; the GG genotype was associated with ~6% higher Native American ancestry (P=0.023). The age and sex-adjusted risk of BAVM associated with the IL6-174GG genotype was 1.85 (95% CI=0.99-3.48, P=0.055); further adjustments for IAE yielded an OR of 1.96 (95% CI=1.03-3.72, P=0.039). The increased OR after accounting for genetic ancestry differences suggests subtle but negative confounding and illustrates the importance of addressing population stratification in case-control studies conducted in admixed populations.

Genetic and functional characterization of sequence variants in GRIPAP-1, a neuronal rasGEF protein and a candidate gene for X-linked mental retardation. *Y.W. Jiang[1], S. Bhat[1], F. Abidi[2], Y. Wu[1], L.L. Zhang[1], E. Marcocci[4], I. Meloni[4], A. Renieri[4], C.E. Schwartz[2], R. Huganir[3], T. Wang[1]* 1) Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) Greenwood Genetic Center, Greenwood, SC; 3) Department of Neuroscience, Johns Hopkins University, Baltimore, MD; 4) Department of Medical Genetics, University of Siena, Italy.

X-linked mental retardation (XLMR) occurs in 1 in 600 males and is genetically highly heterogeneous. Among the estimated 150-200 XLMR genes, <60 were cloned. Using a human X chromosome cDNA microarray screen, we identified GRIP-associated protein-1 (GRIPAP1) mapped to Xp11.2 as a candidate gene for XLMR. GRIPAP-1 has a predicted GEF-activation domain and a PDZ-like protein interaction domain. GRIPAP-1 expresses abundantly in neurons and is involved in AMPA receptor trafficking (Neuron 26:603, 2000). By sequencing DNA samples from 288 males with XLMR, we found four nonsynonymous (S73N, P179L E578A, R822Q) and three synonymous (E161E, L504L, H554H) coding variants in GRIPAP1. S73N was found in two unrelated XLMR males and is absent in 500 control males. Both P179L and E578A were also found in control males and are likely nonpathogenic variants. R822 in the PDZ-like domain is a highly conserved residue from zebrafish to human. R822Q co-segregates with MR phenotype in the proband family and is absent in 500 normal males. R822Q results in a stable protein and is predicted to have a significant impact on phosphorylation status of nearby serine [NetPhos2.0]. Functional studies of GRIPAP-1-knockout mice suggest that GRIPAP-1 may be involved in the regulation of ERK1/2 pathway. Further genetic and functional characterization of molecular defects in GRIPAP1 in XLMR patients will contribute to our understanding of the physiological function of GRIPAP1 and potential roles of these defects in the pathogenesis of MR in humans.

THE PATTERN OF RET MUTATIONS AND VARIANTS IN HIRSCHSPRUNG DISEASE: A MEDICAL SEQUENCING CASE STUDY. *L. Hao[1], S. Arnold[1], J. Albertus[1], M. Dao[1], A. Rea[1], P. Cruz[2], J. Mullikin[2], A. Young[2], E.D. Green[2], A. Chakravarti[1]* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) Genome Technology Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD.

Gene-based medical sequencing is critical to our understanding of complex diseases, following the discovery of new genes by association studies. One limitation for medical sequencing studies is the difficulty of interpreting base changes when functional annotation is incomplete. We present here a case study for a model complex genetic disorder, Hirschprung disease (HSCR), in which enteric ganglion cells are absent along variable lengths of the GI tract. RET, encoding a receptor tyrosine kinase, is functionally necessary, but not sufficient, for normal enteric development. Genetic data suggest that RET mutations must exist in each affected despite the involvement of other genes and, thus, many RET mutations and polymorphisms interact to produce disease. To identify both common and rare genetic variants, we are sequencing all 20 exons and 20 additional conserved non-coding regions at RET from 680 individuals including 237 probands and their families (~20Mb). Based on our analysis of 67% of the data, we have identified very high genetic variability with a total of 239 variants including 10 indels and 37 coding alterations, most of which are novel, rare and non-synonymous. The comparison of the frequency of sequence changes associated with transmitted and non-transmitted alleles in HSCR families validated the association of a previously identified RET enhancer variant. Interestingly, we identified a new premature stop mutation in the RET kinase domain that appears to interact with the non-coding enhancer mutation and contribute to the severest forms of HSCR. In addition, sequencing in families has allowed us to identify a few potentially large indels from Mendelian inconsistencies that would have been missed without family data. Our data answers questions such as the contribution of RET to HSCR, the parental origin of mutation and the role of rare and common mutations and, thus, their genetic mechanisms of action.

Cytogenetic approaches for identifying novel genes and regulatory elements associated with hearing loss. *K. Kocher[1], R. Williamson[1,2], K. Arnos[3], K. Crow[4], J. Reiss[4], C.C. Morton[1,2]* 1) Harvard Medical School, Boston, MA; 2) Brigham and Women's Hospital, Boston, MA; 3) Gallaudet University, Washington, DC; 4) Kaiser Permanente Northwest, Portland, OR.

Genetic linkage analysis has been a powerful method for deafness gene discovery. However, this approach only detects mutations when families with sufficient numbers of deaf members are available. Additionally, genes affected by non-genic regulatory mutations are difficult to identify with this method. As an alternative, we have ascertained individuals with hearing loss and apparently balanced chromosomal rearrangements to assess candidate deafness genes lying near the rearrangement breakpoints. To illustrate the utility of this approach, we present two cases. In the first case, mapping the breakpoints of a t(2;13)(p24;q21) in an individual with profound sensorineural deafness revealed a novel gene, *FLJ21820*, disrupted by the translocation. RNA *in situ* hybridization experiments showed that the gene is expressed in the spiral ganglion, stria vascularis, and Organ of Corti of the inner ear suggesting it may be a deafness gene. Biochemical assays to determine the function of *FLJ21820*, mutation screening of a panel of deaf individuals, and characterization of a mouse model are in progress to verify the role of this gene in the auditory system. For the second case, an inv(7)(q21.3q35) segregating with conductive hearing loss in a family with five affected members seems to disrupt tissue-specific expression of the nearby *DLX5/6* genes. Transgenic mouse experiments suggest that a 5 kb region of 7q21.3 deleted at the breakpoint contains an enhancer necessary for proper expression of *DLX5/6* in the developing middle ear. Gel shift assays and *in vitro* expression experiments are planned to identify proteins that bind and activate the enhancer. These findings confirm the value of cytogenetics for discovery of novel genes and regulatory elements essential for development of the auditory system.

Semaphorins and *RET* are associated with Hirschsprung Disease. *S. Arnold[1], M. Guy[1], K. West[1], C. Kashuk[1], F. Lantieri[2], G. Burzynski[3], R. Fernandez[4], A. Pelet[5], Y. Sribudiani[3], S. Borrego[4], I. Ceccherini[2], R. Hofstra[3], S. Lyonnet[5], A. Chakravarti[1]* 1) IGM, Johns Hopkins Univ Sch Med, Baltimore, MD; 2) Lab di Genetica Molecolare, Ist Gaslini, Genova, Italy; 3) Dept Medical Genetics, Univ Groningen, The Netherlands; 4) UC Genética y Reproducción, HH UU Virgen del Rocio, Sevilla, Spain; 5) Dept de Génétique and INSERM U781 , Hôpital Necker Enfants Malades, Paris, France.

Hirschsprung Disease (HSCR), or aganglionic megacolon, is an oligogenic disease that varies in severity from short segment disease to total colonic aganglionosis. Current evidence suggests that down-regulation of the gene encoding the receptor tyrosine kinase *RET* is necessary, but not sufficient, for disease expression. Coding sequence *RET* mutations that inactivate the protein are most often associated with the most severe forms of disease, while noncoding variants, like the recently described *RET+3* enhancer mutation, are associated with the least severe, most common form of HSCR. In an effort to identify genes acting in concert with *RET* to explain the majority of HSCR cases, we analyzed 220 isolated short segment HSCR trios (~ 4:1 male:female) on the Affymetrix 500K SNP array platform. Transmission analysis (using the disequilibrium-based TDT) identified the *RET* locus as the most significantly associated with disease, with 10 SNPs displaying p-values ranging between 2.97×10^{-8} and 9.87×10^{-21}. A second, striking cluster of 70 SNPs was identified on chromosome 7 between Semaphorins 3A and 3D, with 15 SNPs displaying p-values between 9.64×10^{-5} and 7.10×10^{-6}. We genotyped the two chromosome 7 SNPs with lowest p-values in a broader HSCR sample for replication. In this sample, representative of all segment lengths, one SNP obtained greater significance with a p-value of 4.53×10^{-10}, while the second maintained a p-value on the order of 10^{-6}. As chemo-attractive/-repulsive molecules involved in the development of the enteric nervous system, the semaphorins are logical candidates for modification of *RET* function. Our ultimate goal is to elucidate the specific variant responsible for producing the identified association and its possible interaction with *RET*.

***Bicc1* zebrafish model for Polycystic Kidney Disease (PKD).** *D.J. Bouvrette[1,2], V. Sittaramane[1,3], A. Chandrasekhar[1,3], E.C. Bryda[1,2]* 1) University of Missouri-Columbia, Columbia, MO; 2) Department of Veterinary Pathobiology; 3) Department of Biological Sciences.

Polycystic kidney disease (PKD) is a common genetic disorder with a prevalence of 1/500. There is no cure for PKD. Clinical manifestations include progressive cyst formation, renal enlargement, and ultimate progression into end-stage renal disease. The molecular mechanisms leading to cyst formation remain unclear. A defect in the *Bicaudal-C* (*Bicc1*) gene results in a PKD phenotype in the *j*uvenile *c*ongenital *p*olycystic *k*idney (*jcpk*) mouse model. The function of *Bicc1* is unknown; however, there is a high degree of conservation at both the nucleotide and amino acid levels across >9 species. **Statement of Purpose:** In this study, we use the unique characteristics of zebrafish to further investigate *Bicc1* function in the kidney. Early kidney development in zebrafish parallels that of mammals to the mesonephros stage. The zebrafish pronephros forms between 12-72 hours post fertilization (hpf) and can be visualized easily in the transparent embryos. **Methods/Results:** The expression of *Bicc1* in zebrafish was evaluated by RT-PCR and *in situ* hybridization, demonstrating that *Bicc1* is expressed throughout pronephros development. An antisense morpholino was used to knockdown *Bicc1* expression in zebrafish to examine the effects of loss of *Bicc1* function. Histological analyses of the resulting morphants reveal large, epithelial-lined cysts throughout the tubules of the pronephric kidney, closely resembling the cystic phenotype in the mouse. The morphant cystic phenotype was rescued with the addition of mouse *Bicc1* mRNA. **Conclusion:** These data provide convincing evidence that *Bicc1* has a similar functional role in both the mouse and zebrafish. This work supports the validity of using a zebrafish model to study *Bicc1* function in the kidney.

Approaches to testing regional significance in whole genome association scans. *P.H. Kuo[1], E.J.C.G. Van den Oord[2], B.S. Maher[1]* 1) Department of Psychiatry, VIPBG, VCU, Richmond, VA; 2) Center for Biomarker Research and Personalized Medicine, VCU, Richmond, VA.

The recent escalation of whole genome association scans (WGAS) has introduced an entire set of novel problems to statistical genetics. A major issue that faces the field is interpretation of results from these scans. The primary difficulty arises from the large number of significant single marker signals these scan will generate. An alternative to assessing interesting regions across the genome is to analyze many markers in concert. Importantly, several investigators, including Marques-Bonet et al (2005), Hoh & Ott (2000) and Guedj et al (2006) have proposed methods for testing multiple markers simultaneously that do not account for, or are naïve to, genetic or physical distance. We propose a methodology that tests for clusters of significant signals across a region of the genome while accounting for the correlation between the markers. Our method, using effect statistics, corrects for the initial signal in the region to assess residual significance beyond that signal. The approach is especially useful in regions (genes) where multiple modest-sized signals are present. Similar to the previously described approaches, significance is assessed via permutation. We examined the performance of the approach on simulated whole genome association scan data.

22q13 deletion syndrome with severe language delay without social communication disturbance in a 8 years old girl with moderate mental retardation. *K. Dahan[1], X. Pepermans[1], X. Schlogel[2], N. Lannoy[1], C. Sibille[1]* 1) Dept Genetics, UCL Saint-Luc Hosp, Brussels, Belgium; 2) Pediatric Dept, UCL Saint-Luc Hosp, Brussels, Belgium.

The terminal 22q13.3 deletion syndrome is characterized by neonatal hypotonia, global developmental delay, normal to accelerated growth, absent to severely delayed speech, autistic behavior, and minor dysmorphic features. Even if deletions were extremely variable in size, extending from 160 kb to 9 Mb, the minimal critical region should include the three subtelomeric genes (*RABL2B*, *ACR*, *SHANK3*). A less severe phenotype as well as discordance for the minimal telomeric region prompt us to report the present observation. The proband is an 8 years old girl with a severely impaired speech and moderate mental retardation (overall IQ 56). Hypotonia is evident without tendency to overgrowth and dysmorphic facial features. Behavioral disturbances are poor concentration and hyperactivity in a very engaging child. We used FISH, MLPA and High-resolution SNP analysis and found a *de novo* deletion of 22q13.3. The proximal deletion breakpoint was mapped between *ECGF1* and *CPT1B* and removed 172 kb of the terminal 22q13, including *ARSA*, *SHANK3* and *ACR*. The terminal deletion breakpoint was located upstream the 3UTR of *RABL2B*. The parental origin was paternal. We show for the first time that a *de novo* deletion of the paternal chromosome 22q13 respecting the integrity of the *RABL2B* gene may cause severe language delay in a girl with moderate mental retardation without disturbance in social communication.

Molecular Diagnostic Testing for Retinal Diseases. *A.J. Karoukis[1], K. Branham[1], L. Chen[1], R. Aaatre-Keshavamurthy[1], K. Downs[1], R. Caruso[2], J.R. Heckenlively[1], R. Ayyagari[1]* 1) Ophthalmology , University of Michigan, Ann Arbor, MI; 2) National Eye Institute, National Institutes of Health, Bethesda, MD.

Retinal dystrophies are a phenotypically and genotypically heterogeneous group of diseases that are inherited in autosomal dominant, recessive, X-linked, mitochondrial and complex modes. The phenotype of these diseases covers a broad and overlapping spectrum of clinical signs and symptoms. We have provided molecular diagnostic testing to patients with retinal conditions associated with mutations in the genes ABCA4, ELOVL4, EFEMP1, RDS, Bestrophin, TIMP3, CRX, CTRP5 and RPE 65. Mutation analysis was carried out by sequencing all coding exons and flanking intronic sequence. A total of 501 diagnostic tests were performed and the molecular basis of disease was identified in 227, while the disease associated mutations were not detected in the rest. Segregation of mutations was confirmed by analyzing 49 samples of parents and/or siblings. Part of this data was presented in an earlier publication. Ophthalmic molecular diagnostic testing is still in its infancy. We will present case studies to illustrate benefits and limitations of diagnostic testing including the value of genetic counseling and patient education prior to ordering testing.

FTO genotypes and weight gain in early life in two prospective birth cohort studies from Finland and the UK. *M-R. Jarvelin[1,2,3], P. Elliott[1], T.M. Frayling[4], R.M. Freathy[4], U. Sovio[1], A.J. Bennett[5], A. Ruokonen[2], A. Pouta[3], J. Laitinen[6], A-L. Hartikainen[2], D.A. Lawlor[7], E. Zeggini[5], C.M. Lindgren[5], S.M. Ring[7], A. R. Ness[7], A.T. Hattersley[4], M.I. McCarthy[5], G. Davey Smith[7], N.J. Timpson[5,7]* 1) Imperial College London, United Kingdom; 2) Oulu University, Finland; 3) National Public Health Institute, Finland; 4) Peninsula Medical School, Exeter, UK; 5) Oxford University, UK; 6) Finnish Institute of Occupational Health, Finland; 7) Bristol University, UK.

In large-scale association studies on nearly 40,000 individuals, we have recently shown that a cluster of variants within the FTO gene on chromosome 16 is strongly associated with overweight/obesity. This association was not seen at birth but from age 7y onwards. We studied here the effect of FTO variant (rs9939609) on body mass until age 4y. We analyzed data on singletons in Northern Finland Birth Cohort born in 1966 (NFBC, n= 3849) collected at ages 6 and 12mo and in the Avon Longitudinal Study in Parents and Children born in 1991-2 (ALSPAC, n=7126) collected at 6 wks, 9mo, 18mo and 4y, adjusting for gestational age until 1y and for sex. In ALSPAC, at ages 4 and 11y, 19% were overweight or obese by IOTF age-gender specific criteria, and in NFBC at 14y (assessed about 20y earlier than ALSPAC) 7% were overweight or obese. In neither cohort was the A allele at rs9939609 associated with higher body mass index (BMI, log-transf.) during the first year: in NFBC, percentage change in BMI varied from -0.06% (95%CI -0.53,0.40) to 0.20% (-0.21,0.61) and in ALSPAC from -0.34% (-0.68,-0.0004) to -0.15% (-0.51,0.21) per allele. In ALSPAC, there was no evidence of weight gain by increasing number of A alleles from second year up to 4y; between-homozygote-groups differences in BMI (geometric means, AA-TT) were -0.11 kg/m2 at 18mo (p 0.04) and -0.02 kg/m2 at 4y (p 0.69). Taken together with our earlier publication, these studies suggest that this variation in FTO gene is not associated with excessive weight gain in utero or early life. They indicate that the variant is associated with an acceleration in weight gain during pre-school and early school years between age 4 and 7 years.

Loss of *Smad1* and *Smad5* in proliferating chondrocytes leads to a shortened growth plate and craniofacial phenotype. *B. Keller[1], P. Hermanns[2], B. Zabel[2], B. Lee[1]* 1) Dept Molecular & Human Gen, Baylor Col Medicine, Houston, Tx; 2) Centre for Pediatrics and Adolescent Medicine, University Hospital of Freiburg, Germany.

Bone morphogenetic proteins (BMPs), members of the TGF superfamily, play a pivotal role in the development of the vertebrate skeleton. The BMP-Receptor BMPR-1B (ALK-6) is expressed in all types of cartilage and expression of a dominant-negative form of BMPR-1B is able to block chondrogenesis and osteogenic differentiation. Smad1, Smad5 and Smad8 are the mediators of the BMP signaling pathway. Binding of BMP to the receptor leads to the phosphorylation of the Smads. They undergo a conformational change and are able to bind the Co-receptor (Co-Smad) Smad4. This complex translocates into the nucleus and activates or represses the transcription of target genes. *Smad1* and *Smad5* are expressed in proliferating and maturating chondrocytes, whereas Smad1 and Smad8 have been shown to be expressed in mesenchymal cells. We examined the role of *Smad1* and *Smad5* in chondrogenesis by knocking out *Smad1* in proliferating chondrocytes using the Cre-loxP system on a *Smad5* heterozygous background. P1 mutant mice skeletons stained with alcian blue and alizarin red appeared to be normal and no obvious patterning defect could be observed. On cellular level we could detect a slight shortening of both, the prehypertrophic and hypertrophic zones due to a decrease in the proliferation rate. *Ihh* expression in mutant animals is reduced as well. Additionally, adult mutant mice exhibit a subtle craniofacial phenotype with a shortening of the head and missing nasal septum.

Enhanced accumulation of A in neurons in autism. *W. Brown, I. Kuchna, K. Nowicki, J. Wegiel, T. Wisniewski, J. Wegiel* NYS Inst Basic Research, Staten Island, NY.

Studies of amyloid in neurons has revealed the absence of, or only minimal, intraneuronal A immunoreactivity in normal brains. The appearance of intraneuronal A immunoreactivity has been suggested as a sign of neuronal pathology leading to fibrillar plaque formation in the brains of people with AD. However, detection of variable A immunoreactivity in neurons in our 32 brains of control children, adults and aged subjects indicates that amyloid beta immunoreactivity is not a predictor of Alzheimer's disease (Wegiel et al., 07). We performed immunocytochemistry for intraneuronal A immunoreactivity in 10 brains of subjects with autism. Remarkably, this revealed very strong A immunoreactivity in 50% of the brains, including one 5-year old child and 4 adults of 20, 23, 52, 62 years of age. Also, numerous diffuse plaques were in the amygdala and neocortex in the 52 year-old subject. In five other children and adults the levels of intraneuronal A were similar to those detected in control brains. Striking differences in A immunoreactivity were observed in different neuronal populations, including very strong A immunoreactivity in neurons in the granule layer of the dentate gyrus in the hippocampal formation, in the globus pallidus and in Purkinje cells. A in neurons in control and autistic subjects was mainly a product of - and -secretases (17-40/42 aa). Our observations are in accord with biochemical studies of sera showing that in children with severe autism and aggression the level of secreted APP is higher than in children with mild autism, and much higher than in normal children (Sokol et al., 2006). We suggest an increased -secretase (anabolic) pathway of APP processing exists in some autistic subjects that results in excessive intraneuronal accumulation of A. The link between the clinical phenotype and pattern of APP processing suggests there are functional consequences of an abnormal accumulation of A in autism.

A de novo 3.3 Mb deletion on 1p34.2 in a patient with autism and microcephaly. *W.B. Dobyns[1], J. Sudi[1], R.A. Kumar[1], J. Conroy[2], D. McQuaid[2], N.J. Nowak[2], S.L. Christian[1]* 1) Dept Human Genetics, Univ Chicago, Chicago, IL; 2) Roswell Park Cancer Institute, Department of Cancer Genetics.

Autism spectrum disorder (ASD) is characterized by impaired social interactions, communication deficits, and restricted and repetitive behaviors and interests. Cytogenetic and array-based studies show that ASD may be associated with chromosome abnormalities are smaller copy number variants. We report a new ASD locus detected by array comparative genome hybridization (aCGH) in a boy with ASD and postnatal microcephaly. He was born at term and appeared normal except for right hydronephrosis and vesicoureteral reflux, which both resolved. His birth OFC was 34 cm (10-25%), but his head growth was slow so his OFC dropped to -3 SD by 15 months and thereafter followed a curve at the same percentile. His motor development was normal at first, but he walked late at 16 months. He used his first words at 15 months and slowly increased to 50-75 words by 2.5 years, but then stopped using almost all speech by age 3 years. Has has poor social communication including poor eye contact and limited interactive play, striking anxiety, difficulty with transitions, constant chewing, short attention span, poor sleep pattern, and repetitive activities such as bouncing on an exercise ball. Neurpsychological testing supported a diagnosis of ASD. Chromosome analysis was normal, but no other genetic tests were obtained. We performed aCGH on the patient using a 19K whole genome tiling path BAC microarray, and detected a 3.3 Mb deletion extending from RP11-769L8 to RP11-483I17 (chr1:39587288-42908332). FISH studies confirmed the deletion and microsatellite analysis determined that the deletion was de novo. This region contains 44 RefSeq genes, including several potential candidate genes. Given that microcephaly is uncommon among patients with ASD, we hypothesize that different genes in this region are responsible for the ASD and microcephaly.

Automatic Haplotype Construction in PedGenie. *R.P. Abo, J. Wong, N.J. Camp* Biomedical Informatics, University of Utah, Salt Lake City, UT.

A popular design for candidate gene association analyses is to use tagging-SNPs (tSNPs). To maximize the potential for the tSNPs to detect signals from an underlying disease variant, these SNPs should be analyzed both independently and in multi-SNP combinations (as haplotypes or composite genotypes). These haplotypes need not span all SNPs nor be from contiguous SNP loci. Approaches to construct and test multiple SNPs are therefore required. The difficulty is in establishing which SNPs to consider and how to construct the association analysis (haplotypes/composite genotypes, monotype/diplotype tests). A common multi-SNP construction strategy is to add SNPs to extend haplotypes that exceed a significance threshold; however, with large numbers of SNPs this procedure can become very cumbersome. The approach proposed here consists of constructing and testing multi-SNP combinations for association through a forward-backward stepwise process. Rather than considering exhaustive SNP subsets, the stepwise approach narrows the subset considered through a sequence of steps. The user can define whether the contingency tables tested are for diplotype (individuals) or monotype (chromosomes) data. For diplotype tests, both haplotypes (phase important) and composite genotypes (phase ignored) are considered. The stepwise forward process begins by considering association between the disease and all single SNPs. Each subsequent forward step considers an additional SNP. A user-defined significance threshold determines which SNPs or group of SNPs move to the next step based on their statistical test results. The backward process is initiated if the third step ($\geq$3-SNP sets) is reached. A backwards step consists of testing all (n-1)-sized subsets that were not considered in the previous step. Chi-square and odds-ratio test results are noted at each step. The software implementation of this approach is an extension to PedGenie (Allen-Brady et al. 2006). By utilizing PedGenie, these multi-SNP construction analyses can be performed for independent individuals as well as related individuals in pedigrees of arbitrary size. PedGenie also provides the Monte Carlo framework for appropriately assessing statistical significance of the constructed multi-SNP sets.

Familial Small Bowel Perforation in Siblings with Thin, Hyperextensible Skin, Tissue Fragility, Minor Joint dislocations, occasional Hypermobility and Co-Occurance of Intestinal Disease. *C.A. Bay[1], R. Kelleher[2], S. Morrill-Cornelius[1], R.G. Cadle[1], B.D. Hall[1]* 1) Clinical/Biochemical Genetics, Univ Kentucky, Lexington, KY; 2) Central Baptist Hospital, Lexington, KY.

We have observed a sibship of 4 affected individuals with small bowel perforation, skin hyperextensibiity, easy bruisability, tissue friability, and occasional mild joint dislocation/hypermobility, most closely resembling the Ehlers-Danlos class of connective tissue disorders. Of the 4 individuals with bowel perforation, one died of postoperative complications at age 23. Each affected individual had been diagnosed with an additional intestinal diagnosis of either diverticulitis (3) or celiac disease (1). The proband is a 46 yo white female who perforated her small bowel at age 45. Surgeons noted extremely friable tissue, with no associated areas of hemorrhage. PMH + for episodic diverticulitis starting in 20's; increased skin distensibility, easy bruisability, and recurrent dislocation of one shoulder. PE + for normal stature, thin face, not pinched. Skin was extremely soft and hyperextensible, normal scars. She was not hypermobile. Family history was notable for 4 of 7 siblings (3F:1M)with bowel perforations at age 20's - 45. Consanguinity was denied. Both parents: + for diverticulitis, but no connective tissue signs/symptoms. Affected siblings: loose, redundant skin with easy bruisability. One affected female could hyperextend her fingers and wrists, but no other joints; One had postoperative abdominal wall hernia, another Addison's disease. Laboratory investigations to date include: normal type I and III procollagen studies for EDS IV (U of Washington Collagen Dx Laboratory); normal lysyl hydroxylase, serum copper and renal ultrasound. Echocardiogram:normal aortic root diameter; thin and pliable pulmonic valves, rest unremarkable. Ophthalmic exam: normal. All 4 individuals in this sibship who experienced bowel perforation had similar cutaneous findings, and had an additional intestinal disease (diverticulitis, celiac disease). This suggests that the co-occurance of severe intestinal disease in a family with thin, friable tissues, can result in bowel perforation.

Results of plasma cell specific FISH analysis of 1,971 patients. *R.A. Knudson, R.P. Ketterling* Div. of Laboratory Genetics, Mayo Clinic, Rochester, MN.
