The plasma cell proliferative disorders (PCPD) are a heterogeneous group of plasma cell dyscrasias which account for approximately 10% of all hematologic malignancies. Subgroups of PCPD include such disparate clinical entities as monoclonal gammopathy of undetermined significance, amyloidosis, smoldering myeloma and plasma cell leukemia. Herein, we report our results on 1971 individual patients referred to the Mayo Cytogenetics Laboratory for a plasma cell-specific FISH assay. The patients had a wide range of reasons for referral encompassing all types of PCPDs. Our homebrew plasma cell FISH assay combines a cytoplasmic immunoglobulin labeled in blue and subsequent FISH analysis for 8 different recurrent abnormalities, including CCND1/IGH translocations, monosomy/deletion of chromosome 13, deletions of 17p, and trisomies of chromosomes 3, 7, 9 and 15. If an IGH rearrangement is detected which does not involve CCND1, we reflex to probes that detect FGFR3/IGH and IGH/c-MAF translocations. A total of 1286 patients (65%) had abnormal results with this targeted FISH assay while the remaining samples had insufficient plasma cells for analysis. Of the 1548 patients that had both conventional chromosome analysis and plasma cell FISH testing performed, 1031 (67%) had abnormal FISH results while 160 (10%) had abnormal chromosome results. Of the 1,286 patients abnormal by FISH, 690 (54%) had a trisomy of at least one chromosome, 627 (49%) had an IGH translocation, 615 (48%) had monosomy/deletion of chromosome 13, 94 (7%) had a deletion of 17p and 62 (5%) had a tetraploid clone. Of those with IGH translocations, 290 (46%) had fusion with CCND1, 112 (18%) with FGFR3, 54 (9%) with c-MAF, and 171 (27%) with an unknown translocation partner. These data fit well with previously established percentages for the common recurrent abnormalities observed in myeloma patients with the exception of a much higher rate of CCND1/IGH fusion. We conclude that a targeted plasma cell specific FISH assay is an important modality for detecting the common genetic abnormalities observed in the PCPD and should be applied to all patients with sufficient plasma cells to determine the prognostic subgroup associated with their genetic signature.

Amino acid analysis in physiological fluids by liquid chromatography/mass spectrometry (LCMS): A fast, sensitive method for detection of disorders of amino acid metabolism and nutritional deficiencies. *S. Goldman, D. Salazar, J.A. Neidich, T. Lynn, C.M. Strom* Biochemical Genetics Laboratory, Quest Diagnostics Nichols Institute, San Juan Capistrano, CA.

We have developed a rapid, sensitive new method for amino acid analysis in plasma, urine, and cerebrospinal fluid that relies on liquid chromatography/mass spectrometry (LCMS). Accurate, quantitative amino acid testing is necessary for the diagnosis of a large number of disorders of amino acid metabolism, and is also used for the ongoing dietary monitoring required for patients once a diagnosis has been made. Our new method utilizes derivitization of terminal amino groups with phenylisothiocyanate (PITC), followed by separation of analytes on a C18 column, and allows for a rapid analysis time (25 minutes injection to injection) compared to traditional methods, while providing greater sensitivity than either ion-exchange chromatography (by amino acid analyzer) or HPLC alone. Greater than 45 analytes can be separated and quantitated in physiological fluids, most having a limit of quantitation (LOQ) well below 1.0 umol/L, with typical linear ranges of 1-1500 umol/L. Compared to the traditional platforms used for amino acid analysis, this method has the advantage of providing absolute amino acid identification through its combination of elution time and mass data, thus enhancing accuracy in reporting. Problems encountered due to interfering substances derived from diet or medications that are inherent to older amino acid analysis methods are not an issue with this test. In addition, the enhanced sensitivity of this method enables accurate quantitation of amino acids at very low levels, enhancing the utilization of such testing for nutritional status.

Identity and Carrier Frequency of Cytochrome P450 1B1 Mutations in the U.S. Population: Implications for Primary Congenital Glaucoma Disease Incidence and Newborn Screening. *F.M. Hantash, D.M. Goos, W. Conlon, B. Anderson, S. Strom, W. Sun, C.M. Strom* Molecular Genetics, Quest Diagnostics Nichols Institute. SJC, CA.

Several studies have associated the CYP1B1 gene with PCG. Untreated or late treated PCG accounts for an appreciable amount of adult blindness in the United States. Our DNA sequencing of CYP1B1 gene from a number of suspected PCG patients identified several mutations. However, there have been no comprehensive studies of carrier rate, mutation frequency, or PCG disease incidence in the U.S. population. We conducted comprehensive DNA sequencing analysis of the two coding exons 2 and 3 of CYP1B1 on anonymized DNA samples. Sixteen hundred forty five samples were analyzed. A total of seventy-eight DNA samples harbored one of twenty missense mutations, while one sample harbored a frame-shift mutation. Only eight mutations identified are predicted to be pathogenic based on prior published studies and/or consensus algorithm analyses. Results showed that the most common pathogenic mutations in the U.S. population to be R368H (N=12) and Y81N (N=9), with a carrier frequency of 0.67% and 0.55%, respectively. The R368H and Y81N mutations occurred on the same haplotypes as those reported previously. Interestingly, another predicted pathogenic mutation affecting codon 368 was identified in one sample. The combined carrier rate of different pathogenic mutations identified is 1.52% (~1:66). Since various studies showed delayed or reduced penetrance of homozygotes or compound heterozygotes for deleterious CYP1B1 mutation alleles in PCG, our data would predict an incidence of PCG in the U.S. population to be 1:17313-1:34626, a range of the same order of magnitude for many inherited disorders in established newborn screening programs. Since PCG can be confirmed by measuring intraocular pressures and visual impairment can be prevented or minimized with timely surgery, PCG is an excellent candidate for newborn screening. We designed a rapid carrier mutation assay for 10 pathogenic CYP1B1 mutations and showed the assay to work on DNA from blood spot cards, showing feasibility of genetic newborn screening test.

Common sequence variation in genes that cause hypogonadotropic hypogonadism and association with age at menarche. *Z. Gajdos[1,2], K. DeLellis Henderson[3], J. Butler[1,2], P. Clayton[5], L. Le Marchand[6], L. Kolonel[6], B.E. Henderson[3], M.R. Palmert[4], J.N. Hirschhorn[1,2]* 1) Children's Hospital, Boston, MA; 2) Broad Institute, Cambridge, MA; 3) Univ. Southern Calif., Los Angeles, CA; 4) Case Western Reserve Univ., Cleveland, OH; 5) Univ. of Manchester, Manchester, UK; 6) Univ. of Hawaii, Honolulu, HI.

Background: Genetic factors are estimated to account for more than half of the population variation in the timing of puberty, yet the specific genes responsible are unknown. At the extreme, patients with hypogonadotropic hypogonadism (HH) have absent or severely delayed puberty. Genes that carry severe mutations that cause HH have been identified (*FGFR1*, *KAL1*, *KISS1*, *GNRHR*, *GPR54*, *LEP*, *LEPR*, *PROK2*, *PROKR2*, and *FGF8*). We hypothesized that common sequence variants in these genes might influence the normal spectrum of variation in pubertal timing. **Results:** We genotyped 393 SNPs (217 in all subjects, 176 additional in the African-American subjects) in 8 HH genes or their ligands (*FGFR1*, *KAL1*, *KISS1*, *GNRHR*, *GPR54*, *LEP*, and *LEPR*) in 1801 women with early (age < 11 years, N=909) or late (age > 14 years, N=892) menarche drawn from the Hawaii and Los Angeles Multiethnic Cohort. SNPs were selected using HapMap genotype data and the Tagger software package as implemented in Haploview. We performed an association analysis, stratified by self-reported ethnicity, using the Cochran-Mantel-Haenszel test in the software package PLINK to test SNPs for association with age at menarche. Nominally significant associations were identified in *KISS1*, *GPR54*, and *LEPR*. Interactions between SNPs were also tested for association, with several nominally significant interactions observed. To further control for effects of ancestry on menarche, we genotyped 69 ancestry informative markers specific for all HapMap populations. We will also analyze these SNPs to test for the association of ancestry with age at menarche. **Conclusion:** Although the HH genes tested here are important for pubertal development, we have not found strong evidence that common variants in these genes substantially regulate the timing of puberty.

Intragenic deletions represent a significant disease causing mechanism: Evidence from a select group of rare genetic disorders. *E.V. Haverfield, A.J. Platteter, M.A. Dempsey, W.B. Dobyns, S. Das* Department of Human Genetics, University of Chicago, Chicago, IL.

Genetic abnormalities associated with human diseases range from whole chromosome abnormalities to point mutations within genes. Chromosome gain or loss and structural rearrangements as well as most microdeletions or duplications are identified by chromosome analysis, FISH and array CGH. Point mutations and small insertions or deletions are detectable by DNA sequencing and mutation scanning methods. Intragenic deletions and duplications that affect single or multiple exons are an important disease-causing mechanism and are a category of mutations that remain undetected by these methods. We determined the frequency of intragenic deletions and duplications in a select group of rare genetic disorders: lissencephaly and subcortical band heterotopia (*LIS1* and *DCX* genes), Sotos syndrome (*NSD1* gene) and Cornelia de Lange syndrome (*NIPBL* gene). Analysis was performed with multiplex ligation probe amplification (MLPA) and real-time quantitative PCR. All patients were negative for mutations in their respective gene and large microdeletions were excluded in *LIS1* and *NSD1*. In 43 phenotypically well-characterized patients with lissencephaly, deletions or duplications in the *LIS1* gene were identified in 19 (44%). In 11 patients with subcortical band heterotopia, deletions in the *DCX* gene were identified in 3 (27%). *NSD1* deletions were found in 1 of 6 patients (17%) with suspected Sotos syndrome and *NIPBL* deletions were observed in 1 of 52 patients (2%) with suspected Cornelia de Lange syndrome. Partial deletions of the *PANK2* gene in patients with autosomal recessive pantothenate-kinase associated neurodegeneration were identified when apparent homozygosity for a rare mutation was due to compound heterozygosity for a mutation and an intragenic deletion. A systematic study of intragenic deletions in the *PANK2* gene is in progress. Our studies illustrate the presence of intragenic deletions and duplications in rare genetic disorders and indicate that they may contribute significantly to disease etiology. Our results have important implications for the diagnostics of genetic disease.

A new paradigm for the inheritance of familial Mediterranean fever (FMF). *I. Aksentijevich, M.G. Booty, E.F. Remmers, D.L. Kastner* Genetics & Genomics Branch, NIH/NIAMS, Bethesda, MD.

FMF is a recessively inherited autoinflammatory disease caused by mutations in MEFV, which encodes pyrin. To date, substantial numbers of patients have been observed with only one demonstrable MEFV mutation, and rare cases of dominant inheritance have been documented. Here, we report 10 patients with typical FMF clinical histories and good responses to colchicine treatment. Eight patients were carriers of M694V, a mutation associated with the most severe FMF phenotype, one patient was a carrier of R653H and the other of the complex allele E148Q /V726A. To identify the second disease-associated mutations, all patients were sequenced using two methods. Standard sequencing using the ABI 3100 was performed on all 10 exons of MEFV, and the entire 15 kb genomic region encompassing MEFV was sequenced using a chip-based resequencing system (Callida). A second FMF mutation was not identified, but numerous heterozygous nucleotide changes were found throughout the gene, downplaying a potential role for genomic deletions. To investigate the presence of both transcripts, we evaluated allelic expression in 6 patients by cDNA sequencing. We considered a digenic model of inheritance by looking for mutations in pycard and siva, proteins known to interact with pyrin, and in POP1 and POP2, proteins known to have a similar function to pyrin in the regulation of IL-1 pathway. We identified two novel nucleotide changes and one of them proved to be a polymorphism after evaluating panels of Caucasians and ethnically matched controls. The second missense mutation is still under investigation. We compared the relative levels of MEFV transcripts between FMF patients with one mutation, to FMF patients with two mutations and healthy controls in an attempt to examine possible copy number variation. We did not observe a significant difference in MEFV expression between FMF patients with one mutation compared to patients with two mutations after using two different Taq-Man probes. Our data indicate that the existence of one MEFV mutation may be sufficient in some patients in the presence of some other modifying genes to cause the inflammatory phenotype in FMF patients. *MEFV*.

The essential role of *Ikbkap* in embryogenesis: Developing a model for Familial Dysautonomia. *Y.T. Chen[1,2], R.S. Shetty[1,2], M.M. Hims[1,2], M. Leyne[1], L. Liu[1], J. Mull[1], J. Pickel[3], S.A. Slaugenhaupt[1,2]* 1) Center for Human Genetic Research, MGH, Boston, MA; 2) Harvard Medical School, Boston MA; 3) NIMH Transgenic Core, National Institutes of Health, Bethesda, MD.

Familial dysautonomia (FD) is one of the best known recessive sensory and autonomic neuropathies. Among the disease-causing mutations identified, an intronic non-coding point mutation (IVS20+6T>C) is present in all FD patients. Studies from our lab have revealed that this mutation causes variable skipping of exon 20 in the *IKBKAP* transcript. This point mutation does not completely abolish all wild-type *IKBKAP* mRNA synthesis, but rather reduces the level of normal message and protein. In fact, the existence of both the wild-type and mutant *IKBKAP* mRNA were observed in various tissues from FD patients with the lowest relative amount of wild-type isoform in the neuronal tissues. To better understand the role of the *IKBKAP* gene in vivo, we have established an *Ikbkap* knock-out mouse model. Analyses of homozygous *Ikbkap* knock-out (*Ikbkap*-/-) embryos shows that deletion of mouse *Ikbkap* results in failure during embryogenesis, which leads to the reabsorption of these defective embryos at later embryonic stages (E12.5). Gross morphological analyses of *Ikbkap*-/- embryos at earlier stages (E8.5-E11.5) revealed several abnormal configurations, including a failure of germ layer inversion, a disruption of cephalic neural tube closure and a smaller body size when compared with wild-type littermates. Further, the expression of several genes required in early embryogenesis is reduced in the *Ikbkap*-/- embryos, suggesting a crucial role of IKAP during development. We have also created transgenic mouse lines using the human FD *IKBKAP* gene, which exhibit tissue-specific mis-splicing of human *IKBKAP* in a pattern similar to that observed in FD patients. Currently, we are in the process of generating an accurate phenotypic model of FD by crossing the knock-out and transgenic lines. These mice should accurately model the human disease and will not only allow us to examine the role of IKAP during development, but will also serve as a platform for testing potential therapeutic agents.

DIMORPHIC EFFECTS OF NOTCH SIGNALING IN BONE HOMEOSTASIS AND DYSREGULATION IN OSTEOSARCOMA VS. AGE RELATED OSTEOPOROSIS. *F. Engin[1], T. Yang[1], G. Zhou[1], T. Bertin[1], M.M. Jiang[1,2], Y. Chen[1,2], L. Wang[3], H. Zheng[1], Z. Yao[4], B. Boyce[4], B. Lee[1,2]* 1) Dept Molec & Human Genetics, Baylor Col Medicine, Houston, TX; 2) Howard Hughes Medical Institute, Houston, TX; 3) Department of Pediatrics, Baylor College of Medicine, Houston, TX; 4) Department of Pathology and Laboratory Medicine, University of Rochester Medical Center, Rochester, NY.

Notch signaling plays an important role in various developmental processes including cell fate determination, differentiation, proliferation, and apoptosis. Dysregulation of Notch pathway has been implicated in many different diseases including spondylocostal dysostosis and cancer. However, its in vivo function in bone homeostasis remains largely unknown. Here, we show that osteoblast-specific gain of function of Notch1 results in severe osteosclerosis. Transgenic mice over-expressing Notch1 intra cellular domain (N1ICD) from the *Col1a1* promoter have increased proliferation of immature osteoblasts that produce immature woven bone. Under these pathological conditions, Notch stimulates early osteoblastic proliferation by up-regulating *Cyclin D*, *Cyclin E* and *Osterix*. Notch also regulates osteoblastic terminal differentiation by binding *Runx2*, an essential transcription factor for osteoblastogenesis, and repressing its transactivation function. Consistent with this proliferative effect, human osteosarcomas show evidence of increased Notch signaling and its inhibition by a -secretase inhibitor in vitro decreases the proliferation of human osteosarcoma cells. In contrast, loss of all physiologic Notch signaling in osteoblasts, generated by deletion of *Presenilin 1* and *2* in osteoblasts, is associated with late onset, age-related osteoporosis. Double knock-out mice show decreased expression of *Osteoprotegrin* (*Opg*) expression indicating an increased osteoblast-dependent osteoclastic activity. Moreover, co-culture and flow cytometric analyses reveal increased differentiation of osteoclast precursors explaining the low bone mass phenotype in these mice. Together, these findings highlight the potential dimorphic effects of Notch signaling in bone homeostasis, and importantly, they may provide direction for novel therapeutic applications.

A silent substitution in the MCAD gene causes exon 2 skipping by disruption of a crucial SRp40 binding exonic splicing enhancer which is fundamental for MCAD gene expression. *B.S. Andresen[1,2], A.V. Jensen[1,2], L.D. Schroeder[1,2], E. Naylor[3], L. Halaby[4], C.A. Stanley[4], N. Gregersen[2]* 1) Inst of Hum Genet, Aarhus University,Denmark; 2) Res Unit f. Molec Med, Aarhus University Hospital, Denmark; 3) Dept. Pediat, Med College of S. Carolina, USA; 4) Dept Pediat, The Children's Hosp of Philadelphia, USA.

Correct splicing of exons is determined by a fine balance between cis-acting regulatory sequences like exonic splicing enhancers (ESE) and exonic splicing silencers (ESS). Mutations that create or disrupt ESS/ESEs may disturb this balance and cause missplicing and disease. Two unrelated newborns who were identified by MS/MS screening were found to be compound heterozygous with the prevalent c.985A>G mutation and a synonymous c.87A>G substitution. Analysis of cells from one of the newborns and her father showed skipping of exon 2. To investigate if this is caused directly by c.87A>G or alternatively by an undetected intronic mutation we used a MCAD minigene. Transfection studies confirmed that c.87A>G causes exon 2 skipping. In silico analysis indicated that c.87A>G disrupts a binding motif for the splicing regulatory protein SRp40. We used a heterologous splicing reporter minigene to confirm that c.87A>G also causes missplicing in another genetic context and tested other substitutions to delineate the consensus sequence of this ESE. Using nuclear extracts and RNA affinity purification with wild type and c.87A>G RNA oligonucleotides we confirmed that c.87A>G disrupts binding of SRp40. This suggests that an ESE encompassing position c.87 harbors a SRp40 binding ESE, which is fundamental for splicing of MCAD exon 2. The present study provides an detailed example on how synonymous substitutions can be deleterious by disrupting the finely tuned balance between splicing regulatory elements in constitutive exons. Moreover, it could be speculated if this SRp40 regulated ESE may cause vulnerability to fasting stress, and thus contribute to the general pathology of MCAD deficiency, since SRp40 activity is known to be regulated by insulin levels, and MCAD exon 2 skipping in patient cells seems to be influenced by the metabolic status.

Advances in Sequencing Technology : Enabling and Expanding Applications in Human and Cancer Genetics.

S.B. Gabriel[1], C. Russ[1], J. Baldwin[1], C. Sougnez[1], S. Fisher[1], P. Cahill[1], R. Onofrio[1], R. Nicol[1], T. Bloom[1], K. Cibulskis[1], W. Brockman[1], P. Alvarez[1], D.B. Jaffe[1], D. Altshuler[1,2], C. Nusbaum[1], E. S. Lander[1] 1) Broad Institute of MIT and Harvard, Cambridge, MA; 2) Massachusetts General Hospital, Boston, MA.

Targeted re-sequencing is critical for identifying genetic variation contributing to common human disease and for discovering mutations driving the development of cancer cells. Recently genome-wide association studies have pointed to new regions harboring heritable variation that impacts the risk of various common disease. Re-sequencing is the only way to characterize the full allelic spectrum in these regions to determine the full role of genetic variation in risk. Similarly genomic studies in cancer are identifying important regions. However, large-scale re-sequencing in many samples has not been practical due to high cost and technical limitations (e.g.,the requirement for high sample purity).

New single-molecule-based sequencing can dramatically impact the scope, feasibility and quality of re-sequencing projects through decreased cost and increased sensitivity. Lower cost allows for deep sampling. The ability to read out individual DNA strands obviates calling heterozygous sequence and thus has the potential to deliver high sensitivity and specificity. In addition, the technologies have the potential to detect variants present at lower molarity, such as in a mixed sample of tumor and stroma.

We describe various applications of new sequencing technologies. In a pilot study, we re-sequenced germline DNA in a 500kb ENCODE region sequenced as part of the HapMap project. We observe near-complete sensitivity and specificity in 7 HapMap samples. Results for somatic mutation detection are equally encouraging. We sequenced 60 genes in tumor DNAs and matched controls for which conventional sequencing data is available. We identified all mutations previously found, as well as additional mutations. Studies underway are aimed at complete characterization of several disease associated regions (~5 Mb) and sequencing of ~1000 genes in hundreds of tumor samples.

Development and validation of array CGH for detection of copy number mutations in the Duchenne muscular dystrophy (DMD) gene. *B.A. Boggs, D. del Gaudio, Z. Ou, Y. Yang, J. Wiszniewska, J.R. Lupski, A.L. Beaudet, A.C. Chinault, C.M. Eng* Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Duchenne/Becker muscular dystrophy (DMD/BMD) is caused by mutations in the DMD gene located at Xp21. This is one of the largest genes identified in the human genome with 79 exons spanning ~2.2 megabases that are expressed as multiple isoforms in different tissues. A large percentage of mutations (~70%) in the DMD gene are due to deletions or duplications affecting one or more exons. Current diagnostic evaluation for such mutations involves several different approaches in male and female patients. These include dosage-sensitive Southern hybridization analysis, multiplex PCR amplification of DMD exons, and/or multiplex ligation-dependent probe amplification (MLPA). Given recent progress with array based CGH for high-resolution detection of genomic copy number gains and losses, we designed an Agilent oligonucleotide-based array with high-density coverage of the DMD gene to test the ability of this platform to detect and precisely map the end points of deletions and duplications in both male DMD/BMD patients and heterozygous females (which are more difficult to detect by current methodology). Initially, 6 samples (3 male, 3 female) were analyzed in a blinded study using an array that included 1125 oligos at DMD. Four deletions of 35-728 kb and a duplication of 113 kb were detected; in addition a non-contiguous duplication of 535 kb and 325 kb separated by a non-affected region of ~71 kb was found. All these findings were in complete concordance with the known abnormalities from previous studies. We subsequently obtained results for additional clinical samples, which included a male patient with a 5-kb duplication and a female with an apparent whole gene deletion that was actually shown to be due to loss of an entire X chromosome in ~30% of the cells. These studies provide initial experience with the use of the oligoarray platform to enhance detection of gene rearrangements in this and other disease genes as well as potentially replace existing methodologies in the clinical diagnostic laboratory.

Dysfunction of the GH/IGF pathway and human longevity. *G. Atzmon[1], M. Cho[1], T. Budagov[1], D. Hwang[2], B. Liu[2], N. Barzilai[1], P. Cohen[2], Y. Suh[1]* 1) Department of Medicine, Albert Einstein College of Medicine, Bronx, NY,NY; 2) Mattel Children's Hospital and David Geffen School of Medicine at UCLA, LA, CA.

The role of altered GH/IGF signaling in lifespan extension is well established in lower species but has not been shown in humans. To investigate the role of GH/IGF axis in human longevity we analyzed chemotypic, phenotypic and genetic variations in the GH/IGF axis molecules in a cohort of Ashkenazi centenarian (n=180), their offspring (n=147)and unrelated matched control (n=221). Female offspring of centenarians were shorter and had higher serum IGF-1 levels than control females ($p<0.01$), a gender-specific response similar to a report in heterozygote IGF1R-KO mice. We thus comprehensively screened genomic DNA for all possible genetic variants throughout the coding exons of the IGF1R gene. We discovered 2 novel non-synonymous mutations in the IGF1R in female centenarians with short stature and/or elevated IGF-1 that were not seen in controls, as well as 3 novel synonymous mutations detected only in centenarians. We also studied the Exon 3 deletion polymorphism of GHR gene (d3GHR), and demonstrated that the frequencies of the d3GHR homozygote were significantly higher in male centenarians (14%) and in their male offspring (12%) as compared to male controls (4%). The d3GHR carriers male centenarians were 3 inches shorter than centenarians carrying the wt GHR variant and had lower serum IGF-1 ($p=0.03$). To assess the functional consequences of the genetic variations identified in this study, we analyzed immortalized lymphocytes. Lymphocytes from the D3GHR carriers displayed significantly slower growth rates and lower activation of ERK at baseline, but higher growth and activation of ERK in response to GH treatment, as compared to wild type carriers ($p<0.01$). Furthermore, lymphocytes from the IGF1R mutation carriers showed significantly lower level of both basal and IGF-induced activation of AKT, and reduced levels of IGF1R protein. These findings provide the first genetic, functional, sexual dimorphism, and phenotypic links between the GH/IGF pathway and aging in humans, supporting the role of this conserve pathway in exceptional longevity.

Genome-Wide Association Study for Longevity Using 550,000 SNPs in the Quebec Founder Population. *S. Kebache[1], J. Raelson[1], P. Van Eerdewegh[1], Q. Nguyen-Huu[1], G. Lepage[1], T. Fülöp[2], M. Dugas[3], H. Fournier[1], B. Paquin[1], J. Hooper[1], A. Belouchi[1], T. Keith[1]* 1) Genizon BioSciences, St-Laurent, QC, Canada; 2) University of Sherbrooke, Sherbrooke, QC, Canada; 3) Université Laval, Centre de recherche du CHUQ, Quebec, QC, Canada.

To identify genes involved in longevity, we performed a GWAS using 530 cases (94 years of age) and 530 matched controls (18-65 years of age) from the Quebec founder population (QFP). Cases and controls were individually genotyped using the Hap550 chip (Illumina). 499,217 SNPs and 523,160,414 genotypes with a call rate of 99% and a minor allele frequency 4% were used in genetic analyses. Haplotype and single-marker association analyses were performed, with a sliding window defining haplotypes of 1, 3, 5, 7 and 9 markers. The genome-wide significance of the obtained P values was assessed by permutation studies. Regions with P values that met the criteria for genome-wide significance were identified both with the haplotype and single marker association tests, indicating that a well-powered GWAS with the QFP can be achieved with a relatively small sample size. Among the significant signals, haplotype analysis yielded 5 regions with P values 10^{-7} including 2 with P values 10^{-8}, whereas single-marker association identified 7 regions with P values 10-5 including 1 with a P value 10^{-6}. Examples of top candidate loci are described, including information on the length of the regions and the relevance of the encoded genes in relation to longevity. Regions were well resolved with ~40% containing a single gene. About half of the regions contain genes relevant to longevity including neurological function, cardiovascular function, insulin metabolism and DNA repair. Using only the centenarians as cases (196 individuals), we identified 1 region that met the criteria for genome-wide significance (P ~10^{-3} in the full sample to P ~$10^{-7.5}$, even though the sample size was drastically reduced). The identified genes have been used to build a GeneMap, consisting of networks of genes and their biological pathways relevant to ageing processes. We are currently performing genome-wide conditional analyses to detect gene-gene interactions.

Meta-analysis of the MHC2TA -168A/G polymorphism and rheumatoid arthritis. *P.G. Bronson[1], L.A. Criswell[2], L.F. Barcellos[1,3]* 1) Division of Epidemiology, School of Public Health, University of California, Berkeley, CA; 2) Rosalind Russell Medical Research Center for Arthritis, Department of Medicine, University of California, San Francisco, CA; 3) Kaiser Permanente Division of Research, Oakland, CA.

Background: An association between major histocompatibility complex (MHC) genes, particularly those within the class II HLA region, and rheumatoid arthritis (RA) is well established, and accounts for an estimated 30% of the genetic component in RA. The MHC class II transactivator gene (MHC2TA) on chromosome 16p13 has recently emerged as the most important transcription factor regulating genes required for class II MHC-restricted antigen presentation. Previous studies of a promoter region polymorphism (-168A/G, rs3087456) in the MHC2TA gene and RA have yielded conflicting results.

Objective: To assess the association of the MHC2TA -168A/G polymorphism and risk for RA by meta-analysis.

Methods: Meta-analysis was performed for 6,861 RA patients and 9,270 controls from ten case-control studies. Odds ratios (ORs) and 95% confidence intervals (CIs) were calculated for each study. Summary ORs and 95% CIs were calculated in random effects models.

Results: No effect was observed for the G risk allele (OR 1.02, 95% CI 0.93-1.12, P=0.70) or the GG risk genotype (OR 1.14, 95% CI 0.95-1.36, P=0.16).

Conclusions: Our results indicate that the MHC2TA -168A/G polymorphism is not associated with RA yet underscore the importance of including shared epitope alleles, secondary phenotypes and more complete characterization of MHC2TA variation in future studies.

The Development of a Broad-Based ADME Panel for use in Pharmacogenomic Studies and Drug Development.

A.M.K. Brown[1], Y. Renaud[1], I. Mongrain[1], N. Gaudreault[1], C. Ross[2], C. Taylor Lawley[3], R. Shen[3], C.H. Lin[3], J-C. Tardif[1], M.S. Phillips[1] 1) Genome Quebec & Montreal Heart Institute Pharmacogenomics Centre, Montreal, QC, Canada; 2) University of British Columbia, Vancouver, BC, Canada; 3) Illumina, Inc. San Diego, CA.

While the mechanisms of action and the therapeutic uses of many drugs may differ, they are all metabolized by a well known set of genes and pathways that can influence their pharmacokinetic responses. In order to address the inter-individual variability observed in these genes and pathways, we have set out to create a genotyping assay that encompasses the majority of the known variation present in key genes involved in the Absorption, Distribution, Metabolism and Excretion (ADME) of many therapeutic agents. We have incorporated into the panel previously published and predicted functional markers, as well as tag SNPs that account for blocks of Linkage Disequilibrium (LD) across all HapMap populations. The consensus candidate gene list was composed with input from both academia and the pharmaceutical industry. These genes can be grouped into four categories: Phase I and II metabolism enzymes, responsible for the modification of functional groups and the conjugation with endogenous moieties respectively; transporters, responsible for the uptake and excretion of drugs in and out of cells; and modifiers, that can either alter the expression of other ADME genes or affect the biochemistry of ADME enzymes. Many of the genes described above have been difficult to assay successfully in the past due to underlying polymorphisms and regions of homology. In collaboration with Illumina, we have used novel design strategies to overcome the genomic interference, resulting in optimized and validated assays. To date, the panel will support two of our current studies; one involving the toxicity of lipid lowering and novel anti-atherosclerotic agents, and a second involving cisplatin and anthracycline adverse reactions in children. Moreover, our panel has broad applicability to any study or clinical trial that would benefit from the evaluation of an extensive list of ADME genes.

Translocation (11;11)(p15;q22) in Acute Myeloid Leukemia - a case report. *S. Gupta[1], Y. Saffari[2], R. Nagwekar[3], R. Forte[4], J. Brody[1], P. Koduru[1]* 1) Department of Laboratory Medicine, North Shore University Hospital, NY; 2) Pathology, Long Island Jewish Medical Center, NY; 3) Pathology, Nassau University Medical Center, NY; 4) North Shore Hematology/ Oncology, PLLC, NY.

A spectrum of cytogenetic aberrations of diagnostic and prognostic implications is associated with acute myeloid leukemia. Molecular analysis of the genes involved in these chromosome abnormalities has led to the understanding of leukemic transformation. 81-year-old female with macrocytic anemia developed fever. Blasts were present in peripheral blood and bone marrow. Immunophenotyping revealed immature myelomonocytic population, positivity for HLA-DR, CD117, CD33, DC13, CD15, partial CD4; negative DC34. Most cells stained positive with myeloperoxidase; chloroacetate esterase and naphthly butyrate esterase positivity was more than 20%. A diagnosis of acute myelomonocytic leukemia was made. Chromosome analysis of bone marrow cells showed 46,XY,t(11;11)(p15;q22)[17]/46,XY,-6,+9,t(11;11)(p15;q22)[3]. Establishing cytogenetic profiles in leukemia is important in making treatment choices and monitoring the response, as well as in search for new targets. Chromosome bands 11p13~15 and 11q22~23 are involved in many recurrent, nonrandom rearrangements both in leukemia and lymphoma. Putative oncogenes and tumor suppressor genes involved in leukemogenic process are discussed.

Familial Aggregation of Prostate and Breast Cancer in African Americans and Hispanics. *T.J. Costello[1], C. Pettaway[2], C.J. Etzel[3], S.S. Strom[3]* 1) Health Disparities Research, UT MD Anderson Cancer Center, Houston, TX; 2) Urology, UT MD Anderson Cancer Center, Houston, TX; 3) Epidemiology, UT MD Anderson Cancer Center, Houston, TX.

Although prostate cancer familial aggregation has been well studied in Caucasians and African Americans, similar information about Hispanics is rare. Family history of prostate cancer is considered one of the major risk factors, along with age and race, associated with prostate cancer risk. We investigated the role of having a positive family history of prostate cancer on cancer risk in minority populations in an ongoing case/control study. The 578 prostate cancer cases were treated at various hospitals in the Texas Medical Center in Houston, Texas between 1995 and 2004. The 669 controls that were recruited in the Houston area were matched to the cases based on ethnicity, race, residency and age (5 years). We obtained detailed family cancer history for 5703 first-degree relatives (FDR) of the cases and 5981 first-degree relatives of the controls. We compared the reported cancer among relatives of cases to that of controls to evaluate whether there was an excess of cancer using multivariable logistic regression for Hispanics and African American probands, respectively. We also conducted stratified analyses by type of cancer (prostate and breast), relationship to the case/control and age of diagnosis of the case (or > 60 years old).

Positive family history of prostate cancer increased risk for both Hispanics (OR=2.74 (1.50-5.21)) and African-Americans (OR=1.99 (1.37-2.87)). Stratified analyses also revealed a higher risk if the affected relative is a brother for both Hispanics (OR=5.07) and African Americans (OR=1.95). No increased risk of breast or colon cancer was observed in FDR of either Hispanic or African American of prostate cancer probands. Together with additional analyses that we conducted, this evidence confirms that a positive family history of prostate cancer is a risk factor for both populations and suggests that continued research is required to characterize and identify the genetic factors that influence prostate cancer susceptibility.

Fine mapping of the Blmpf2 lung fibrosis locus in bleomycin-treated congenic mice. *F. D. Depault, C. H. Haston*
Human Genetics, McGill University, Montreal, Quebec, Canada.

Bleomycin is a drug used to treat cancers, which produces pulmonary fibrosis (p-f) in up to 10% of patients. From clinical studies it is suggested that the development of p-f has a genetic component. Inbred strains of mice differ in their propensity to develop p-f following bleomycin treatment: the B6 strain develop fibrosis while those of the C3H (C3) strain do not develop any disease. This phenotype variability serves as a model to address our hypothesis that genetic factors influence the development of p-f. We have previously used a QTL approach and identified two genomic regions that modify the development of p-f in B6 x C3 bleomycin-treated mice. The present study focuses on the chr.11 Blmpf2(B-2)locus, which produces a drastic diminution of p-f when carrying the C3 alleles at that position. However, the QTL locus remains large (25.9 Mb) and requires further mapping. Therefore, we created a congenic lineage, which have a B6 background except inside the B-2 locus that contains the C3 allele. By intercrossing the recombinant animals, we created 13 sublines carrying different length of the C3 allele. By identifying the position of C3 alleles that result in p-f reduction in congenic bleomycin-treated mice, we have succeeded in defining a resistant locus which contains 50 genes. It is postulated that the candidate gene expression will be divergent between the B6 and C3 strains in the lung. Our previously completed RNA microarray datasets inform us that one gene is differentially expressed and maps inside the reduced B-2 locus. To confirm the action of this gene in p-f development, we derived four additional sublines with recombination in the vicinity of the candidate gene. By the fine mapping of B6/C3 recombination breakpoints, we propose to narrow down this locus to a length that is amenable to molecular analysis. Ultimately, the candidate genes will be functionally studied to confirm whether they encode transcripts influencing lung fibrosis. Susceptibility genes discovered in this study may be useful for predicting a patient response to the chemotherapy side-effects and may serve as a clinical target.

FINE-MAPPING AN 18Mb ALCOHOL DEPENDENCE SUSCEPTIBILITY LOCUS ON 4q22-q32 IN THE IRISH AFFECTED SIB-PAIR STUDY OF ALCOHOL DEPENDENCE (IASPSAD). *G. Kalsi[1], P-H. Kuo[1], J. Alexander[1], P.F. Sullivan[2], E.J.C.G. van den Oord[1], D.G. Patterson[3], D. Walsh[4], C.A. Prescott[5], K.S. Kendler[1], B.P. Riley[1]* 1) Dept Molecular Genetics, Virginia Commonwealth Univ, Richmond, VA; 2) Dept of Genetics, University of North Carolina, Chapel Hill, NC; 3) Shaftesbury Square Hospital, Belfast, Northern Ireland, UK; 4) Health Research Board, Dublin, Eire; 5) Dept of Psychology, University of Southern California, Los Angeles, CA.

A genome wide linkage scan conducted in the IASPSAD produced significant evidence for linkage to number of DSM-IV alcohol dependence (AD) symptoms over a broad region of chromosome 4, from 4q22 to 4q32 (peak multipoint LOD=4.59, P=2.1 x 10-6, at D4S1611). A one-LOD interval under this peak delineates a 17.6Mb region defined by the markers D4S1572 and D4S427. We fine-mapped a region extending 18.5Mb region which includes the one-LOD interval and flanking regions on either side to include full genes. The region contains 65 genes and ESTs in the Jan 06 build of HapMap (hg18, NCBI Build 36.1). We used Tagger and Phase 2 HapMap data to select a minimum set of gene- and EST-based tagSNPs based on pairwise r2 to efficiently extract maximum information with the smallest genotyping burden. This approach identified 523 tagSNPs, of which 460 (88%) were suitable for high-throughput multiplex genotyping in a sample of 562 cases and 569 controls. Single marker and haplotype analyses were done in Haploview v3.3. Genes which pass the nominal significance level of $p<0.05$ include the PAPSS1 (rs9569, p=0.0155), ANK2 (rs313956, p=0.0141; rs1351998, p=0.0162), ARSJ (rs12645879, p=0.0266; rs4441820, p=0.0124) and KIAA1627 (rs298998, p=0.0149). Haplotype analyses produced nominal statistical significance. Other genes, which showed single marker, but not haplotype, significance include DKK2, ALPK1, CAMK2D and SEC24D. The data is being analysed for possible multilocus interactions. Fine-mapping of the linkage region has produced evidence of association with AD. Functional roles of genes identified include cell architecture, binding with neurotransmitters and sulfonation, all of which are processes with possible physiological link to alcohol dependence.

Ordered Subset Analysis for Association Mapping. *R.H. Chung[1], S. Schmidt[1], X. Qin[1], X. Lou[1], E.R. Martin[2], E.R. Hauser[1]* 1) Ctr Human Genetics, Duke Univ Medical Ctr, Durham, NC; 2) Institute for Human Genomics, Univ of Miami, FL.

Complex diseases are caused by multiple factors such as sequence variants in multiple genes, environmental effects, gene-gene and gene-environment interactions. Genetic heterogeneity refers to different variants resulting in the same disease phenotype. Genetic heterogeneity can reduce the power for complex disease gene mapping since there may be only a portion of families carrying a specific disease susceptibility allele in collected samples. Ordered subset analysis (OSA) is a linkage test that identifies a subset of families that has the strongest linkage signal based on the ranking of covariates. The same strategy can be applied to association analysis to find a subset that has the most informative families. APL is a family-based association test that uses nuclear families with multiple affected sibs and can infer missing parental genotypes properly by accounting for linkage. We developed APL-OSA, which applies the OSA algorithm to the APL statistic. Each family is assigned a covariate based on the covariates for affected sibs in the family and then families are ranked according to their covariates. Each family is added one by one into a set S based on the ranking. Since the APL test statistic is not additive over families, unlike a LOD score for linkage, the APL test statistic is re-calculated each time a family is added into S. The most significant APL statistic, which is noted as the APL-OSA statistic, is chosen after all families have been added into S. The null hypothesis for APL-OSA is that there is no relationship between the family covariate and the APL-OSA statistic. A permutation procedure is used to approximate the distribution for the APL-OSA statistic under the null hypothesis. The permutation procedure randomly orders the families and then performs the APL-OSA analysis as before. We performed a comprehensive simulation study to verify that APL-OSA has the correct type I error rate under the null hypothesis. This simulation study also showed that APL-OSA has greater power than other association tests (APL, FBAT and FBAT with covariate adjustment) in the presence of genetic heterogeneity.

How modifiers genes influence in pulmonary disease? An overview in a group of Mexican patients with Cystic Fibrosis. *M. CHAVEZ-SALDAÑA[1,2], E. YOKOYAMA[1], C. VILLARROEL[1], F. CUEVAS[3], A. CARNEVALE[4], J.L. LEZANA[5], S. FRIAS[1], B. MOLINA[1], L. OROZCO[6]* 1) Depto. de Investigación en Genética Humana, INP; 2) Universidad Autónoma Metropolitana; 3) Servicio Neumología, INP; 4) Coordinación Nal de Medicina Genómica, ISSSTE; 5) Depto. de Neumología, HIM; 6) Lab de Genómica de Enf Multifactoriales, INMEGEN.

Introduction. Cystic fibrosis (CF) is the most common autosomal recessive disorder in the Caucasian population. There are reports about the strong correlation between pancreatic function and the *CFTR* genotype, whereas others clinical signs may be different in patients with the same genotype. Because of this, it has been proposed that modifiers genes such as *TNF-, MBL, 1-AT, 1-ACT, -2AD, IL-10,* and others influence the severity of CF. **Objectives.** The aim of this study is to determine the frequency of allelic variants of the genes previously mentioned and their association with severity of pulmonary disease in Mexican patients with CF. **Methodology.** Sixty patients with CF were included. Thirteen single nucleotide polymorphisms (SNPs) of the genes already mentioned were analyzed. The typification was done with Taq-Man methodology. Pulmonary phenotype was measured by positive *Pseudomona* (Pae) cultures, health condition, age at diagnosis and death, age of onset of symptoms, first positive Pae culture, Brasfield's score and the best FEV1 in three years. The association was analyzed with the statistics program SPSS, and a value of p0.05 was considered significant. **Results**. The frequency of allelic variants does not show differences with the literature reports. Significant differences were found in the variables MBL-550 with health condition, *IL10-819* and *-2AD/16GlyArg* with age at diagnosis, *1-ACT/*$^{-15}$*Thr>Ala* with age at death and Brasfield's score, and *1-AT/alleleZ* with best FEV1 in three years. **Conclusion.** This is the first report on the association of some SNPs in genes of specific response with the pulmonary phenotype among Mexican patients with CF. Our results suggest that genomic analysis of patients with CF may predict the clinical evolution of the disease and may be useful to establish an individualized treatment of patients.

Next-generation Sequencing of 1000 Samples To Detect Rare Variants - Opportunities and Constraints. *F.C.L. Hyland[1], H. Peckham[1], J. Malek[1], E. Cuppen[2], J. Sorenson[1], K. McKernan[1], F.M. De La Vega[1]* 1) Applied Biosystems, Foster City, CA and Beverly, MA; 2) Hubretch Lab, Utrecht, The Netherlands.

Next generation, rapid, low-cost sequencing promises to address a broad range of genetic analysis applications, including quantitative sequencing for identification of somatic mutation profiles in cancer or for allele-specific expression. Additionally, validation of whole genome association studies involves sequencing many samples at specific regions of the genome. Ideally individual samples would be barcoded; in the interim, sequencing of pooled cases or controls can detect rare mutations to elucidate the genetic basis of complex disease. The Applied Biosystems SOLiD system (Sequencing by Oligonucleotide Ligation and Detection) can sequence over 1500 MB of paired-end reads at 32 spots/run, so pooling 33 samples per spot could potentially enable the detection of variants from 50 kb in 1000 individuals at 30x coverage/sample in a single run, while simultaneously detecting large InDels. We developed a model to simulate digital sequencing in pooled samples in the presence of error. We estimate the coverage that is necessary to discover rare variants. We discover that the number of samples that can be pooled is critically dependant on the threshold for SNP calling, which in turn is strongly influenced by the measurement error rate. The higher the error rate, the fewer samples can be pooled for detection of rare variants. Beyond a certain point, increasing the coverage cannot reduce the limit of detection of low frequency variants in pooled samples below the error rate, highlighting the advantage of using two-base encoding to eliminate error reads and increase the base accuracy above 99.9%. We validated this model through SOLiD sequencing of 81 PCR amplicons from exons of EMS-mutagenized C. elegans encompassing ~25kb of sequence with over 1500x coverage on 100 pooled samples (1:200 ratio for alleles). The results were compared with di-deoxy sequencing data carried out independently for each amplicon. To date, 1/3 of the top hits have been validated. Our results suggest that low error rate is the most critical factor for detecting rare variants using next generation sequencing.

***WDR36*: a Potential Modifier Gene Altering Glaucoma Severity in a Huge French-Canadian *Myocilin* Family.** *P. Belleau[1], K. Lebel[1], R. Arseneault[1], J.L. Anctil[2], A. Duchesne[1], M.A. Rodrigue[1], G. Côté[2], M. Amyot[3], V. Raymond[1,2], The Québec Glaucoma Network* 1) Ocular Genetics & Genomics, CREMO, Laval University Hospital (CHUL) Res Ctr, Québec City, PQ, Canada; 2) Ophthalmology, Laval Univ, Québec City; 3) Ophthalmology, Univ of Montréal, Montréal, PQ, Canada.

Primary open-angle glaucoma (POAG), characterized by optic nerve degeneration and blindness, is genetically heterogenous. Three POAG genes are known: *myocilin* (*MYOC*), *optineurin* and *WDR36*. *MYOC* accounts for about 4 % of cases while contributions of *WDR36* are not well understood. In the French-Canadian CA family, the $MYOC^{K423E}$ mutation causes wide phenotypic variability of autosomal dominant POAG. In the pedigree, we observed distinct clusters for age-at-onset (AAO) of glaucoma supporting the presence of 1 modifier gene. To assess if *WDR36* was 1 of these modifiers, we studied genotype/phenotype correlations in double variants who simultaneously carried $MYOC^{K423E}$ and WDR36 variations. The family comprises 749 members with 156 $MYOC^{K423E}$ heterozygotes. Ophthalmologic records, some going back to the 1950s, were examined for 142 carriers; all of them were screened for *WDR36* variations by sequencing. AAO, defined as age at which ocular hypertension (OHT) or POAG was first detected, varied from 7 to 63 years old. 95 carriers were diagnosed POAG or OHT with *Rx*, 19 were OHT, 28 were still asymptomatic. Penetrance was 78% in carriers aged 40. Six WDR36 amino acid (AA) changes were detected in our 142 carriers. When we excluded the I264V polymorphism, 24 double variants were found to harbor $MYOC^{K423E}$ and one WDR36 AA change. To assess for an effect of these WDR36 variations on AAO, we compared AAO of glaucoma in these double variants to the median of AAO of the $MYOC^{K423E}$ heterozygotes who were $WDR36^{wild\text{-}type}$ and who shared a kinship coefficient 0,0625 (neighborhood). 18 double variants remained for analysis. Of these 18 individuals, 10 showed a younger AAO and 5 were below, but within, the range of the median AAO of their neighborhood. Interestingly, 4 $WDR36^{D658G}$ double variants were diagnosed 10 years younger than their median AAO. In conclusion, *WDR36* may contribute to the glaucoma phenotype as a disease-modifier gene.

A balanced 2;7 translocation associated with hereditary gingival fibromatosis. *P.S. Hart[1], J.H. Guo[2], S.I. Jang[2], M.J. Pettenati[3], D. Pallos[4], T.C. Hart[2]* 1) Office of the Clinical Director, NHGRI, Bethesda MD; 2) Section of Human and Craniofacial Genetics, NIDCR, Bethesda MD; 3) Section on Medical Genetics, Wake Forest University, Winston-Salem NC; 4) Department of Periodontics, University of Taubate, Sao Paulo, Brazil.

Hereditary gingival fibromatosis (HGF) can occur as an isolated or syndromic trait. Genetic heterogeneity has been documented for the isolated, nonsyndromic forms, with at least 4 loci localized by linkage studies. Mutation of the *SOS1* gene on 2p22 is the only causative gene identified to date. The mutant SOS1 protein constitutively activates the MAP kinase signaling pathway, and is associated with increased fibroblast proliferation. We ascertained a father and son with isolated HGF who carry a balanced translocation: 46,XY,t(2;7)(p23.3;p13). Sequence analysis of *SOS1* revealed no mutations. Gingivectomy was performed on the son and excised tissue provided a source of RNA, DNA and gingival fibroblasts. A Nimblegen CGH array constructed to analyze small gains or losses of material in the translocated regions revealed no alterations. FISH analysis was subsequently undertaken to refine the breakpoints. The chromosome 2 breakpoint was localized to 777 kb, between BACs RP11-156M23 and -195B17. The chromosome 7 breakpoint localized to the last 386 kB of 7p13. Proliferation assays revealed higher growth rates in HGF fibroblasts compared to control fibroblasts, documenting the clinical phenotype of HGF. After 3 days of growth, BrdU incorporation in the HGF fibroblasts reached steady state and was 50% higher than in control fibroblasts. Increase in total cell numbers, monitored up to day 11, revealed the HGF growth rate was 3X higher than that of controls. Analysis of gene expression profiles in cultured fibroblasts using CodeLink Human Whole Genome Arrays revealed a pattern of expression similar to that seen in HGF due to *SOS1* mutation, including up-regulation of cyclins E1 and E2, DP1, E2F1 and E2F2, all of which function in the cell cycle progression from G1 to S phase. These findings indicate further genetic heterogeneity for HGF, but indicate common underlying alterations in gene expression and cell behavior.

SNPs at the INSIG2 Locus are Associated with Plasma Lipid Phenotypes. *R. Do[1], G. Paré[1,2], A. Montpetit[2], S.D. Bailey[1], K. Desbiens[3], T.J. Hudson[1,2,4], C. Bouchard[5], L. Perusse[6,7], M.C. Vohl[7,8], D. Gaudet[9], J.C. Engert[1,3,4]* 1) Dept of Human Genetics, McGill Univ, Montreal; 2) McGill Univ and Genome Québec Innovation Centre, Montreal; 3) Research Institute of the McGill Univ Health Centre, Montreal; 4) Dept of Medicine, McGill Univ, Montreal; 5) Pennington Biomedical Research Centre, Baton Rouge, Louisiana; 6) Dept of Social and Preventive Medicine, Division of Kinesiology, Laval Univ, QC; 7) Lipid Research Center, Laval Univ Hospital Research Center, QC; 8) Dept of Food Science and Nutrition, Laval Univ, QC; 9) Dyslipidemia, Diabetes and Atherosclerosis Group and Community Genomics Research Center, Univ de Montréal and Chicoutimi Hospital, QC.

Elevated cholesterol is a major risk factor for coronary heart disease (CHD). Endogenous cholesterol biosynthesis is regulated by proteins in the insig-scap pathway, particularly INSIG1 and INSIG2. Recently, a genome-wide scan identified an association between a SNP (rs7566605) 5' of INSIG2 and BMI in the Framingham Heart study as well as in another 4 out of 5 cohorts. However, some studies could not replicate these results. Based on these inconsistent results, we hypothesized that INSIG2 variants may influence plasma cholesterol levels and that such variants would thus only be inconsistently associated with BMI. In addition, we believe that a denser SNP map will help to localize the association signal. To test this hypothesis, we analyzed 10 tSNPs at the INSIG2 loci in family-based and case/control CHD study samples from the Saguenay region of Quebec. Analysis of the combined samples identified a SNP (rs2422166) 5 of the transcription start site that was significantly associated with total apoB (0.016) and LDL-C (p=0.010). In addition, we identified a SNP (rs2113485) in the 3 region of the gene that was also associated with total apoB (p=0.045) and LDL-C (p=0.027). This SNP was not in linkage disequilibrium with the 5 SNP. To identify novel SNPs, we sequenced all exons and intron-exon boundaries as well as conserved promoter and intronic regions for a total of 18,434 bp in the INSIG2 gene locus of 24 French Canadian individuals. Our sequencing identified 37 SNPs, 19 of which have a MAF > 0.05 and 15 of which are novel.

Diagnosis of Pompe disease in different age groups using a dried blood spot assay. *D. Bali, M. Changela, JL. Goldstein, SP. Young, PS. Kishnani, H. Zhang, J. Dai, DS. Millington* Dept Pediatric Med Genetics, Duke Univ Medical Ctr, Durham, NC.

Pompe Disease (acid maltase deficiency; Glycogen Storage disease type II) is caused by a deficiency of the lysosomal enzyme, acid alpha-glucosidase (GAA). GAA deficiency results in glycogen accumulation in multiple tissues, particularly skeletal, cardiac and smooth muscles. Measurement of GAA activity in dried blood spots (DBS) (Zhang et al, Genet. Med. 2006, 8: 302-306) is a rapid and reliable method for diagnosing Pompe disease, being less invasive than assays in cultured skin fibroblasts or muscle biopsies. We report our diagnostic experience of this assay, in both younger (3 yrs) and older (3 yrs) patient populations, including correlation with urinary tetrasaccharide biomarker, GAA activity in fibroblasts and muscle and DNA mutation analysis. In the older patient population we have reviewed the reported clinical indications for testing, including symptoms of limb girdle muscular dystrophy and other myopathies that resemble late-onset Pompe disease. 18% of younger patients tested (14 of 79) had DBS GAA deficiency, and follow-up testing was performed in 9 patients for whom samples were received. 12 of 14 younger patients were referred because of cardiomyopathy. A similar incidence of GAA deficiency (20%; 45 of 220 samples) was observed for older patients and follow-up testing was performed for 19. Muscle weakness (71%) was the most common reason for testing in the older patient population. One third of these cases were defined as proximal muscle weakness and 2/3rd were undefined. Family history (21%) was the second most common reason. 16% of the older patient group were reported to have respiratory involvement. The majority of patients (>50%) were referred from genetics or neurology clinics. Approximately 20% of tested patient population had GAA activity below the control range, but above the range for known affected patients. Additional testing was recommended for these patients. These results will aid our understanding of patients who will benefit from DBS GAA testing. Correlation with other diagnostic tests will improve recommendations for confirmatory testing.

Association analyses of the 7q34-36 language region support *CNTNAP2* as an autism QTL. *M. Alarcon[1,2], B.S. Abrahams[1,2], J.L. Stone[3], R.M. Cantor[1,3,4], J.A. Duvall[1,2,3], J.V. Perederiy[2], J.M. Bomar[2], S.F. Nelson[2,3], D.H. Geschwind[1,2,3]* 1) UCLA Neurology, Reed Neurological Research Ctr. and UCLA CART, Semel Institute of Neuroscience and Program in Neurogenetics, Neurology, David Geffen School of Medicine, Los Angeles, CA; 2) UCLA Center for Neurobehavioral Genetics, Semel Institute of Neuroscience, Los Angeles, CA; 3) Human Genetics, David Geffen School of Medicine, Los Angeles, CA; 4) Pediatrics, David Geffen School of Medicine, Los Angeles, CA.

Autism Spectrum Disorders (ASD) is quickly becoming the most prevalent neurodevelopmental disorders in the United States. Characteristic features include social and communicative deficits, repetitive and stereotypic behaviors, and language impairments. About half of individuals with ASD have language difficulties. Considering the male to female ratio of ASD (approximately 3:1), and the increased frequency of language delays in typically-developing boys, sex may be a major contributor to heterogeneity of the disorder and, thus, hinder the identification of autism susceptibility genes, when unrecognized. Despite the complexity of the disorder, we have identified a region on chromosome 7q35 that is linked to a language trait (age at first word) in 291 families from the Autism Genetic Resource Exchange (AGRE). Here, we report results of a two-stage quantitative, block-based association analysis of 2758 single nucleotide polymorphisms that exhaustively cover 15Mb of this linked language region in over 400 AGRE trios. Evidence for quantitative association to Contactin Associated Protein 2 (*CNTNAP2*), specifically attributed to the families with affected males only, is observed. Moreover, we investigated the expression of genes in developing human brain and identified the same gene, *CNTNAP2*, as having a specific expression pattern in circuits involved in cognition and language. These results suggest that *CNTNAP2* may contribute to autism susceptibility as well as language development.

Cigarette Smoking Modulates Genetic Effects on Chromosome 3q13-21 in Early-Onset Coronary Artery Disease.

B.D. Horne[1], L. Wang[2], J.B. Muhlestein[3], J.L. Anderson[3], J.F. Carlquist[3], E.R. Hauser[2], S. Shah[2,4], W.E. Kraus[4], J.M. Vance[5], P.J. Goldschmidt-Clermont[6] 1) Cardiovasc Dept, LDS Hosp & Genet Epidemiol, Univ Utah, SLC, UT; 2) Dept Medicine & Cent Human Genet, Duke Univ, Durham, NC; 3) Cardiovasc Dept, LDS Hosp & Cardiol Div, Univ Utah, SLC, UT; 4) Dept Medicine & Div Cardiology, Duke Univ, Durham, NC; 5) Miami Inst Human Genomics, Miami, FL; 6) Miller School Med, Univ Miami, Miami, FL.

Consistent linkage evidence has been found for coronary artery disease (CAD) at chromosome 3q13-21. We previously reported genes within the linkage peak associated with early-onset CAD in the CATHGEN dataset, implicating the Kalirn-RhoGTPase pathway (KALRN, CDGAP, and MYLK) and the transcription factor GATA2. We sought to validate associations in those genes in a large independent dataset of early-onset CAD cases and controls (IHCS, N=1325). Eleven previously studied single nucleotide polymorphisms (SNPs) in KALRN, CDGAP, MYLK, and GATA2 were examined. Single SNP association was evaluated adjusting for classic risk factors. Given the much higher prevalence of smoking in CATHGEN than IHCS (41% vs 11% in controls, 74% vs 29% in cases), stratified analysis on cigarette smoking and genotype-smoking interaction analysis were performed. Overall, suggestive association was found at SNP rs2713604 in GATA2 (p=0.057, OR=1.2). Among smokers in IHCS, significant associations were found at rs10934490 in CDGAP (p=0.019, OR=1.6) and rs12637456 in KALRN (p=0.011, OR=2.0) and suggestive association at rs16834871 in MYLK (p=0.051, OR=1.8, adjusting for gender only). No association was found in any SNPs among non-smokers in IHCS. Strong interactions between SNP genotype and smoking status were detected in CDGAP (rs10934491, p=0.017) and KALRN (rs12637456, p=0.010) with suggestive interaction in MYLK (rs16834817, p=0.08, adjusting for gender only). We validated the associations with early-onset CAD in KALRN, CDGAP, MYLK, and GATA2. These data suggest that the genetic risk conferred by those genes may be modified by cigarette smoking. Interaction between smoking and genotype could explain all or part of the difference in genetics effects observed in different datasets.

_N_-acetylmannosamine therapy for podocytopathies and other kidney disorders due to hyposialylation. *E. Klootwijk[1], I. Manoli[1], D. Hickey[1], C. Ciccone[1], D. Darvish[2], D. Krasnewich[1], W.A. Gahl[1], M. Huizing[1]* 1) MGB, NHGRI, NIH, Bethesda, MD; 2) HIBM Research Group, Encino, CA.

We created knock-in mice with a M712T missense mutation in *GNE*, encoding the key enzyme of sialic acid biosynthesis, UDP-GlcNAc 2-epimerase/ManNAc kinase (Gne/Mnk). Homozygous mutant ($Gne^{M712T/M712T}$) mice, deficient in sialic acid synthesis and glycoprotein sialylation, died before postnatal day 3 (P3) and exhibited severe hematuria, proteinuria and significantly abnormal glomerular structure. Ultrastructural findings included segmental splitting of the glomerular basement membrane (gbm) and effacement of the podocyte foot processes. Biochemical analysis of the mutant mice kidneys revealed decreased Gne-epimerase enzyme activity and deficient sialylation of the major podocyte sialoprotein, podocalyxin, after sialylated proteins were isolated using the sialic acid-specific lectin *Limax Flavus Agglutinin* (LFA). In contrast, overall kidney protein glycosylation, assessed by periodic acid-Schiff staining, was normal at age P2. Nor were significant differences detected in the expression of the podocyte marker podocin, the mesangial cell markers alpha smooth muscle actin and desmin, the endothelial cell marker Pecam-1, or the gmb component laminin beta-1. Oral administration of the sialic acid precursor *N*-acetylmannosamine (ManNAc) to the pregnant mothers allowed survival of 43% of the $Gne^{M712T/M712T}$ pups beyond P3. Survivors exhibited improved renal histology, increased sialylation of podocalyxin, and increased Gne/Mnk protein expression and Gne-epimerase activities. These findings establish this $Gne^{M712T/M712T}$ knock-in mouse as the first genetic model of podocyte injury due to hyposialylation. Moreover, the results support evaluation of ManNAc, a simple and well-tolerated intervention, as a treatment for renal disorders involving proteinuria and hematuria due to podocytopathy and/or segmental splitting of the gbm. Candidate disorders include Alports syndrome, minimal change nephrosis, focal and segmental glomerulosclerosis, glomerulonephritis and other forms of idiopathic nephritic syndrome.

Linkage disequilibrium mapping of common myopia susceptibility loci using an LD map for a replicated linkage region at 3q26. *T. Andrew[1,2], N. Maniatis[3], T.D. Spector[2], C.J. Hammond[2]* 1) EPH, Imperial College, London, United Kingdom; 2) Twin Research & Genetic Epidemiology Unit. St Thomas' Hospital, London; 3) 2Department of Epidemiology & Public Health, Imperial College, London. 3Human Genetics Division, Southampton General Hospital, University of Southampton, Southampton.

Purpose: Common myopia has a strong heritable component (Hammond et al 2001) and affects ~25%-61% of the population. In this study we aim to map susceptibility alleles that contribute to myopia. Methods: In a genome-wide linkage study, evidence of linkage to chromosome 3q26 was observed (LOD 3.7) using 221 healthy dizygotic (DZ) female twins measured for myopia using a high-precision autorefractor (Hammond et al 2004). In a replication study, evidence of linkage to 3q26 is also observed (LOD 1.9) using 485 DZ pairs based upon a spectacle prescription from their optometrist. Both measures are on a continuous scale, with a cohort 1-99th percentile range of -10 (myopic) to +6.5 (hyperopic) dioptres. For the fine mapping stage of the study, we defined 241 genetically enriched cases (individuals with < -1 dioptres and a twin pair mean of =<-0.75 dioptres) and 257 super controls (individuals with >+1 dioptres and a twin pair mean of >+1 dioptres). Based upon previous work (Maniatis et al 2002 and 2007), we defined a genetic LD map using HapMap Phase II data. The map is defined in LD units (LDU), discriminates blocks of conserved LD and has additive distance and locations monotonic with physical (kb) and genetic (cM) maps. We use an innovative and efficient study design, in which 3-6 SNPs per LDU for a range of common allele frequencies were placed evenly across the LD map, resulting in a total of ~2300 SNPs capturing most of the common genetic variation (MAF>=0.05) in the ~25MB 3q26 region. Results and conclusions: Preliminary analyses indicate 2 short kb regions are significantly associated with myopia. Work is underway to replicate these.

Two, non-identical, *de novo* markers derived from chromosome 1 associated with cardiac abnormalities and cleft lip and palate. *C. Astbury[1], L. Christ[2], C.A. Curtis[2], R.L. Hassan[1], M. Jamehdor[1], G.E. Tiller[1]* 1) Genetic Testing Laboratory and Department of Genetics, S Calif Permanente Med Group, Los Angeles, CA; 2) Center for Human Genetics Laboratory, University Hospital Case Medical Center, Cleveland, OH.

Marker chromosomes are seen in approximately 1 in 1,000 prenatal studies, generally in a mosaic form with a normal cell line, and, when de novo, require rapid and precise characterization. Amniocentesis performed at our institution on a 37 year old G5P3sAb1 woman referred for AMA revealed two abnormal cell lines. Thirteen of 20 colonies revealed 48,XY with two small, non-identical marker chromosomes; the remaining colonies showed 47,XY with one marker chromosome. The markers were de novo, non-satellited, and not derived from the X or Y chromosomes or chromosomes 15 or 22 (excluding the centromeric region). Prenatal ultrasound at 16 weeks only revealed cleft lip. A 3,230g infant was born at term with unilateral cleft lip and palate, hypoplastic aortic arch, ventricular septal defect, and patent ductus arteriosus. He underwent successful cardiac surgery in the newborn period. In peripheral blood leukocytes, three cell lines were seen {mos 48,XY,+2mar dn[20]/47,XY,+mar dn[7]/46,XY[3]}; following FISH with alpha satellite-specific probes, the non-identical markers were determined to be derived from chromosome 1. Phenotypes associated with chromosome 1 markers thus far reported in the literature vary from normal to mild facial dysmorphism with developmental delay. We propose that trisomy/tetrasomy for pericentric loci from chromosome 1 is responsible for the infants structural defects. Breakpoint mapping studies in this case are in progress.

Development of a customized genetic information manual. *K. Christensen[1,2], K. White[1], S. Haga[3], B.C. Burke[4], K. Zonno[4], L. Tuttle[5], L. Wise[1], S.F. Terry[1]* 1) Genetic Alliance, Washington, DC; 2) Univ. of Michigan School of Public Health; 3) Institute for Genome Sciences and Policy, Duke University; 4) New England Public Health Genetics Education Collaborative; 5) NERGG, Inc.

As genetics is increasingly integrated into healthcare, it is important that healthcare providers understand basic genetics, newborn screening, genetic diseases, and genetic services and be able to present these topics to their patients clearly. This information is most useful if it is customized for the users state or region: they should have information about community-specific resources to allow rapid and accurate referrals. Understanding Genetics: A Guide for Patients and Health Professionals, is a manual about genetic services customizable for any state or region. Given the need to refer individuals, the guide includes culturally sensitive information on local newborn screening programs, patient stories, and local resources. The first version of the manual was customized for the needs of underserved populations in Washington, D.C. To begin, the authors reviewed genetics materials from a broad range of organizations. The next step consisted of an informal needs assessment of area healthcare providers. We also conducted focus groups at Bread for the City, a nonprofit organization that provides vulnerable residents of Washington, DC with comprehensive services, about what they knew or thought about genetics and the types of materials they found helpful. The manual was created and critiqued by an Advisory Council consisting of leaders in medical genetics, public health, consumer advocacy and health education. The DC Dept. of Health distributed the manual to area health providers in DC community health clinics. The six member states of the New England Public Health Genetics Education Collaborative (a subcommittee of NERGG, Inc.) worked together and with Genetic Alliance on a customized version of the guide that incorporated information on newborn screening, community health resources, consumer fact sheets, and personal health stories from all six states. This version appears on the websites of Genetic Alliance, NERGG, and the departments of health of the six states, as well as in print.

Independent genetic mechanisms downregulate genes involved in catecholamine biosynthesis, storage and secretion in the spontaneously hypertensive rat. *M.L. Jirout[1], R.S. Friese[1], N.R. Mahapatra[1], M. Mahata[1], S.K. Mahata[1], M. Pravenec[2,3], V. Kren[3,2], N. Hubner[4], T.J. Aitman[5], M.G. Ziegler[1], N.J. Schork[1,6], D.T. O'Connor[1]* 1) University of California, San Diego, La Jolla, CA, USA; 2) Czech Academy of Sciences, Prague, Czech Republic; 3) Charles University, Prague, Czech Republic; 4) Max-Delbruck-Center for Molecular Medicine, Berlin-Buch, Germany; 5) Imperial College, London, UK; 6) Scripps Health/TSRI, La Jolla, CA, USA.

We investigated the regulation of genes involved in catecholamine biosynthesis, storage and secretion in the chromaffin cell of the spontaneously hypertensive rat (SHR). Integration of transcriptional profiling, biochemical phenotyping and quantitative trait locus (QTL) mapping was pursued in the adrenal tissue of the HXB/BXH recombinant inbred (RI) strains, which segregate the SHR genome. The results suggest that several independent genetic mechanisms in the SHR lead to downregulation of genes involved in the biosynthesis, storage and secretion of catecholamines. These mechanisms converge on *Dbh*, *Pnmt* (catecholamine biosynthesis) and *Vamp1* (catecholamine secretion) whose expression levels appear to be regulated by variations in these genic regions (i.e., in *cis*). In the SHR, *Dbh* is decreased (both, mRNA and tissue enzymatic activity), coupled with increased dopamine. Expression and physiological QTLs overlap and map in *cis* to chr 3 at 6 Mbp. The dopamine QTL co-localizes with the *Dbh* QTLs. *Pnmt* is also decreased (both, mRNA and tissue enzymatic activity). Expression and physiological QTLs overlap and map in *cis* to chr 10 at 90 Mbp. *Vamp1* expression QTL maps in *cis* to chromosome 4 at 161 Mbp. In addition, expression QTLs for *Vmat1* and *Chga* (both involved in catecholamine storage) co-localize to the *Pnmt* region. *Pnmt* re-sequencing revealed several promoter polymorphisms, which result in a decreased in-vitro promoter responsiveness to dexamethasone in the SHR. Finally, the SHR allele at the QTL peak locus for all above genes was associated with lower transcript levels, underscoring the additive nature of apparently independent genetic modulators of the catecholamine biology in the SHR.

Whole genome methylation profiling of aortic smooth muscle cells as a model for the development of atherosclerosis. *D. Biscocho[1], J.J. Connell[1], E.R. Hauser[1], W.E. Kraus[2], S.G. Gregory[1]* 1) Department of Medicine and Center for Human Genetics; 2) Department of Medicine and Division of Cardiology.

DNA methylation is a mechanism used by the cell to control transcription through modification of chromatin structure in specific regions of the genome. This type of transcriptional control allows for heritable epigenetic inactivation of a gene, as well as temporal control of gene activation. DNA methylation changes have been shown to play a role in the proliferation of smooth muscle cells (SMCs) during the initiation of coronary artery disease. However, these changes have only been characterized in a limited number of genetic loci. We have carried out genome-wide profiling of DNA methylation in proliferating aortic SMCs to identify novel markers for use in diagnosis of severity of disease and to identify atherosclerosis-susceptibility and atherosclerosis-protective genes. DNA isolated from aortic SMCs from passages (p) 5, 6, 7 and 8 was digested with methylation sensitive enzymes and linker mediated PCR was carried out to discriminate between differentially methylated loci. A self-self experiment from p5 provided the baseline for clone variation of a genomic tiling path array. PCR products of DNA from p6, 7, and 8 were co-hybridized with DNA from p5 to the genomic array. Differentially methylated regions were correlated with annotated genes, predicted regulatory regions and CpG islands. Analysis of genome-wide methylation patterns showed an expected general trend towards hypomethylation with progressive passaging. We have begun to investigate two loci, one hypomethylated and one hypermethylated, that are adjacent to the transcription factor Fli-1 and the ITGB1 gene, respectively. Both genes represent candidates involved in the etiology of SMC proliferation. Over expression of Fli-1 has been shown to lead to erythroblast survival and proliferation, while ITGB1 belongs to a family of proteins that have major roles in biological processes including cell migration, tissue organization, growth and differentiation. Here we describe the detailed analysis of our genome-wide methylation profiling of aortic SMCs and their implication in the development of atherosclerosis.

PPLD: Extension of the PPL framework to detect trait-marker LD and estimate D' in general pedigree structures. *Y. Huang[1], L. Brzustowicz[3], V. Vieland[1,2]* 1) Ctr for Quant & Comp Biology, Columbus Children's Res Inst, Columbus, OH; 2) Dept Pediatrics, Ohio State University, Columbus, OH; 3) Dept Genetics, Rutgers University, Piscataway, NJ.

Linkage disequilibrium (LD) analyses are frequently used to conduct fine mapping once a genomic region of interest is identified and to identify potentially causal SNPs. Under the framework of the PPL (Posterior Probability of Linkage), our group previously developed a statistic called the LD-PPL, which measures the evidence of linkage while allowing for trait-marker LD. Our new statistic, the Posterior Probability of LD given Linkage (PPLD), an extension of the LD-PPL, directly measures the evidence for (or against) LD conditional on linkage. In current applications, we set the prior probability of LD (D'0) given linkage at 2%; (and the prior probability of linkage at 2%;), and apply uniform weight over D' for small recombination values. Like the LD-PPL, the PPLD is on the probability scale with possible values ranging from 0 to 1. The posterior mode of the PPLD provides an estimate of D'. We have evaluated the behavior of the PPLD in application to a set of medium to large pedigrees originally ascertained for a study of schizophrenia. Using a variety of disease models, we simulated data containing either one or two susceptibility loci and a set of 10 flanking SNP markers exhibiting a range of LD (D from .14 to .86) with the susceptibility locus. Compared with two other family-based association methods, the PPLD has higher power to detect LD, and the estimate of D' is quite accurate even with moderate sample sizes and in the presence of two causal SNPs. Because the PPL and the PPLD are on the same scale, we now have a ready mechanism for sequentially updating the posterior map (of potential trait-gene locations) obtained from linkage analyses with LD evidence obtained from fine-mapping or WGA data, in a mathematically rigorous manner. Of special note is that the method applies immediately, without any modification, to trio or case-control data structures, enabling us to assess the overall evidence for linkage and/or LD based on multiple data sets involving different pedigree structures.

Concept and design of a custom 50K SNP array for large-scale interrogation of vascular disease cohorts. *B.J. Keating[1], T. Bhangale[2], T.S. Price[1], S.S. Tischfield[3], J.C. Barrett[4], P.I. de Bakker[3], M. Fornage[5], D.A. Nickerson[2], M.I. McCarthy[4], S.S. Anand[6], J.C. Engert[7], S.B. Gabriel[3], D.J. Rader[1], J.N. Hirschhorn[3], G.A. FitzGerald[1]* 1) Inst Translational Medicine & Therapeutics, Uni. Pennsylvania, Philadelphia, PA; 2) Dept Genome Sciences, Uni. Washington, Seattle, WA; 3) Broad Inst of Harvard & MIT, Cambridge, MA; 4) Wellcome Trust Centre Human Genetics, Uni. The recent wave of genome wide association studies (GWAS) has identified many novel genes of unknown function linked to cardiovascular, metabolic and inflammatory phenotypes in humans. Delineation of the actual causal variants, and any context specific functionality, requires very large cohorts with carefully defined phenotypic data for robust within and across cohort meta-analyses. Analyses with large cohorts are also critical for effective assessment of gene-gene and gene-environment interactions. We have designed a 50K SNP array to extensively assess the genetic diversity relevant to a spectrum of cardiovascular and metabolic diseases. The array employs a cosmopolitan tagging approach to assess diversity in all major populations represented in HapMap and Seattle SNPs across ~2100 genes. The gene content is based on recent GWAS; expression quantitative trait loci mapping of disease related genes; pathways based approaches and a comprehensive literature search. Over 140,000 extensively phenotyped individuals will be interrogated initially. The 50K array has significantly denser coverage for most cardiovascular related candidate genes compared to WGA panels and will greatly increases power for association testing in those regions. It will also facilitate unprecedented collaborative power to perform cross cohort meta-analyses for the replication of primary CVD associations in similar and different populations as well as allowing for rigorous assessment of gene-gene and gene-environment interactions.

New process using next generation sequencing for the fine mapping of variations in genomic DNA regions identified by whole genome association studies. *P. Bouffard[1], M. Yeager[2,3], R. Welch[2,3], Z. Markovic[1], B. Desany[1], T.P. Jarvie[1], T.T. Harkins[5], S.J. Chanock[3,4]* 1) 454 Life Sciences, Branford, CT; 2) Core Genotyping Facility, Advanced Technology Program, SAIC-Frederick, Inc, NCI-Frederick, Frederick, MD, 21702; 3) Division of Cancer Epidemiology and Genetics, National Cancer Institute, National Institutes of Health, Department of Health and Human Services; 4) Pediatric Oncology Branch, Center for Cancer Research, NCI, NIH, DHHS; 5) Roche Applied Science, Indianapolis, IN.

We developed a process that uses the power of next generation sequencing to screen for known and novel genetic variants within chromosomal regions identified by whole genome association studies.

Upon identification of a genomic region, PCR primers are designed to amplify overlapping amplicons ranging in size from 2 to 15 kb. PCR conditions are optimized on a control human genomic DNA sample to obtain a single agarose gel band of appropriate size for each primer set.

The resulting panel of amplicons is amplified from samples of interest, visualized on an agarose gel, quantified and pooled at an equimolar ratio. The pools are then fragmented into 300 to 800 bp fragments and sequenced on a next generation sequencing platform. We developed and tested this new process on a 136 kb region of human chromosome 8. Thirty two amplicons ranging in size from 2,059 to 5,439bp were amplified from four samples from the HapMap - CEPH panel. The 32 amplicons cover all but three small regions within the 136 kb segment. The sequencing run generated an average mapped depth of 160 and average read length of 250 bp, which was sufficient for detecting all known SNPs within the region covered.

Funded by NCI-Contract N01-CO-12400.

FREQUENCY OF p190BCR-ABL AND p210BCR-ABL FUSION TRANSCRIPTS IN COLOMBIAN PATIENTS WITH CHRONIC MYELOID LEUKEMIA (CML) AND PHILADELPHIA POSITIVE -ACUTE LYMPHOID LEUKEMIA(ALL-Ph+). *C.A. Aya[1], C. E. Muskus[2], F. Cuéllar-Ambrossi[3], J.D. Torres[4], F. Quintero-Rivera[5], G. Vásquez-Palacio[1]* 1) Unidad de Genética Médica, Facultad Medicina Universidad de Antioquia, Medellin, Antioquia, Colombia; 2) Programa de Estudio y Control de Enfermedades Tropicales, Universidad de Antioquia, Medellín Colombia; 3) Unidad de Transplantes de Sangre y Médula, HUSVP, Universidad de Antioquia, Medellín Colombia; 4) Laboratorio de Hematología Adultos, HUSVP, Universidad de Antioquia, Medellín Colombia; 5) Department of Pathology & Laboratory Medicine, School of Medicine at UCLA,Los Angeles, CA, USA.

The t(9;22)(q34;q11) generates different BCR-ABL fusion transcripts. Three BCR-ABL fusion proteins have been described: p190BCR-ABL(e1a2), p210BCR-ABL (b2a2 or b3a2) and p230BCR-ABL (e19a2) These fusion events are related to ALL, CML and CNL, respectively. The aim of this study was to determine the frequency of p190BCR-ABL and p210BCR-ABL fusion transcripts in patients with CML and ALL-Ph+, from a Colombian population. Total RNA for the cDNA synthesis was isolated from peripheral blood samples of 38 patients. 63.16% (24/38) of the patients had CML (15-78 years) and were either recently diagnosed or already receiving Imatinib treatment. The remaining 36.84% (14/38) were diagnosed with B-ALL (n=3 (<15 years); n=11 (>15 years)). The p210BCR-ABL transcript was seen in 95.8% (23/24) of the CML and in 27.3% (3/11) of the ALL (all >15 years) cases. We also found p190BCR-ABL fusion in 33.3%(1/3) <15 years, and in 9.1% (2/14) >15 years. Co-expression of p210BCR-ABL and p190BCR-ABL was detected in a patient with CML resistant to Imatinib . Our study demonstrated that the frequency of p210BCR-ABLtranscript in the CML population studied is similar to previous reports. In our ALL patient population the p210BCR-ABL transcript was found to be the most common, this transcript is usually less common (5-40%) in comparison to the p190BCR-ABL. Our results show a high frequency of BCR-ABL positive ALL patients (<15 years) compared to what it has been previously reported. This may due to a small sample population or represent a new subgroup of BCR-ABL positive childhood-ALL.

Analysis of the MET and Neurexin Genes in Autism. *J. Bartlett[1], N. Schnetz-Boutaud[1], B. Anderson[1], K. Gainer-Luci[1], M. Cuccaro[2], J. Gilbert[2], M.A. Pericak-Vance[2], J.L. Haines[1]* 1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Miami Institute for Human Genomics, University of Miami, Miami, FL.

Autism, Aspergers Syndrome, Childhood Disintegrative Disorder, Rett Disorder and Pervasive Developmental Disorder (PDD-NOS) are all classified as Autism Spectrum Disorders (ASD). ASDs are complex neurodevelopmental disorders with an onset early in childhood and 4:1 male:female ratio. It is characterized by impairments in language, reciprocal social interactions, combined with repetitive and stereotypic behaviors. Concordance rates for MZ twins have been estimated between 60%-90% and 0%-10% for DZ twins, suggesting a strong genetic etiology. Despite substantial efforts, very little of the genetic etiology has yet been explained, and no common genetic variation has been universally associated with ASD. Two different studies have recently suggested that variations in the MET gene on chromosome 7 and the Neurexin gene on chromosome 2 are associated with ASD. We used a dataset consisting of 730 Caucasian families (578 trios, 152 multiplex) to test these associations. We performed 2pt linkage analysis using FASTLINK and family association tests using PDT and FBAT. We genotyped 8 SNPs in MET and 12 SNPs in Neurexin. The analysis of the MET SNPs revealed only a marginally significant p-value in RS39748 (FBAT p-value=0.051), but this does not survive correction for multiple comparisons. Our preliminary analysis of the Neurexin gene found a recessive LOD score of 1.55 at RS1045874 and a marginally significant association between ASD and RS7606758 (p-value-0.020), which again does not survive correction. Thus these data suggest that any effect of these two genes is likely to be very modest.

Transgenic Mice for 4 bp Deletion Mutation in DLX3 Gene Cause Severe Taurodontism in Tooth Development.

T.C. Hart[1], S.K. Lee[1], J.Q. Feng[2], S.J. Choi[1] 1) NIDCR, NIH, Bethesda, MD; 2) University of Missouri, Kansas City, MO.

Tricho-dento-osseous (TDO) syndrome is an autosomal dominant disorder characterized by anomalies in hair, tooth, and bone development. A 4 base-pair deletion mutation in the Distal-Less 3 (DLX3) gene is etiologic for the condition. To investigate the in vivo effect of mutant DLX3 (MT-DLX) on tooth development in TDO, we established transgenic (TG) mice expressing MT-DLX3 driven by a mouse 2.3 k bp type I collagen promoter. TG mice were fertile and body lengths were not significantly changed, however, body weights were reduced about 30% from age 6 weeks compared to wild-type littermates. Incisors in MT-DLX3 TG mice were yellowish and misshapen. High-resolution radiography of incisors and molars revealed an enlarged pulp chamber in the molars and incisors of MT-DLX3 TG mice, consistent with clinical findings in patients with TDO. Histochemical studies of teeth demonstrated that the polarization of odontoblasts in both molars and incisors were markedly disrupted in MT-DLX3 TG mice and dentin matrix mineralization was markedly reduced. Immunohistochemical studies revealed that differentiating odontoblasts, which were type I collagen positive, expressed both WT-DLX3 and MT-DLX3 protein. However, biglycan, decorin, and dentin sialophosphoprotein expression were dramatically restricted in the pre-dentine zone in MT-DLX3 TG mice. Backscatter and resin casted scanning electron microscopy demonstrated that dentinal tubule formation was totally ablated in MT-DLX3 TG mice. In vitro studies also revealed that the transduction of MT-DLX3 into odontoblastic MDPC-23 cells totally inhibited calcium deposition on the culture plate compared to those of WT-DLX3 or EV transduced cells, while the growth rate of those cells were not significantly different. These findings demonstrate that MT-DLX3 inhibits the dentin matrix mineralization in tooth development and causes severe taurodontism consistent with what is clinically seen in patients with TDO syndrome. This mice model mimicking TDO syndrome could be a valuable tool for the investigation of odontoblast biology in dentin mineralization.

Roberts syndrome in siblings, associated with ESCO2 gene mutation: outstanding intrafamilial variability of the clinical spectrum and the natural history. *M. Giovannucci Uzielli[1], G. Scarselli[1], H. Vega[2], E. Lapi[1], S. Stagi[3], N. Dayan[1], A. Zeffiri[1], M. Isoldi[1], S. Guarducci[1], L. Giunti[1]* 1) Dept. of Paediatrics, Human and Medical Genetics, University of Florence, Italy; 2) Johns Hopkins University USA and Universidad Nacional de Colombia; 3) Dept. of Paediatrics, Endocrinology Unit, University of Florence, Italy.

Roberts syndrome (RBS) (MIM#268300) is an extremely rare, autosomal recessive developmental disorder, characterized by growth retardation, craniofacial and eyes anomalies, and tetraphocomelia. RBS is caused by mutations in ESCO2, one of the two human homologs of Eco1, a gene essential for the establishment of cohesion in yeast. Irrespective of the position and type of mutation, the defect in RBS is most likely the loss of ESCO2 function, in particular of the acetyltransferase domain. Abnormal cellular characteristics of this disorder were first described by James German in 1979 as heterochromatin repulsion, puffing and Premature Centromere separation (PCS). This first report assumes a special significance, after the identification in subjects with Cornelia de Lange syndrome, of mutation in the cohesion regulator NIPBL, and more recently in the cohesion complex structural component SMC1A and in the complementary subunit of the cohesion heterodimer SMC3, another gene of the cohesion complex. RBS and CdLS represent the most important part of the Cohesinopathies. We report the observation, in the course of a long follow-up, of a family, with two siblings, children of consanguineous parents. The homozygous mutation c1595delT (pA532fsX4) is associated with a mild phenotype in the girl, who died a few days after birth. A severe clinical spectrum was observed, viceversa, in the boy, who lived for 16 years, though with a true craniofacial disruption and tetraphocomelia. In this child, weight and length were, at the time of death, only slightly higher than at the birth. Genotype-phenotype analysis.

Delineation of the genes responsible for the clinical features of monosomy 1p36. *M. Gajecka, K.L. Mackay, L.G. Shaffer* Health Research & Education Center, Washington State University, Spokane, WA.

Deletions of 1p36 are relatively common, occurring in approximately 1 in 5,000 new borns. To date, we have ascertained 145 cases with monosomy 1p36, representing four possible classes of rearrangements: pure terminal deletions, interstitial deletions, unbalanced translocations, and complex rearrangements. For each individual, the type of rearrangement, deletion size, and parental origin of the deletion was determined. The purpose of this study was to identify the genes involved in the various clinical features of monosomy 1p36. We chose to analyze pure terminal and interstitial deletions to narrow the regions that are essential for monosomy 1p36 clinical manifestations. Translocations and complex rearrangements were excluded. Clinical data was obtained through a comprehensive questionnaire completed by the subjects physician or genetic counselor. Clinical information was collected for 67 individuals presenting with pure terminal deletions and 12 individuals with interstitial deletions. An 11 Mb distal region of 1p36 was evaluated for the eight most commonly observed features: cardiomyopathy, structural congenital heart defects, seizures, speech delay, large anterior fontanel, hearing impairment, hypotonia, and strabismus. This analysis has led to narrowed critical regions for each feature. The smallest region identified is for cardiomyopathy, a 1 Mb region containing 10 candidate genes. Two features, hearing loss and seizures, resulted in two critical regions each, separating the mild forms from the more severe presentation of each feature. In general, it was possible to map a critical region for each clinical feature and identify candidate genes in these narrowed regions.

The *C. elegans Hya-1* mutant: insights for human hyaluronidase and MPS IX. *J.A. Hobert[1], A. Chatel[2], R. Hemming[2], B. Triggs-Raine[2], M.R. Natowicz[1], D.C. Merz[2]* 1) Genomic Medicine Institute, The Cleveland Clinic, Cleveland, OH; 2) Department of Biochemistry & Medical Genetics, University of Manitoba, Winnipeg, MB, Canada.

Deficiency of human hyaluronidase-1 (EC# 3.2.1.35) is the underlying cause of mucopolysaccharidosis IX (OMIM #601492). Human hyaluronidase-1 is a lysosomal endoglycosidase that functions primarily in the degradation of hyaluronan, but also exhibits activity with the related glycosaminoglycan, chondroitin. Invertebrates, such as *C. elegans*, are unable to synthesize hyaluronan yet contain an orthologue of human hyaluronidase, T22C8.2, which we have termed *hya-1*. We have created a deletion mutant of *C. elegans hya-1* and have assessed both the phenotype and relative enzymatic activity against the substrates hyaluronan and chondroitin. Initial observations indicate that animals deficient in *hya-1* are viable and grossly normal but have phenotypic abnormalities in both egg-laying and vulval morphogenesis. In agreement with observations in hyaluronidase-deficient human tissues, microscopic analysis of *hya-1* deficient *C. elegans* revealed some cell types contain enlarged lysosome-related granules. Consistent with the hypothesized function of *hya-1*, mutant animals have increased Alcian Blue staining, suggesting an accumulation of glycosaminoglycan. Enzymatic analyses of extracts from wild-type and *hya-1* deficient *C. elegans* extracts indicate that hya-1 protein is enzymatically active against chondroitin but not hyaluronan and has both acidic (pH 3.8 and 4.4) and near neutral (pH 6.6) optima. Our data suggest that chondroitinases are evolutionary precursors of the vertebrate hyaluronidases. This *C. elegans hya-1* mutant model will: (1) facilitate studies of the trafficking and regulation of this important lysosomal enzyme that, in humans, traffics to lysosomes by an as yet unknown pathway; (2) further our understanding of structure-function issues of the catalytic regions of hyaluronidases and chondroitinases; and (3) serve as a tool to dissect the roles of glycosaminoglycans in the developmental biology of *C. elegans*.

Genome-wide analysis shows unexpected CNV in monozygotic twins - its potential clinical implications. *J.T. den Dunnen[1], A.C.J Gijsbers[1], Y. Ariyurek[1], H.H. Thygesen[1], C.A.L. Ruivenkamp[1], D.I. Boomsma[2], E.P. Slagboom[3], M.H. Breuning[1], G.J.B. van Ommen[1]* 1) Center of Human and Clinical Genetics, Leiden University Medical Center, Leiden, Nederland; 2) Biological Psychology, Vrije Universiteit, Amsterdam, Nederland; 3) Molecular Epidemiology, Leiden University Medical Center, Leiden, Nederland.

Array-based technologies now facilitate straightforward genome-wide screening of the human genome for the presence of deletions and duplications (Copy Number Variation, CNV). Recent data show a surprising variety and frequency of (likely) non-pathogenic CNVs. These are estimated to affect up to 10% of the human genome. In several genetic diseases these tools have also been successfully used to identify the genes involved or they are applied to identify new genes in cases with e.g. malformation syndromes and mental retardation. In the process of implementing genome-wide SNP arrays for CNV screening in clinical diagnosis we analysed blood-derived DNA samples of 10 monozygotic twin pairs. Based on shared CNVs patterns the individual twin pairs could be easily recognized. However, we also detected an unexpected number of unique differences within the monozygotic twin pairs. The number of CNVs identified depends mainly on the settings of the scoring algorithms used; in the size range of 0.3-1.2 Mb we detect 1-2 per twin pair. Preliminary validation data appear to confirm the findings while showing that the CNVs are not present in 100% of the cells. This suggests - not unexpectedly given the source material - somatic mosaicism, ie a postmeiotic emergence. This would have impact not only on the understanding of phenotypic diversity in MZ twins, but also on the use of somatic material (eg. lymphocyte DNA) for DNA diagnostics. A larger deletion / duplication identified in de novo cases might be somatic in nature. In these cases confirmation is thus in order using an independent second sample from another tissue.

Identification of long-range interactions between the *FOXL2* core promoter and three *cis*-regulatory elements. *D. Beysen[1], J. Dostie[2], A. De Paepe[1], J. Dekker[2], E. De Baere[1]* 1) Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium; 2) Program in Gene Function and Expression, University of Massachusetts Medical School, Worcester, USA.

Recently, defects in long-range transcriptional regulatory elements have emerged as potential mechanisms underlying human developmental genetic disorders. One of them, the blepharophimosis syndrome (BPES), an autosomal dominant condition affecting eyelid and ovary development, is caused by mutations in the forkhead transcription factor gene *FOXL2*. *FOXL2* expression has been shown to occur in a spatiotemporally specific manner. The need for a strict regulation of *FOXL2* expression was emphasized by the recent identification of deletions upstream and downstream of the transcription unit of *FOXL2* as underlying cause of BPES. We demonstrated that these rearrangements remove several conserved nongenic sequences (CNGs) harbouring potential long-range *cis*-regulatory elements.
Here, we used the chromosome conformation capture (3C) method to identify long-range interactions of *cis*-regulatory elements with the *FOXL2* promoter in two adult *FOXL2* expressing cell systems. We found that in adult ovarian granulosa cells and adult fibroblasts three long-range *cis*-regulatory sequences located 177 kb, 283 kb and 360 kb upstream of *FOXL2* come in close vicinity to the *FOXL2* core promoter. Interestingly, 3C analysis in a human adult fibroblast cell line derived from a BPES patient with a heterozygous deletion of the region encompassing the regulatory element at 283 kb, revealed decrease of interaction of the deleted element and the *FOXL2* core promoter and the two other regulatory elements. Interestingly, the element at 283 kb corresponds to a sequence deleted in the Polled Intersex (PIS) goat, which is an animal model for BPES. In conclusion, we hypothesize that the interaction between the *cis*-regulatory element located at 283 kb and the *FOXL2* core promoter is essential to establish efficient transcriptional regulation of *FOXL2* expression.

Association of gene expression levels in small airway epithelium with genotype for adjacent SNPs. *N.R. Hackett, T.P. O'Connor, J. Salit, T. Raman, I. Dolgalev, R.G. Crystal* Weill Cornell Medical College, New York, NY.

Smoking is the major risk factor for chronic obstructive pulmonary disease (COPD), but only 15-20% of chronic smokers develop the disease. Given that abnormalities in the small airways are the initial site of COPD, we hypothesize that gene expression pattern for protective and susceptibility genes in the small airway epithelium of smokers determines risk for COPD. Further, we propose that the gene expression level for these genes is genetically determined by single nucleotide polymorphisms (SNPs) in the vicinity of the gene. The gene expression profile of 42 subjects (14 non-smokers, 17 healthy smokers and 11 smokers with COPD) was determined on the Affymetrix Human Genome U-133 2.0 Plus array. The same subjects were then subjected to genotyping for SNPs using the Affymetrix 5.0 SNP array. For all genes expressed in >50% of the small airway epithelial samples according to the Affymetrix P call, the correlation of expression level with genotype was assessed for all SNPs within 25,000 bp either side of the location of the gene. A total of 294 SNPs yielded strong associations with expression levels with a p value of $<10^{-6}$. These represented 114 unique genes with 1 to 10 associated SNPs that correlate with expression level. When these genes were sorted into functional categories it was noticeable how three protease inhibitors gave multiple SNPs associated with small airway expression level, including SERPIN A6 (corticosteroid-binding globulin / transcortin), SERPIN B5 (serpin peptidase inhibitor, clade B, member 5/ maspin) and SERPIN B11 (serpin peptidase inhibitor, clade B member 11) with 3, 4 and 6 associated SNPs respectively. As an example for SERPIN A6, the mean expression level for subjects with TT as genotype for SNP rs11160168 was 0.9 0.3 *vs* 2.4 0.7 for heterozygotes and 3.6 0.4 for CC genotype. However, the mean expression levels for smokers and non-smokers was the same ($p>0.6$). Due to the known role of 1-antitrypsin deficiency in susceptibility to emphysema, these three SERRPINs represent candidates for further investigation as susceptibility factors for smoking induced pulmonary disease.

Telegenetic Use in the United States: Results of 2007 NCC Telegenetics Workgroup Survey. *H.C. Andersson[1], B. Butler[2], J. Benkendorf[3,4], B. Bowdish[5], M. Watson[3,4]* 1) Hayward Genetics Ctr, Tulane Univ Medical Ctr, New Orleans, LA; 2) Genetic Counseling, Univ. Arkansas Med Sciences; 3) National Coordinating Center for National Coordinating Center for Regional Genetics and NBS Collaboratives; 4) American College of Medical Genetics; 5) Digital Union, LLC.

As supply of genetic specialists falls short of demand, a mechanism for increasing access to services is telecommunications. Telemedicine makes clinical services available at a distance, allows real-time conferencing of multiple parties, and online education. As technology has improved in quality, become more user-friendly, and decreased in cost, no information exists about current use of telecommunications in: 1)providing clinical genetic services; 2)meeting for research and administration; 3)providing genetics education; and 4) laboratory planning. To understand current telegenetic use, we developed a web-based survey and emailed it to ~1350 ACMG members and to public health communities through the Regional Genetics and NBS Collaboratives. After 2.5 weeks (of the 4-week survey period), > 390 surveys were completed. Respondents were genetic counselors(32%), MD geneticists(29%), PhD geneticists (14%) and various other genetic professionals in academic medical centers/university hospitals(52%), state health departments (10%), private community hospitals(7%), commercials laboratories(6%) and other health related sites. 44% of respondents had used telegenetics to provide some genetic services or education. Of the 57% who responded they never used telegenetics, 79% indicated they see telegenetics useful for their activities but only 16 % had plans for telegenetics. The greatest barriers identified by nonusers were unavailability of technology(54%), high cost(22%), and institutional barriers(20%). Some telegenetics users have systems that cross state lines(45%) and even national boundaries(17%). Survey results include data on encryption protocols, legal barriers, funding mechanisms, and specific telegenetic use, such as technical equipment, frequency of use, and barriers to sustainability. The results of this survey will be used to tailor recommendations for collaboration, education, public policy and funding.

Adenoviral mediated gene delivery rescues a neonatal lethal murine model of mut0 methylmalonic acidemia*mut*^{0}.
R.J. Chandler, C.P. Venditti Genetic Disease Research Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD.

Methylmalonic acidemia (MMA) is an autosomal recessive metabolic disorder caused by mutations in the mitochondrial matrix localized enzyme, methylmalonyl-CoA mutase (MUT). Patients presenting with a severe phenotype (mut0 MMA) typically present in crisis in the first 24-48 hours and can perish despite intervention. Survivors display a well-recognized phenotype of extreme metabolic instability and secondary complications throughout life. Elective liver transplantation has been successfully used as an adjunctive treatment in severely affected patients and can prevent frequent decompensations but does not normalize methylmalonic acid levels. Potential alternatives to liver transplantation, inherently limited due to donor organ supply, are hepatocyte-directed therapies to restore methylmalonyl-CoA metabolism. We have used Mut -/- mice, an animal model of severe mut0 MMA that displays uniform neonatal lethality in the first 48 hours of life, to assess the efficacy of viral gene delivery as a potential therapy for MMA. A bi-functional adenovirus that independently expresses both the Mut gene as well as GFP was used to deliver these genes via direct injection of newborn Mut-/- pups. None of the mutants that received the intramuscular injection survived until weaning; all Mut-/- pups died within the first 48 hours of life. However, Mut-/- newborn pups treated by intrahepatic injection with the same virus were rescued, with 44% of the injected Mut-/- pups surviving beyond weaning (day 15). Methylmalonyl-CoA mutase mRNA and protein were present in the rescued mutants, and metabolite levels were decreased. The results demonstrate that adenoviral mediated, hepatic methylmalonyl-CoA mutase expression can rescue the Mut-/- pups from neonatal lethality. These experiments represent the first successful viral gene delivery in any lethal organic acidemia murine model and provide proof of principle for liver directed gene delivery approaches in methylmalonic acidemia. *Mut*$^{-/-}$*mut*^{0}*Mut*intramuscular.

Genome-wide Linkage Study of Periodontitis. *R.L. Hanson[1], W.A. Shultis[1], H.C. Looker[1], M. Shlossman[2,3], R.J. Genco[2], R.G. Nelson[1], W.C. Knowler[1]* 1) Diabetes Epidemiology Clin Res, NIDDK, Phoenix, AZ; 2) Dept of Oral Biology, SUNY-Buffalo, Buffalo, NY; 3) Arizona School of Dentistry and Oral Health, Mesa, AZ.

Periodontal disease may have important genetic determinants, but there have been few genome-wide studies to identify susceptibility loci. We conducted genome-wide linkage analyses of periodontitis in 758 Pima Indians from 243 sibships who had participated in a genome-wide linkage study of type 2 diabetes.

Periodontitis severity was assessed for each tooth from the percentage of alveolar bone loss on a panoramic radiograph. The sum of the severity scores for all teeth was adjusted for age, sex and, among those with diabetes, for duration of diabetes, and these residuals were normalized to create an overall periodontitis severity score for genetic analyses. Genotypes from 516 autosomal microsatellite markers were used for linkage studies. Variance components methods were used to assess heritability and for linkage analyses.

The periodontitis severity score was significantly heritable among the 407 nondiabetic individuals (h^2=0.28, 95% CI 0.03-0.54) and among the 351 diabetic individuals (h^2=0.61 95% CI 0.36-0.84). Since bivariate analyses suggested substantial, but incomplete, overlap between genetic determinants in diabetic and nondiabetic individuals (genetic correlation=0.63, 95% CI 0.12-0.91), linkage analyses were conducted in each group separately and in the combined group. Among diabetic individuals, there was suggestive evidence for linkage on chromosome 17 (LOD=2.17) at 46 cM, and among all individuals there was suggestive linkage on chromosome 5 (LOD=2.49) at 102 cM. The highest LOD score among nondiabetic individuals was 1.64 on chromosome 16 at 38 cM.

These analyses suggest that a genetic locus that influences susceptibility to periodontitis in diabetic individuals is located on chromosome 17 and one that influences susceptibility in both diabetic and nondiabetic individuals is located on chromosome 5.

Reducing Selection Bias: Efficiency and Robustness of Parametric & Non-parametric Effect Estimation. *L. Faye[1,2], L. Sun[1,3], S.B. Bull[1,2]* 1) Public Health Sciences, University of Toronto, Canada; 2) Samuel Lunenfeld Research Institute, Mount Sinai Hospital, Toronto, Canada; 3) Hospital for Sick Children, Toronto, Canada.

Genome wide association (GWA) studies cast a wide net for genetic associations. Samples showing positive results tend to arise from the tail of the true distribution due to the low power common in GWA studies. When an effect is detected, genetic association parameters are typically estimated in the same sample. Conditioning on observing a large test statistic introduces upward bias into the effect estimate, which is exacerbated by strict testing criteria. We compare two methods proposed to correct selection bias. A statistical resampling approach, based on the bootstrap (Sun and Bull 2005, Genet Epidemiol), is a flexible approach that does not require specification of the data distribution under selection. It can be easily extended to the multiple-marker GWA situation and no assumptions about marker correlation structure are required. In contrast, a maximum-likelihood-based approach (Zollner and Pritchard 2007, AJHG), incorporates information about the distribution of the data and the power to detect association, and considers a single marker in isolation.

We used simulations of selection at a single marker assuming a normally distributed parameter estimate to quantify the bias and relative efficiency of the bootstrap estimator compared to the MLE when the model is correctly specified. We further explore the robustness of the MLE to an incorrectly specified model. Under scenarios with low power and stringent testing, both estimators have moderate bias, but on average the MLE over-corrects while the bootstrap estimates under-correct. When power is between 50% and 80%, we find the bootstrap shrinkage estimator to have smaller mean bias and smaller mean squared error than the MLE. At high power levels, both estimates are unbiased on average, but have larger variance than the original estimate. Evaluation of the performance of each estimator under situations of correct and incorrect model specification is key in selecting a good practical approach.

Combinatorial analysis of loci on chromosomes 7, 9, and 17p supports individual and interactive contributions to vitiligo susceptibility. *Y. Jin, P.R. Fain, R.A. Spritz* Hum Med Genet Prog, Univ Colorado Hlth Sci Ctr, Aurora, CO.

Generalized vitiligo is a common, multifactorial, polygenic disease in which autoimmune loss of melanocytes results in depigmented spots of skin and overlying hair, with frequent co-occurrence of other autoimmune diseases. By genetic linkage analysis we previously mapped common vitiligo/autoimmunity loci to chromosomes 7, 9, and 17p, and recently identified the 17p gene as *NALP1*, with two high-risk loci within the gene. By genetic linkage analysis and pedigree-based association analysis of 114 multiplex families with vitiligo and associated autoimmune diseases, we have identified high-risk SNPs on chromosomes 7 and 9, though the corresponding genes are not yet known. Whereas classical linkage and association analyses can detect individual genetic locus that contribute to disease risk, deeper insights into complex patterns of inheritance can be obtained by simultaneous analysis of multiple susceptibility loci. We have carried out stepwise-conditional logistic regression analysis of the four vitiligo susceptibility loci, two in *NALP1* and one each in chromosomes 7 and 9, in cases and pseudocontrols derived from these 114 families, to analyze the individual and interactive contributions of the four loci to disease risk. We detected significant main effects for all four loci, and furthermore found that the full four-locus interaction model fitted significantly better than any of the nested three-locus interaction models. These results suggest that each of the two risk variants within *NALP1*, as well as each of the risk variants on chromosome 7 and chromosome 9, contributes to disease via both locus-specific effects and interactions with the other loci. Our findings illustrate how combinatorial analysis of multiple loci can help elucidate the complex gene interactions that contribute to susceptibility to complex diseases.

Purine/Pyrimidine Motif Differences in Recombination Hotspots and Coldspots. *J. Cai[1], P.R. Calkins[2], J.C. Cohen[3], A.F. Wilson[1]* 1) Genometrics Section, NHGRI, NIH, Baltimore, MD; 2) Dept of Pathology, Texas Children's Hospital, Baylor College of Medicine, Houston, TX; 3) Dept of Pediatrics, Stony Brook University Health Science Center, School of Medicine, Stony Brook, NY.

During the past few years, it has become apparent that the locations of recombination events are clustered in a small proportion of the human genome. Recombination hotspots are regions of one or two thousand base pairs of DNA where the recombination rate is significantly higher than elsewhere in the genome. Hotspots are often flanked by coldspots, regions of lower than average frequency of recombination. With the identification of a large set of hotspots in the human genome, the frequency and distribution of specific sequence motifs can be compared in hotspot and coldspot regions. To date, relatively few sequence motifs have been associated with hotspots. The frequency of every 7bp motif was compared in hotspot relative to coldspot regions, and paired t-tests were calculated; however, based on previous unpublished work, sequence composition was considered at the purine/pyrimidine level (RY) rather than at the ACGT nucleotide level. Of all possible 7-mers at the purine/pyrimidine level, 0.86 fewer copies of the RYYRRYR/YRYYRRY motifs were found in the hotspots relative to the coldspots (p $1.37x10^{-23}$), while the RRRRRRR/YYYYYYY motifs were more frequent in the hotspots than in the coldspots (1.82 copies, p $1.83x10^{-30}$). When the regions flanking hotspots were compared to the regions flanking the coldspots, the differences between the frequencies of both motifs in hotspots relative to coldspots approached zero as the distance from the hotspot/coldspot boundary increased. Permutation tests, where motif frequencies in hotspot or coldspot regions were compared to those of size-matched random sequences from the genome, confirmed that the RYYRRYR/YRYYRRY motifs were less frequent in hotspots while the RRRRRRR/YYYYYYY motifs were more frequent in coldspots. Studying the composition of recombination hotspots may help elucidate the factors that affect recombination and understand the molecular mechanism and regulation of crossover events as well as the evolutionary forces affecting recombination.

A recurrent frame-shift mutation of *PMS2* occurs within a short common haplotype from ostensibly unrelated individuals and is suggestive of an early founding event. *M. Clendenning[1], L. Senter[1], H. Hampel[1], A. Lindblom[2], K. Lagerstedt Robinson[2], M. Nilbert[3], J. Green[4], J.D. Potter[5], A. de la Chapelle[1]* 1) Comprehensive Cancer Center, The Ohio State University, Columbus, Ohio; 2) Karolinska Institute, Department of Molecular Medicine, Stockholm, Sweden; 3) Department of Oncology, Clinical Sciences, Lund University, Sweden; 4) Discipline of Genetics, Faculty of Medicine, Memorial University of Newfoundland, Canada; 5) Fred Hutchinson Cancer Research Center, Seattle, Washington.

When compared to the other mismatch repair genes involved in Lynch syndrome, the identification of mutations within *PMS2* has been limited (<2% of all identified mutations), yet the immunohistochemical analysis of tumor samples indicates that approximately 5% of Lynch syndrome cases are caused by PMS2. The primary reason for this disparity is due to complications in the study of this gene caused by interference from pseudogene sequences. We recently developed a method for detecting mutations in the *PMS2* region and have routinely screened selected patients for *PMS2* variants. We have identified a frequently occurring frame-shift mutation (c.736_741del6ins11) within a region not affected by pseudogene sequences. To date, we have detected this mutation in 10 ostensibly unrelated Lynch syndrome patients (~30% of patients we have identified with a deleterious mutation in *PMS2*, n = 33) who all carry the rare allele (population frequency = 0.033) at a SNP (c.1531A>G) in exon 11. Six of these individuals have been studied in more detail and have been shown to possess a very short common haplotype; however the characterization of a larger haplotype has been made difficult due to extensive homologous sequences which flank the 3 end of the gene. Ancestral analysis of the affected individuals indicates that this mutation might be enriched in the British Isles and Scandinavia. The identification of both the mutation and the common haplotype in one Swedish control sample (n = 225), along with evidence that Lynch syndrome associated cancers are rarer than expected in the probands families would suggest that this is a prevalent mutation with low penetrance.

Epigenomic profiling of major depression. *F. Haghighi[1], J.R. Edwards[3], A.H. O'Donnell[2], A.J. Dwork[4], J.J. Mann[1], T.H. Bestor[2]* 1) Psychiatry; 2) Genetics and Development; 3) Columbia Genome Center; 4) Pathology, Columbia University, New York, NY.

The etiology of psychiatric disorders such as Major Depression has genetic, environmental, and epigenetic components. The epigenetic component has received very little attention but is likely to involve pathological abnormalities in genomic methylation patterns that regulate genes involved in the development or physiology of the brain. We have developed new methods for the characterization of genomic methylation patterns and for the purification of sequences that are differentially methylated between control and depressed brains. Application of these methods will improve our understanding of the causes of a major and too often fatal psychiatric disorder. As the aim of this study, we explore the epigenetic profile of major depression; postmortem brain specimens were ascertained with comprehensive clinical and toxicological profiles. We used brain tissues from the ventral prefrontal cortex that is thought to be involved in depression based on neuroanatomical studies. Using experimentally and computationally validated methods, genomic DNA from brain tissue of normal and depressed subjects were digested using methylation sensitive and dependent enzymes, thus fractionating the genome into methylated and unmethylated compartments. The sequence fragments corresponding to these compartments were used for paired-end library construction and subsequent sequencing via the high-throughput 454 sequencing platform. The paired-end sequences were then mapped to the human genome to detect potential disease specific DNA methylation profiles. We have developed statistical and computational tools to analyze such data and reveal novel genomic patterns concerning the form and function of DNA methylation in the human brain. This provides the first systematic and unbiased investigation into the potential epigenetic basis of major depression, a disease of critical public health importance.

Genome-wide association and platelet system biology studies to unravel the genetic architecture of coronary artery disease. *A.H. Goodall, The Bloodomics and WTCCC Consortia* Cardiovascular Science, Univ of Leicester, Leicester, United Kingdom.

The recently completed WTCCC genotyping of 14,000 cases, representing 7 diseases, and 3,000 shared controls on the Affymetrix GeneChip 500K Array identified association signals for all diseases. For myocardial infarction (MI), 7 genomic regions were identified with robust P values but an additional large number of single SNPs produced signal. Previous studies have shown ~90% of these to be false-positive. To aid identification of true-positives we integrated the WTCCC-GWA MI data with the Bloodomics platelet systems biology study. Platelets play a pivotal role in MI. Platelet response varies between individuals. Family and replication studies indicate a large degree of genetic control. To uncover genes encoding regulatory nodes, we determined platelet response through the ADP and collagen pathway in 500 individuals. Resequencing in 48 CEPH DNA samples of the exons and flanking intronic sequence of 100 genes, selected from a priori knowledge of both pathways doubled the number of SNPs compared to dbSNP to 1949 and enriched for SNPs with a minor allele frequency 0.05. Genotyping of the 500 subjects for 1536 SNPs, tagging sequence variation at r2 >0.9 and capturing all 89 non-synonymous SNPs, identified 26 SNPs that were associated at P values <0.005 with a modification of the cellular response, in either the ADP (n=12) collagen (n=10) pathway, or both (n=4). Microarray studies with platelet RNA from individuals at the extremes of the functional distribution identified 69 transcripts for which abundance correlated with the magnitude of the platelet response. Approximately 50% of the 95 genes were adequately tagged in the WTCCC study and 16 contained SNPs that showed a significant difference in allele frequency between cases and controls. A replication study for the 16 genes in 8,000 MI cases and 8,000 controls is underway to unequivocally define genes that confer risk for MI. Studies of 6 genes with hitherto unknown function in platelets are underway, using morpholino-based silencing in Danio rerio and studies in human platelets, to determine their effect on atherothrombosis.

Whole genome association studies of rheumatoid arthritis and replication of identified susceptibility loci. *X. Ke[1], W. Thomson[1], A. Barton[1], S. Eyre[1], A. Hinks[1], J. Bowes[1], R. Donn[1], S. Hider[1], I.N. Bruce[1], A.G. Wilson[2], A. Morgan[3], P. Emery[3], A. Carter[4], S. Steer[5], L. Hocking[6], D.M. Reid[6], D. Strachan[7], P. Wordsworth[8], J. Worthington[1], YEAR consortium* 1) arcEU, University of Manchester, UK; 2) School of Medicine & Biomedical Sciences, University of Sheffield; 3) Academic Unit of Musculoskeletal Disease, Chapel Allerton Hospital, Leeds; 4) Academic Unit of Molecular Vascular Medicine, University of Leeds; 5) Clinical and Academic Rheumatology, Kings College Hospital, London; 6) Bone Research Group, Dept. Medicine & Therapeutics, University of Aberdeen; 7) Division of Community Health Sciences, St George's, University of London; 8) Nuffield Department of Orthopaedic Surgery Nuffield Orthopaedic Centre, Oxford.

The arcEU is part of the Wellcome Trust Case Control Consortium (WTCCC), conducting whole genome association scans on 7 common diseases including rheumatoid arthritis (RA). In the study, 2,000 Caucasian RA samples were genotyped using the Affymetrix 500K chip and compared with 3,000 common controls. 9 SNPs associated with RA at p=5x10-5-1x10-7, excluding known susceptibility variants of HLA and PTPN22, were identified. These 9 SNPs, located within or close to genes like IL2RA, IL2RB, PODXL and TNFAIP3/OLIG3, were subjected to a replication study. Potentially functional SNPs within these genes were also tested. The replication cohorts comprised 5,063 RA cases and 3,849 controls from the UK, providing at least 80% power to almost all the SNPs being replicated at $p<0.05$. One SNP which located between TNFAIP3 and OLIG3 was found to be significantly associated with RA in the replication study (OR=1.24, 95% CI 1.15-1.33, trend p<1.9x10-8). Stratified analysis revealed patients positive for rheumatoid factor and anti-CCP had a much stronger association with this SNP. Association to SNPs located in or near PODXL (OR=1.09, 95% CI 1.03-1.19, trend $p < 0.0067$), IL2RA (OR=1.09, 95% CI 1.01-1.18, trend $p < 0.04$) and IL2RB (OR=1.12, 95% CI 1.03-1.21, trend $p < 0.0069$) genes were also replicated. Fine mapping with these genes and further replication efforts with other potential SNP variants identified in the initial analysis will be carried out.

First description of A Unique Genetic Isolate of Slavic Origin and possibilities for GWA studies of complex disorders with 500K technology. *P. Kovacs[1], A. Tonjes[1], I. Prokopenko[2], D. Brocklebank[2], Y. Bottcher[1], E. Zeggini[2], R. Rayner[2], J. Halbritter[1], F. Pettersson[2], M. Scholz[1], M.I. McCarthy[2], M. Loeffler[1], M. Stumvoll[1]* 1) University of Leipzig, Germany; 2) WTCHG, University of Oxford, UK.

The study of population isolates with limited genetic variability is predicted to be especially powerful for genome wide association studies offering increased LD and more homogeneous genetic and environmental background. Current technology can offer the opportunity of characterisation of such populations with 500k chip. Here we present a new isolated population of Slavonic origin - the Sorbs of Eastern Saxony, who have been culturally and politically isolated in the small area, lived in an ancient social order consisting of large, extended families for centuries and have a population of ~15,000 individuals living in 10 integrated villages today. External genetic influence is therefore not expected in the population, rendering it a very attractive population for genetic study. We have recruited and extensively phenotyped 1000 individuals. Reconstruction of genealogies is on-going based on church records. Phenotypic data containing laboratory blood tests, anthropometric measures, past medical history of the individual and up to third-degree relatives with focus on diabetes, obesity, hypertension, dyslipidemia, gallstones and goitre is available. All individuals are currently being genotyped using the 500K-Affymetrix-Chips. Based on this data we evaluate the extent of LD and haplotype diversity, and perform a population comparative analysis using HapMap and WTCCC samples. We describe the population using inbreeding coefficient, homozygosity measures and estimation of founding gene pool. Our project offers a unique opportunity to explore the advantages and statistical challenges presented by the study of population isolates, and to use recently developed methodology to incorporated information on relatedness into association analysis.

Assessing Ancestry in an Admixed Population: STRUCTURE vs EIGENSTRAT. *J.E. Below[1], A. Pluzhnikov[2], M.G. Hayes[2], J. Novembre[1], N.J. Cox[1,2]* 1) Human Genetics, The University of Chicago, Chicago, IL., U.S; 2) Medicine, The University of Chicago, Chicago, IL., U.S.

Several analytic methods to detect population structure have been recently developed. STRUCTURE, which uses a model-based clustering method on multilocus genotype data to assign individuals to populations, has been criticized for its intensive computational time on large datasets and its sensitivity to the choice of the number of clusters. EIGENSTRAT, a newer method that identifies population substructure through principal components analysis, is fast and powerful but there are questions surrounding the biological interpretation of results. We report a comparative analysis of the two methods to detect substructure and estimate proportions of ancestry in an admixed Mexican American (MA) population sampled from Starr County, TX. This dataset includes 286 cases representing the youngest age-at-onset individuals diagnosed with type 2 diabetes and 315 individuals (also from Starr County) sampled without regard to diabetes status. Samples were genotyped using Affymetrix GeneChip Human Mapping 100K arrays. 101,150 SNPs passed QC, and were both typed and polymorphic in all four populations (CEU, YRI, ASN, MA). Genomewide STRUCTURE ancestry proportions were determined for the MA samples using the unrelated individuals from the HapMap populations (60 CEU, 60 YRI, and 89 ASN) as learning populations for STRUCTURE which greatly decreased the computational time to a few hours. Our results showed a high linear correlation (R2=0.9537) between the proportion of European ancestry determined by STRUCTURE, and the ancestry values along the first axis of variation, as estimated by EIGENSTRAT (which did not use HapMap samples, and corresponds to an eigenvalue of 7.353, more than three times the values of the subsequent axes). The strong correlation between the results of EIGENSTRAT and STRUCTURE observed in this admixed sample suggests a fundamental similarity in the underlying basis of how these two methods quantify ancestry within individuals, and we will continue to explore the theoretical frameworks of this similarity in more detail using simulations and mathematical arguments.

Clinical diagnosis variability of progressive familial intrahepatic cholestasis (PFIC3). *M. Amyere[1], E. Wiame[2], M. Vikkula[1], E. Van Schaftingen[2], MC. Nassogne[3]* 1) Laboratory of Human Molecular Genetics, de Duve Institute, Université catholique de Louvain, Brussels, Belgium; 2) Laboratory of Physiological Chemistry, de Duve Institute, Université catholique de Louvain, Brussels, Belgium; 3) Department of Pediatrics, Division of Nephrology, Université catholique de Louvain, Saint-Luc University Hospital, Brussels, Belgium.

PFIC3 is an autosomal recessive liver disorder presenting with early onset cholestasis that progresses to cirrhosis and liver failure before adulthood (De Vree et al., 1998). Several MDR3 mutations have been identified in children with PFIC3 and are associated with a low level of phospholipids in bile, leading to a high biliary cholesterol saturation index. This phenotype is characterized by elevated serum gamma-glutamyltransferase levels. Here, we describe a consanguineous family, originating from Morocco, with three children displaying liver disease with cholestasis, but normal gamma-glutamyltransferase level and normal MDR3 staining. We performed autozygosity mapping using Affymetrix SNP Chip 50K and identified a homozygous region of approximately 10 Mb at chromosome 7q21, in the three affected individuals. This region was confirmed by linkage analysis showing a maximum multipoint Z-score of 6.7. The MDR3 gene is located in this locus. Screening of MDR3 cDNA in the three affected individuals showed a homozygous mutation that changes a splice site near exon 2. Despite the normal level of gamma-glutamyl transferase activity in the serum and the normal MDR3 staining in liver sections, it may be that this mutated allele expresses a truncated, but non functional protein, which is nevertheless detectable by immunostaining. Therefore, molecular genetics testing should be performed in patients with classical PFIC3, even if MDR3 immunotest is normal to be sure of diagnosis.(miikka.vikkula@uclouvain.be).

Missense mutations in the forkhead domain of the transcription factor FOXL2 lead to subcellular mislocalization and protein aggregation. *E. De Baere[1], L. Moumne[2], H. Peters[3], B.P. Leroy[1,4], A. De Paepe[1], R.A. Veitia[2], D. Beysen[1]*
1) Center for Medical Genetics, Ghent Univ Hosp, Belgium; 2) INSERM U709, Paris, France; 3) Inst of Medical Genetics, Charité, Berlin, Germany; 4) Dept of Ophthalmology, Ghent Univ Hosp, Belgium.

The FOX family of transcription factors is characterized by a conserved forkhead domain (FHD). To date, disease-causing mutations, many of which are missense mutations in the FHD, have been identified in 8 human *FOX* genes. Mutations of *FOXL2* have been shown to cause the blepharophimosis syndrome (BPES), characterized by an eyelid malformation associated or not with premature ovarian failure (POF).
Here, we report on the subcellular localization and distribution in COS-7 cells of 18 unique naturally occurring missense mutations in *FOXL2*. Their subcellular localization and distribution could be subdivided in four groups: those with (1) a normal nuclear distribution, (2) nuclear aggregation, (3) nuclear aggregation with strong cytoplasmic aggregation and (4) isolated cytoplasmic aggregation. These data enlarge the spectrum of *FOXL2* mutations inducing protein aggregation. In addition, we showed that the N- and C-terminal nuclear localization signals (NLSs) are not the only mechanisms for nuclear targeting of FOXL2. Interestingly, our data suggest that missense mutations leading to nuclear and cytoplasmic aggregation might cause a more severe ovarian phenotype than those that do not alter nuclear localization. Moreover, missense mutations located outside the FHD of FOXL2, leading to normal subcellular localization, give rise to a mild ocular phenotype associated with pituitary deficiency, at least for one missense mutation (S217F). In conclusion, our study is the first to demonstrate that missense mutations in the FHD of FOXL2 lead to mislocalization and nuclear and cytoplasmic aggregation of the mutant protein. These data suggest that this is one of the pathogenetic mechanisms of a major proportion of missense mutations in *FOXL2*.

Detection of novel mutations in mitochondrial tRNA genes by mitochondrial resequencing microarray analysis in two families. *J.H. KYHM, A. MILUNSKY, M. ITO* Center for Human Genetics, Boston University School of Medicine, Boston, MA.

Mitochondrial disorders are believed to be present in 1 per 10000 live births. These disorders are genetically complicated due to maternal inheritance of mitochondrial DNA as well as biparental inheritance of nuclear DNA. It is necessary to screen the whole mitochondrial genome for unknown mutations to confirm the diagnosis precisely. To identify mitochondrial mutations, we used the Affymetrix mitochondrial resequencing microarray to sequence the entire 16.5 kb mitochondrial genome including all 37 genes. We found two novel mutations in mitochondrial DNA. The first case, we found a patient with pseudo-obstruction to be heteroplasmic for C15925G, a well conserved nucleotide in the Ac-Stem region of the tRNA threonine gene. Her daughter, who was also found to be heteroplasmic for the same mutation manifested fatigue and exercise intolerance. The second case, we detected a near homoplasmy for the A10018G, a well conserved nucleotide in the Ac-Stem region of the tRNA glycine gene. This patient had migraine and her child died of lactic acidosis and multiple organ failure with a clinical diagnosis of multiple complex deficiencies. These mutations in tRNA genes may result in the disruption of the Ac-Stem structure, which cause the instability of tRNA tertiary structure. Mitochondrial resequencing microarray analysis is a powerful, fast, reliable and sensitive method to detect mutations.

Familial 15qtel trisomy detected by FISH. *V. Catala[1], E. Geán[2], C. Garrido[1], D. Velasco[3], E. Cuatrecasas[1], P. Poo[3], A. Serés[1]* 1) Molecular Cytogenetics, Prenatal Genetics, Barcelona, Catalonia, Spain; 2) Genetics Unit, Hospital Sant Joan de Deu, Esplugues, Spain; 3) Neurology Service, Hospital de Sant Joan de Deu, Esplugues, Spain.

An 8 years old boy from young and healthy parents, with severe behavior problems and mental retardation, and apparently normal karyotype, was studied with a subtelomeric probes panel (Totelvysion, Vysis Abbot). Three signals for 15qtel probe was observed in all metaphases and nuclei analyzed. The third signal was observed in 15p, over satellites. Chromosomes were revised and big satellites in one chromosome 15 were observed. A family study was carried out and the same result was observed in the younger sister. The girl showed a milder phenotype. The father showed normal subtelomeric regions, and a mosaicism with a normal line and a trisomic line for 15qtel was detected in the mother. These findings are very important for the family, because a prenatal or a preimplantation genetic diagnosis are feasible in future pregnancies.

A Novel Sequence-Based Typing Method for Identification of Killer Immunoglobulin-Like Receptor (KIR) Genes and Alleles to Identify Their Associations with HIV-1 Infection. *R. Hardie[1], T.B. Ball[1], M. Luo[1], D. La[2], J. Kimani[3], C. Wachihi[4], E. Ngugi[4], F.A. Plummer[1,2,3]* 1) Medical Microbiology, University of Manitoba, Winnipeg, MB, Canada; 2) National Microbiology Laboratory, Winnipeg, MB, Canada; 3) Department of Medical Microbiology, University of Nairobi, Nairobi, Kenya; 4) Department of Community Health, University of Nairobi, Nairobi, Kenya.

Host genetics are important in HIV-1 infection and disease progression, but the role of natural killer (NK) cell receptors has not been studied comprehensively. NK cells act in the innate immune response against viruses by producing cytokines/inducing cytotoxicity. KIRs are NK receptors with HLA class I as their ligands, which activate or inhibit NK function. KIR-encoding genes have evolved and are polymorphic, suggesting a role for KIRs in infectious disease pathogenesis. We hypothesize that KIRs play a role in susceptibility to HIV-1 in highly-exposed but uninfected women in a sex worker cohort from Nairobi, Kenya. To genotype these KIRs, PCR primers were designed in introns flanking the most polymorphic typing exons of KIR 2DL2/2DL3 and 3DL1/3DS1. DNA was isolated from 1154 women defined as HIV resistant/susceptible, with varying disease progression within the susceptible individuals, genes were amplified, then sequenced with nested sequencing primers. Taxonomy-based sequence genotyping software CodonExpressTM was used to genotype KIR genes. Of thoses typed, 10% had only 2DL2 genes and alleles, 35.3% had both 2DL2/2DL3 and 3DL1/3DS1, 46.3% had only 2DL3 and 7.3% had no sequence. About 10% of sequences did not match currently identified alleles, which are potentially new alleles. Next, SPSS 13.0 will be used for correlation and Kaplan-Meier analysis of seroconversion and progression. In conclusion, this method is superior to sequence-specific PCR methods used by others because it is rapid, requires less template, requires fewer reactions, is able to co-amplify two genes and all alleles of each gene simultaneously, is highly specific and has the potential to identify new alleles. This novel technique will facilitate large-scale associations analysis of KIR genotypes and susceptibility to HIV and other infectious agents.

Novel approaches to whole genome methylation profiling applied to epigenetic alterations in breast cancer. *J. Edwards[1], A.H. O'Donnell[2], C. Lee[4], H. Peckham[4], F. Haghighi[3], T.H. Bestor[2]* 1) Columbia Genome Center; 2) Genetics and Development; 3) Psychiatry, Columbia University, New York, NY; 4) Applied Biosystems, Foster City, CA.

The nature of the methylation abnormalities undergone by cancer genomes is of great importance to cancer research and treatment, but one major limitation has been the lack of a method for analyzing the methylation patterns of the entire genome simultaneously in a rapid, cost-effective, unbiased manner. Other methods, such as array-based techniques, by their very nature, cannot be used to look at the methylation status of repetitive elements, which are known to undergo methylation changes in cancer. The novel method presented here combines fractionation of DNA according to methylation status and ultra-high throughput DNA sequencing using ABIs SOLiD platform to allow efficient whole-genome methylation profiling even when the amount of DNA available is limited. A new pipeline that can organize the flood of sequence data generated during this study has been implemented. These tools have allowed us to examine for the first time the complete methylation profile of a panel of breast cancer samples including the MCF7 cell line, primary tumors and matched controls. Data pertaining to differential methylation in mammary carcinoma has been compiled and annotated, and zoomable chromosome ideograms have been created that allow immediate comparison of methylation patterns from two or more sources. Data is also presented as tracks on the UCSC genome browser that show the relationship of methylation profiles to a large number of annotated features. New software has been developed to map sequence tags and for higher-level analyses, such as the search for genomic signatures that may regulate methylation patterns and the identification of key pathways which undergo methylation changes that may play a role in breast cancer. This project, via an unbiased, whole-genome methylation profiling method, capable of investigating methylation status of all sequences, has provided a first look into the complete methylation landscape of the human genome and provides new insights into epigenetic abnormalities in cancer.

The Role of Germ Cells in Cancer. *R. Goradia, S. Merchant* Cytogenetics Center, Rolling Hills, CA.

Germ cells may play a crucial role in the origin of cancer. Current literature suggests a correlation of various forms of cancer to chromosomal abnormalities. Although not all chromosomal defects result in cancer, every form of cancer appears to be associated with one or more chromosomal abnormalities. These abnormalities originate from genomic imbalances during recombination. Germ cells and nongerm cells divide mitotically. Both of these cell types maintain the entire genome content and replicate from their original cell. However, only germ cells divide meiotically. During a meiotic division of a germ cell its homologous chromosomes exchange/recombine their genomic material with one another altering the original genome. This recombination produces diversity. However, when an abnormal recombination occurs, either spontaneously or due to radiation or chemicals exposure etc., a genomic imbalance may occur resulting in structural rearrangements of one or more chromosomes. These abnormalities may result in cancer. Any breakage of DNA that may occur during mitosis is due to external factors but breakage of DNA occurring during meiosis is due to internal factors. Genomically imbalanced germ cells may migrate to adjoining organs or infiltrate the lymphatic system and blood vessels, and manifest themselves at various levels of severity. Infertility is the highest level of severity followed by embryonic lethality, developmental abnormality and then cancer. Therefore expression of cancer may be delayed for many years. Chances of accelerated expression of cancer would be higher in cases of preexisting chromosomal abnormalities such as Down syndrome. Finally, cancer develops in multi stages. Its origin may be a germ cell whose genome has been altered, and has migrated to a different location with delayed expression.

Screening of Total N-Glycans by Mass Spectrometry of Filter Paper Specimens. *D.C. Dannaway[1], B. Xia[2,3], J.J. Mulvihill[1], R.D. Cummings[2,3]* 1) Department of Pediatrics, Oklahoma University Health Sciences Center, Oklahoma City, OK; 2) Department of Biochemistry and Molecular Biology, Oklahoma University Health Sciences Center, Oklahoma City, OK; 3) Oklahoma Center for Medical Glycobiology, Oklahoma University Health Sciences Center, Oklahoma City, OK.

Many human congenital disorders of glycosylation (CDGs) are caused by defects in assembling or processing of *N*-glycans on glycoproteins, which are typically diagnosed by isoelectric focusing and immunoblotting to identify altered glycoforms of serum transferrin. Since CDGs affect all tissue-derived glycoproteins, we sought to develop a sensitive and non-invasive mass spectrometry (MS) approach to analyze *N*-glycan structures and composition from total blood glycoproteins and to facilitate analysis of neonatal heel-stick blood samples on filter paper. *N*-glycans in total blood glycoproteins from eight normal adult volunteers were released by direct treatment with *N*-glycanase and processed by their binding to Carbograph cartridges and subsequently profiled by matrix-assisted laser desorption/ionization and time-of-flight mass spectrometry (MALDI-TOF-MS). The expected *N*-glycan structures in serum were found in all donors with a high sensitivity and a high degree of reproducibility. We also prepared total *N*-glycans for MALDI-TOF-MS profiling using whole blood spotted on filter paper and found reproducible sensitivity with as few as 75 microliters of blood. This sensitive procedure or its modifications for analyzing total *N*-glycan structures using serum or filter paper samples and MALDI-TOF-MS may be useful in future studies of screening newborn blood samples for CDGs.

Comparison of gene expression filters in the eQTL study. *L. Chen[1], T. Metha[1], G.P. Page[1], R. Feng[1], X. Cui[1,2]* 1) Biostatistics, University of Alabama at Birmingham, Birmingham, AL; 2) Department of Medicine, Division of Genetic and translational Medicine, University of Alabama at Birmingham, AL.

Filtering gene expression data is a common practice in eQTL studies to reduce dimensionality. In this paper, we examined the effect of three filters on the CEPH lymphoblastoid cell expression data (Affymetrix Human Focus arrays).

First we evaluated two gene level filtering strategies, the variance-based filter used by Morley et al. and a P/A call based filter. We found that the genes selected by the two filters largely overlap. However, substantial differences are also observed. For the 5541 transcripts selected by the P/A call, 3331(60.1%) probe sets were also selected by the variance-based filter. We then applied the linkage mapping for the selected transcripts and comparing the linkage peaks between these two filtering methods. Most of the peaks identified by the variance filter were also identified by the P/A call filter.

We also examined the effect of a probe-level filter for removing the SNP-containing probes from the probe sets. We then do the linkage mapping on the two set of the transcript measurement with/without filtering the SNP-containing probes. We found that overall less than 67% of the significant peaks agreed between the two analysis regardless of the choice of significance threshold. The agreement decreases as the number of SNP-containing probes in a probe set increases. The comparison of correlation coefficients between the probe set summaries before and after filtering showed that removing the SNP-containing probes did reduce the correlation coefficient more than randomly removing equal numbers of probes from a probe set in some genes.

At probe set level, both variance-based filter and P/A call filter were able to select probe sets with high signal/noise ratio, increased the power of downstream analysis and reduced the number of hypotheses. At probe level, filtering out the SNP-containing probes showed some impact on the downstream analysis. The impact partially comes from the reduced probe affinity due to presence of SNPs in the targeted sequences.

Development of a Hypertension Candidate Gene Panel for use in Clinical Pharmacogenomics Studies. *N. Gaudreault[1], S. de Denus[2], M. White[2], M.S. Phillips[1]* 1) Genome Québec & Montreal Heart Institute Pharmacogenomics Centre, Montreal, Quebec, Canada; 2) Montreal Heart Institute, Montreal, Quebec, Canada.

Heart failure (HF) has reached epidemic proportions in the US with more than 5 million patients affected by the disease. The treatment of HF is complex, and although many treatments have been shown to be effective in selected populations, marked variability exists in the response of individuals. Currently, little data are available to identify which patients are most likely to benefit from specific treatments. Therefore, there is an urgent need to conduct studies to help identify which patients can benefit from specific therapeutic options. Pharmacogenomic studies have the opportunity to identify some of the variability contributing to a patients specific response. Although thousands of polymorphisms have been identified, little is known about their biological and/or clinical significance. In this study, we propose to develop a focused panel (~300 SNPs) for genes involved in RAAS; hypertension and HF. Our comprehensive approach will evaluate an important number of candidate genes by genotyping both functional and haplotype tag SNPs in order to evaluate genotype-phenotype interactions. Some of the candidate genes incorporated into the panel include: REN, AGT, ACE, ACE2, ATR1, CYP11B2, NOS3, ADD1 and TGFB1. The panel will initially be used to support studies within the NIH HF Network. For this purpose, we have selected genes that might play a role in HF development, prognosis and modulation of its pathophysiology. Genes related to the biomarkers measured as part of the NIH HF Network were also included in the panel designs. Each assay has been optimized and validated for PCR genotyping reaction conditions against samples of known genotype (where available), as well as on multiple populations of diverse ethnic backgrounds. We are currently using this panel in a number of studies and believe that the combined use of rare variants and common haplotype SNPs within a target set of pathway-specific genes will expedite our ability to identify genes that are predictive for specific therapeutic responses observed in standard HF treatment.

Absence of EGFR mutations in Papillary Renal Cell Carcinoma. *S.J. Bender[1], B. Wondergem[1], K. Buzzitta[1], M. Avallone[1], P. Condit[1], M. Condit[1], A. Massie[1], S.K. Khoo[2], B.T. Teh[1]* 1) Cancer Genetics, Van Andel Research Institute, Grand Rapids, MI; 2) Germline Modification, Van Andel Research Institute, Grand Rapids, MI.

Purpose: EGFR is a transmembrane receptor tyrosine kinase that when activated engages in mitogenic signaling and other tumor promoting activities. Activation of this receptor can happen several ways, including receptor overexpression, gene amplification, overexpression of receptor ligands and activating mutations. Reports of high levels of EGFR and mutations on various exons in a variety of tumor types have led to treatment strategies to be developed to block EGFR and therefore inhibit growth of cancer cells. Anecdotal observations have been reported in papillary renal cell carcinoma which is the second most common type of renal cell carcinoma. The purpose is to examine if papillary RCC harbors any EGFR mutations that may suggest response to EGFR inhibitors. Methods and Results: DNA from 22 cases of papillary RCC and 6 cases of matched normal kidney were extracted and bidirectional sequencing of all coding exons and splice junctions of the EGFR gene were carried out on the tumor DNA. If a variant was detected, DNA was re-amplified and re-sequenced on those papillary cases and the matching normal. Known polymorphisms were detected but no DNA mutation is detected. Conclusion: EGFR mutation does not play an important role in papillary RCC. Other activating mechanisms such as protein expression, gene copy number may be worth exploring in papillary renal cell carcinoma.

Homozygous silencing of the T-box transcription factor TBR2/EOMES locus results in a microcephaly syndrome with polymicrogyria and corpus callosum agenesis. *L. Baala[1, 2], S. Briault[3], H.C. Etchevers[2], F. Laumonnier[3], A. Natiq[1], J. Amiel[2], N. Boddaert[4], C. Picard[5], A. Sbiti[1], A. Asermouh[6], T. Attié-Bitach[2, 7], F. Encha-Razavi[2, 7], A. Munnich[2, 7], A. Sefiani[1], S. Lyonnet[2, 7]* 1) Département de génétique médicale, INH Rabat, Morocco; 2) Genetique INSERM U781, Hosp Necker, Paris 15, France; 3) INSERM U-619 Faculté de Médecine, Tours, France; 4) Service de Radiologie Pédiatrique, Hôpital Necker-Enfants Malades (AP-HP), Paris, France; 5) Centre détude des Déficits Immunitaires, Hôpital Necker-Enfants Malades (AP-HP), Paris, France; 6) Hôpital dEnfants Avicenne, Rabat, Maroc; 7) Université René Descartes - Paris 5, Paris, France.

Mechanisms regulating brain size during neurogenesis include the regulation of neural progenitor proliferation and migration. We report a large consanguineous Moroccan family with a marked prenatal-onset microcephaly (mean occipito-frontal circumference at birth -4 SD) and severe motor delay with hypotonia in 4 affected children. Early lethality was observed in 3 children (death at 15-18 months of age), due to respiratory distress following chronic infections. The surviving child has had a persistent fever since birth. Recurrent infections have been noted. This autosomal recessive microcephaly syndrome was co-segregating with a homozygous balanced translocation between chromosomes 3p and 10q. The translocation was found at the homozygous status in all affected individuals (46,XY,t(3;10)(p24;q23)2x), while unaffected parents were heterozygous. We established a fine physical mapping and cloned the breakpoints on 3p24 and 10q23. Interestingly, neither of the two translocation breakpoints disrupted a known or predicted gene coding sequence. However, we showed that a position effect at the breakpoint on chromosome 3 silences the Tbox-brain2/Eomesodermin (TBR2/EOMES) transcript. Together with its expression pattern in the developing human brain, our data suggest an involvement of TBR2/EOMES in neuronal division and/or migration. Thus, mutations in not only mitotic and apoptotic proteins but also transcription factors may be responsible for malformative microcephaly syndromes.

Screening multiplex Tunisian kindreds for known PD mutations. *M. Hulihan[1], J. Kachergus[1], A. Soto[1], J. Stone[1], S. Lincoln[1], L. Ishihara-Paul[2], S. Oldham[2], R. Amouri[3], R. Gibson[2], F. Hentati[3], M. Farrer[1]* 1) Dept of Neuroscience, Mayo Clinic Jacksonville, Jacksonville, FL, USA; 2) Research and Development, GlaxoSmithKline, USA and UK; 3) Dept of Neurology, Institut National de Neurologie, Tunis, Tunisia.

Mutations in several genes have been implicated in familial Parkinsons disease (PD). We looked for mutations within five of these genes in 88 multiplex Tunisian families with PD. Population frequencies for all coding changes were assessed in a case/control series with similar ethnic origins. Exonic deletions/multiplications in four of the genes were also screened for within these families.

All samples were screened for the LRRK2 G2019S mutation. The proband from each of the 88 families was also sequenced for PRKN, PINK1, and DJ-1. Taqman probes were then designed for all coding changes seen in the sequenced genes so that remaining family members could be checked; subsequently, the probes were run in the case/control series. Additionally, variations in SNCA, PRKN, PINK1, and DJ-1 exonic copy number were assessed in the probands. Dosage abnormalities were checked in family members for consistency with disease segregation. Results were analyzed to determine which families appear to have PD-causing mutations consistent with disease segregation and what the estimated frequency of these mutations are within the Tunisian population.

Of the 88 families screened, 39 have G2019S mutations; 12 are homozygous for PINK1 mutations; and 5 are homozygous for PRKN mutations. One of the PRKN families had two different homozygous mutations for that gene. Each of these changes was seen in less than 2% of Tunisian controls. While 64% of the pedigrees now have an identified genetic cause of Parkinson's within the family, the remaining families have an as-yet unknown cause of disease. Further studies will be conducted to determine the novel gene(s) responsible for PD within these remaining kindreds.

.

Clinical delineation of sleep disturbance in Cornelia de Lange syndrome (CdLS). *A.D. Kline[1], G. Saba[2], R. Morse[3], W.C. Duncan[4], A.C.M. Smith[3]* 1) Harvey Inst Human Gen, Greater Baltimore Medical Ctr, Baltimore, MD; 2) Division of Human Gen, Univ of Md. Hosp., Baltimore, MD; 3) NHGRI/NIH, Bethesda, MD; 4) NIMH/NIH, Bethesda, MD.

Significant progress has been made in recent years characterizing the clinical and molecular aspects of CdLS. The specific facial features, multiple malformations, developmental delays and behavioral issues are due to mutations in genes related to the cohesin complex, important in cell division and regulation of gene expression. Although other multiple malformation syndromes are associated with sleep disturbance, characterization of sleep issues in CdLS has been largely unknown. A parental questionnaire, regarding sleep behavior, sleep environment, and other behavioral or medical concerns, was received from 74 caretakers of patients attending the national CdLS Foundadtion conference or a regional multidisciplinary aging clinic, or through the Foundation newsletter. Fifty-nine (80%) of the 74 individuals experienced at least one indicator of sleep disturbance, including difficulty falling asleep (51%), frequent nocturnal awakenings (65%), consecutive days without sleep (30%), and frequent daytime napping (14%). Parental perceptions of sleep disturbance varied. There is a higher prevalence of reported sleep disturbance in individuals with gastroesophageal reflux and self-injurious behavior (SIB); SIB was associated with significantly decreased night sleep. Frequent nocturnal awakenings were positively correlated with anxiety. An increased severity of sleep disturbance in adolescence occurred in 39%. In addition, 53% of individuals 18 years and older experienced consecutive days without reported sleep, compared to 36% of those below 18 years. Symptoms of possible sleep apnea have been noted in the older population, and sleep apnea was documented on one previous sleep study. Additional studies, using measures of sleep such as wrist actigraphy on mutation-positive individuals or polysomnography, are being conducted currently to more objectively characterize sleep disturbance in CdLS. This may lead to improved treatment and management, likely to benefit individuals with CdLS as well as their caregivers.

Comparing platforms to genotype human copy-number variants. *G.M. Cooper[1], J.D. Smith[1], T.R. Zerr[1], E. Tuzun[1], J.M. Kidd[1], D.A. Nickerson[1], E.E. Eichler[1,2]* 1) Genome Sciences, University of Washington, Seattle, WA; 2) Howard Hughes Medical Institute.

Copy-number variants (CNVs) in the human genome are likely to be contributors to common traits. Recent studies demonstrate that some CNVs can be genotyped using high-throughput SNP-typing platforms. However, the power of these platforms to genotype CNVs has not been systematically evaluated. To explore this, using Illumina arrays we genotyped 8 individuals known to carry large (>100 kbp), clinically relevant deletion or duplication events; we also genotyped 8 HapMap individuals that are concurrently being analyzed by fosmid-end sequence pair mapping (FESPM) and oligo-array CGH. The latter 8 have been elsewhere subjected to CNV discovery using Affymetrix 500K SNP arrays and BAC comparative genomic hybridization (BAC-CGH; Redon et al. 2006). We find that 6/8 of the large, clinically relevant mutations are robustly detectable. We also find high sensitivity (>90%) to variants identified using Affymetrix arrays. However, we find weak sensitivity for the SNP-platforms to identify CNV regions identified through BAC-CGH and FESPM. A substantial fraction of these CNVs are not covered with enough SNPs to allow detection on any available SNP platform; also, many CNVs that do span multiple assayed SNPs exhibit intensity values that lie within the noise ranges defined by random sampling. We estimate, for example, that less than 25% of deletions detected via FESPM or BAC-CGH can be robustly genotyped on the HH300 array. Our results indicate that genotyping success rates for large, clinically relevant CNVs are likely to be high for SNP-typing platforms. However, most smaller and more common CNVs cannot be readily genotyped via the current, widely available SNP-genotyping platforms. Nucleotide-level annotation of CNVs and higher-density SNP arrays should yield significant improvements in sensitivity; preliminary analyses of upcoming array designs indicate dramatically improved coverage of CNV regions. Continued analysis of individuals with precise CNV annotations spanning a range of sizes and genomic locations will facilitate sensitivity evaluations of future array designs.

Identification of a clinical and biological role for TGIF in leukemogenesis and hematopoiesis. *R. Hamid[1], J. Patterson[1], S. Brandt[2]* 1) Dept Pediatrics, Div Med Gen, Vanderbilt Univ Sch Medicine, Nashville, TN; 2) Department of Medicine, Vanderbilt University, Nashville, TN. 37232.

To identify genes with prognostic potential in acute myeloid leukemia (AML), we applied microarray analysis and real-time PCR to RNA from cryopreserved bone marrow or venous blood samples from 61 patients with newly diagnosed or relapsed AML, and the expression of one gene, TG-interacting factor (TGIF) was found to be highly predictive of relapse and survival (p=0.00001). TGIF is a transcriptional repressor belonging to the TALE (three amino acid loop extension) class of homeobox proteins, and deletion or mutation of a single allele of TGIF is associated with the craniofacial genetic disorder holoprosencephaly (HPE). In order to better understand its role in hematopoiesis, we characterized an in vitro model system to study the effects of its knockdown and enforced expression. We show that TGIF increases during granulocytic differentiation of both leukemic and normal myeloid precursors, likely indicating that adequate expression of TGIF has to be achieved along with monocyte/neutrophil/ maturation of myeloid progenitor cell lines as well as normal hematopoietic stem cells (HSC). shRNA mediated TGIF knockdown results in significant growth inhibition of myeloid progenitor cell lines while enforced expression results in accelerated growth. Cell cycle analysis indicates that this growth inhibition is due to a block at G2M stage of cell cycle. Our results suggest a new role for TGIF: as a prognostic indicator in AML. TGIF is a modifier (inhibitor) of TGF pathway, which plays a significant role in both normal and leukemic hematopoiesis by its action of HSC quiescence and renewal. Decreased TGIF may then be expected to lead to increased TGF- pathway activity resulting in HSC quiescence and thus escape from the toxic effects of chemotherapy. Our data raises the intriguing possibility that baseline levels of TGIF (a genetic trait) in individuals could predict a priori their prognosis if they develop leukemia in future. This and further definition of biological and genetic role of TGIF in leukemogenesis continues to be an active area of research in our laboratory.

Absence of Ras and Raf mutations in Clear Cell Renal Cell Carcinoma. *S.K. Khoo[1], K. Buzzitta[2], B. Wondergem[2], M. Avallone[2], P. Condit[2], M. Condit[2], A. Massie[2], S.J. Bender[2], B.T. Teh[2]* 1) Germline Modification, Van Andel Research Institute, Grand Rapids, MI; 2) Cancer Genetics, Van Andel Research Institute, Grand Rapids, MI.

Purpose: The Ras/Raf/MEK/ERK kinase pathway is a major intracellular mediator of mitogenic signals. This important pathway contributes to cell differentiation, proliferation and survival. Mutations of Ras and Raf are common in human cancer. Davies et al reported that a B-raf mutation leading to constitutive activation is common in many human cancers. More recently, an orally active small molecule inhibitor of B-raf and C-raf kinases, BAY 43-9006, has been approved for treating renal cell carcinoma, especially the clear cell type. The purpose is to examine if clear cell RCC harbors any mutations in the Ras and Raf-related genes that may suggest response to this drug. Methods and Results: DNA from 40 cases of clear cell RCC and matched normal kidney was extracted and bidirectional sequencing of all coding exons and splice junctions of the B-raf, H-ras, N-ras, K-ras and C-raf genes were carried out on the tumor DNA. If a variant was detected, the matched normal kidney DNA was sequenced to determine its somatic nature followed by re-amplication and re-sequencing of both DNA. Only known polymorphisms were detected but no DNA mutation is detected. Conclusion: We did not detect any mutation in Raf and Ras genes in clear cell RCC. It will be worthwhile to examine other activating mechanisms of the Ras/Raf/MEK/ERK kinase pathway such as expression pattern and the phosphorylation status of these genes in this group of tumors.

Wikigenetics. *A.M. Chappelle[1], Y. Konno[1], K. White[1], P.F. Terry[2,3], K. Battle[4], K. Christensen[1,5], S.F. Terry[1]* 1) Genetic Alliance, Washington, DC; 2) Genomic Health, Inc; 3) PXE International; 4) Tucker Capital; 5) Univ. of Michigan School of Public Health.

The public needs credible and up-to-date information on human genetics. It is difficult for any one entity to provide a comprehensive overview of genetics that retains currency and is understandable by the lay public. In addition, though entities such as Wikipedia have tried to provide a comprehensive overview of scientific topics, they have found that the culture of professional science does not encourage collaboration and sharing of information in an open access forum. WikiGenetics (wikigenetics.org), a web-based encyclopedia of human genetics, allows the lay public to obtain quality, current information on human genetics. A professional advisory committee comprised of experts in genetics, genomics, policy, education, and advocacy developed the policies, principles and structure for WikiGenetics, with the dual purpose of maintaining its quality and keeping its literacy level appropriate for the lay public. These committee members have encouraged their fellows, students, and/or staff to create and edit articles. The information from the lay publication, Understanding Genetics: A Guide for Patients and Health Professionals, was used as a basis for the Wiki, since it was well vetted and its literacy level was appropriate for the lay public. Additionally, experts are invited to author various articles in order to keep the content areas balanced. Similar to other Wikis, both invited and self-identified volunteers proctor WikiGenetics to keep its quality high. The 10,000 organizations in Genetic Alliances network were notified about and encouraged to use WikiGenetics. WikiGenetics is linked to related articles in Wikipedia so that people looking for information on genetics can easily find WikiGenetics. By recognizing users as stakeholders, WikiGenetics will generate collaboration among all members of the genetics community to result in a current, accurate, and accessible resource.

X-linked gene expression in fibroblasts and brain tissue from patients with supernumerary X chromosomes. *T. Helling[1], C. Jie[2], L. Zhang[1], T. Wang[1]* 1) Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) Microarray Core, Johns Hopkins University, Baltimore, MD.

Sex chromosome number abnormalities in humans occur 1 in 400 males and 1 in 650 females. Patients with supernumerary X chromosomes (SNX) have significant defects in cognitive and language development. With each extra X chromosome, there is ~15 points of IQ reduction with increasing severity of language defect. The apparent dependency of the phenotype on copy number of the X chromosome strongly suggests a dosage effect of certain X-linked genes. We hypothesize that steady-state transcript levels of certain X-linked genes at given stages of development may have an effect on the clinical phenotype of SNX patients. Using a custom human X chromosome cDNA microarray, we examined the relative abundance of X-linked transcripts in fibroblasts from SNX patients. We used 1.5-fold change as an arbitrary cut-off for significance and identified 57 genes that showed altered transcript abundance in fibroblasts with 49XXXXY. We observed the expected increase of transcripts from XIST (2.76 fold) and 8 out of 9 genes in the pseudoautosomal regions (PAR) in 49XXXXY fibroblasts. The folds of increase for the 34 non-PAR genes ranged from 1.55 to 3.48. Among these, 16 (47%) were mapped to Xp22; 5 (14.7%) to Xp11, 3 (8.8%) to Xq13, 6 (17.6%) to Xq21-22, 1 (2.9%) to Xq26, and 3 (8.8%) to Xq28. This observation is consistent with the published report (Nature 434:400) that ~50% of the genes that escape X-inactivation reside in the distal Xp near PAR1. Among 22 genes that have comparable data with the published report, 16 (72.7%) showed consistent (n=12) or variable (n=4) escape of X-inactivation. Additionally, we identified 11 genes that showed transcript reduction (1.8 to 2.5 fold) in fibroblasts with 49 XXXXY as compared to that with 46 XY. We performed qRT-PCR or northern blot to validate microarray data from selected genes using RNA from fibroblasts with 49XXXXY and brain tissue from a patient with 49XXXXY. Results of the study will help to understand the mechanism of copy number-dependent dosage effects of X-linked genes on human cognitive and language function and diseases.

Adrenergic system in adult cardiac myocytes. *X. Bao[1], J. Lopez[2], B. Myagmar[2], C.M. Lu[3], P.C. Simpson[2], M.G. Ziegler[1]* 1) Dept Medicine, Univ California, San Diego, Novato, CA; 2) Cardiology Division, VA Medical Center, University of California San Francisco; 3) Department of Laboratory Medicine, VA Medical Center and University of California San Francisco.

Endogenous norepinephrine (NE) and epinephrine (E) play an important role in augmenting cardiac function. Although an intrinsic cardiac adrenergic cell independent of sympathetic neuron cell has been identified in rodent and human heart, it is not clear whether adult cardiac myocyte itself synthesizes catecholamine (CA). To address this question, we inserted the Cre-recombinase gene into the locus encoding phenylethanolamine N-methyltransferase (PNMT), a last enzyme in CA biosynthsis pathway, and crossed these PNMT-Cre mice with ROSA 26 and Z/EG reporter mice to activate lacz and green fluorescent protein (GFP) expression in cells that were selectively derived from the adrenergic lineage. We found that both LacZ and GFP expression were activated in about 10 % adult cardiac myocytes isolated from left ventricle. RT-PCR analyses demonstrated that the cardiac myocytes contained mRNA of catecholamine biosynthetic enzymes aromatic-L-amino-acid decarboxylase, dopamine b-hydroxylase, and PNMT except for tyrosine hydroxylase. Further radioenzymatic assays revealed that there were PNMT activity (6.2 0.4 pmol/g/h) and CA synthesis (66 6 pg/mg for dopamine, 2605 142 pg/mg for NE, and 46 8 pg/mg for E, respectively) in the cardiac myocytes. These findings suggest that a subset of adult cardiac myocytes constitute an adrenergic signaling system capable of synthesizing CA.

Clinical and molecular characterization of Hermansky-Pudlak Syndrome type-6. *R. Hess[1], M. Huizing[1], A. Helip-Wooley[1], L. Vincent[1], R. Fischer[1], J. White[2], W.A. Gahl[1]* 1) Medical Genetics Branch, NHGRI/NIH, Bethesda, MD; 2) Univ Minnesota, Minneapolis, MN.

Hermansky-Pudlak syndrome (HPS) is a rare disorder of vesicle formation characterized by oculocutaneous albinism, a bleeding diathesis and, in some patients, granulomatous colitis or pulmonary fibrosis. Eight autosomal human genes have been shown to cause various HPS phenotypes, and at least five additional genes correspond to murine models. We previously described clinical, molecular and cellular characteristics of HPS subtypes 1 through 5. Here we report our detailed clinical and genetic studies on patients with HPS-6. The human *HPS6* gene (murine *ruby-eye*) is located on 10q24.32 and consists of a single large exon coding for a protein of 775 aa. We screened 19 patients, without defects in other HPS causing genes, and identified 4 patients with 7 different novel *HPS6* mutations, including two frameshift (c.238dupG, c.1938delTG), three nonsense (Q305X, Q75X, Q412X), one large chromosomal deletion, and one missense mutation (T272I). Most nonsense and frameshift mutations generating premature termination codons cause nonsense mRNA mediated decay (NMD), while intronless genes, like *HPS6*, are usually not monitored by NMD. Expression analysis in two HPS-6 patients revealed no mRNA decay in fibroblasts; hence a truncated protein is most likely produced. Clinically, our HPS-6 patients exhibited a relatively mild HPS phenotype, including mild iris transillumination, variable hair and skin pigmentation, and absent platelet dense granules. Pulmonary fibrosis and granulomatous colitis were not observed in these patients, although they were all under 27, an age before which lung disease rarely develops in HPS. It is important to continue to follow adults with HPS-6 for the development of restrictive lung disease. The clinical features of HPS-6 resemble those of HPS-3 and HPS-5, presumably because HPS3, HPS5 and HPS6 interact with each other in BLOC-2 (biogenesis of lysosome-related organelles complex -2). These findings are important for the prognosis of newly diagnosed HPS-6 patients, and for studying the role of the HPS6 protein in the biogenesis of lysosome-related organelles.

Bilateral dysplastic kidneys as a feature in patients with duplication 17p11.2 syndrome. *E. Goh[1], M. Shago[2], M. Sgro[3], D. Chitayat[1], R. Mendoza-Londono[1]* 1) Division of Clinical & Metabolic Genetics, The Hospital for Sick Children, Toronto, ON, Canada; 2) Department of Paediatric Lab Medicine, The Hospital for Sick Children; 3) Department of Paediatrics, St. Michael's Hospital, Toronto, ON.

The duplication 17p11.2 syndrome (MIM 610883) is a recently described clinical entity characterized by mild dysmorphic features, mild mental retardation, and behavioural difficulties. Its incidence has been predicted to be 1:20,000, which is an estimate derived from the frequency of its reciprocal deletion syndrome, Smith-Magenis. However, duplications may go undetected because the symptoms tend to be nonspecific and less well recognized than those seen in microdeletion syndromes. This poses difficulties in the accurate diagnosis, management and counselling for families of individuals with this disorder. We describe three cases of duplication 17p11.2 that were diagnosed by routine cytogenetic analysis with confirmation by interphase FISH. One of our patients presented at 19 months of age with bilateral dysplastic kidneys, patent ductus arteriosus, failure to thrive and developmental delay. Review of the literature revealed renal abnormalities are seen in at least one previous patient with 17p11.2 duplication. A thorough review of the phenotype in this condition illustrates the variability in the syndrome's clinical manifestation. The results have been compared to previous cases of known isolated dup(17)(p11.2p11.2) as well as a few cases with chromosomal or single gene disorders involving this region. This analysis suggests that hypotonia, seizure disorder, hearing impairment, ocular involvement, feeding difficulty, scoliosis, and renal abnormalities are features that should alert the clinician to the possibility of this diagnosis. The 17p11.2 region harbours genes known to be related to attention deficit-hyperactivity (ADHD2), deafness (MYO15A), and scoliosis (IS2). Understanding how the dosage of these genes contributes to the syndrome can aid in understanding the underlying molecular mechanism that leads to the phenotype. In addition, the presence of dysplastic kidneys in some of these patients suggests that renal ultrasound should be part of the initial assessment of these patients.

TCF7L2, a risk gene for type 2 diabetes, shows association with cystic fibrosis-related diabetes. *S. Blackman[1], S. Hsu[1], S.E. Ritter[2], K.M. Naughton[2], A. Bowers[2], G.R. Cutting[2], CF Twin and Sibling Study group* 1) Division of Pediatric Endocrinology, Johns Hopkins University, Baltimore, MD; 2) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD.

About 20% of adults with cystic fibrosis (CF) have a form of diabetes with features of type 2 diabetes (T2DM) but with earlier onset and 5-10-fold greater prevalence in comparable age ranges. To test whether modifier genes play a significant role in CF-related diabetes (CFRD), we determined concordance rates in monozygous CF twins (75% in 12 pairs) and dizygous CF twins and CF siblings (14% in 71 pairs). These concordance rates generate heritability estimates of ~1.0, indicating a significant role for modifier genes in the development of CFRD. Heritability estimates were the same after controlling for age, sex, and CF-causing mutation. To assess whether genetic variants that cause diabetes in the general population contribute to CFRD, we examined three-generation pedigrees of CF families and determined that family history of diabetes (1 first-degree or 2 second-degree relatives) correlated with increased rates of CFRD (20 of 69 vs. 34 of 271 with no family history; OR=2.84; p=0.001). Variants in TCF7L2, a transcription factor involved in Wnt signaling, have repeatedly associated with T2DM. We hypothesized that these variants may predispose to CFRD. Genotyping of TCF7L2 SNPs and transmission disequilibrium testing (TDT) of 53 trios revealed overtransmission for rs7903146 (p=0.03), rs12243326 (p=0.05) and rs12255372 (p=0.03). In every case, the TCF7L2 allele overtransmitted in CFRD is the same allele that increases risk of T2DM. In a separate analysis of 109 CFRD cases and 37 CF controls (including affected individuals from the trio analysis), association was suggestive at both the genotype (p=0.07, p=0.09, p=0.05) and allele (p=0.12, p=0.047, p=0.02) levels. Finally, individuals with CFRD who were homozygous for risk alleles were diagnosed at a significantly earlier age (average 14.6 vs. 20.1; p=0.03). These data support a key role for modifier genes in development of CF-related diabetes, and suggest that CFRD and type 2 diabetes share disease mechanisms such as alteration in Wnt signaling.

Clinical Study on 137 Patients with Subtelomeric FISH Analysis: Comparaison of two Checklists. *C. Brunel-Guitton, E. Lemyre* Medical Genetics, CHU Ste-Justine, University of Montreal, Montreal, PQ.

Detection rate of subtelomeric abnormalities in patients with mental retardation varies from 3-6%. Discordance between studies reflects differences in inclusion criteria. Clinical checklists have been proposed to improve the diagnostic yield. Here, we present a study where two checklists (de Vries, 2001; Walter, 2004) were compared on 137 children with mental retardation: 25 with a subtelomeric defect and 112 controls. The 4 main clinical criteria in both checklists (MR, dysmorphism, growth & pedigree anomaly) were compared between cases and controls for their diagnostic yield and use in clinical preselection. 48% of cases had 4 criteria, 48% had 3 criteria. Controls showed a wider distribution range: 3.7% 1 criteria, 34% 2 criteria, 41% 3 criteria and 21% 4 criteria. Overall, patients with subtelomeric abnormalities had more malformations with a predominance of cardiac, ophthalmologic and genital malformations, hearing impairment and cleft palate. 96% vs. 63% of cases vs. controls tested positive for Walters checklist. 96% vs. 71% of cases vs. controls tested positive for de Vriess checklist. One patient scored negative for both checklists. In contrast to previous studies, prenatal onset growth restriction was not discriminant, 8% vs. 11.6% in controls. Positive predictive value was 25% for Walters checklist and 23% for de Vriess; results correlate with the detection yield identified previously. Sensitivity was 96% for both. Specificity was slightly higher with Walters checklist 37% vs. 29% ($p=0.0001$). Conclusions: Patients with subtelomeric defects are more dysmorphic and possess a contributive family history in a greater proportion. Frequency of pre and postnatal growth anomalies does not appear to differ from controls. 96% of patients with subtelomeric abnormalities had 3-4 clinical criteria on both checklists. Diagnostic yield for subtelomeric abnormalities triples when a checklist is used. However, these checklists can miss cases and cannot be the only indicators for subtelomere testing. The checklist proposed by Walter seems more specific and could help to prioritize testing in patients fulfilling these criteria.

Identification of OXTR and MAFF deletions within independent autism families by whole genome tilepath microarray analysis. *S.G. Gregory[1], J.J. Connelly[1], S. Donnelly[3], R. Abramson[1], H. Wright[2], M. Cuccaro[3], J.P. Hussman[4], J.R. Gilbert[3], M.A. Pericak-Vance[3]* 1) Duke Center for Human Genetics, Durham, NC; 2) Dept of Neuropsychiatry, SOM-USC, Columbia; 3) Miami Institute for Human Genomics, University of Miami, Miami, FL; 4) The Hussman Foundation, Elliott City, MD.

Autistic disorder (AutD) is a neurodevelopmental disorder characterized by disturbances in social, communicative, and behavioral functioning. It has been established that at least 5% of individuals with idiopathic autism contain chromosomal rearrangements, suggesting that genomic loss or gain could underlie the development of AutD. Here we describe use of genome-wide tilepath microarrays, at 100kb resolution, to identify regions of chromosomal rearrangement within 119 unrelated probands (78% male, 22% female) from our unique multiplex AutD families. We identified 23 regions of genomic gain or loss (average 0.8 Mb) contained within one or more of the 119 AutD probands. Sixteen of these regions contain known copy number variants (CNVs) and segmental duplications, while seven regions did not. Six of the 23 regions localize to previous areas of possible genetic linkage, including 3p25.3 within an AutD male that contains the oxytocin receptor gene (OXTR). We also identified a small (250kb) deletion in 22q13.1 in an unrelated female AutD proband that contains the transcription factor MAFF, which has previously been shown to regulate OXTR. Quantitative RT-PCR analysis of OXTR and MAFF deletions in the parents and affected siblings of the probands show that the two deletions are familial and do not segregate with the disorder. However, given the coincidence of independent deletions within the oxytocin signaling pathway within unrelated affected individuals, we are carrying out detailed bisulfite sequencing to establish the methylation status of both genes which have previously been shown to be differentially methylated. Here we present the results of this analysis which further suggests the involvement oxytocin signaling pathway in the etiology of autism spectrum disorders and identifies MAFF as a new candidate gene in the development of autism.

Decreased hospitalization and recurrent infections in a child with 22q11 microdeletion syndrome after start of triweekly intravenous gamma-globulin therapy. *A. Khan[1], P. Dent[2]* 1) Dept Medical Genetics and Pediatrics, Alberta Children's Hospital, University of Calgary, Calgary, AB, Canada; 2) Dept Pediatrics, McMaster Children's Hospital, McMaster University, Hamilton, ON, Canada.

Humoral immunodeficiency may contribute to frequent infections in 22q11 microdeletion syndrome. We describe a girl with 22q11 microdeletion syndrome who, after repair of her truncus arteriosus, had prolonged admissions with bacterial infections and a persistent state of poor health. With the repetitive use of antibiotics, multi-drug resistant organisms developed. Because her immunoglobulin levels were consistently in the low normal range despite her frequent infections, we started intravenous gammaglobulin (IVIG) infusions at 9 months of age. Infusions were initially given every 4 weeks at a dose of 900 mg/kg. To achieve pre-infusion IgG levels of >6 g/L at 14 months the frequency was increased to triweekly and the dose to 1800 mg/kg. Prior to the start of triweekly IVIG infusions, she had a total of 339 inpatient hospital days at 821 days of age. She had 8 respiratory, 2 gastrointestinal and 2 gastrostomy site infections. After the start of triweekly IVIG, she had 3 respiratory infections over 302 days and was hospitalized 2 days for pneumonia. After starting IVIG therapy, she made developmental gains and had improved growth commensurate with decreased hospitalization. She had a modest reduction in T cell numbers as is seen in most 22q11 patients. We did not find a correlation between the frequency of infections or hospitalizations with reference to white blood cell populations: total leukocyte count, absolute neutrophils, absolute lymphocytes, and T-cell subsets. The need for IVIG replacement therapy at these doses suggests hypercatabolism of IgG may have contributed to her susceptibility to infection. We conclude that defects in humoral immunity in 22q11 microdeletion syndrome can exist despite normal immunoglobulin levels. IVIG infusions can be one option in cases with difficult to control infections, however more detailed studies are required to determine whether there are any benefits overall in 22q11 microdeletion.

Apoptosis inducing effects of the signal sequence mutation in preproparathyroid hormone explains autosomal dominant familial isolated hypoparathyroidism and is corrected by a chemical chaperone. *R. Datta, A. Waheed, G.N. Shah, W.S. Sly* Edward A. Doisy Department of Biochemistry and Molecular Biology, Saint Louis University School of Medicine, St. Louis, MO.

Autosomal dominant familial isolated hypoparathyroidism (AD-FIH) is caused by a Cys to Arg mutation (C18R) in the hydrophobic core of the signal peptide of human preproparathyroid hormone (PPTH). Although it has been shown that this mutation prevents secretion of the mutant hormone, the mechanism by which it produces an autosomal dominant disease is unexplained. The primary objective of this study was to clarify the pathogenic mechanism of AD-FIH. We hypothesized that impaired processing of the mutant hormone leads to endoplasmic reticulum (ER) stress and apoptosis of the hormone-producing cells, which would explain the autosomal dominant effects of the mutation. We also proposed that the chemical chaperone, PBA (4-phenylbutyric acid), would correct the adverse effects of the mutation.

Our data confirm that very little C18R PPTH is secreted into the media. The processing-incompetent mutant hormone is trapped intracellularly, predominantly in the ER. The ER retention of the mutant hormone was found to be toxic for the cells, which exhibited clear signs of apoptosis, as evident from the dramatic increase in cell staining positive for Annexin V binding and for the TUNEL reaction. Cells producing the mutant hormone also had marked upregulation of the ER stress markers, BiP and PERK, as well as the proapoptotic transcription factor, CHOP. Upregulation of these markers of the unfolded protein response suggested a causal link between the ER stress and the cell death cascade. When the C18R PPTH was expressed in the presence of 2 mM PBA, intracellular accumulation was reduced and normal secretion was restored. This treatment also produced remarkable reduction of ER stress signals and protection against cell death.

These data implicate ER stress induced cell death as the underlying mechanism for AD-FIH and suggest that pharmacological manipulation of this pathway using chemical chaperones offers a novel therapeutic option for treating this disease.

Brain MRI voxel based morphometry in 1q23 linked familial schizophrenia. *A. Bassett[1], A. Ho[1], N. Costain[1], A.P. Crawley[2], D.J. Mikulis[2], E.W.C. Chow[1]* 1) Dept Psychiatry, Univ Toronto, CAMH, QS, Toronto, ON, Canada; 2) Dept Medical Imaging, TWH, Univ Toronto, Toronto, ON, Canada.

Familial schizophrenia (FS) is a hereditary form of schizophrenia involving families with several individuals affected with the illness and where the illness appears to be transmitted. Region-of-interest (ROI) and voxel based morphometry (VBM) studies on schizophrenia have reported decreased grey matter in the anterior cingulate gyrus. This study examined VBM findings from MRI brain scans of families with FS previously shown to be linked to 1q23 and the NOS1AP gene. We scanned 12 subjects with FS, 18 unaffected siblings (UA1) and 7 second degree relatives (UA2) from 6 families from one site and 7 subjects with FS and 7 UA1 subjects from 4 families from a second site. An ANCOVA on grey matter covaried with age, IQ, gender and intracranial volume revealed differences in the 3 groups from the first site in the left post-central gyrus, right anterior cingulate gyrus, right superior temporal gyrus, and the cerebellum. Post-hoc t-tests between FS patients and UA1 subjects showed no significant difference in voxel clusters. Results from T-tests with mapwise correction show that UA1 subjects have significantly decreased volume at the right anterior cingulate ($p = 0.001$), the left postcentral ($p = 0.022$) and the left superior temporal ($p =0.048$) gyri compared to UA2 subjects. In addition, FS patients showed decreased volume after mapwise correction at the right anterior cingulate gyrus ($p = 0.001$), the right angular gyrus ($p = 0.008$), and the cerebellum ($p = 0.001$) compared to UA2 subjects. Similar findings were found in subjects from the other site. Results suggest that UA1 subjects may be more similar neuroanatomically to FS patients than to UA2 subjects in these 1q23-linked FS families. Moreover, the right anterior cingulate gyrus may represent an endophenotype for 1q23-linked FS. These findings need to be replicated in other forms of FS.

Contribution of Chaperonin-like BBS Genes (BBS6, BBS10, BBS12) in a Multiethnic Canadian Population Affected with Bardet-Biedl Sydrome. *G. Billingsley[1], L. Deda[1], S. Herd[1], D. Chitayat[2,3], K.J. Fieggen[4], J.L. Duncan[5], G.A. Fishman[6], E. Héon[1,7]* 1) Dept Genetics & Genome Biology, Hosp Sick Children, Toronto, ON, Canada; 2) Prenatal Diagnosis and Medical Genetics Program, Mt Sinai Hosp, Toronto; 3) Dept of Clinical and Metabolic Genetics, Hosp Sick Children, Toronto; 4) Division of Human Genetics, University of Cape Town, Cape Town, S Africa; 5) Dept of Ophthalmology, UCSF, San Francisco, CA, US; 6) Dept of Ophthalmology & Visual Sciences, University of Illinois at Chicago, Chicago, IL; 7) Dept of Ophthalmology and Vision Sciences, Hosp Sick Children, University of Toronto.

Bardet-Biedl syndrome (BBS: OMIM 209900) is a genetically heterogeneous disorder characterized by the primary features of progressive retinal dystrophy, obesity, polydactyly, renal malformations, cognitive impairment and genital abnormalities. 12 BBS genes have been identified to date. BBS6 (NM_018848), BBS10 (NM_024685), and BBS12 (NM_152618) define a novel branch of the type II chaperonin superfamily and together are reported to account for about one-third of the mutational load in BBS patients (Stoetzel et. al. AJHG 80: 1-11, 2007). Mutational analysis of these 3 genes was performed on a Canadian BBS patient cohort (n=62) of mixed ethnicity. Family segregation and control screening (n=150) confirmed the pathogenicity of novel sequence changes. Three of 33 probands were found to have 4 mutations (1 novel) in BBS6. BBS10 was found to be a major contributor to BBS in our patient cohort, accounting for 26% of the mutational load. Sixteen different BBS10 mutations, 10 of which are novel, were observed. In addition, 10 (9 novel) pathogenic changes in BBS12 were found to contribute to 9.7% of the patient mutational load. Together these 3 genes account for ~45% of the mutational load in our patient cohort. Three patients have at least 3 pathogenic changes in 2 of the chaperonin-like genes. One of these, a young female diagnosed with MKKS (fundus appears normal at ~3 years of age), has a heterozygous BBS6 mutation as well as compound heterozygous BBS12 changes. Our results support the major importance of these three chaperonin-like proteins in BBS, together accounting for ~45% of our BBS cases.

A Pediatric Genome-Wide Association Study Identifies A Type 1 Diabetes Locus on 12q13. *H. Hakonarson[1,2], S.F.A. Grant[1,2], J.P. Bradfield[1], L. Marchand[3], C.E. Kim[1], J.T. Glessner[1], R. Grabs[3], T. Casalunovo[1], S.P. Taback[4], E.C. Frackelton[1], M.L. Lawson[5], L.J. Robinson[1], R. Skraban[1], R.M. Chiavacci[1], C.A. Stanley[6], S.E. Kirsch[7], D.S. Monos[8,9], M. Devoto[2,10], H.Q. Qu[3], C. Polychronakos[3]* 1) Applied Genomics, Children's Hosp Philadelphia, Philadelphia, PA; 2) Human Genetics, Children's Hosp Philadelphia, Philadelphia, PA; 3) Departments of Pediatrics and Human Genetics, McGill University, Montreal; 4) Department of Pediatrics and Child Health, University of Manitoba, Winnipeg; 5) Division of Endocrinology, Childrens Hospital of Eastern Ontario, University of Ottawa, Ottawa; 6) Division of Endocrinology, Children's Hosp Philadelphia, Philadelphia, PA; 7) Markham-Stouffville Hospital, Markham, Ontario; 8) Department of Pediatrics University of Pennsylvania, School of Medicine, Philadelphia, PA; 9) Department of Pathology and Laboratory Medicine, Children's Hosp Philadelphia, Philadelphia, PA; 10) CCEB, University of Pennsylvania, Philadelphia, PA.

Type 1 diabetes (T1D) is a common, strongly heritable disease that most often manifests in childhood. To identify novel T1D risk loci, we performed a genome-wide (GW) association study using the Illumina Infinium HH550 platform. The first stage, involving 563 T1D probands and 1,146 controls plus 483 complete T1D family trios of the same ancestry, confirmed previously known loci and identified one novel locus on Chr16p, which reached GW significance in the first stage as we previously reported; a second stage in an independent cohort of 939 nuclear families confirmed this association using TDT. While a full second stage is underway, we fast-tracked to examination in the same replication cohort an additional locus that came within an order of magnitude of statistical significance in Stage 1 (three common non-coding variants in strong LD yielded *P* from 4.05×10^{-6} to 7.16×10^{-7}, OR range= 1.34 - 1.40). This association was replicated in Stage 2 (*P* from 3.74×10^{-4} to 1.34×10^{-4}). These SNPs reside in a block of linkage disequilibrium on 12q13, containing six genes. This result provides evidence of a promising locus that could lead to new T1D therapeutics.

Verification of CNVs identified with high density oligo aCGH using an optimized Q-RT PCR assay. *X. Hu[1], M.M. Li[1,2,3]* 1) Louisiana Cancer Research Consortium; 2) Hayward Genetics Center; 3) Dept. of Pediatrics; Tulane Univ. Sch. Med, New Orleans, LA.

High density oligo microarray CGH (aCGH) has been revolutionizing the diagnosis of patients with developmental delay and mental retardation. However, higher density oligo arrays also brought with it a higher rate of copy number variations (CNVs). How to distinguish true CNVs from artifacts, especially those duplications/deletions smaller than 0.5 Mb, has proved to be a significant challenge. In this study, we attempted to develop a SYBR Green-based quantitative Real Time PCR (Q-RT PCR) method to verify small deletions and duplications identified by CGH. Five genes, UTS2D and CLND from 3q, ANXA29 and AMAD10 from 4q, and DSCR1 from 21q were selected for this study. In addition, two housekeeping genes, ABL and GUSD were utilized as internal controls. The sensitivity and linearity of the Q-RT PCR assay were established using serial dilutions of reference DNA (Promega). The standard curves showed a correlation coefficient between 0.99 and 0.997 for starting templates ranging from 101 to 106 copies. The specificity of the test was validated by a single peak melting curve with an identical melting temperature for all samples. The intra-assay coefficient of variation (CV) was < 2%, and the inter-assay, < 5%. Using this method we studied DNA samples from a patient with an unbalanced translocation der(4)t(3;4)(q27.2;q32.2) and a patient with Down syndrome. The Q-RT PCR data were analyzed using the standard curve method and three relative quantification methods. The results confirmed a duplication of the UTS2D gene (1.63 fold, $p<0.05$) and the CLND gene (1.67 fold, $p<0.05$) and a deletion of the ANXA29 gene (0.5 fold, $p<0.05$) and the AMAD10 gene (0.49 fold, $p<0.05$) in the patient with partial trisomy 3q and partial monosomy 4q and a duplication of the DSCR1 gene (1.67 fold, $p<0.05$) in the patient with Down syndrome. In conclusion, we have developed and optimized a Q-RT PCR assay that can quantify copy number changes in genomic DNA with high sensitivity and specificity. This assay can be used to confirm small deletions or duplications identified with high density oligo aCGH.

A chromosome 19p deletion in a patient with SHFM, tetralogy of Fallot and a clinical phenotype of Angelman syndrome. *E. Aten[1], N.S. den Hollander[1], C.A.L. Ruivenkamp[1], J. Knijnenburg[2], H. van Bokhoven[3], J.T. den Dunnen[1], M.H. Breuning[1]* 1) Center of Human and Clinical Genetics, Leiden University Medical Center, Leiden, Nederland; 2) Molecular Cell Biology, Leiden University Medical Center, Leiden, Nederland; 3) Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, Nederland.

Congenital limb malformations are the second most common birth defects observed in infants. Split hand foot malformation (SHFM) also known as central ray deficiency, ectrodactyly and cleft hand/foot, can occur as an isolated malformation or in combination with other malformations such as the EEC (ectrodactyly-ectodermal dysplasia- cleft lip/palate) syndrome. This variability causes the phenotypic classification of SHFM to be very difficult. Management of affected patients and their families is further complicated by the genetic heterogeneity observed, with already five genomic loci implicated. Identification of genes involved in defects in human limb patterning has been limited, in part, by the enormous spectrum of phenotypes. Currently the five types are referred to as SHFM1 (7q21-q22), SHFM2 (Xq26), SHFM3 (10q24), SHFM4 (3q27), and SHFM5 (2q31). Molecular testing is only available for SFHM4 since patients mapped to this locus have been shown to carry mutations in the TP73L (p63) gene. We report a male patient with SHFM, tetralogy of Fallot and a clinical phenotype of Angelman syndrome. Using 1 Mb BAC array genome analysis we identified a deletion with a maximal deleted size of 1.4 Mb at chromosome 19p, confirmed by FISH analysis. Analysis of the parents of the patient showed that the deletion was de novo. To determine the borders of the deletion more precisely we used a 250K oligonucleotide SNP array (Affymetrix). The deletion was found to be 0.96 Mb in size, containing 27 genes. We screened 21 additional SHFM patients with ectrodactyly (TP73L mutation negative) for rearrangements in this region using a home-made MLPA assay but did thus far not detect other deletions or duplications. The 27 genes in the deleted region have been prioritised and are currently screened for possible mutations.

HLA-DRB1 alleles in MS: twin concordance and sexual dimorphism. *B. M. Herrera[1,2], S.V. Ramagopalan[1,2], D.A. Dyment[1], M.R. Lincoln[1,2], G.C. Deluca[1], S. Orton[1,2], M.J. Chao[1,2], C.J. Willer[1], D.A. Sadovnick[3], G.C. Ebers[1,2]* 1) Wellcome Trust Centre for Human Genetics,Oxford University, Oxford, UK; 2) Department of Clinical Neurology, John Radcliffe Hospital, Headley Way, Oxford,UK; 3) Department of Medical Genetics, University of British Columbia Vancouver, Canada.

Population-based twin concordances in multiple sclerosis are 30% for monozygotic (MZ) and 5.4% for dizygotic (DZ) twins in Canada. Stratification by sex showed that concordance is gender and gene-interactive, being 34% for female MZ and 3.8% for female-female DZ pairs vs. male-male rates of 6.5% for MZ and 11.4% for DZ. Recent studies have revealed susceptibility (S) and resistance (R) alleles at HLA-DRB1, the only consensus locus associated with MS risk. In this investigation we analysed the frequency of S(HLA-DRB1*08, *15 and 17) and R (HLA-DRB1*01, *11 and *14) alleles and genotypes in 489 MS twins. We found that HLA-DRB1 mediated susceptibility to MS in twins is sexually dimorphic. Together with differential female sensitivity to the environment, gene-environment interactions involving the HLA-DRB1 region itself are strongly implied in MS pathogenesis.

Analysis of FFPE Specimen for Somatic Mutations and Epigenetic Alteration. *J.A. Durocher[1], K.B. Walters[2], S. Mahurkar[1], J.D. Karkera[1], M.L. Nickerson[1]* 1) Genome Research Division, Transgenomic Inc, Gaithersburg, MD; 2) Department of Biological Sciences, The George Washington Univesity, Washington, DC.

Formalin-fixed, paraffin-embedded (FFPE) tissue has traditionally been used to archive pathological samples from patients. The FFPE procedure preserves tissues for extended periods of time while retaining histologic information. This method of archiving samples is commonly used to preserve sections of tumors from cancer patients. Although they are a benefit for histological examination, use of FFPE samples for molecular genetic analysis has been a challenge due to degradation, crosslinked nucleic acids, and other chemical modifications which vary depending on where and how the specimen was fixed. Genomic DNA isolation from FFPE samples is difficult and previous methods resulted in insufficient quality and quantities of nucleic acids for subsequent analyses. As the field of oncology transitions to personalized medicine, researchers and physicians require additional genetic information from cancerous cells to provide a better understanding of the disease at the molecular level and to aid in determining the optimal course of treatment. Here we describe methods for isolation and analysis of genetic material from FFPE samples. Ample quantities of nucleic acids have been obtained using optimized DNA isolation protocols and we have found that quality is most accurately accessed by quantitative PCR. Genetic regions associated with disease phenotypes, including G-C rich regions, can be amplified from FFPE isolated using improved and highly developed PCR protocols. We have successfully detected inherited and low-level somatic mutations using endonuclease scanning combined with double stranded sequencing. An approach using bisulfite treatment and DNA sequencing has been used to locate methylation sites in CpG islands in gene promoters associated with disease status and drug response. All results obtained from our assays are confirmed through repeated analysis of independent PCR products. This comprehensive approach allows detailed, accurate and robust genetic data to be generated from FFPE samples to facilitate an insight to the molecular mechanisms of carcinogenesis.

Neuroaxonal dystrophy associated with osteopetrosis and brain dysgenesis: Prenatal diagnosis and neuropathological findings. *D. Chitayat[1,4,7], P. Shannon[2,7], W. Halliday[3,7], G. Seaward[4,7], A. Toi[5,7], M. Thompson[2,7], S. Blaser[6,7]* 1) The Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital, Toronto, Canada; 2) Department of Pathology and Laboratory Medicine, MSH; 3) Division of Pathology, Hospital for Sick Children, Toronto; 4) Department of Obstetrics and Gynecology, MSH; 5) Department of Diagnostic Imaging, MSH; 6) Diagnostic Imaging and Neuroradiology, HSC; 7) University of Toronto, Toronto, Canada.

Neuroaxonal dystrophy (ND) is a progressive disease characterized by widespread swelling of axons and neuropathy. Infantile, late infantile and juvenile forms have been reported and genetic heterogeneity has been recognized. The association of ND with osteopetrosis and brain dysgenesis have been reported only twice before. We report the prenatal presentation of such a condition in a fetus born to a consanguineous couple.

The mother was 17 years old and her husband was 32 years old. They were of Afghani origin and consanguineous. The pregnancy was complicated with fetal ultrasound findings of a small cerebellum and scalp edema at 24 weeks gestation. Fetal MRI showed severe hypoplasia of the cerebellum, medulla and pons and delayed abnormal sulcation and agenesis of the corpus callosum.

The pregnancy was interrupted and the autopsy showed coarse facial features, microcephaly with lissencephaly, absent olfactory bulbs and tracts, absent corpus callosum, a small cerebellum with posterior fossa cyst, bilateral cataract and dramatic central and peripheral nervous system axonal spheroids. There was an increased density of all long bones with bone in bone appearance. The karyotype was 46, XX and FISH for 17p13.3 was normal.

The combination of ND with osteopetrosis and brain dysgenesis has been reported initially by Rees et al., (1995). To the best of our knowledge, no further cases have been reported and this is the first case diagnosed in utero.

Depletion Analysis of Ultraconserved Elements among Copy Number Variants. *C.W.K. Chiang[1], A. Derti[2], J.N. Hirschhorn[1,3,4], C.-t. Wu[5]* 1) Dept of Genetics; 2) Dept of Biol. Chemistry and Mol. Pharmacology, Harvard Medical School, Boston, MA; 3) Div of Genetics and Endocrinology, Childrens Hospital, Boston, MA; 4) Broad Institute, Cambridge, MA; 5) Div of Genetics and Molecular Medicine, Harvard Medical School, Boston MA.

Alignment of the human, mouse, and rat genomes identified 481 sequences that are 200 bp in length and 100% conserved (Bejerano et al. 2004). This set of ultraconserved elements (UCEs) was later expanded to 896 elements by adding human-dog-mouse and human-chicken UCEs (Derti et al. 2006). UCEs are hypothesized to be functional, given the apparent negative selective pressure estimated for UCEs (Chen et al. 2007), and the assumption that conservation is indicative of function (Bejerano et al. 2004, Drake et al. 2005). Recently, Derti et al. (2006) reported UCEs to be depleted from segmental duplications and copy number variants (CNVs), suggesting that UCEs may be dosage sensitive. This dosage sensitivity was further proposed to be at least partly responsible for the uniqueness and ultraconservation of UCEs. Here we expand on the study by Derti et al. (2006) by analyzing several published genome-wide CNV datasets obtained from normal subjects and patients with cancer, autism, or mental retardation. Depletions of UCEs, especially of the intronic and intergenic subclasses, were observed (P ranging from < 0.0003-0.02) in several, although not all, datasets. Variability in depletion may reflect technical challenges in determining the extent of CNVs, which may improve with the use of the new Affymetrix GenomeWide 6.0 array. The variability in depletion may also be due to differences between the CNVs of patients as versus healthy individuals, differences between common as versus rare CNVs, and/or other biologically-driven features. To begin addressing these issues, we are expanding on the diversity of datasets we analyze, especially those associated with cancer, as well as generating *in silico* sets of recurrent CNVs based on published datasets. We anticipate these studies to clarify the relationships between UCEs and CNVs, and their potential implication to human variations and diseases.

Two genome-wide association studies suggest DFNB31 as a risk locus for bipolar disorder. *A.E. Baum, M. Cabanero, N. Akula, F.J. McMahon* National Institute of Mental Health, National Institutes of Health, Bethesda, MD.

At this writing, two genome-wide association studies in three datasets have been published for bipolar disorder. Our group (NIMH) screened 555,235 SNPs in two independent samples (Illumina HumanHap550 platform, 1233 cases/1439 controls). We identified 88 SNPs in 80 genes (Baum et al 2007) and 78 SNPs in intergenic regions that met replication criteria in both samples. The Wellcome Trust Case-Control Consortium (WTCCC 2007) screened an independent sample (1868 cases/2398 controls) with the Affymetrix GeneChip 500K Mapping Array Set. They reported 14 SNPs associated with bipolar disorder at $p < 1x10^{-5}$. Since each study used a different platform, direct comparison of SNPs is largely impossible. Each study identified one SNP reaching genome-wide significance levels, but the two SNPs are on different chromosomes. However, the list of replicated SNPs from the NIMH study includes 2 SNPs (rs942518 and rs16929770) that tag a ~40 kb region on 9q32 which has been previously linked to bipolar disorder. This region also contains one SNP reported by WTCCC to be associated with bipolar disorder at $p = 8.8x10^{-6}$. The 2 NIMH SNPs are located 5.2kb and 7.4kb upstream of the promoter region of the gene DFNB31. The WTCCC SNP is located ~13 kb away in the first intron of the gene. DFNB31 encodes the neuronally-expressed protein whirlin, a component of the Usher protein complex, which affects neuronal morphogenesis and structural plasticity and is an effector of -catenin. Additional high-density genotyping in this region is now underway to answer the question of whether the same allele is associated with bipolar disorder in both studies.

Stratified analysis of RELN in autism using the Language Acquisition Discrepancy (LAD) score. *J. Jaworski[1], J. Brinkley[1], R.K. Abramson[2], H.H. Wright[2], J.L. Haines[3], J.R. Gilbert[1], M.A. Pericak-Vance[1], M.L. Cuccaro[1]* 1) MIHG, University of Miami, Miami, FL; 2) Dept. of Neuropsych, USC-SOM, Columbia, SC; 3) Center for Human Genetics, Vanderbilt University, Nashville, TN.

Several chromosome 7 candidate genes have shown association with autism (AUT) including RELN which is involved in neuronal migration and development. Previously, our group reported association for a repeat in the RELN 5UTR in a Caucasian family dataset (N=327). However, this effect was not observed when the dataset was increased (N=471), most likely due to genetic heterogeneity. To deal with such heterogeneity, we have developed the Language Acquisition Discrepancy (LAD) score, based on the difference in age at first words and age at phrase speech as measured by the ADI-R. Clustering algorithms using age at first words [normal18 months delayed] and LAD score [normal 15 months delayed] yielded four clusters in our AUT dataset: DD = delayed first words/delayed LAD score; DN = delayed first words/normal LAD score; ND = normal first words/delayed LAD score; NN = normal first words/normal LAD score. Using the pedigree disequilibrium test (PDT) we tested for association to seven SNPs in RELN in our overall dataset (436 Caucasian families) and the cluster defined strata. Hcv2632989 showed association to AUT in two clusters (p=0.012 in NN and p=0.023 in the ND) both of which are characterized by normal age at first words. In addition, rs144525 showed association only in the DN cluster (p=0.032). These findings reveal associations to RELN that were apparent only in the language defined strata. While it does not appear that LAD influenced the association results, the findings support a potential role for RELN in a language based AUT subphenotype. This is consistent with previous work identifying age at first words as a QTL chromosome 7q. In sum, RELN continues to be a gene of interest in understanding genetic risk for AUT. .

Noninvasive Prenatal Testing for RhD Status by Matrix-Assisted Laser Desorption/Ionization Time of Flight (MALDI-TOF) Mass Spectrometry: A Pilot Study. *M.J. Basehore[1], J. Wiszniewska[1], B. Dragon[2], J. Tynan[2], J.A. Lee[1], T. Legler[3], D. van den Boom[2], M. Ehrich[2], C.M. Eng[1]* 1) Baylor College of Medicine, Department of Molecular and Human Genetics, Houston, TX; 2) Sequenom Inc., San Diego, CA; 3) University Medicine Goettingen, Germany, SAFE Network Partner.

Prenatal genetic analysis of fetal status is currently performed using techniques that require invasive procedures to obtain fetal-derived samples. Chorionic villous sampling and amniocentesis are associated with fetal loss rates ranging from 0.5-1%. The discovery that cell-free fetal DNA circulates in maternal plasma has lead to the consideration of its use as a source of fetal material, thereby providing a noninvasive approach to determining prenatal genetic status. Cell-free fetal DNA is detectable around four weeks of gestation and comprises approximately 6% of total free plasma DNA by the third trimester of pregnancy. However, the limited amounts of fetal DNA in maternal plasma and the need to differentiate fetal genotype from the maternal background present challenges that have hindered the implementation of noninvasive prenatal genetic testing in clinical diagnostics. In this study, peripheral blood samples were obtained from 130 RhD-negative, pregnant women at an average gestational age of 26 weeks. Cell-free fetal DNA was extracted from maternal plasma and fetal samples were tested for RhD status, as well as the presence or absence of SRY, by MALDI-TOF mass spectrometry. These results showed complete concordance with fetal RhD genotype determined by real-time PCR and gender determined postnatally. Additionally, 30 of the 130 samples were also tested in a clinical laboratory on a research basis and results were concordant with previous studies for RhD genotype by real-time PCR and MALDI-TOF, gender, and postnatal serological phenotype. These preliminary studies indicate that MALDI-TOF mass spectrometry is a potential method for the noninvasive prenatal assessment of RhD status. Further studies are needed to delineate the stability and optimal extraction conditions for cell-free fetal DNA before this method can be routinely implemented in a clinical diagnostic setting.

Efficient Control of Population Structure in Model Organism Association Mapping. *H. Kang[1,2], N. Zaitlen[4], C. Wade[6], A. Kirby[6], D. Heckerman[5], M. Daly[6], E. Eskin[2,3]* 1) Computer Sci Engineering, Univ California, San Diego, La Jolla, CA; 2) Department of Computer Science, University of California Los Angeles, Los Angeles, CA; 3) Department of Humna Genetics, University of California Los Angeles, Los Angeles, CA; 4) Bioinformatics Program, University of Calfornia San Diego, La Jolla, CA; 5) Microsoft Research, Redmond WA; 6) Broad Institute of MIT and Harvard, Cambridge, MA.

Genome-wide association mapping in model organisms such as inbred mouse strains is a promising approach for the identification of risk factors related to human diseases. However, genetic association studies in inbred model organisms are confronted by the problem of complex population structure among strains. This induces inflated false positive rates, which can not be corrected using standard approaches applied in human association studies such as Genomic Control or Structured Association. Recent studies demonstrated that mixed models successfully correct for the genetic relatedness in association mapping. However, the currently available mixed model methods suffer from computational inefficiency and unknown convergence properties. We propose a new method, Efficient Mixed Model Association (EMMA), which corrects for confounding due to population structure in model organism association mapping. Our method takes advantage of the specific nature of the optimization problem in applying mixed models for association mapping, which allows us to substantially increase computational speed and reliability of the results with improved convergence properties and global optimization. We applied our EMMA method to in silico whole genome association mapping of inbred mouse strains involving hundreds of thousands of SNPs. We also performed an extensive simulation studies to estimate the power of EMMA under various effect of SNP, population structure, and multiple measurements. In spite of limited power of model organism association mapping due to the limited number of inbred strains, we are able to identify significantly associated SNPs, which fall into known QTLs or genes identified through previous studies without an inflation of false positives.

Recognizing A Milder Phenotype Of Tuberous Sclerosis. *H. Gaddipati, K. Nathanson* Division of Medical Genetics, Children's Hospital of Philadelphia, Philadelphia, PA.

The tuberous sclerosis complex (TSC) is an autosomal dominant hamartomatous tumor syndrome.The severity of the TSC phenotype can range from mild skin abnormalities to life-threatening complications. The spectrum of clinical features, natural history and management recommendations for a subset of TSC patients who present with a milder phenotype has been less well characterized. We follow 50 patients in our TSC clinic at the Hospital of the University of Pennsylvania. A subset of nine patients were identified with normal development and intellect. They were diagnosed after the age of 18 because of subtle clinical stigmata, incidental imaging, positive family history or acute complications of TSC. Adolescents with no history of seizures or complications from TSC were also included in the study. Two of the patients presented with sudden hemorrhage of renal angiomyolipomas (AML) requiring embolization. Two patients were diagnosed by biopsy of facial angiofibroma and one of them was noted to have a lesion suspicious for renal cell carcinoma on routine surveillance imaging. Three patients were evaluated based on a positive family history of TSC and two of them were found to have cortical tubers. One patient was diagnosed when subependymal nodules were incidentally found on brain imaging while investigating the etiology of her headaches. She has subsequently required embolization for renal AML. Another patient presented with micronodular pneumocyte hyperplasia (MNPH). Three patients had TSC1 mutations, two patients were mutation negative. The result was inconclusive in one case and unknown in two other. After reviewing the natural history of TSC in our study population we conclude that the risk for serious and sometimes life-threatening complications remains significant and unpredictable. No specific genotype-phenotype correlations are apparent. Therefore, it is important for physicians to recognize these subtle phenotypes and facilitate timely referral of patients to specialized TSC clinics. Even for patients with seemingly benign initial presentations close surveillance and timely intervention may help prevent significant morbidity and mortality.

Integrated Detection and Analysis of SNPs and Copy Number Variation for Genomewide Association and Cancer Studies. *F.G. Kuruvilla[1,3,4], S.A. McCarroll[1,4], S. Cawley[2], J. Korn[1,4,5], A. Wysoker[1], J. Blume[2], M.J. Daly[1,4], S. Lincoln[2], S.B. Gabriel[1], R.P. Rava[2], D.M. Altshuler[1,4]* 1) Broad Institute of Harvard and MIT, Cambridge, MA; 2) Affymetrix Inc, Santa Clara, CA; 3) Brigham & Women's Hospital, Boston, MA; 4) Massachusetts General Hospital, Boston, MA; 5) Harvard-MIT Division of Health Sciences and Technology, Cambridge, MA.

While the roles of SNPs and Copy Number Variants (CNVs) both should be assessed in each disease study, their measurement platforms have until now been separate. We have developed a next-generation microarray platform with 906,600 SNPs, capturing 3.8 million SNPs with an average maximum r squared of 0.85, as well as 202,000 high-density probes of regions of known copy-number variation and 744,000 probes tiled throughout the genome for identification of novel or de novo CNVs. SNP genotyping is 99.6% concordant with Hapmap data with an average 99.7% call rate across all SNPs. The arrays make it possible to accurately genotype clinical samples for more than 500 common CNVs, allowing common CNVs to be systematically assessed, for the first time, for association with clinical phenotypes. Moreover, we find that integrated analysis of SNPs and CNVs improves the analysis of both forms of variation, allowing us to fill in physical coverage gaps in LD across the genome, allowing copy number to be inferred at an allelic level, and allowing inference of the actual copy numbers that underlie reported regions of copy number variation. Integrated analysis of SNPs and CNVs will enable powerful and novel inference in whole genome association studies.

Fanconi Anemia D1 Presenting as Breast Cancer caused by bi-allelic BRCA2 gene mutations. *M. Dasouki[1], K. Penning[2], A. Shwaiki[2], S. Mundt[2]* 1) Pediatrics, University of Kansas , Kansas City, KS; 2) Saint Luke's Hospital, Kansas City, MO.

Fanconi Anemia (FA) is a premalignant, autosomal recessive syndrome characterized by highly variable congenital abnormalities, progressive bone marrow failure, and susceptibility to cancer. Approximately 25-40% of individuals with Fanconi anemia have no congenital abnormalities. The Fanconi anemia phenotype is caused by mutations in 13 genes. Fanconi anemia complementation group D1 (FANC-D1) accounts for about 3.3% of all Fanconi anemia cases. Breast cancer is also a genetically heterogeneous disease. Inherited breast cancer is associated with germline mutations in ten different genes in pathways critical to genomic integrity. Mono-allelic (heterozygous) BRCA1 and BRCA2 mutations confer a high risk of breast cancer and are major causes of familial breast cancer. Recently, bi-allelic BRCA2, BRIP1 and PALB2 mutations were shown to cause FANC-D1, FANC-J and FANC-N respectively. Few kindreds had been reported with recurrent solid tumors due to recessive BRCA2 mutations. Here, we report on Hispanic kindred with breast and colon cancer associated with compound heterozygous BRCA2 germline mutations. The proband, a 22 year old, G1P1 previously healthy female presented with right breast, stage T2N1M0, Her2/nu and estrogen/progesterone receptor negative invasive ductal carcinoma. BRCA1 gene sequencing was normal, while BRCA2 analysis showed E49X (maternal) and 9927del4 (paternal) mutations. Her healthy 15 year old brother was found to carry both mutations and both siblings had abnormal chromosomal stress testing using MMC. Neither sibling had any physical features of Fanconi anemia. Identification of Fanconi anemia as the cause of breast cancer in this family necessitated a tailored chemotherapy regimen for the proband and close monitoring of affected family members for hematologic and solid tumors known to occur frequently in patients with Fanconi anemia.

The NFKia gene is a novel PPAR Cardiac target gene. *N. Buroker[1], J-Y. Huang[2], M. Ge[1], X-H. Ning[1,2], M. Portman[1,2]* 1) Dept Cardiology, Seattle Children's Hosp, Seattle, WA 98105; 2) Department of Pediatrics, University of Washington, Seattle, WA 98195.

The peroxisome proliferator-activated receptors (PPARs) and the retinoid X receptors (RXRs) are members of the nuclear receptor superfamily, which consists of a large number of special transcription factors whose activities are regulated by their cognate ligands. These steroid hormone receptors are important regulators of gene expression and differentiation. These receptors form homo- (RXR) and hetero- (PPAR-RXR) dimers that bind DNA at various response elements (PPAR and RXR). We identify the PPAR/RXR response elements in the promoter of the nuclear factor of kappa light polypeptide gene enhancer in B-cells inhibitor alpha gene (NFKbia). In this study a known PPARactivator (WY14, 643) and DMSO (vehicle) was introduced into control and 337T thyroid hormone receptor (TR transgenic mice. The 337T TR transgenic mouse has been created to reproduce the human genetic disease known as resistance to thyroid hormone (RTH). Heart tissue was extracted and NFKbia gene expression was compared using Affymetrix 430_2 expression arrays and qRT PCR among four studies groups [control, control with WY14, 643, 337T TR and 337T TR with WY14, 643] consisting of seven mice per group. The gene expression of NFKbia in the WY14, 643 control and transgenic mouse groups was significantly up regulated over the vehicle mouse groups for both the array ($p<0.05$) and qRT PCR ($P<0.01$) studies. Duplex oligo DNAs containing the PPAR/RXR motif (aggtca/tccagt) from the NFKbia promoter were used in EMSA to verify binding of the PPAR and RXR receptors to their response elements. pGL4.0 [Luc] constructs of the NFKbia promoter with and without the PPAR/RXR motifs were co-transfected with mouse PPAR, into HepG2 cells and used in Lucerifase assays to verify gene activation. In conclusion our study revealed that PPARregulates the mouse cardiac NFKbia gene in both the control and transgenic mouse.

The role of HLA-DRB5 and -DRB1 loci in susceptibility to multiple sclerosis: a study of 769 African-American cases and 751 controls. *F. Briggs[1], S.J. Caillier[2], L.F. Barcellos[1], B.A.C. Cree[2], S.L. Hauser[2], J.R. Oksenberg[2]* 1) School of Public Health, Univ of California,Berkeley, CA; 2) Department of Neurology, Univ of California, San Francisco, CA.

Genetic susceptibility to multiple sclerosis (MS) is associated with the major histocompatibility region (MHC) region located on chr. 6p21. A strong consistent signal maps to a 200 kb region encompassing the HLA-class II loci and segregates with the HLA-DQB1*0602, DQA1*0102, DRB1*1501, DRB5*0101 haplotype. Very strong linkage disequilibrium between these loci (and therefore lower haplotype diversity) in northern Europeans has made it difficult to fully characterize individual genetic contributions of this region to MS risk. A recent study in African-Americans (greater MHC haplotype diversity), however, has demonstrated selective MS associations with HLA-DRB1*1501 and *1503 independent of DQB1*0602, confirming the power of this approach to fine-map susceptibility loci. While HLA-DRB1 appears to mark the centromeric border of the class II association in MS, the telomeric border has not been defined. This haplotype carries two functional DR beta chain genes, DRB1 and DRB5, and two different DR dimers can thus be formed by pairing with the non-polymorphic DR alpha chain; results suggesting an important functional role for HLA-DRB5 in MS have been reported. In this study, molecular typing of HLA-DRB5, -DRB1 and seven informative SNPs was performed in 769 African-American MS cases and 751 controls to define the telomeric border of this region. Extended MHC haplotypes were characterized and compared in cases and controls using Fishers exact testing and logistic regression modeling. While strong associations were observed for HLA-DRB1, DRB5 and two SNPs, our results are consistent with a primary role for the HLA-DRB1 gene in conferring susceptibility to MS.

Gene-language correlations in the Luo population of Kenya. *J. Hirbo[1], F. Reed[1], S. Omar[2], M. Ibrahim[3], S. Tishkoff[1]* 1) Dept Biol, Univ Maryland, College Park, MD; 2) Kenya Medical Research Institute, Centre for Biotechnology Research and Development, Nairobi, Kenya; 3) Dept. of Molecular Biology, Institute of Endemic Diseases, University of Khartoum, Khartoum, Sudan.

The Luo speak an Eastern Sudanic (Nilotic) language and are found predominantly in the Western part of Kenya (East Africa), as well as in parts of Western Uganda and the upper tip of Tanzania. The eastern Sudanic (Nilotic) language is a sub-family of the Nilo-Saharan language family, typically spoken by pastoralist populations of eastern Africa. Although the Luo speak a Nilo-saharan language, previous blood group studies done in East African populations found no significant difference in allele frequencies between the Luo and populations from Kenya and Uganda that speak a Bantu language (classified as part of the Niger-Kordofanian language family). In addition, preliminary results from a larger study of African population structure using a panel of ~1200 autosomal microsatellite and indel polymorphisms show that the Luo are genetically similar to eastern African Bantu-speaking populations. To determine both the maternal and paternal contribution to the observed profiles, we genotyped 50 unique event polymorphisms and 16 microsatellites on the Y chromosome, and sequenced the entire mitochondrial D-loop region, in a total of 300 individuals from the Luo and seven other populations living in the vicinity of the Luo populations, who speak eastern Sudanic or Bantu languages. Although the maternal mtDNA lineages among the Luo are similar to the lineages from Bantu-speakers, the paternal Y chromosome lineages are most similar to lineages present in Nilotic-speaking populations. The discordance between gene-language correlations for the mtDNA and Y chromosome lineages is most likely due to differential male and female gene flow into the Luo population.

Development of a community-based education initiative for genomic medicine. *V.C. Henrich[1], C. Christianson[1], K. Potter-Powell[1], S. Estabrooks Hahn[2], L. Evans[1], D. Bartz[1], T. Roxbury[1], S. Blanton[2], P. Lietz[3], J. Vance[2], M. Pericak-Vance[2]* 1) Ctr for Biotech, Genomics, and Health Research, University of North Carolina-Greensboro, Greensboro, NC 27402; 2) Miami Institute for Human Genomics, University of Miami, Miami FL 33136; 3) Moses Cone Health System, Greensboro, NC 27401.

The success of utilizing genomic medicine in the community health setting will depend on an informed interaction between the patient and their health care provider followed by appropriate interventions, as needed. This requires the understanding by these two groups that family history is essential for risk assessment, this risk can be reduced through medical intervention and lifestyle changes, and genetic testing is appropriate for a subset of people. As the basis for developing a community education program surrounding these concepts, the Guilford Genomic Medicine Initiative (GGMI) conducted 3 physician focus groups and 13 community focus groups to ascertain gaps in knowledge, perceptions, and attitudes related to genomic medicine. Physicians reported that they collect some family history information, but it is often incomplete. They also expressed concerns about the lack of guidelines for follow-up of at-risk patients and genetic services. To further assess community knowledge, attitudes, and awareness, the findings from the community focus groups were used to produce a telephone survey for residents in Guilford County, NC. Collectively, the focus groups and survey identified gaps in knowledge and misconceptions that highlighted the need for complementary learning objectives for each of the target audiences. For genomic medicine to be successfully integrated into health care, community members must be educated in basic genetics, understand the importance of family history and know what information to collect, patient education materials must address misconceptions and concerns, and physicians must have clear recommendations for risk assessment and evidence-based guidelines regarding follow-up.

Understanding the molecular basis of mucolipidosis type IV. *G. Borsani[1], A. Benini[1], M. Beltrame[2], L. Calvarini[1], S. Moleri[2], S. Barlati[1], A. Bozzato[1]* 1) Department of Biomedical Sciences and Biotechnology, University of Brescia, Brescia, Italy; 2) Department of Biomolecular Sciences and Biotechnology, University of Milano, Milano, Italy.

Mucolipidosis type IV (MLIV, MIM 252650) is an autosomal recessive lysosomal storage disorder that causes mental and motor retardation as well as visual impairment. The lysosomal storage defect in MLIV is consistent with abnormalities of membrane traffic and organelle dynamics in the late endocytic pathway. MLIV is caused by mutations in the *MCOLN1* gene, which codes for mucolipin-1 (MLN1), a member of the large family of transient receptor potential (TRP) cation channels. Although a number of studies have been performed on mucolipin-1, the pathogenesis of MLIV is not fully understood. We are studying the molecular mechanisms underlying this disorder using a combination of experimental approaches. To identify genes that characterize pathogenic changes in mucolipidosis type IV, we compared the expression profiles of MLIV and normal skin fibroblasts cell lines using oligonucleotide microarrays. Genes that were differentially expressed in patients cells were identified. 231 genes were up-regulated, and 116 down-regulated. This study allowed to evidence the modulation at the transcriptional level of a discrete number of genes relevant in biological processes which are altered in the disease such as endosome/lysosome trafficking, lysosome biogenesis, organelle acidification and lipid metabolism. The analysis of the Zv6 assembly of the zebrafish genome led us to the identification of *mcoln1*, the putative ortholog of *MCOLN1* in *Danio rerio*. Quantitative real-time PCR has been used to evaluate the expression of the gene at different developmental stages. Whole mount *in situ* hybridization analysis of zebrafish embryos allowed to determine the expression profile of zebrafish *mcoln1*. The subcellular localization of the encoded protein has been studied in human cell lines and compared to that of human mucolipin-1. The study of the phenotypic consequences of *mcoln1* gene knockdown using morpholino-based antisense oligonucleotides is currently in progress.

MTSS1 and TRPS1 As Potential Susceptibility Genes for Alzheimers Disease in the Chromosome 8q. *J. Deng[1], Y.J. Li[2], G.M. Mayhew[3, 4], J. Grimsley[2], X. Hu[1], M.A. Pericak-Vance[3, 4], J.M. Vance[3, 4]* 1) Neurobiology, Duke Univ, Durham, NC; 2) Center for Human Genetics, Duke Univ, Durham, NC; 3) Center for Molecular Genetics and Genomic Medicine, Univ of Miami, Miami, FL; 4) Miami Institute for Human Genomics, Univ of Miami, Miami, FL.

We previously conducted a whole genome screen for age-at-onset (AAO) of Alzheimers Disease (AD) using 449 families and identified several linkage regions including chromosome 8q and 4q. The initial linkage region of chromosome 8q covers 46cM interval (between 119 to 165cM; LOD>1.0) with a peak multipoint LOD score of 2.09. At the Stage Two study, we re-genotyped the same microsatellite markers under the chromosome 8q and 4q linkage regions on the additional new 158 families to refine the intervals. We applied the variance component linkage analysis method implemented in SOLAR (Almasy and Blangero 1998) using this expanded dataset (607 families). The chromosome 4q peak disappeared, while 8q peak was strengthened with an updated two-point LOD score of 2.34 at the marker D8S1179. In addition, the new analysis narrowed the peak region to about 20cM (between 128 to149cM; LOD>1.0). We then designed our Stage Three study to follow up the chromosome 8 interval using an Illumina Goldengate custom SNP arrays. We selected 1536 SNPs to cover ~24mb area at one LOD score below the peak marker (1-LOD down region between q23.3-q24.23), resulting in a density of one SNP per 10000 bps in most part of the region. We included 1192 samples selected from 279 families with the highest linkage score from Stage Two study. The APL and PDT were used for detecting risk gene(s) for AD and QTDT was used for detecting genes regulating AAO of AD. After genotyping quality controls and correction for multiple testing using qvalue, we identified two SNPs that are the most significantly associated with AD risk. The best SNP is located in metastasis suppressor 1 (MTSS1), with p-values of 2.8×10^{-5} by APL and 0.0063 by PDT. The second significant SNP is in the front of a zink finger transcription factor, TRPS1, with a p-value of 0.0019 by APL and 0.0001 by PDT. Additional SNPs are being tested in these gene regions to identify the key areas of association.

Importance of functional studies for diagnosing effects of rare disease-causing missense mutations. *K.V. Krasnov[1], M. Tzetis[2], J. Cheng[1], G.G. Germino[1], W.B. Guggino[1], G.R. Cutting[1]* 1) Johns Hopkins Univ, Baltimore, MD; 2) Athens Univ, Athens, Greece.

Over 1,300 putative disease-causing mutations are reported in the Cystic Fibrosis (CF) Mutation Database and almost half (~630) are rare mutations predicted to substitute a single amino acid. We have investigated functional consequences of rare disease-associated mutations that alter amino acids in CFTR cytosolic loop 4 that are completely conserved across 36 diverse species. Three substitutions of the conserved R1070 residue are associated with different disease consequences: patients with R1070P and R1070Q have severe pancreatic insufficient (PI)-CF, while those with R1070W have mild pancreatic sufficient (PS)-CF. Intriguingly, CFTR bearing each of these mutations maintains chloride channel function in non-polarized cells. To determine whether R1070 mutations cause disease by affecting CFTR localization in native epithelia, we used the FLP-In system to create stable polarized MDCK cell lines that express wildtype or mutant CFTR from the same genomic integration site. Confocal microscopy revealed that R1070P was cytoplasmic, R1070Q was apical, and R1070W was apical and cytoplasmic. Quantitative biotinylation studies revealed that R1070P was not membrane inserted, R1070Q was inserted into the apical membrane at wildtype-like levels, and R1070W had apical membrane protein at levels considerably lower than wildtype. Localization of R0170P and R1070W were distinctly different from wildtype CFTR, which is consistent with their proposed deleterious role in CF patients. However, the profile of R1070Q was inconsistent with a PI-CF phenotype. Re-analysis of 12 patients bearing R1070Q revealed that each carried an in cis nonsense mutation (S466X). Discovery of the in cis S466X mutation reconciles the apparent discrepancy between functional studies of R1070Q and the phenotype of patients bearing this mutation. Our results demonstrate that substitutions of evolutionarily conserved amino acids are not necessarily deleterious and emphasize that functional studies in relevant model systems are valuable for the interpretation of the disease-causing potential of rare missense mutations.

Genome-wide linkage analysis finds significant imprinting effects on obesity in HyperGEN. *C. Gu[1], J. Zhou[1], K. North[2], R.H. Myers[3], Y.J. Sung[1], S.C. Hunt[4], D.K. Arnett[5], D.C. Rao[1]* 1) Washington University in St Louis, St Louis, MO; 2) University of North Carolina, Chapel Hill, NC; 3) Boston University, Boston, MA; 4) The University of Utah, Salt Lake City, UT; 5) University of Alabama, Birmingham, AL.

Obesity is a complex metabolic disorder affecting millions; both genetic and non-genetic risk factors may contribute to its development and manifestation. Recent reports suggest that imprinting effects might play an important role in its development. We performed a genome-wide linkage analysis incorporating imprinting effects at 380 microsatellite markers genotyped by Marshfield Genotyping Service in a sample of white and black families from the HyperGEN study sponsored by NHLBI. There were 2,105 white subjects (1,003 men and 1,102 women in 884 nuclear families) and 2,300 blacks (843 men and 1,457 women in 951 nuclear families). NHLBI unisex clinical guidelines for obesity (http://www.nhlbi.nih.gov/guidelines/obesity/sum_clin.htm) were used to classify subjects as obese or non-obese. BMI are available for all whites (29.04.8 in men and 29.16.8 in women) and almost all blacks (29.56.3 in men and 33.48.1 in women). Using a computer program implementing parametric imprinting models (GENEHUNTER-IMPRINTING, Strauch et al. AJHG, 66(6):1945-57, 2000), we performed analysis separately in both race groups. Using the maximum LOD (MOD) score approach, we found significant linkage to obesity on Chromosome 2 (MOD = 4.20 at 30.3 cM near GGAA20G10) and Chromosome 10 (MOD = 3.44 at 22.1 cM near AFM063XF4) in blacks, of which the linkage on Chromosome 10 was heavily influenced by genetic imprinting (imprinting index = 0.48). In whites, we also found significant linkage to obesity on Chromosome 6 (MOD = 3.35 at 166.9 cM near AFM242ZG5) and Chromosome 19 (MOD = 3.54 at 26.8 cM near GATA21G05), both of which were influenced by imprinting (imprinting index = 0.49 and -0.82, respectively). There were other suggestive signals (MOD 2.0) in both samples. We are currently performing additional analyses using different definitions of obese or quantitative phenotypes, such as waist to hip ratio or percent of body fat.

Linkage disequilibrium and haplotype variation in Sub-Saharan Africa. *M. Jakobsson[1], F.A. Reed[2], T.J. Pemberton[3], G. Coop[4], D.F. Conrad[4], J.D. Wall[5], J.K. Pritchard[4], S.A. Tishkoff[2], N.A. Rosenberg[1]* 1) Dept. Human Genetics, University of Michigan, Ann Arbor, MI; 2) Department of Biology, University of Maryland, College Park, MD; 3) Institute for Genetic Medicine, University of Southern California, Los Angeles, CA; 4) Department of Human Genetics, University of Chicago, Chicago, IL; 5) Department of Epidemiology and Biostatistics, University of California, San Francisco, CA.

In most populations, the HapMap provides an excellent resource for the design of association mapping studies aimed at finding disease-susceptibility genes. However, the major exception to this general rule has been Sub-Saharan Africa. While Africa is the region in which association mapping is most challenging, current knowledge of African linkage disequilibrium (LD) is based largely on a limited sample of populations. We investigate LD at 2,810 SNPs in 8 Sub-Saharan African populations - Beja, Borana, Fulani, Hadza, Iraqw, Mada, Sandawe, and Sengwer. These data are analyzed jointly with SNP data on a worldwide panel of 53 populations, including 7 additional Sub-Saharan populations.

Within Sub-Saharan Africa, isolated hunter-gatherer populations stand out in having the largest number of private haplotypes. These populations also have the largest number of missing haplotypes - haplotypes that are found in all except a single population. For a few East African populations - but not for other Sub-Saharan populations - we find extensive haplotype sharing with populations of the Middle East. We also find that every Sub-Saharan population has considerably less LD than every non-African population, confirming that the low level of African LD is a continent-wide pattern. The portability of tag SNPs based on the HapMap Yoruba sample is smaller in all Sub-Saharan populations compared to the portability of the HapMap CEU and CHB/JPT samples in non-African populations. These results have implications both for the history of human migrations out of Africa and for improving the prospects for association studies in populations of African descent.

Copy number variability in patients with Pelizaeus-Merzbacher disease. *G. Hobson[1,2], J. Garbern[3], K. Woodward[4], Y. Wu[5], M. Maisenbacher[6], M. Henneke[7], L. Banser[1], K. Sperle[1]* 1) Nemours Biomedical Research, duPont Hosp Children, Wilmington, DE; 2) Thomas Jefferson University, Philadelphia, PA; 3) Wayne State University, Detroit, MI; 4) Western Diagnostic Pathology, Perth, WA, Australia; 5) UCSF, San Francisco, CA; 6) University of Florida, Gainesville, FL; 7) University of Gottingen, Gottingen, Germany.

Duplication of a genomic region of Xq22 that includes the proteolipid protein 1 gene (*PLP1*) is the most common mutation causing Pelizaeus-Merzbacher disease (PMD), an X-linked dysmyelinating leukodystrophy. The duplications in PMD are heterogeneous in size and in location of breakpoints. They arise most frequently by a grandpaternal intrachromosomal event and have a tandem head-to-tail orientation. Our data on 59 PMD cases suggested a coupled homologous and nonhomologous mechanism for formation of the duplications in PMD. This is in contrast to other genomic disorders where recurrent rearrangements are formed by nonallelic homologous recombination. Further, we reported that patients with three or more copies of *PLP1* have a more severe phenotype than those with duplication. We have examined copy number variability in patients with PMD in the genomic region around *PLP1* by X-chromosome oligonucleotide array CGH and by semiquantitative multiplex PCR. Five patients have three copies of a genomic region that includes *PLP1*. These patients also have duplicated regions in addition to the triplicated regions. Three other patients have higher copy number regions that do not include *PLP1*, while their *PLP1* gene is duplicated. One of these patients has a classic PMD presentation like that of most *PLP1* duplication patients; one has a severe phenotype like that of patients with triplication of *PLP1*; and the third has a severe connatal phenotype. Although the locations of the proximal ends of the higher copy number regions are variable, the distal ends are all within a 200 Mb low copy repeat region (LCR) distal of *PLP1*, suggesting involvement of this LCR region in formation of these complex rearrangements. Our data underscore the importance of genome architecture in the region around *PLP1* in the formation of complex genomic rearrangements.

Individualized risk predictions to estimate the clinical benefit of risk reduction mastectomy (RRM) and oophorectomy (RRSO) in BRCA carriers with breast cancer. *H. Burke[2], A. Hoang[2], K. Metcalfe[3], J. Culver[1], D. MacDonald[1], M. Grant[1], A. Thornton[1], M. Robson[4], S. Narod[3], J. Weitzel[1]* 1) City of Hope, Duarte, CA; 2) George Washington University, Washington, DC; 3) University of Toronto, Toronto, Ontario, Canada; 4) Memorial Sloan Kettering CA Ctr., New York, NY.

Background: Breast cancer (BC) patients with a BRCA mutation have a markedly elevated risk for new cancers. Health care providers must communicate complex information about risk-reducing surgeries. We created models that provide individualized 5-year BC survival and contralateral BC predictions and the benefit of RRM and RRSO. Method: The study population was 491 BRCA+ women treated for stage I or II BC between 1975 and 2000 (BRCA1, n = 327; BRCA2, n = 152; both BRCA1 and BRCA2, n = 12). The independent variables were age (< vs.≥50 years old), tumor size (continuous), ER status (+/-), and lymph node status (+/-). Logistic regression was used to create the model which estimate the probability of each outcome for RRM and for RRSO. Accuracy is assessed by the ROC. Results:

	RRM	RRSO
5-year BC- specific survival	Model ROC = 0.707; NS	Model ROC = 0.804; significant
5-year contralateral BC	Model ROC = 0.749;significant	Model ROC = 0.611; NS

The breast and ovary cancer-specific survival model did not differ significantly from the BC-specific survival model and is not reported here. Conclusion: In this population of BRCA women who had BC, we found that, with the exception of RRSO and risk of contralateral BC, the models were highly accurate predictors of the two outcomes. An unexpected finding was the beneficial effect of RRSO on BC survival. These are preliminary results and await validation on an independent dataset. The individualized output of the predictive models will then be incorporated into a decision support tool for use in cancer risk counseling.

High throughput testing for common and recurrent mutations responsible for Mendelian diseases. *J.W. Belmont[1], R. Chen[1,2], L. Nazareth[2], D. Stockton[3], W. Craigen[1], C. Shaw[1], A. Beaudet[1], J. Lupski[1], R. Gibbs[1,2]* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 3) Children's Hospital of Michigan, Detroit, MI.

Clinical testing for common and recurrent mutations can be used for disease diagnosis, presymptomatic diagnosis, carrier testing, and disease risk analysis. We wished to examine the technical feasibility of using a high throughput genotyping platform to test large numbers of disease-causing mutations. We selected 114 disease genes and used information from a variety of databases and from the published literature to select 1238 validated common/recurrent mutations. Single nucleotide substitutions leading to nonsense, missense, splice site alterations, and small indels were included. We employed Molecular Inversion Probe chemistry (Affymetrix) which allows 4-color interrogation of single base positions in a highly parallel assay format. Indel assays were designed so that there were separate assays for the expected junctional base positions. To aid in QC, each single assay was duplicated within the entire multiplex assay. We genotyped all 270 HapMap subjects and an additional set of 96 European American samples. A subset of samples were genotyped in duplicate. These results demonstrated the general feasibility of genotype calling when the variant position is rare in the sample. The results also demonstrated the feasibility of indel genotyping assays on this platform. Overall, there was 85% assay conversion. Selecting the subset of assays that gave 95% completion the duplicate sample concordance was >99.8% and the on-chip duplicate assay concordance was 98.9%. A total of 197 mutations were confirmed in our subject sample with individuals bearing 0-6 different mutations. These results suggest the possibility of using a single assay to test for very large numbers of known disease causing mutations. Many detailed questions concerning the distribution of deleterious mutations in individuals and populations, assay quality standards and ethical implementation of such testing must be addressed in future research on this concept.

Genetic and epigenetic evidence for gain of active X-linked genes in ovarian cancer cell lines. *S. Harbord, C.J. Brown, A. Cotton, C. Salamanca, N. Auersperg, W.P. Robinson* Depts. of Medical Genetics and Obstetrics & Gynaecology, UBC, Vancouver, BC, Canada.

Skewed somatic X-inactivation, X-linked gene over-expression and abnormal X content have all been associated with breast and/or ovarian cancer. Partial or complete reactivation of the inactive X in females may be a step in breast and ovarian cancer by leading to over-expression of a tumour enhancing gene. We examined markers of X reactivation including X-gene dosage, expression, and methylation in 8 ovarian cancer cell lines(OVCAR 2,3,5,8,10; CaOV3; SKOV3; A2780). An immortalized ovarian surface epithelium cell line (IOSE 397) and a 3-X cell line (GMO4626) were used as controls. Combined RNA/DNA FISH was used to quantify the number of inactive Xs compared to total number of Xs within a cell line. There were more than 2 Xs in 5 cell lines and 2 cell lines were highly variable in X content. Three cell lines with more than one X localized XIST to the presumptive inactive X, however the number of inactive Xs was variable. Expression levels of 8 X-linked genes were assessed by real-time PCR. Expression was inconsistent between different genes and among cell lines, ranging from a 2 to 300-fold increase compared to a control. Overall, expression was greatly increased for genes subject to inactivation but not increased in genes that escape inactivation for most ovarian cancer cell lines. Methylation at AR and FMR1 was quantified by a real-time PCR based assay and SNuPE respectively. Methylation was lower than expected for 7 of 8 ovarian cancer cell lines at AR or FMR1, while 3 cell lines had low or no methylation for both genes. In addition, we assayed 2 markers of X reactivation in 2 low passage cultures of normal ovarian surface epithelium from BRCA1 mutation positive breast cancer patients. One sample did not localize XIST to the inactive X and 3 of 5 genes subject to inactivation were over-expressed. Thus, changes to the X chromosome appear in non-cancerous ovarian tissue of BRCA1 heterozygous individuals. In summary, we find evidence for loss of X silencing or gain of an active X in ovarian cancer cell lines and normal ovarian surface epithelium of BRCA1 mutation carriers.

A novel high resolution genome-wide method identifies over 1,500 very small deletion CNVs and triallelic SNPs.

L. Franke[1], C.G.F. de Kovel[1], Y.S. Aulchenko[2], D.A. van Heel[3], L.R. Cardon[4], P. Deloukas[5], R.A. Ophoff[1], L.H. van den Berg[6], C. Wijmenga[7] 1) DBG-Dept Medical Genetics, UMC Utrecht, Netherlands; 2) Department of Epidemiology & Biostatistics, Erasmus MC Rotterdam, Netherlands; 3) Centre for Gastroenterology, Institute of Cell and Molecular Science, Queen Mary University of London, UK; 4) Wellcome Trust Centre for Human Genetics, Oxford, UK; 5) Wellcome Trust Sanger Institute, Hinxton, UK; 6) Department Neurology, UMC Utrecht, Netherlands; 7) Genetics Department, UMC Groningen, Netherlands.

Various disorders are associated with chromosomal aberrations. Recently, the availability of genome wide DNA chips have allowed for the identification of considerable amounts of common copy number variation (CNV) throughout the genome. However, the methods employed for detecting these have a limited resolution as they identify only regions of multiple consecutive SNPs. We have developed a novel method that can identify deletion CNVs and triallelic SNPs within genome wide SNP chips in a SNP-by-SNP way. Our method is based on a maximum likelihood estimation procedure, assuming Hardy-Weinberg equilibrium under a triallelic model. It is straightforward and can be applied to single SNPs. Additionally it provides functionality for performing association tests for these SNPs as it can estimate allele frequencies. Analyses in two samples (> 2,700 individuals) with the Illumina HumanHap300 and HumanHap550 platforms identified ~1,500 common triallelic SNPs. Only 20% of these triallelic SNPs map within known deletion CNV regions of the Database of Genomic Variants, whereas only 10% of the 1,500 SNPs span multiple consecutive SNPs included on the platorms, suggesting the presence of many very small deletion CNVs that have not yet been identified before. Interestingly, many of the identified triallelic SNPs have major consequences for haplotype based analyses, as many loci turn out to have incorrect haplotype structures when not assuming these SNPs are triallelic. We will present our method and will show the results of this CNV association analysis in genome-wide data for celiac disease (778 cases, 1422 controls).

Analysis of five late-onset Alzheimers disease (LOAD) candidate genes. *M. Allen[1], N. Ertekin-Taner[1,2], C. Cox[1], F. Zou[1], S. Younkin[1], M. Carrasquillo[1], L. Younkin[1], D. Dickson[1], N. Graff-Radford[2], R. Petersen[3], S.G. Younkin[1]* 1) Department of Neuroscience, Mayo Clinic Jacksonville, Jacksonville, FL; 2) Department of Neurology, Mayo Clinic Jacksonville, Jacksonville, FL; 3) Department of Neurology, Mayo Clinic, Rochester, MN.

We present follow up studies for five previously reported LOAD candidate genes. Glutathione-S-Transferase 1 and 2 (GSTO1 and GSTO2) are located on chromosome 10 which has been repeatedly demonstrated to show linkage with LOAD and its intermediate phenotypes. Others have shown significant association between GSTO variants and age at onset of AD, as well as differential expression levels, implicating these genes in AD etiology. We genotyped four variants within GSTO1 and 2, two of which were previously reported. Three of the four SNPS analyzed in our combined case control data set (n>3700) revealed suggestive association (p=0.045-0.21) with LOAD. These four SNPs form five common haplotypes and nine multilocus genotypes (MLG). All of the haplotypes and four of the MLGs show suggestive association in the combined dataset that is strongest in subjects with an age at diagnosis above 80 (p=0.05-0.23). Glyceraldehyde-3-phosphate dehydrogenase (GAPD) and related genes GAPDS and pGAPD (GAPD pseudogene) have been implicated in LOAD. We genotyped three previously reported SNPs in these genes. Others reported MLGs with replicable significant association in three LOAD series. Though we were unable to replicate the MLG result, analysis of the independent variants supported a role for GAPD in disease etiology (rs1136666, OR 0.867, p=0.009) for our combined case control series (n>3700). Expression studies and analysis of additional variants in these genes are underway.

Test of Association between quantitative traits and haplotypes using haplotype similarity. *H. Chen, Q. Sha, S. Zhang* Dept Mathematical Sci, Michigan Technological Univ, Houghton, MI.

The association tests based on multi-marker haplotypes may be more powerful than those based on single markers. For case control design, the association tests based on multi-marker haploytpes include Pearsons chi-squared test which tests for the difference of haplotype distributions in cases and controls, and haplotype-similarity based methods which compare the average similarity among cases with that of the controls. Recently, a new association test proposed by Sha et al. (2007) compares the average similarities within cases and controls with the average similarities between cases and controls. They show that in most cases, their new proposed method is more powerful than both Pearsons chi-squared tests and other haplotype-similarity based methods. In this paper, we extend the approach in Sha et al. (2007) to obtain a new haplotype similarity tests that can deal with both quantitative trait data and case control study design. The new method can be applied to either phase-known or phase-unknown data. We have conducted several simulation studies and a real data analysis based on the new method.

Molecular population genetics of *PCSK9*: a signature of positive selection. *I.J. Kullo, K. Ding* Division of Cardiovascular Diseases, Mayo Clinic, Rochester, MN.

Proprotein convertase subtilisin-like kexin type 9 (*PCSK9*) is a newly discovered serine protease that plays a key role in regulating plasma low-density lipoprotein (LDL) cholesterol levels. Both rare mutations and common variants in the *PCSK9* coding regions influence LDL cholesterol levels and coronary heart disease risk, as well as response to lipid-lowering therapy. We characterized the pattern of variation at the *PCSK9* locus in African-Americans and European-Americans using resequenced data from the SeattleSNPs database (pga.gs.washington.edu). We performed tests for evolutionary neutrality, including tests based on nucleotide diversity, tests of population differentiation and the long-range haplotype (LRH) test, to detect signatures of recent position selection on *PCSK9*. No significant deviation from neutrality was found using the Tajima's D and Fay and Wu's test. However, using the LRH test, we found non-neutral evolution in two gain-of-function single nucleotide polymorphisms (SNPs) in *PCSK9*, with differential modes of selection in African-Americans and European-Americans. We observed signals of recent positive selection on the derived alleles of SNP rs562556 (I474V, $P = 0.0227$ in simulated distribution, and $P = 0.0001$ in empirical distribution) and rs505151 (E670G, $P = 0.0227$ and 0.0001) in African-Americans, but the ancestral allele of SNP rs562556 ($P = 0.1320$ and 0.0370) appeared to be under positive selection in European-Americans. A significantly high F_{ST} (a measure of population differentiation) between African-Americans and European-Americans was also noted for SNP rs505151 ($F_{ST} = 0.309$). Our findings suggest that evolutionary dynamics may underlie the gain-of-function mutations in *PCSK9* that influence inter-individuals variation in LDL cholesterol levels, susceptibility to coronary heart disease and response to lipid-lowering drugs therapy.

In vivo reduction of storage cells and glycosphingolipid accumulation in a mouse model of a generalized glycosphingolipid storage disease using a new inhibitor of glucosylceramide synthase. *S. Barnes[1], Y. Sun[1], D. Copeland[2], K. McEachern[2], C. Siegel[2], G. Grabowski[1]* 1) The Divistion and Program in Human Genetics, Cincinnati Children's Hospital Medical Center and University of Cincinnati College of Medicine, Cincinnati, OH; 2) Genzyme Corporation, Framingham, MA.

Substrate reduction therapy seeks to abate aberrant lysosomal accumulation of glucosylceramide (GC) through inhibition of glucosylceramide synthase. Here, a murine model of Gaucher disease (4L/PS-NA) was used as a model system. 4L/PS-NA has an acid -glucosidase (GCase) V394L/V394L (4L) point mutation combined with a hypomorphic (6% wild-type) expression of the mouse prosaposin transgene (PS-NA). The combined deficiencies of GCase and prosaposin resulted in accumulation of several glycosphingolipids, including GC, lactosylceramide and globotriaosylceramide. A ceramide analog, C9, was a potent inhibitor (IC50 ~20 nM) of glucosylceramide synthase. In this study, 3 wk old 4L/PS-NA mice received C9 orally for 12 wks. These mice showed reduced number of storage cells and CD68 positive staining in the spleen, liver and lung compared to age-matched untreated control animals. No effect was seen in the brain and spinal cord. Lipid analysis revealed decreased levels of lactosylceramide and globotriaosylceramide with more moderate effects on accumulated glucosylceramide in visceral tissues. These results indicated that the synthesis pathway is inhibited, but the residual GCase mutant enzyme activity in these tissues was not sufficient to clear accumulated GC. This study demonstrates that substrate reduction therapy with ceramide analogues inhibition of glucosylceramide synthase represents an alternative approach for treating the visceral pathology in severe variants of glycosphingolipid storage diseases.

Consumers' attitudes towards current and prospective reproductive genetic testing. *F.M. Hathaway[1, 2], E. Burns[3], H. Ostrer[1]* 1) Human Genetics Program, New York University School of Medicine, New York, NY; 2) New York University Clinical Cancer Center, New York, NY; 3) Stern College for Women at Yeshiva University, New York, NY.

Purpose: As our knowledge and abilities in molecular genetics continues to expand, so does our ability to prenatally detect certain conditions and traits. It is, however, unknown if this increase in knowledge and ability will be accepted by the consumers of genetic services. Our study gauges the consumers opinion towards reproductive testing for diseases and enhancements. **Methods:** From the period of July 2006 until February 2007, every patient that came to the NYU Human Genetics Program for prenatal counseling was asked to participate in the survey prior to their initial visit with a genetic counselor. A total of 999 surveys were collected. Consumers were asked to indicate traits and conditions for which they would want reproductive testing. **Results:** The majority of respondents would elect to have genetic testing for mental retardation (75%), deafness (54%), blindness (56%), heart disease (52%), and cancer (51%). We found consistency in respondents reaction to testing depending on the degree to which the condition was life-altering. Of those who would want testing for heart disease, approximately 88% would also want testing for cancer (p 0.001). Similarly, of those that wanted testing for blindness, 99% would also have testing for deafness (p 0.001). A small group indicated interest in prenatal genetic testing for enhancements, such as superior athletic ability (10%) and superior intelligence (12%). Although most respondents did not desire testing for enhancements, few respondents were able to identify what specific restraints on genetic testing should be put in place. **Conclusion:** Our study suggests that consumers, in one medical genetics practice, desire more reproductive genetic testing than what is currently offered. Their selection of tests, however, suggests self-imposed limits on testing for diseases and enhancements. In addition, this study found that the majority of consumers would continue with reproductive testing knowing that it might reveal information about themselves.

Modeling Genetic Imprinting of Quantitative Traits in Humans. *W. Hou[1], S. Wu[2], T. Liu[2], J. Yang[2], J. Yap[2], R. Wu[2]*
1) Epidemiology and Health Policy, University of Florida, Gainesville, FL; 2) Department of Statistics, University of Florida, Gainesville, FL.

Gene imprinting is thought to affect many developmental and disease traits in humans. With the availability of high-throughput single nucleotide polymorphisms (SNPs), there is a pressing need to quantify the effects of imprinting DNA sequence variants on complex traits. Here, we describe a general statistical strategy for testing and estimating imprinted quantitative trait nucleotides (iQTNs) that contribute to genetic variation in a natural population. This strategy was made by implementing parent-of-origin effects of iQTNs within a mixture model framework, thus allowing the test of imprinting genomic effects on the phenotypic value of a trait. We derived the closed forms for the EM algorithm to estimate haplotype frequencies, allele frequencies and linkage disequilibria, and additive, dominant and imprinting genetic effects. A series of hypotheses are formulated to test the genetic control mechanisms of trait variation. Simulation studies were performed to examine the statistical behavior of this model. The new model provides a standard procedure for genomic mapping of iQTNs involved in the genetic control of complex traits in human populations.

Assessment of copy number variants (CNVs) using high resolution whole genome analysis: A strategy for confirmation of genomic changes. *C. Harvard[1,5], C. Tyson[1], Y. Qiao[1,2,5], C. Fawcett[1], J. Hurlburt[2], X. Liu[3,5], JJA. Holden[3,4,5], MES. Lewis[2,5], E. Rajcan-Separovic[1,5]* 1) Departments of Pathology and; 2) Medical Genetics UBC, Vancouver, BC, Canada; 3) Departments of Psychiatry; 4) and Physiology, Kingston, Ontario; Canada; 5) ASD-Canadian American Research Consortium (www.autismresearch.com).

Array CGH using BAC arrays has been shown to successfully detect sub-microscopic chromosomal gains and losses. High resolution oligo arrays, now commercially available, can detect smaller CNVs and better characterize their breakpoints. However, the number of CNVs can be overwhelming for confirmation in a routine cytogenetic setting. We analyzed results from Nimlegens 325K oligo array for 15 karyotypically normal subjects with idiopathic intellectual disability (ID) to provide the rationale for selecting CNVs most likely to be clinically relevant. A total of 103 CNVs were detected in our study group (2-10/subject). The criteria we used to select CNVs for further follow-up included: 1) size of the deletion (>100kb) and duplication (>200kb) respectively as these changes have a high probability of being real (Hehir-Kwa et al, 2007); 2) overlap with normal CNVs (http://projects.tcag.ca/variation/), duplicons and gaps (overlap with variants from at least 2 studies and across the entire length was considered a normal variation) and; 3) gene content. After eliminating the small CNVs (44) and those likely to be variants (55) as described above, only 4 changes remained for follow-up involving gains of: a) 9.78Mb at 5q14.1-q14.3, 0.72 Mb at 1q21.1, 0.42 Mb at 7q31,1 and 2.46 Mb at 9q21.13-31. Because some CNVs show changes in both normal and affected individuals (eg 1q21. 1, Klopocki et al, 2007) and the majority of normal CNVs in the genomic variants database have not been confirmed using an independent method, we also selected two CNVs having complete overlap with normal variants and/or duplicons that contain brain function related genes (gains of 1.2Mb at 9p31. and 0.36Mb at 16p13.11). The results of FISH/qPCR confirmation and family studies of the selected CNVs resulting from our analysis will be presented.

REDUCTION OF GENOMIC COMPLEXITY FOR RE-SEQUENCING BY REGION-SPECIFIC EXTRACTION. *J. Dapprich[1], D. Ferriola[1], M. Kunkel[1], A. Gabriel[2], M. Dunham[3]* 1) Generation Biotech, Lawrenceville, NJ; 2) Rutgers University, Piscataway, NJ; 3) Princeton University, Princeton, NJ.

Structural variation can have significant influence on the accuracy of SNP typing, sequencing and haplotype analysis. Interpretation of typing results can be affected by the underlying genomic context. Molecular analysis to determine the positions of non-fixed or copy number variable elements throughout the genome can be difficult or impossible by sequence analysis alone. Further, the assembly of short, random shot-gun sequencing reads within the context of genomic structural variation has become an acute problem for next-generation sequencing due to the presence of repetitive regions in complex genomes. Region-specific extraction (RSE) is an automated method that reduces complexity of genomic DNA by physically isolating targeted genomic elements, including flanking sequences. A coupled enzymatic hybridization and tagging process achieves single-base specificity and high capture efficiency of genomic regions. RSE is able to resolve sequence ambiguities caused by missing cis-trans linkage, copy number variation or mobile genetic elements. Here we demonstrate the selective separation and analysis of a highly homologous, duplicated gene region called MICA/MICB, located in the Major Histocompatibility Complex. This region is implicated in numerous autoimmune and other diseases such as diabetes. RSE probes were used to selectively extract the duplication containing the MICA gene from the duplication containing the MICB gene using sequence variation between the two copies. A similar approach was used to resolve homologous gene cassettes in the killer immunoglobulin-like receptor region on chromosome 19 and map the location and copy number of mobile genomic elements in yeast on DNA microarrays. RSE is directly compatible with essentially any typing method and can be carried out in a 96-well format on commercially available systems. This provides a sample preparation tool that can deconvolute complex genomic regions in a high-throughput mode by combining the flexibility of current whole genome analysis methods with the more informative content of site-directed screening methods.

Community Concerns Regarding Genomic Medicine. *S. Hahn[1], K. Powell[2], S. Letvak[2], D. Spoon[2], C. Christianson[2], D. Wallace[2], S. Blanton[1], P. Lietz[3], M. Pericak-Vance[1], V. Henrich[2]* 1) Miami Institute for Human Genomics, University of Miami, FL; 2) The University of North Carolina at Greensboro, NC; 3) Moses Cone Health System, Greensboro, NC.

The Guilford County Genomic Medicine Initiative is a demonstration project aimed at developing a model to incorporate genomic medicine into community health care. Included in this model are broad-based education programs for target populations: the community, health professionals, and patients. Community focus groups were conducted as part of the educational needs assessment. One question focused on participants concerns about the use of genetics in medicine, as these may influence their acceptance and use of genomic medicine services. Furthermore, concerns may stem from lack of complete information or misconceptions that may be addressed by focused education. 13 focus groups were conducted with a total of 121 participants. The average group size was 9, ranging from 6 to 16. Overall, the demographics approximated the ethnic and racial diversity in Guilford County. Focus group transcripts were analyzed and coded for themes. Common themes include the cost of genomic medicine to the individual and affordability to all (equity); unanticipated physical harm from the use of technology; mistrust in the government, doctors, and/or scientists; downstream effects such as overpopulation from healthier people; playing God/disturbing the natural order; need for regulations; privacy; and genetic discrimination. Concerns about one or more moral issues such as genetic engineering (e.g. cloning and stem cells), choosing traits, and abortions resulting from genetic information were also raised in almost all focus groups. In some cases, responses were grounded in personal experiences, and in many cases reflected topics in the media. Some respondents mentioned concerns about issues they did not understand or were unsure of, and some had misconceptions about the use of genetics in medicine. These data reveal perceptions that must be acknowledged in order to produce an effective education program and were used to generate questions for a community telephone survey that further examined areas of concern.

Association between TGFB1 and age-related cortical cataract. *C.J. Hammond[1,2], F. Zhang[1], T.D. Spector[1]* 1) Twin Research Unit, Kings College London School of Medicine, London, United Kingdom; 2) West Kent Eye Center, Bromley Hospitals NHS Trust, Orpington, UK.

Purpose: Our twin studies have previously shown a significant heritability for age-related cataract: cortical cataract (0.58) and nuclear cataract (0.48). TGFB1, a gene containing 7 exons and spanning 23.5kb on chromosome 19q13 (MIM 190180), has been linked with aging traits including osteoporosis, cerebrovascular disease and cancer. It has also been associated with anterior subcapsular cataract and posterior capsule opacification in animal studies, by promoting epithelial to mesenchymal transition. We performed an association study to examine whether TGFB1 might be involved in age-related cataract.

Methods: 1012 twin subjects (mean age 63, range 50-79 years) from the TwinsUK Adult Twin Registry were phenotyped for cataract with lens photography (Scheimpflug and retroillumination images) and graded automatically. Some twins underwent genotyping of 6 TGFB1 SNPs (2 promoter region, 3 exonic, 1 intronic) which had previously been shown to be of functional importance. Logistic regression including subjects' age was used to calculate associations, with family cluster analysis to take into account twin association.

Results: 327 subjects were genotyped, and of these 71 were cases (>5% lens area cortical cataract) and 256 controls. All SNPs were in Hardy-Weinberg equilibrium. There was no association with nuclear cataract for any SNPs in TGFB1. Significant association with cortical cataract was found for 2 SNPs in the promoter region of TGFB1 ($p=0.001$ and $p=0.017$), but there was no association for 4 exonic SNPs examined.

Conclusions: TGFB1 may play a role in susceptibility to age-related cortical cataract. Replication of these results is required, and further investigation including the possible role of TGFB1 in racial differences of prevalence of cortical cataract.

Large-scale transcriptional profiling for the identification of genes influencing biological aging. *J.C. Charlesworth, J.W. Kent Jr., J.E. Curran, M.P. Johnson, H.H.H. Göring, T.D. Dyer, S.A. Cole, J.W. MacCluer, E.K. Moses, J. Blangero, S. Williams-Blangero* Southwest Foundation for Biomedical Research, San Antonio, TX.

The genetic architecture of biological aging is complex, involving multiple genetic and environmental factors and their interactions; however the specific genes involved in the biological pathways of aging are largely unknown. In this study, we employ an integrative genomic approach that utilizes large-scale transcriptional profiling to rapidly identify novel genes influencing differential aging. Using RNA extracted from lymphocytes, we obtained genome-wide transcriptional profiles from 1,240 individuals in the San Antonio Family Heart Study. High-dimensional endophenotypic search procedures identified 4,136 transcripts that were significantly correlated with chronological age (corrected for multiple testing using a FDR of 0.05). Functional annotations of genes within this set indicate significant over-representation of genes in several critical pathways including reactive oxygen species production ($p=1.36\times10^{-4}$), immune response ($p=3.08\times10^{-4}$) and DNA replication/repair ($p=4.20\times10^{-4}$). Of these age-associated genes, 781 exhibited expression levels that showed significant evidence for genotype-by-age (G×A) interaction as determined by a quantitative genetic test. G×A interaction is interpretable as evidence for a heritable basis of biological response to aging. Of the transcripts that showed both a significant relationship with age and evidence for G×A interaction, 144 also showed nominal evidence for *cis*-regulation, as inferred from quantitative trait linkage analysis. Examples of these *cis*-regulated genes include *VSTM1* (evidence for *cis*-effects: $p=2\times10^{-23}$; evidence for G×A effects: $p=2.5\times10^{-6}$) and the mitochondrial gene *MTCO1* (evidence for *cis*-effects: $p=1.4\times10^{-11}$; evidence for G×A effects: $p=1.9\times10^{-12}$). Such genes are likely to harbor regulatory variants close to their structural locations that are involved in differential aging. This empirically determined set of genes influenced by G×A interaction represent excellent candidates for the rapid identification of genetic variation influencing aging.

Association of non-synonymous coding SNPs with risk of colon cancer. *M.S. Cicek[1], S.L. Slager[2], T.C. Smyrk[1], K.C. Halling[1], K.G. Rabe[2], S.J. Achenbach[2], L.A. Boardman[3], D.J. Sargent[4], G.M. Petersen[5], J.R. Cerhan[5], S.N. Thibodeau[1], P.J. Limburg[3]* 1) Departments of Laboratory Medicine and Pathology; 2) Biostatistics; 3) Gastroenterology; 4) Cancer Center Statistics; 5) Health Sciences Research, Mayo Clinic College of Medicine, Rochester, MN.

Rationale: Despite its morbidity, much remains unknown about the etiology and progression of colon cancer. It is the third leading cause of cancer-related mortality affecting both gender in the US. Colon cancer is a complex disease and believed to be heterogeneous, with the presence of several low penetrant susceptibility genes. Alterations that are present on these genes are likely to play a crucial role in colon tumorigenesis. **Methods:** We have taken a two-stage approach. In stage 1, we screened 10,000+ non-syn cSNPs using the Affymetrix GeneChip Human 10K cSNP Panel I in 195 cases and 130 controls. Cases were ascertained between the years 1995-1999 and age- and gender-matched controls were ascertained after 2000 at Mayo Clinic Rochester. In stage 2, we genotyped the top significant cSNPs (MAF0.05 and $p<0.05$) from stage I in 991 cases and 1009 matched controls using the Illumina Golden Gate Assay. The DNA MMR status, as determined by testing tumor for MSI and the absence of protein expression by IHC for hMLH1, hMSH2, hMSH6, was available for each case in stage I (65 MSI-H and 130 MSS) and has been collected on the majority of new cases in stage II (130 MSI-H and 752 MSS). Associations were assessed by single SNP logistic regression analyses. **Results:** In stage I, we found 281 cSNPs and 917 cSNPs were significant at a p-value of 0.01 and 0.05, respectively. Of the 917 cSNPs, we selected 587 cSNPs that had MAF>0.05 for genotyping in stage II. We found that 58 of these cSNPs remained significant in stage II with a p-value < 0.05. Among these, 10 cSNPs were significant with a p-value of 0.01 and one cSNP was significant at each of the p-values; $p<0.0001$ and $p<0.001$. **Conclusion:** These data provide new target genes for further research in colon tumorigenesis. Additionally, since outcome information is available on a subset of the cases, we will also test whether these cSNPs are associated with overall survival.

Moyamoya Disease: Identification of the First Gene for the Disease and Insight into the Genetic Basis. *S.J. Bourgeois, V.T. Tran-Fadulu, D. Guo, S.L. Swineford, E. Regalado, D.M. Milewicz* Internal Medicine, Univ of Texas HSC Houston, Houston, TX.

Moyamoya disease (MMD) is a premature stroke disease due to occlusive lesions in the terminal portion of the internal carotid arteries. A genetic basis of MMD is well established; 10% of patients having a family history of MMD. Using families with multiple members with thoracic aortic aneurysms and dissections (TAAD), we identified that ACTA2 missense mutations cause of familial TAAD. ACTA2 encodes smooth muscle cell (SMC) specific -actin, a contractile protein that is the most abundant protein in SMCs. Although we identified a spectrum of ACTA2 mutations causing FTAAD, 3 unrelated TAAD families with mutations altering ACTA2 R258 had the surprising finding of strokes under the age of 30 years in 6 mutation positive members, including 4 individuals diagnosed with MMD and therefore establishing ACTA2 as the first gene for MMD. Based on the fact that a single gene mutation can lead to both TAAD and MMD, we hypothesized that MMD is a systemic vascular disease, and patients may have a family history of MMD or other premature or rare vascular diseases. We obtained medical and family histories on 27 probands with MMD (86% Caucasian). There was a bimodal distribution of age of onset of MMD (36% with onset <10 yrs of age and 32% onset ages of 30-40 yrs). In the probands, 100% of those examined had livedo reticularis (purplish rash due to occlusion of dermal capillaries), 22% had migraines, 7% had renal artery stenosis, and 4% had a cerebral aneurysm. On family history (1st and 2nd degree relatives due to the young probands), 18% had a history of MMD, 18% had a history of only premature strokes (< 55 years, not MMD), 26% had a history of premature coronary artery disease (CAD < 55 years) and 22% both strokes and CAD. Therefore, we conclude that MMD is a manifestation of a systemic vascular disease and a family history of premature strokes and CAD is present in the majority of MMD patients (85%). These findings suggest that inherited genes leading to a spectrum of premature vascular diseases, with MMD at the severe end of the spectrum, may be more common than previously reported.

Truncations in the Carboxyl-terminus of Human 3'-5' DNA Exonuclease TREX1 Cause Autosomal Dominant Retinal Vasculopathy with Cerebral Leukodystrophy. *J.C. Jen[1], A.M.J.M. van den Maagdenberg[2,3], A. Richards[4], D. Kavanagh[4], P. Bertram[4], D. Spitzer[4], M.K. Liszewski[4], M. Barilla-LaBarca[4], G.M. Terwindt[3], Y. Kasai[5], K.R.J. Vanmolkot[2], B. de Vries[2], J. Wan[1], M.J. Kane[1], H. Mamsa[1], S.F. Nelson[6], R.R. Frants[2], R.W. Baloh[1], M.D. Ferrari[3], J.P. Atkinson[4]* 1) UCLA Neurology; 2) Human Genetics, Leiden U Med Ctr, The Netherlands; 3) Neurology, Leiden U Med Ctr; 4) Medicine/Rheumatology, Washington University, St. Louis, MO; 5) Genome Sequencing Center, Washington Uiversity; 6) UCLA Human Genetics.

Retinal vasculopathy with cerebral leukodystrophy (RVCL,MIM192315) is an autosomal dominant vascular syndrome of middle age onset due to a systemic microvascular endotheliopathy with an unusual ultrastructural appearance of multilaminated subendothelial basement membrane. We identified a large American family with cerebroretinal vasculopathy (CRV), characterized by retinal vasculopathy reminiscent of diabetic retinopathy and white matter brain lesions often mistaken for neoplasm or demyelination. The disease locus of CRV mapped to 3p21 that is shared by a Dutch family with hereditary vascular retinopathy (HVR) and a Chinese American family with hereditary endotheliopathy with retinopathy, nephropathy, and stroke (HERNS). These allelic disorders were henceforth designated RVCL. A collaborative effort led to the discovery of heterozygous carboxyl-terminal frameshift mutations in TREX1, a ubiquitously expressed 3'-5' repair exonuclease whose physiological function is largely unknown. Nonfunctional TREX1 mutations were recently demonstrated to cause Aicardi-Goutières syndrome (AGS1 [MIM225750] & AGS5 [MIM610905]) as well as chilblain lupus (MIM610448), suggesting a role for TREX1 in clearing altered DNA to prevent destructive autoimmune response. The involvement of TREX1 in the maintenance of systemic vascular integrity has not been previously recognized. The RVCL-causing truncated TREX1 proteins retain exonuclease activity but lose normal perinuclear localization, suggesting a toxic gain of function. Understanding the pathogenesis of RVCL may provide insight to stroke and vascular cognitive impairment as well as possibly shared mechanisms between RVCL and diabetic retinal vasculopathy.

Disruption of clock genes confers a breast cancer phenotype. *J. Esposito, S. Rossetti, F. Corlazzoli, N. Sacchi* Cancer Biology, Roswell Park Cancer Institute, Buffalo, NY.

Exposure to artificial light correlates with higher incidence of breast cancer. Shift workers, whose day/night rhythms are altered by their odd hours, appear more prone to develop breast cancer. In response to natural light, a master clock in our brain regulates molecular clocks in cells of the peripheral tissues, triggering clock-regulated genes that govern fundamental cellular functions. Critical clock genes - the period genes PER1, PER2, and PER3 - were found to be deregulated in breast cancer. It is currently unknown whether disruption of the peripheral clock in human breast epithelial cells leads to transformation. By using a modified serum shock protocol, we entrained human untransformed breast epithelial cells in vitro and found that a few key clock genes, including the PER genes are indeed transcribed in a rhythmic fashion in untransformed but not in transformed breast epithelial cells. For this reason we tested whether disruption of one of the key clock genes, PER2, can induce breast epithelial transformation in vitro. Stable knock down of PER2 in human untransformed breast epithelial cells by RNA interference leads to three-dimensional (3D) morphological phenotypes recapitulating the changes observed in early breast tumorigenesis. These findings support our hypothesis that disruption of peripheral circadian rhythm genes initiates breast tumorigenesis. A US Army DOD Concept Award (BC052954) to NS supported this work; SR is supported by A Susan Komen Postdoctoral Fellowship; FC is supported by a DOD Predoctoral fellowship.

Serendipitous detection of a constitutional microdeletion 16p13.11 in a patient with AML-M4eo. *H. Bruyere[1,2], C.J. Jensen[1], K.W. Song[2,3]* 1) Pathology and Laboratory Medicine, Vancouver General Hospital, Vancouver, BC, Canada; 2) University of British Columbia, Vancouver, BC, Canada; 3) Division of Hematology, Leukemia/Bone Marrow Transplantation Program, Vancouver General Hospital and BC Cancer Agency, Vancouver, BC, Canada.

A 35-year-old male patient was diagnosed with AML-M4eo. His karyotype revealed a pericentric inversion 16 in 23/25 metaphases. FISH, performed with a break-apart MYH11 probe located at 16p13.11, showed an unexpected signal pattern. In 78% of the interphase nuclei, one green signal and one red signal separated from each other were detected. The fusion signal corresponding to the normal homologous chromosome 16 was missing. In 18% of the nuclei, only one fusion signal was seen. On the 15 metaphases analyzed, one green signal and one red signal separated from each other were detected with no evidence of a fusion signal. Five metaphases from a peripheral blood specimen were apparently normal at 500-550 band resolution. Fish with the MYH11 probe showed only one normal (fused) signal. Therefore, a constitutional microdeletion at 16p13.11 was diagnosed. Two copy-number-variation databases were searched for a MYH11 copy number's alteration and revealed the loss of one copy of the MYH11 gene in 6/364 control individuals. The patient is reportedly phenotypically normal. He achieved remission after induction therapy. Further characterization of the microdeletion is pending. The MYH11 probe designed for the diagnosis and follow-up of patients with an inv(16)(p13q22) or t(16)(p13;q22) may be located at a site of a genome copy number polymorphism.

Power of measured genotype-based association analysis, conditional on a variance components-based linkage model, in related individuals. *H.H.H. Goring, J.W. Kent Jr., V.P. Diego, T.D. Dyer, J. Blangero* Department of Genetics, Southwest Foundation for Biomedical Research, San Antonio, TX.

Linkage analysis is often the initial step for gross localization of genetic factors influencing complex traits. Once a linkage region has been identified using a sample of families, it is generally advantageous, for a variety of reasons, to pursue fine mapping by LD analysis in the same sample, rather than to collect a new sample of unrelated individuals for this step. A complication in any family-based LD analysis method is that the relatedness of individuals must be properly modeled. In penetrance model-based analysis, it is conceptually straightforward to do this and conduct LD analysis conditional on the existence of linkage. In popular alternative statistical approaches to gene mapping, such as variance components-based analysis, it is much more difficult to separate the linkage and LD components. We have previously shown (Kent Jr. *et al.* 2007 Genet Epidemiol 31:173) that measured genotype analysis within variance components-based pedigree analysis is a valid approach to test for association in related individuals, as long as a QTL linkage component is included in the model to account for the non-independence of family members at that point in the genome. Here, we have used analytical and simulation-based methods to examine the power of such an approach as a function of the family size/structure, the strength of evidence of linkage, the degree of linkage disequilibrium and the effect size of a functional variant. We observe that the power to detect association is diminished in a sample of related individuals versus a sample of unrelated individuals of the same size. However, using all individuals in the association analysis while simultaneously accounting for their overall and pointwise genetic similarity is much more powerful than using only unrelated individuals in the association analysis. The general implication is that the power to detect association in a sample of related individuals previously used for linkage analysis can be substantial, even if the number of unrelated individuals embedded in the families is small.

Sanfilippo syndrome type D: Natural history and identification of three novel mutations in the GNS gene. *E. Andermann[1,2], H. Cao[3], P. Kaplan[4], K. Silver[5], L. De Meirleir[6], M. Veilleux[2], F. Andermann[2], W. Lissens[7], R.A. Hegele[3], A. Jansen[6]* 1) Departments of Human Genetics, McGill University; Neurogenetics Unit, Montreal Neurological Hospital and Institute, Montreal, PQ, Canada; 2) Department of Neurology and Neurosurgery, McGill University, Montreal, Canada; 3) Robarts Research Institute, and University of Western Ontario, London, Ontario, Canada; 4) Biochemical Genetics, Childrens Hospital of Philadelphia, Philadelphia, USA; 5) Paediatric Neurology, The University of Chicago Childrens Hospital, Chicago, Illinois, USA; 6) Department of Pediatric Neurology, UZ Brussel, Brussels, Belgium; 7) Department of Medical Genetics, UZ Brussel, Brussels, Belgium.

Background: Mucopolysaccharidosis (MPS) IIID or Sanfilippo syndrome type D is a rare autosomal recessive lysosomal storage disorder caused by mutations in the GNS gene on chromosome 12q14. Objective: We have studied the natural history of MPS IIID in two siblings of Italian ancestry who were reported by Kaplan and Wolfe in 1987. In addition, we report the phenotype in two other unrelated families with MPS IIID and have identified three novel mutations in the GNS gene. Methods: Clinical and molecular data on three families with enzyme based diagnosis of MPS IIID were collected. Results: The course of the disease was characteristic for MPS IIID in all four patients, although survival may be longer than was previously reported. In Family 1, both siblings were homozygous for a novel nonsense mutation in the GNS gene (p.Gln390Ter). In Family 2, the proband carried a heterozygous mutation occurring in a splicing recognition site in the intron 7 boundary c.876-2A>G. The second mutation in this patient remains to be identified. In Family 3, the proband was homozygous for a novel frameshift mutation in GNS (p.Asp380GlyfsX9). Conclusions: Major issues in the care of MPS IIID patients include behavioral problems, recurrent infections and pain from orthopedic complications. To date, all mutations in the GNS gene predict premature termination of translation, and there is no obvious genotype-phenotype correlation.

Utility of microarrays in characterizing two patients with 11q deletions and clinical features of Jacobsen syndrome. *C. Haldeman-Englert[1], D.M. McDonald-McGinn[1], E. Geiger[1], L. Medne[1,2], C. Bonnemann[1,2], K. Brigatti[1], N.B. Spinner[1], E.H. Zackai[1], T.H. Shaikh[1]* 1) Human Genetics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Neurology, Children's Hospital of Philadelphia, Philadelphia, PA.

Terminal deletions of 11q have previously been associated with Jacobsen syndrome (11q23-qter), which is characterized by FTT, thrombocytopenia, MR and dysmorphia. Here we report two patients with overlapping deletions of 11q identified cytogenetically, which we have further characterized using high-density oligonucleotide arrays. Patient 1, a 5 month-old male, had a perimembranous VSD, ASD, umbilical hernia, undescended testis, hypotonia with resultant motor delay, FTT and dysmorphia. Patient 2, a 3 year-old male, had unilateral cerebellar and vermis hypoplasia, coarctation of the aorta, thrombocytopenia, truncal ataxia, hyperreflexia, global developmental delay with autistic behaviors and dysmorphia. Patient 1 was found to have an 11q terminal deletion using standard cytogenetic techniques [46,XY,del(11)(q24)], whereas, Patient 2 was initially reported to have an interstitial 11q deletion [(46,XY,del(11)(q24.2q25)]. However, using high-density oligonucleotide array we more precisely mapped the proximal breakpoint in Patient 1s 11 Mb deletion to 11q24.1 and Patient 2s 5.7 Mb deletion to be nested within the deletion of Patient 1. Of note, Patient 2 appears to have the smallest 11q interstitial deletion reported to date which contains 20 genes. Importantly, one of the genes, *FLI-1*, is thought to be associated with hematopoiesis, and haploinsufficiency of this gene may effect platelet production causing thrombocytopenia, as seen only in Patient 2. In summary, the cases presented here do in fact have some overlapping features of Jacobsen syndrome, but they do not match entirely and have smaller deletions. Thus, using high-density oligonucleotide microarrays to analyze identified patients with 11q deletions will certainly help to further characterize the nuance of this diagnosis and may provide important genotype-phenotype correlations which will aide in providing appropriate management and counseling.

Phylogenetic analysis in 14 primates reveals positive selection in the C-terminal domain of the cholesterol metabolism gene *PCSK9*. *K. Ding, S.J. McDonough, I.J. Kullo* Division of Cardiovascular Diseases, Mayo Clinic, Rochester, MN.

Cholesterol homeostasis is maintained through finely tuned mechanisms regulating dietary uptake, hepatic biosynthesis and secretion as well as plasma clearance. The low-density lipoprotein (LDL) receptor gene (LDLR) plays a key role in cholesterol homeostasis by receptor-mediated endocytosis of LDL cholesterol. *PCSK9* (proprotein convertase subtilisin/kexin type 9), is a newly discovered regulator of LDLR that encodes a secreted enzyme of the serine protease family and reduces cellular uptake of plasma LDL cholesterol by promoting LDLR degradation. An evolutionary analysis of *PCSK9* may aid in the identification of conserved elements with functional importance. In addition, non-conserved regions involved in the generation of novel biological functions may also be detected. We compiled the sequences of the coding regions of *PCSK9* from 14 primates in the clade of Hominids, Old World monkeys and New World monkeys (sequences for six species were downloaded, and eight species were resequenced in our laboratory). A comparative analysis describing the evolutionary relationships across the primate *PCSK9* gene was carried out. The ratios of nonsynonymous/synonymous substitution rate (d_N/d_S) under different evolutionary models (e.g., one-ratio model and free-ratio model) were calculated across the phylogeny of *PCSK9* to detect selective pressure at the protein level. Maximum likelihood analyses of d_N/d_S ratios for the aligned coding regions sequences among 14 primate species suggested that *PCSK9* was subject to a strong functional constraint (i.e., purifying selection). However, a relaxed selective constraint or positive selection was noted in the functional carboxyl-terminal (C-terminal) domain of *PCSK9* across the phylogeny, especially in the lineage leading to the orangutan. Further, at least five positively selected amino acids were detected using the branch-site model A (i.e., the Bayes Empirical Bayes probability > 0.95) in the lineage leading to the orangutan. We speculate that differential selective pressure among primates has shaped evolutionary patterns in different functional domains of *PCSK9*.

MRI and MRA brain anomalies in 22q11 Deletion Syndrome. *E. Chow[1,2], D.J. Mikulis[3,4], A.S. Bassett[1,2]* 1) Department of Psychiatry, Univ Toronto, Toronto, ON; 2) Clinical Genetics Research Program, Centre for Addiction and Mental Health, Toronto, ON; 3) Department of Medical Imaging, University of Toronto, ON; 4) Department of Medical Imaging, Toronto Western Hospital, Toronto, ON, Canada.

22q11 Deletion Syndrome (22qDS) is associated with congenital cardiac defects (CHD), cognitive dysfunction, and psychiatric conditions including schizophrenia (SZ). This study aims to systematically assess for anomalies in brain, skull, and head and neck vessels in a large group of adults with 22qDS. A neuroradiologist blind to the deletion and psychiatric status of subjects systematically reviewed multi-planar sequences MRI brain scans and MR angiography (MRA) through the circle of Willis and neck vessels of 65 adults with 22qDS (26 M, 39F; mean age = 26.4y, SD = 9.6y) and 20 adults without 22qDS (10 M, 10 F;mean age = 29.6y, SD = 7.4y) for visually detectable anomalies. The 22qDS sample comprised of 28 subjects with SZ (22qDS-SZ) and 37 with no history of psychosis (22qDS-NP), and the comparison sample comprised of 11 subjects with SZ and 9 with no history of psychosis. Rates of anomalies in cortical and subcortical structures, skull base, circle of Willis and neck blood vessels were compared between the 22qDS and non-22qDS subjects and their subgroups. The 22qDS subjects had significantly more anomalies than the non-22qDS subjects, especially in the skull base, the most common being an enlarged C1, present in 39%; of 22qDS subjects and only 5%; of comparison subjects (p=0.0045). Cerebellar atropy, but not cortical atrophy, was also more common in 22qDS subjects (17% vs 0%; in comparison subjects; p=0.047). On MRA, low bifurcation of the carotid arteries was more common in 22qDS subjects than in comparison subjects (32% vs 6%, p=0.049), even though both groups had similar rates of CHD. When comparing 22qDS-SZ subjects to 22qDS-NP subjects, the two subgroups had similar age, IQ and rates of CHD, but the 22qDS-SZ subgroup had more intracanial anomalies such as cavum anomalies, cortical atrophy, and bright foci. The results suggest that in 22qDS intracranial anomalies are more associated with a history of psychosis, and skull base and vascular anomalies with the genetic condition.

Analysis of the interdependency of Pearson correlation (r^2) and p-values from association tests and development of an evaluation tool. *J.L. Curry[1,2], Y.J. Li[1]* 1) Ctr Human Genetics, Duke Univ Medical Ctr, Durham, NC; 2) Biomathemetics Program, Dept of Statistics, North Carolina State Univ, Raleigh, NC.

Pearson correlation (r^2) is the most frequently used measurement for linkage disequilibrium (LD) between two markers. An r^2 ranges from 0 to 1 where 0 signifies no linkage disequilibrium and 1 indicates complete linkage disequilibrium. An LD block or LD bin is arbitrarily defined as r^2 >1/3. By definition, markers within an LD block evolve together and play the same role if they are involved in the development of the disease. Due to this reason, genotyping a tagging SNP (1 represented SNP per block) has been a favorable approach in association studies. However in real data analysis there tends to be a discrepancy between the LD indicated by r^2 and the association signified by p-values. The relationship between r^2 and the p-value from association tests has not been widely investigated. We revisited the theoretical relationship of association test statistics and r^2 and we performed an intensive simulation to examine the impact of r^2 to the p-values derived from population and family based association tests. We created both family based and population based simulations of multiple sample sizes with a range of marker to marker correlations from 0 to 1 and with various disease locus to marker correlations from 0 to 1. We used PDT and chi-squared tests to find significant p-values and thus ascertain proper cut-offs of r^2 depending on the relation of marker to disease locus. We developed a program that will provide assembled visualization of the p-values as they relate to Pearsons correlation and will determine accurate cut-offs of r^2 for verifying association results for both population and family based association tests.

Polymorphisms in the SNAP25 gene are associated with early-onset bipolar affective disorder. *S. Jamain[1, 2], B. Etain[1, 2, 3], A. Dumaine[1, 2], F. Mathieu[1, 2], F. Chevalier[1, 2], J. Deshommes[1, 2], C. Henry[4], J.P. Kahn[5], F. Bellivier[1, 2, 3], M. Leboyer[1, 2, 3]* 1) INSERM U 841, IMRB, dept of Genetics, Psychiatry Genetics, Creteil, F-94000, France; 2) University Paris 12, Faculty of Medicine, IFR10, Creteil, F-94000, France; 3) AP-HP, Henri Mondor-Albert Chenevier Group, Department of Psychiatry, Creteil, F-94000, France; 4) Department of Psychiatry, Charles Perrens Hospital, Bordeaux, France; 5) Psychiatry and Clinical Psychology Department, CHU de Nancy, Jeanne-d'Arc Hospital, 54200 Toul, France.

The gene encoding the synaptosomal associated protein-25 kDa (SNAP25) has been associated to attention-deficit hyperactivity disorder (ADHD) in several independent studies. This gene is located on chromosome 20p12, in a region that we recently reported to be more frequently shared in early-onset bipolar affective disorder (BPAD) families, which is known to be a frequent ADHD comorbid condition. As an altered level of SNAP25 has been reported in bipolar patients brains, we assumed that ADHD and early-onset BPAD may share common susceptibility variants in SNAP25. To test this hypothesis, we genotyped 7 polymorphisms along the SNAP25 gene in 197 patients with early-onset BPAD, 202 patients with late-onset BPAD and 136 unaffected subjects. Among patients, 154 were also assessed for ADHD symptoms. Early-onset BPAD was associated with two variants of SNAP25, one located in the promoter region ($p=0.005$) and another in the intron 7 of the gene ($p=0.04$). These associations were not explained by comorbid ADHD. Haplotype analysis showed the strongest association for a 4-markers haplotype in the 5 region of the gene ($p=0.002$), whereas the haplotype previously associated to ADHD was located in the 3UTR. Altogether, these results suggest SNAP25 may be divided in two blocks of haplotypes, one located in the 5 part of the gene and containing a susceptibility variant for early-onset BPAD, and a second located in the 3UTR and leading to ADHD vulnerability. This result may explain the high comorbidity rate between the two disorders.

Screening for 15q duplications/triplications using real-time PCR. *S. Bleoo, S. Chan, D. Hildebrand, N.J. Leonard, J.S. Bamforth, L. Vicen, M.J. Somerville* Department Medical Genetics, University of Alberta & Stollery Children's Hospital, Edmonton, AB, Canada.

Duplications and triplications of the proximal arm of chromosome 15 have been reported in patients with developmental delay and in patients with autistic behaviour. As developmental delay is one of the most frequent indications for molecular testing in our lab, we designed a real-time PCR assay to detect copy number variations at this locus. Our assay included probes within the SNRPN, UBE3A and GABR3 genes. This assay failed to detect any new cases of 15q duplication in our sample population which included 238 patients referred for developmental delay. However, this assay correctly identified a 15q triplication in a developmentally delayed male patient who demonstrated abnormal maternal dosage by Southern blot analysis for Angelman syndrome. This patient presented to genetics at age 30 months with hypotonia, and global developmental delay, including fine and gross motor skills, social and language skills. In addition to this patient, we have also been able to confirm two 15q duplication cases initially detected through cytogenetic analysis. One involves a fetus with a maternal 15q duplication; this fetus was subsequently terminated. Although there are very few reports that support the pathogenicity of paternal 15q duplications, our second case involved three brothers who each inherited a 15q11-13 duplication from their father. The father and all three of his sons have intellectual delays and the father has been diagnosed with schizophrenia. Therefore, we conclude that 15q duplications and triplications, although not common in our developmentally delayed population, are rapidly detected though a real-time PCR assay. Our data also provide evidence that some paternal 15q duplications are likely pathogenic.

Genetic Analysis of Serum BDNF Levels. *M. Carless[1], D. Glahn[2], J. Curran[1], H. Goring[1], L. Almasy[1], M. Johnson[1], T. Dyer[1], E. Moses[1], J. Blangero[1]* 1) Southwest Foundation for Biomedical Research, San Antonio, TX; 2) University of Texas Health Science Center at San Antonio, San Antonio, TX.

Serum levels of brain-derived neurotrophic factor (BDNF) represent an important biomarker for a growing number of brain-related disorders, particularly major depression. However, little is known about the genetic factors influencing normal BDNF serum level variation. To examine the genetic determinants of this quantitative endophenotype, we measured serum BDNF using a commercial ELISA assay in existing samples from 867 Mexican American individuals who are members of approximately 40 large extended pedigrees. All of these individuals have been previously genotyped for a 10cM genome-wide scan. Using variance-component-based analysis, we estimated the heritability of BDNF serum levels to be 0.286 0. 067 ($p = 2.1 \times 10^{-8}$). A genome-wide linkage analysis identified a single QTL in chromosomal region 22q13 (LOD score=3.90, nominal p-value=1.1×10^{-5}; genome-wide p-value=0.004). Three other genomic regions (chromosomal regions 1p32, 3p26, and 19p13) exhibited suggestive evidence for linkage with LOD scores greater than 2. To empirically nominate positional candidate genes in this region, we examined lymphocyte-derived transcriptional profiles in relation to serum BDNF levels. In the 6Mb 1-LOD support interval for the QTL on chromosome 22, we identified a *cis*-regulated (p-value=0.002) transcript for the gene *UPK3A*, whose expression level was significantly correlated with serum BDNF (p-value=0.019). We are currently examining sequence variation within the *BDNF* structural locus and the *UPK3A* candidate gene to identify specific genetic variants that may influence BDNF levels. Our demonstration of a significant genetic component to BDNF levels provides support for its utility as a quantitative endophenotype that may be useful as a measurable risk factor for various brain-related disorders.

Deficiency of a member of the immunoglobulin superfamily causes a form of C (Opitz trigonocephaly) syndrome.

T. Kaname[1, 11], K. Yanagi[1], Y. Chinen[2], Y. Makita[4], N. Okamoto[5], H. Maehara[3], I. Owan[3], F. Kanaya[3], Y. Oike[6], T. Yamamoto[7], K. Kurosawa[7], Y. Fukushima[8, 11], J.M. Opitz[9], K. Yoshiura[10, 11], N. Niikawa[10, 11], K. Naritomi[1, 11] 1) Dept Medical Genetics, Univ Ryukyus, Nishihara, Japan; 2) Dept Pediatrics, Univ Ryukyus, Nishihara, Japan; 3) Dept Orthopedics, Univ Ryukyus, Nishihara, Japan; 4) Dept Pediatrics, Asahikawa Medical College, Asahikawa, Japan; 5) Osaka Medical Center and Research Institute for Maternal and Child Health, Izumi, Japan; 6) Dept Mol Genet, Kumamoto Univ, Kumamoto, Japan; 7) Kanagawa Children's Medical Center, Yokohama, Japan; 8) Dept Medical Genetics, Shinshu Univ, Matsumoto, Japan; 9) Dept Pediatrics, Pathology, Obstetrics and Gynecology, and Human Genetics, Univ Utah Schl Med, Salt Lake City, UT; 10) Dept Hum Genet, Nagasaki Univ Graduate School of Biomedical Sciences, Nagasaki, Japan; 11) SORST, Japan Science and Technology, Kawaguchi, Japan.

The C syndrome is characterized by trigonocephaly associated with unusual facies, psychomotor retardation, redundant skin, joint and limb abnormalities, and visceral anomalies. In an individual with the C syndrome harboring a balanced chromosomal translocation, t(3;18)(q13.13;q12.1), we identified a gene (*OTCS*), which encodes a member of the immunoglobulin superfamily, was disrupted at the 3q13.3 breakpoint. In mutation analysis of nine karyotypically normal patients with the C or C-like syndromes, we identified a missense mutation in exon 6 of the *OTCS* gene in one patient. The missense mutation was not found among 420 normal Japanese individuals. Cells with the mutated OTCS protein lost adhesion and growth activities in vitro. These findings may indicate that OTCS mutations cause a form of the C syndrome by interfering with cell adhesion and growth.

Comparisons of genome diversity between the Okinawan and four HapMap populations. *W.-C. Hsueh[1], Q. He[2], D.C. Willcox[2,3,4], M. Suzuki[4], J.W. Chen[1], R. Chen[2], K. Yano[2], T. Donlon[2], J.D. Curb[2], J. Grove[2], W.S. Browner[1,5], S.R. Cummings[1,5], M. Boehnke[6], P.-Y. Kwok[1], B.J. Willcox[2]* 1) UCSF, San Francisco, CA; 2) Pacific Health Research Institute, Kuakini Medical Center & Univ. of Hawaii, Honolulu, HI; 3) Okinawa International Univ., Okinawa, Japan; 4) Okinawa Research Center for Longevity Science, Okinawa, Japan; 5) California Pacific Research Institute, San Francisco, CA; 6) Univ. of Michigan, Ann Arbor, MI.

The Okinawans reside on an island prefecture of Japan and have among the worlds greatest longevity. We conducted a pilot genome-wide study to investigate (a) whether Okinawans are genetically similar to Japanese and Chinese, as has been historically documented, and (b) whether they may be more homogeneous than these two populations.
We genotyped 26 DNA samples from randomly selected Okinawans using the Affymetrix 500k GeneChips and compared the genetic diversity of their genomes to 26 randomly selected subjects from each of 4 HapMap samples (West Africans, Caucasians, Japanese, and Chinese; or YRI, CEU, JPT and CHB). Previous studies have shown strong similarity between the JPT and CHB genomes compared to the CEU, and the YRI genome is more diverse. Based on data from ~345k SNPs available in all 5 samples, we observed that Okinawan allele & haplotype frequencies are similar to those of the JPT and CHB than the CEU or YRI, but that the Okinawan samples showed increased linkage disequilibrium (LD) and somewhat decreased haplotype diversity compared to the JPT and CHB samples. For instance, in 300 kb chromosomal segments, the 10 most common haplotypes on average account for 83% of haplotypes present in Okinawans, compared to 61% in JPT and CHB, 55% in CEU and only 38% in YRI.
Our findings suggest that information from the HapMap Project and commercial high-throughput genotyping platforms will be useful for genetic studies in the Okinawans, and that while Okinawans are genetically similar to Chinese and Japanese, they show reduced genetic diversity. This reduced genetic diversity may increase the coverage and hence the power of LD-based genetic association studies for complex traits such as longevity.

Genotyping Triallelic SNPs in Drug Metabolizing Enzymes. *T. Ceccardi, T. Hartshorne, C. Chen* Molecular Cell Biology, Applied Biosystems, Foster City, CA.

Applied Biosystems currently offers over 2,500 TaqMan SNP Genotyping Assays for Drug Metabolizing Enzyme (DME) genes. These genes are involved in the processes that break-down and eliminate chemicals, such as drugs or carcinogens, in the human body. Single nucleotide polymorphisms (SNPs) or mutations in these genes can affect their functionality. Knowing their genotypes can be critical during pharmaceutical development and clinical trials. Although commercially available TaqMan DME Genotyping Assays detect many of the most important genetic mutations, some highly-valued SNP assays were not yet designed since they did not follow the rules necessary for successful automated design. One of the rules broken by these high-value SNPs is that, rather than being typical biallelic SNPs where one nucleotide base is substituted for another, three different nucleotide bases or tri-alleles are seen in the human population. When testing these triallelic SNPs, a researcher would like to know the frequency of all three alleles. However, standard FAM/VIC-labeled TaqMan assays only measure two alleles. Here we examined two different approaches for triallelic SNP genotyping. The first was by running two FAM/VIC-labeled assays, each with a probe for the major allele and one of the minor alleles, and analyzing the resulting two cluster plots in concert, with a map of expected cluster positions. Alternatively, a probe for the third allele was labeled with a third dye (NED), and mixed together with FAM and VIC probes which target the first two alleles. We designed assays for two different triallelic SNPs to test the two alternate workflows and analysis methods. We found that although the workflow is simpler for a 3-probe triallelic SNP assay, it is complicated in data analysis to resolve all possible allele/dye combinations.

The challenge of counseling families with results of unclear clinical significance by array CGH as illustrated by duplications of the BCR gene region at 22q11.23. *J. Coppinger[1], D. McDonald-McGinn[2], E. Zackai[2], K. Shane[3], J.F. Atkin[3], R. Leland[4], K. Schmidt[5], H. Feldman[5], W. Cohen[5], J. Phalin[6], B. Powell[6], B.C. Ballif[1], B.A. Bejjani[1,7,8], T. Shaikh[2], S. Saitta[2], L.G. Shaffer[1]* 1) Signature Genomic Laboratories, LLC, Spokane, WA; 2) Children's Hospital of Philadelphia, PA; 3) Columbus Children's Hospital, The Ohio State University, Columbus, Ohio; 4) Cheyenne Childrens Clinic, Cheyenne WY; 5) Childrens Hospital of Pittsburgh, PA; 6) Childrens Hospital Central California, Madera, CA; 7) Sacred Heart Medical Center, Spokane, WA; 8) Health Research and Education Center, Washington State University, Spokane, WA.

Deletions of the BCR locus at 22q11.23 have recently been described in individuals with mental retardation and congenital anomalies. Because these deletions are mediated by low-copy repeats, which are located distal to the 22q11.21 DiGeorge/VCF microdeletion region, duplications of the BCR locus are expected to occur with equal frequency. We have processed over 13,000 clinical array CGH cases and have detected 11 duplications of 22q11.23. In seven cases, the duplication was also detected in a parent, two of whom reportedly have learning problems or developmental delay. Of the remaining four cases, one is *de novo*, and three await parental studies. The *de novo* case has an ~368 kb duplication. Four cases (three familial, one awaiting parental studies) have a duplication of an overlapping ~677 kb region, and six cases (two familial/normal parents, two familial/delayed parent, and two awaiting parental studies) have a duplication of an overlapping ~848 kb region. Medical records, available for seven patients, reveal shared characteristics but also several examples of contradicting clinical features (e.g. macrocephaly vs. microcephaly, upslanting vs. downslanting palpebral fissures). The variable phenotypes and preponderance of familial cases necessitate further studies. Increased clinical use of array CGH will result in more frequent genetic counseling dilemmas. Using the 22q11.23 duplication cases as a model, we present counseling strategies for array CGH results of unclear clinical relevance.

Evaluation of the Vyent Cystic Fibrosis Kit, IUO* and NanoChip 400 System for cystic fibrosis newborn screening using dried blood specimens. *G. Hoffman, G. Kopish* Newborn Screening Lab, Wisconsin State Laboratory of Hygiene, Univ. of WI, Madison, WI.

Purpose: The Wisconsin (WI) protocol for CF newborn screening consists of a two tier screen where the highest 4% of the daily immunoreactive trypsinogen (IRT) specimens tested are followed with a DNA test for the 23 mutation panel recommended by ACOG & ACMG. Currently, WI uses the reverse dot blot linear array (Roche, Inc) for DNA testing. The lab evaluated the Vyent Cystic Fibrosis Kit with the automated NanoChip 400 System (Nanogen, Inc) as an alternative CFTR DNA test. The evaluation assessed (1) fit into a routine screening environment, (2) ability to correctly genotype samples, (3) work flow, (4) robustness for newborn screening. **Methods:** DNA extracts were analyzed side-by-side with the linear array and the NanoChip 400. A total of 500 specimens were analyzed in 25 assays over eight weeks. Specimens with known mutations were rotated in each run so all 23 mutations detected with the kit were tested. Reproducibility was assessed by analyzing a standard set of specimens in each run. **Results:** The NanoChip 400 is an automated allele detection system that fits on a standard bench top. The system software and operation were easy to learn and transferable between staff. Concordance for all markers between methods was 100%; (n= 6,003) for 261 specimens and controls analyzed. There were no low signals or indeterminate calls made during the study. Results of the specimen set repeated in each run showed no discrepancies and there was no deterioration in assay performance (e.g. fluorescent signal), showing the assay to be robust and reproducible. The average hands-on time with the linear array was about 5 hours per run while the automated NanoChip 400 reduced the time to about 30 minutes per run excluding DNA preparation (same for both methods). **Conclusions:** The Vyent Cystic Fibrosis Kit when used with the NanoChip 400 is a robust, accurate, highly automated method that significantly reduces the hands-on time for detecting CFTR mutations in dried blood spot specimens for newborn screening. *Investigational Use Only. Performance characteristics have not been established.

Validity of gene testing for neurofibromatosis 1 mutations by direct DNA sequencing. *J.L. Hatfield, R. Rojas, S.M. Purandure, J.J. Mulvihill, S. Li* Department of Pediatrics, University of Oklahoma, Oklahoma City, OK.

Neurofibromatosis (NF1) is one of the most common dominant neurogenetic disorders, affecting 1 in every 3500 individuals worldwide. The NF1 gene spans 350 kb of genomic DNA, containing 60 exons and encoding 12 kb of mRNA. Detection of NF1 mutations is a challenge because of the diversity of genetic mutations, the absence of mutational clustering, the size of the gene, and the existence of numerous pseudogenes. Currently, detection of NF1 mutations is approached by FISH, protein truncation test, and DHPLC followed by DNA sequencing. We used a whole NF1 cDNA screening methodology to study 84 individuals, including 45 definite clinical patients (both familial and sporadic by NIH criteria), 16 normal individuals as controls, and 23 patients with some clinical suspicion of NF1. After informed consent, RNA from peripheral blood was obtained from each individual using the total RNA purification kit (Qiagen). The RNA was reverse transcribed using Superscript II reverse transcriptase (Gibco, BRL). The entire NF1 cDNA was amplified in 15 overlapping fragments, ranging from 562 to 982 nucleotides. The size of the PCR products was verified by electrophoresis in 2% agarose gels before sequencing. Different types of novel and known mutations have been identified in the patient group and, as expected, no pathogenic mutation has been found in the control group. Of the 23 suspected patients, 12 had mutations, most considered pathogenic. Gene testing, especially in young or sporadic cases, performs well in resolving diagnostic uncertainty.

Gastrointestinal Disorders in Patients with Hypermobile or Classical Ehlers-Danlos Syndromes. *A. Gustafson[1], B.F. Griswold[2], L. Sloper[2], M. Lavallee[4], C.A. Francomano[3], N.B. McDonnell[2]* 1) Brown Univ, Providence, RI; 2) LCI, NIA/NIH, Baltimore,MD; 3) GBMC,Baltimore, MD; 4) IUSM, South Bend, IN.

Ehlers-Danlos syndromes (EDS) are a heterogeneous group of hereditary disorders of connective tissue that are characterized by joint, skin, and vascular abnormalities. Most literature reports of gastrointestinal (GI) involvement in EDS have been limited to patients with vascular EDS. Patients with vascular EDS have abnormalities of type III collagen, a constituent of the bowel wall, and thus prone to GI complications and bowel rupture. Patients with other types of EDS, however, also report GI dysfunction. Complete physicals and medical histories were obtained from 90 patients with hypermobile or classical types of EDS enrolled in the National Institutes on Aging protocol 2003-086, Clinical and Molecular Manifestations of Heredity Disorders of Connective Tissue. We found a high prevalence of GI manifestations in this cohort of patients, including severe chronic constipation (17%), irritable bowel syndrome (12%), acid reflux or gastroesophageal reflux disease (14%), and/or chronic abdominal pain (22%). Gastroparesis was noted in four subjects. The prevalence of each of these disorders was significantly higher in our cohort ($P<.0001$) compared with the general population. In our cohort, lack of tissue integrity may cause structural abnormalities, decreased blood vessel wall strength, and/or altered motility or absorption, which may all contribute to development of GI disorders.

Genotype-phenotype correlation in patients with bicuspid aortic valve and aneurysm. *K.C. Kent[1], M.L. Loscalzo[1], D.LM Goh[1], A.L. Cutting[1], H.C. Dietz[1,2]* 1) Institute of Genetic Medicine, Johns Hopkins School of Medicine, Baltimore, MD; 2) HHMI, Baltimore, MD.

Bicuspid aortic valve (BAV) is the most common congenital cardiac defect occurring in 1-2% of individuals. BAV segregates in an autosomal dominant manner with decreased penetrance. BAV is often associated with ascending aortic aneurysm (AscAA). Four BAV/AscAA families with *NOTCH1* mutations have been described. In this study, we sought to determine the contribution of *NOTCH1* mutations to familial BAV/AscAA. We sequenced all exons and splice junctions of *NOTCH1* in probands from 13 affected families. Only 2 changes were identified that were not previously reported as polymorphic variants. Both were synonymous substitutions that did not have an intuitive affect on mRNA processing or stability. There are important phenotypic differences that distinguish families with and without *NOTCH1* mutations. Those with *NOTCH1* mutations show highly penetrant BAV, with uniform presence of early valve calcification and aortic stenosis (AS) and low incidence of aneurysms. In contrast, the more typical presentation of BAV/AscAA, as exemplified in all of our families, shows highly penetrant aortic aneurysm and absent aortic valve calcification. Furthermore, many relatives of individuals with BAV/AscAA show the predisposition for early onset AscAA and dissection without associated BAV or AS. These data suggest that perturbation of Notch signaling has a predominant effect on valve calcification, morphology and function, and that aortic aneurysm may occur secondary to hemodynamic perturbations in this setting. The more common presentation of BAV and aneurysm does not relate to *NOTCH1* and aortic aneurysms in this context are a direct manifestation of an underlying gene defect, which still remains to be identified. Given the variable age of onset of AscAA, these data also mandate ongoing imaging follow-up of relatives of affected individuals with or without BAV.

A mutation in *APOA4* causes an autosomal dominant form of inflammatory bowel disease (IBD). *B.A. Johannes[1], B.G. Elyas[1], M. Hicks[1], S.M. Haase[1], J.S. Bamforth[1,2], H.F. Pabst[2], M.A. Walter[1], K.A. Sprysak[1], L.M. Vicen[1], M.J. Somerville[1,2]* 1) Dept Medical Genetics, University of Alberta, Edmonton, AB, Canada; 2) Dept Pediatrics, University of Alberta, Edmonton, AB, Canada.

The causes of inflammatory bowel disease (IBD), characterized by inflammation of the large and/or small bowel, remain largely unknown. We report on the cause of a severe autosomal dominant form of IBD (Familial Enteropathy with Villous Edema [FEVE; OMIM 600351]) that typically manifests in childhood as a recurrent acute, life-threatening secretory diarrhea associated with distinctive jejunal histologic changes and IgG2 subclass deficiency. Genome-wide linkage analysis on a Mennonite kindred linked FEVE to D11S908 on chromosome 11q23 with a LOD score of 6.2 at theta = 0. A higher density microsatellite marker array refined the critical region to a 2 Mb interval between D11S4142 and D11S1364. We sequenced the open reading frames of nine genes from this critical region before identifying a 198 bp (66 aa) in-frame duplication in the *apolipoprotein (apo) A-IV* gene (APOA4) that segregates with disease in this family. This mutation was not detected in 200 unrelated controls (400 chromosomes). Apolipoprotein A-IV is a 46-kDa protein that is synthesized in the small intestine, upregulated in response to high lipid uptake, and secreted into the mesenteric lymphatic system on chylomicrons. In addition to apoA-IVs involvement in lipid transport, lipoprotein metabolism, and reverse cholesterol transport, recent evidence suggests that it acts as an endogenous anti-inflammatory protein. This has been demonstrated through dextran sulfate sodium-induced experimental colitis in Apoa4 knockout mice. ApoA-IV plasma levels have also been found to be inversely associated with disease activity in Crohns disease patients. Our results, combined with those from previous reports, implicate APOA4 as a susceptibility gene for IBD. Identification of this APOA4 mutation in FEVE warrants further investigation into its role in IBD as well as the anti-inflammatory function of apoA-IV in the gastrointestinal system.

Molecular survey of human Leber congenital amaurosis disease(LCA) in a consanguineous family collection from Saudi Arabia. *R. Chen[1,2,3], Y. Li[1,2], J. Peng[1,2], H. Wang[1,2], K. Lee[1], R. Gibbs[1,2,5], S.M. Leal[1,2], W. Lewis[2,4,6,7], J. Lupski[2,5,7], M.S. Bray[2], G. Mardon[2,3,4,5]* 1) Human Genome Sequencing Center,; 2) Molecular & Human Genetics,; 3) Program of Developmental Biology,; 4) Department of Ophthalmology,; 5) Program in Cell & Molecular Biology,; 6) Department of Medicine,; 7) Department of Pediatrics, Baylor College of Medicine, Houston, TX.

Leber congenital amaurosis (LCA) is the most common hereditary cause of visual impairment in infants and children and affects nearly 1 in 15,000 in the general population. Unfortunately, to date, no medical or surgical intervention has been shown to alter the natural course of LCA, nor has any pharmacologic therapy shown effect on modulating or moderating its progression. However, gene therapy has corrected the blinding phenotype in animal models of selected genetic forms and human clinical trials are in progress.

Analysis of the known LCA genes in patient collections indicates that many additional LCA genes remain to be identified. It has been estimated that mutations in known LCA genes account for about 63% of all cases. To clone additional LCA disease genes, we have collected DNA samples from 38 consanguineous geographically distinct families with recessive LCA. Among them, disease-associated markers in one family were previously mapped to the LCA3 locus on chromosome 14. These families have been screened for mutations in all coding exons of all twelve known LCA genes. As a result, known and novel mutation alleles have been identified in 9 families. Therefore, LCA-associated mutations in the other 28 families remain to be determined. Computer simulations indicated that several families are large enough to independently establish linkage or are sufficiently large to have a high conditional probability of being linked to one locus (LOD score > 3). Progress of analyzing these families will be reported.

***VNN1*, A Novel Gene for Cardiovascular Disease Risk.** *J.E. Curran[1], M.P. Johnson[1], H.H.H. Göring[1], T.D. Dyer[1], J.C. Charlesworth[1], S.A. Cole[1], J.B. Jowett[2,3], L.J. Abraham[4], D.L. Rainwater[1], M.C. Mahaney[1], L. Almasy[1], J.W. MacCluer[1], A.H. Kissebah[5], G.R. Collier[3], E.K. Moses[1], J. Blangero[1,3]* 1) Southwest Foundation for Biomedical Research, San Antonio, TX; 2) International Diabetes Institute, Caulfield, Vic; 3) ChemGenex Pharmaceuticals, Geelong, Vic; 4) University of Western Australia, Perth, WA; 5) Medical College of Wisconsin, Wisconsin, WI.

Our study describes an integrative approach to gene discovery utilizing large-scale transcriptional profiling to identify novel *cis*-acting genes that correlate with HDL cholesterol levels, a risk factor for CVD. Lymphocyte-based RNA samples from 1240 individuals in the San Antonio Family Heart Study were used to obtain genome-wide transcriptional profiles. Statistical analysis identified over 400 *cis*-regulated transcripts whose expression levels significantly correlated with HDL-C levels. One gene, *VNN1*, showed strong support for both *cis*-regulation ($p=1.2\times10^{-11}$) and correlation with HDL-C levels ($p=5.7\times10^{-9}$). *VNN1* expression levels were also significantly correlated with triglycerides (p=0.002), ApoA1 (p=0.0003), ApoA2 (p=0.0014) and LDL peak diameter (8.7×10^{-5}). Given the evidence for *cis*-effects, we resequenced 2kb of the promoter in 96 founders, identifying 22 SNPs. Genotyping in the cohort revealed 5 variants highly correlated with *VNN1* expression: -587 ($p=7\times10^{-85}$), -137 ($p=6\times10^{-83}$), -612 ($p=2\times10^{-36}$), -708 ($p=3\times10^{-34}$) and -667 ($p=8\times10^{-7}$). The variants at sites -667 ($p=3\times10^{-5}$) and -137 ($p=4\times10^{-4}$) also showed strong associations with HDL-C levels. Molecular analyses of the -137 variant using EMSA supported a functional role for this SNP. To identify genes causally downstream of *VNN1*, we tested for the *trans*-effects of *VNN1* promoter variants on the transcriptional profiles. *VNN1* variants were associated with expression levels of several lipid metabolism/CVD-risk genes including *LPL* (p=0.03), *LCAT* (p=0.03), *LRP3* (p=0.018), *ACAT2* (p=0.001) and *IL10* (p=0.001). These results support a significant role for *VNN1* in HDL-C variation, and show the value of transcriptional profiling for identifying genes reflecting causal relationships with complex phenotypes.

Evolutionary, structure-function and physiological considerations of a second mitochondrial ornithine transporter, ORNT2. *J. Camacho, D. Nguyen, N. Rioseco-Camacho* Dept Pediatrics, Univ California, Irvine, CA.

Human ORNT2 is a functional retroposon and member of the mitochondrial carrier subfamily (MCF) of proteins that includes ORNT1, SLC25A20 (carnitine), SLC25A29 (carnitine and ornithine) and SLC25A45 (unknown function). Although a functional ORNT2 protein is present in mammalian species, ORNT2 is not functional in rodentia. Clinically, ORNT2 is important because it may act as a modifier gene in patients with ORNT1 deficiency (Hyperornithinemia-Hyperammonemia-Homocitrullinuria (HHH) syndrome) and is very likely responsible for the residual mitochondrial ornithine transport seen in these patients cell lines. Previous studies of HHH patients revealed three ORNT2 polymorphisms that increased (V181G), decreased (G159C) or had no effect on function (V226I). V181G is noteworthy because it occurs in the putative solute recognition site located in the 4th transmembrane domain (TMD) of ORNT1 & ORNT2, a region containing most of the documented ORNT1 mutations, and is prominent in controls of American Indian descent. Our current goal is to determine if ORNT2 polymorphisms differ in their geographic distribution and to characterize the level of residual ornithine transport in control fibroblast cell lines carrying different ORNT2 polymorphisms. Results demonstrate that both G159C and V226I polymorphisms are prevalent in controls of Old World descent; conversely, the V181G change is more prevalent in controls of New World descent. To achieve our second objective, we knocked down (KD) the ORNT1 gene using targeted siRNAs in cultured human and mouse cell lines. Our preliminary siRNA work demonstrates that the ORNT1 mRNA can be significantly KD 24 hours after electroporation. Functional studies are under way. In conclusion, our preliminary observations suggest that changes in ORNT2 amino acids may have been under selective pressure. A caveat of our work is that seemingly neutral amino acid changes may actually have an important integrative physiological function given their unequal frequency distribution. Our work will further elucidate the potential contribution of MCF protein polymorphisms to the variable phenotype of metabolic disorders such as HHH syndrome.

COALESCENT SIMULATION OF GENOME WIDE ASSOCIATION DATA IN ADMIXED POPULATIONS.

G. Chen[1], S. Kim[1], R. Varma[2,3], P. Marjoram[2], J. Wall[1] 1) Institute for Human Genetics, University of California, San Francisco, CA; 2) Department of Preventive Medicine, Keck School of Medicine, USC, Los Angeles, CA; 3) Doheny Eye Institute and Department of Ophthalmology, Keck School of Medicine, USC, Los Angeles, CA.

Genome wide association (GWA) studies have quickly become a popular approach for elucidating the genetic variants that contribute to the susceptibility of common diseases. Issues regarding the design of GWA studies such as the appropriate sample size or marker density for a desired level of power and specificity in a target population can be addressed by analysis of simulated data reflecting assumptions about that populations history. A widely used model-based approach for simulations is the coalescent, which models the genealogy of a set of sampled chromosomes from the present time back to their most common recent ancestor. Current implementations of the coalescent that precisely incorporate recombination are limited to simulating only short stretches of DNA due to memory constraints. We present an implementation which can more efficiently simulate SNP data across entire chromosomes by providing a close approximation to the coalescent. The simulator also provides the user with the flexibility of modeling population events such as growth (i.e. instantaneous or exponential), population splitting, migration between sub-populations, and sub-population merging, which may be relevant for modeling admixed study populations. We compare summary statistics (e.g. LD decay, haplotype diversity) of data generated from our program to those of real genotype data generated from Affymetrix 500k genotyping arrays in a study of age related macular degeneration in Latinos, a population known to share European and Native American ancestry.

The Tip60 chromatin remodeling complex functions in the Fanconi anemia pathway of DNA interstrand crosslink repair. *J. Hejna, M. Holtorf, A. Hemphill, A. Starks, P.M. Jakobs, Y. Akkari, M. Al-Dhalimy, S.B. Olson, R.E. Moses* Molecular and Medical Genetics, Oregon Health and Science University, Portland, OR.

Fanconi Anemia (FA) is a rare, recessive disease that results in pancytopenia, hematological malignancies, and head and neck cancer. FA cells display genomic instability, which is exacerbated by DNA interstrand crosslinking (ICL) agents. A core FA complex composed of FA proteins interacts with FANCD2 and is required for its activation by monoubiquitination in response to DNA damage. BRCA2/FANCD1, also associates with FANCD2. FANCD2 interacts with a similar protein, FANCI, which is also monoubiquitinated and required for the FA pathway. We have identified the histone acetyltransferase Tip60 as another FANCD2-interacting protein by a yeast two-hybrid screen. Interaction of Tip60 and FANCDC2 was also demonstrated by co-immunoprecipitation and co-localization. The Tip60-interacting region of FANCD2 has been mapped to roughly the same region shown to interact with BRCA2. Site-directed mutagenesis of the acetyl-CoA binding pocket of Tip60 abrogated the interaction with FANCD2. Mutation of FANCD2 lysine 561 to arginine, preventing monoubiquitination, did not alter the interaction. Tip60 has been implicated in repair of ionizing radiation damage. In view of the association of Tip60 with FANCD2, we asked whether depletion of Tip60 in immortalized human fibroblasts sensitized them to ICL agents. Cell survival of Tip60-depleted GM639 cells was significantly reduced after treatment with Mitomycin C. We then tested whether depletion of another member of the Tip60 complex, the RuvB homolog, Tip49, would also lead to increased sensitivity to MMC. Tip49 depletion in GM639 cells gave an FA-like increase in chromosomal aberrations in response to MMC. In summary, there is a direct interaction between FANCD2 and Tip60, independent of the ubiquitination state of FANCD2, but which requires the acetyltransferase domain of Tip60 and a region of FANCD2 that also binds to BRCA2. Our findings establish a role for the Tip60 chromatin remodeling complex in ICL repair.

Clinical and pathological characteristics of Lewy Body disorders in patients with Glucocerebrosidase mutations.

L.N. Clark[1,2,10], R. Wolf Gilbert[3], B. Dorado[1,2], L. Kartsaklis[5], B.M. Ross[1,2], E.D. Louis[1,3,5], L.J. Cote[3,5], H. Andrews[4,5,6], C. Waters[3], B. Ford[3], S. Frucht[3], R. Ottman[3,5,7,8], J.P. Vonsattel[1,2,9], S. Fahn[3], L.S. Honig[3,5], K. Marder[1,3,4,5] 1) Taub Institute for Research on Alzheimers Disease and the Aging Brain; 2) Department of Pathology; 3) Department of Neurology; 4) Department of Psychiatry; 5) G.H. Sergievsky Center, College of Physicians and Surgeons, Columbia University, New York; 6) Department of Statistics; 7) Department of Epidemiology, Mailman School of Public Health, Columbia University, New York; 8) The Epidemiology of Brain Disorders Department, New York State Psychiatric Institute, New York; 9) The New York Brain Bank; 10) The Center for Human Genetics, College of Physcians and Surgeons, Columbia University, New York.

Background: Mutations in the Glucocerebrosidase (GBA) gene have been associated with pathologically proven Lewy body disorders (LBD). Methods: We sequenced all GBA exons in 61 samples enriched for LBD from the NYBB. Results: 24.6 % (15/61) were mutation carriers. Among non-carriers, 72.4% of cases who had cortical LB also had definite or probable AD (CERAD), whereas among carriers, 21.4% had both cortical LB and definite or probable AD. (p=<0.001) .In a logistic regression model, GBA mutation status was associated with cortical Lewy bodies (OR 19, 95% CI 2-175; p=0.009) after adjustment for age, gender, and definite or probable AD. AD pathology was an independent predictor of cortical Lewy body pathology in this sample (OR 14, 95% CI 3-67; p=0.001). In separate Cox Regression models, adjusting for age of onset of Parkinsonism and gender, no association was found between 1) the age of onset of dementia, 2) the time of progression from parkinsonism to dementia, or 3) the rate of developing dementia prior to parkinsonism with mutation status. Conclusions: The presence of GBA mutations may be associated with both cortical Lewy bodies and dementia, independent of AD pathology.

Identification and replication of FAM5C polymorphisms associated with myocardial infarction. *J.J. Connelly[1], A.B. Hale[1], S. Gadson[1], J.F. Doss[1], X. Lou[1], D.R. Crosslin[1], S.H. Shah[1,2], D.C. Crossman[3], C.B. Granger[1], V. Mooser[4], C.J.H. Jones[5], J.M. Vance[6], P.J. Goldschmidt-Clermont[6], W.E. Kraus[2], E.R. Hauser[1], S.G. Gregory[1]* 1) Department of Medicine and Center for Human Genetics, Duke University, Durham, NC; 2) Department of Medicine and Division of Cardiology, Duke University Medical Center, Durham, NC; 3) University of Sheffield, Sheffield, United Kingdom; 4) Genetics Research, GlaxoSmithKline, Collegeville, PA; 5) University of Wales College of Medicine, Cardiff, United Kingdom; 6) Miller School of Medicine, University of Miami, Miami, FL.

We previously identified a 40 Mb region of linkage on chromosome 1q in our early onset coronary artery disease (CAD) genome-wide linkage scan (GENECARD) with modest evidence for linkage (n=420, LOD 0.95). When the data are stratified by acute coronary syndrome (ACS), this modest maximum in the overall group became a well-defined LOD peak (maximum LOD of 2.17, D1S1589/D1S518). This peak overlaps a recently identified inflammatory biomarker (MCP-1) linkage region from the Framingham Heart Study (maximum LOD of 4.27, D1S1589) and a region of linkage to metabolic syndrome from the IRAS study (maximum LOD of 2.59, D1S1589/D1S518). The overlap of genetic screens in independent data sets provides evidence for the existence of a gene or genes for CAD in this region. We conducted a peak-wide association screen (457 SNPs) of the region 1 LOD score down from the peak marker (168-198 Mb) on chromosome 1. We identified polymorphisms within the family with sequence similarity 5, member C gene (FAM5C) that show genetic linkage and are associated with ACS (rs1891586, maximum LOD=1.54, p=0.027). We have confirmed the association with an independent case-control dataset (CATHGEN, p=0.023) and have identified strong association (p=0.0003) between FAM5C and myocardial infarction. In addition, several risk alleles of FAM5C show association with atherosclerotic burden (rs11581737, rs480692, rs12732902, odds ratio 2.5-5.0). FAM5C is known to promote proliferation, migration and invasion of pituitary tumors; a phenotype relevant to the cellular changes associated with the formation of an atherosclerotic plaque.

Molecular Diagnosis of Primary Carnitine Deficiency. *F.R.O. Calderon[1], L. Shwarz[1], C. Amat di San Filippo[4], M. Pasquali[1,2,3], N. Longo[1,2,3,4], R. Mao[1,2,3]* 1) ARUP Inst Clin Exp Pathology, Salt Lake City, UT; 2) Dept Pathology, Univ Utah, Salt Lake City, UT; 3) ARUP Laboratories, Salt Lake City, UT; 4) Dept Pediatrics, Univ Utah, Salt Lake City, UT.

Background: Primary carnitine deficiency is an autosomal recessive disorder of fatty acid oxidation due to defective OCTN2 carnitine transporters. Affected patients can present with hypoglycemia, liver failure and/or cardiomyopathy and diagnosis of this disorder is confirmed by measurement of carnitine transport activity in cultured skin fibroblasts. Here we evaluate full-gene sequencing of the SLC22A5 gene encoding the OCTN2 carnitine transporter as an alternative diagnostic tool. Methods: The 10 exons of the SLC22A5 gene including exon/intron boundaries were amplified by PCR and bi-directionally sequenced in 23 patients with known fibroblast transport activity. Novel missense mutations were analyzed for conservation and functionally expressed in CHO cells. Results: DNA sequencing identified 83% of mutant alleles, allowing a correct diagnosis in 9 out of 13 patients whose fibroblasts had defective carnitine transport (<10% of control). Expression of novel missense mutations (G15W, P46L, A214V, T232M, R399W) in CHO cells confirmed a pathogenic effect of the variations identified. Our results were collected into a locus-specific mutation database for primary carnitine deficiency. Conclusion: Full-gene sequencing of the SLC22A5 gene can identify causative mutations in the majority of cases of primary carnitine deficiency. Measurement of carnitine transport in fibroblasts can completely exclude primary carnitine deficiency in patients with negative DNA studies.

Spondylocostal dysostosis with preaxial polydactyly: a new entity? *M.J. Rodovalho-Doriqui[1], L.R. Giuliani[2], C.M. Lourenço[1], C.D. Martinhago[1], J.M.de Pina-Neto[1]* 1) Medical Genetics Division, Clinical Hospital of Ribeirão Preto - São Paulo University, Ribeirão Preto-SP, Brazil; 2) Pediatrics/Medical Genetics Division, Federal University of Mato Grosso do Sul, Campo Grande-MS, Brazil.

Spondylocostal dysostosis (SCDO) is a genetic Mendelian disorder with autosomal recessive inheritance. Findings include segmentation and formation defects throughout cervical, thoracic and lumbar spine such as hemivertebrae, block vertebra and unsegmented bars with fusion of the ribs at the costo-vertebral junction. Zeller et al (1982) described an unusual association between spondylocostal dysostosis and preaxial polydactyly in a 22 old month boy. We report two patients with spondylocostal dysostosis and preaxial polydactyly. Case 1. Male, 17 years old, the first child of a young, healthy and non-consanguineous couple. He had normal psychomotor and pubertal development. Physical examination showed stature bellow the 3rd percentile, short neck, scoliosis and preaxial polydactyly of the left hand. The radiological findings consisted of hemivertebrae, cervical and thoracic fused vertebrae and costal fusion in superior portion of left hemithorax. Case 2. Female, 1 year and 7 months old, the first child of healthy and non-consanguineous parents. She had normal psychomotor development. Her clinical exam showed stature bellow the 3rd percentile, severe scoliosis and preaxial polydactyly of her right hand. Her x-rays showed segmental defects of thoracic and cervical spine and marked costal anomalies. Abdominal ultrasonography, blood karyotype and echocardiography of both patients were normal. Radiographs of the spines of other members of both families were normal. The rare association between spondylocostal dysostosis and polydactyly suggests a particular pattern of malformation whose etiology seems different from the classical SCDO caused by mutations in DLL3 and MESP2 genes.

Duplication 22q11.2: Clinically Heterogeneous New Syndrome or Genetic Polymorphism? *J.A. Bernstein[1], F.S. Alkuraya[2], L. Armstrong[3], K.C. Chen[1], C. Clericuzio[4], J.M. Graham[5], J. Stoler[2], H.M. Saal[6], C.A. Stevens[7], A.M. Cherry[1], H.E. Hoyme[1]* 1) Stanford School of Medicine, Stanford, CA; 2) Children's Hospital Boston, Boston, MA; 3) B.C. Children's Hosptial, Vancouver, B.C. Canada; 4) University of New Mexico, Albuquerque, NM; 5) Cedars-Sinai Medical Center, Los Angeles, CA; 6) Cincinnati Children's Hospital, Cincinnati, OH; 7) T.C. Thompson Children's Hospital, Chattanooga, TN.

Duplication of 22q11.2 has been described as the mechanism underlying a recently recognized condition featuring a range of physical and developmental abnormalities. We are aware of 50 reported cases. Duplication of 22q11.2 is expected to occur at equal frequency as its deletion, however, the duplication syndrome has been diagnosed much less frequently. This apparent underdetection may result from the clinical variability of the syndrome. In case reports common features include dysmorphic facies, cleft palate, congenital heart disease, poor postnatal growth, seizures and cognitive impairment. However, significant inter- and intrafamilial variation has been described.

In an effort to refine our understanding of duplication 22q11.2, we present twelve new cases from eight families. Our cases demonstrate many recognized characteristics of the syndrome. However, they also include manifestations not previously described: cyclic vomiting, hemihyperplasia, congenital hypothyroidism and radial aplasia. Notably, three of our cases are parents of affected children who carry duplication 22q11.2 without significant clinical sequelae.

Our observations expand the range of anomalies associated with duplication 22q11.2. The finding of unaffected parents carrying the duplication suggests complicated inheritance for this syndrome. Alternatively, duplication 22q11.2 may represent a polymorphism that has incidentally been detected in patients with unrelated conditions. We expect duplication 22q11.2 will be identified increasingly with greater clinical awareness and expanded use of array-CGH. Further study of families with this duplication will be needed to distinguish a new syndrome from a possible polymorphism.

Characterizing the Factor V Leiden (FVL) thrombophilia phenotype: A model to tackle the genetic architecture of complex diseases. *F. Gagnon[1], D.E. Bulman[2], P.S. Wells[2]* 1) Public Health Sciences, University of Toronto, Toronto, ON, Canada; 2) Ottawa Health Research Institute, Ottawa, ON, Canada.

Venous thromboembolism (VTE) is a common complex disease with known environmental risk factors and a well-characterized major gene variant, FVL. FVL thrombophilia is associated to a single point mutation in the factor V gene leading to the Activated Protein C Resistance phenotype, which is associated to an increased risk of VTE. This disorder has an autosomal dominant inheritance and a population frequency of 2-15%, and up to 60% in VTE cases. The predictive clinical value of FVL is limited since only 20-50% of heterozygous individuals develop VTE despite accounting for other known risk factors. Experimental evidence suggests that this variability is more likely due to modifier genes than unknown environmental factors. Several genetically determined hemostatic- and lipid-related quantitative traits (QT) have been associated to VTE but their distributions in specific thrombophilias are unknown. Thus, we are taking advantage of the well-characterized FVL variant to identify genes implicated in VTE. Our major objective is to identify the modifier genes in FVL thrombophilia, and our main strategy is to capitalize on the several QT associated to VTE. We have recruited 7 large French-Canadian families (n=306) through simplex ascertainment of probands with both VTE and FVL. Over 30 QT from the hemostatic and lipid pathways, as well as several putative environmental covariates (e.g. hormonal therapy, smoking), have been collected on all family members. The specific aims of this paper are to phenotypically characterize FVL thrombophilia based on generalized linear models accounting for familial dependences; and to present results from Bayesian Markov chain Monte Carlo-based oligogenic segregation analyses; e.g. In a large meta-analysis, we recently reported that a factor XIII A-subunit variant has a protective effect against VTE. Here, we report that plasma factor XIII activity is significantly higher in FVL carriers vs. non-carriers, and that it is correlated to several lipid-related QT (e.g. plasma cholesterol), as well as other hemostatic QT including plasma levels of factor V.

Genomewide Association Studies: Performance of genomic and WGA DNA sources on Illumina GWA arrays. *K. Hetrick, C. Bark, J. Gearhart, E. Kwasnik, M. Zilka, C. Ongaco, Y. Tsai, J. Romm, E. Pugh, K. Doheny* Center for Inherited Disease Research (CIDR) and Genetic Resources Core Facility (GRCF) SNP Center, IGM, JHUSOM, Baltimore, MD.

CIDR is a centralized facility established to provide genotyping and statistical genetics services for investigators seeking to identify genes that contribute to human disease. Currently we offer GWA SNP genotyping services using Illumina Infinium products. Optimal data quality is obtained from lymphoblast cell line or peripheral blood DNA sources; however, many studies have a limited amount of blood-derived DNA, or only have DNA from other sources. We have conducted a few small-scale controlled experiments exploring the impact of DNA source on data quality and compiled retrospective empiric performance data for all samples run on Illumina Infinium II GWA arrays that we have analyzed to date. Genomic DNA derived from blood samples results; 98.7% (5,463 out of 5,534) sample completion rate (sample call rate 96.5%) after one assay attempt per sample (cut-off set by 0.1% error rate after two assay attempts); average call rate of successful samples, 99.7%. 35.2% (25 out of 71) of the failed blood samples appear to contain multiple genomes when reviewing theta value distributions across the genome. In a completed study of 2,563 blood samples, 61.1% (11 out of 18) of the samples below a 96.5% call rate were recovered after re-attempting them. WGA samples (Amersham Biotech, conc. 100 ng/ul) derived from blood DNA results; 91.7% (143 out of 156) sample completion rate (sample call rate 90%) after clustering the WGA samples with blood samples (cut-off set by call rate distribution); average call rate of successful WGA samples, 97.9%. In a controlled experiment using the HumanHap550 BeadChip, paired WGA/genomic samples were analyzed using a SNP cluster definition derived from a study where both blood and WGA samples were analyzed together. 7 WGA (QIAGEN, conc. 100-200ng/ul)/blood pairs (a trio and a tetrad) results; average call rate, 98.94%; reproducibility between pairs, 99.99%; Mendelian heritability, 99.96%. Analysis of WGA samples derived from other sources is ongoing.

The development of a sarcoma FISH profile to detect recurrent translocations in soft tissue sarcomas. *A.W. Carlson, R.A. Knudson, B.M. Shearer, R.P. Ketterling* Division of Laboratory Genetics, Mayo Clinic, Rochester, MN.

Soft tissue sarcomas (STS) belong to a histologically and genetically heterogeneous group of cancers, accounting for approximately 1% and 7% of all adult and childhood malignancies, respectively. Establishing a precise diagnosis can be challenging due to similar clinical presentations, morphologic appearance and overlapping immunohistochemical staining patterns. The discovery of specific translocations associated with various sarcoma subtypes has led to the development of genetic assays to detect these recurrent rearrangements. Interphase FISH, adapted to formalin-fixed paraffin-embedded tissue, is a rapid and highly sensitive technology that allows for the detection of several specific gene rearrangements associated with various sarcoma subtypes. We have validated the application of several commercially available FISH probes to detect rearrangements involving various sarcoma-related genes, including FKHR (13q14) for alveolar rhabdomyosarcoma; CHOP (12q13) for myxoid liposarcoma; SYT (18q11.2) for synovial sarcoma; EWSR1 (22q12) for Ewings/PNET, clear cell sarcoma and desmoplastic small round cell tumor; and ALK (2p23) for inflammatory myofibroblastic tumor. We have evaluated at least 20 tumors of each sarcoma subtype and proven the effectiveness of FISH testing for detection of these recurrent gene rearrangements. In addition, via the inclusion of 25 normal paraffin-embedded tissues in the evaluation of each probe set, we have established normal cut-offs for each sarcoma probe. The recent clinical implementation of this sarcoma FISH profile has allowed the application of these FISH assays into various clinical algorithms for both diagnostic and follow-up testing in specific sarcoma subtypes. The detection of tumor specific translocations represents an extremely useful diagnostic tool as an adjunct to classical surgical pathology.

Genetic discrimination: a survey of cancer genetics professionals knowledge, attitudes, and practices. *C. Huizenga[1], K. Lowstuter[2], K.C. Banks[3], V. Vandergon[1], C.S. Malone[1], V.I. Lagos[2], J.N. Weitzel[2]* 1) California State University, Northridge, Northridge, CA; 2) Clinical Cancer Genetics Department, City of Hope National Medical Center, Duarte, CA; 3) St. Joseph Hospital, Orange, CA.

Genetic discrimination is an issue of concern among health care providers as well as patients. Lack of knowledge about anti-genetic discrimination laws as well as attitudes about genetic discrimination risk among health care providers may serve as a barrier to obtaining cancer genetics services. This study aimed to assess knowledge, attitudes, and practices regarding genetic discrimination among cancer genetics professionals (CGPs), determine if attitudes of CGPs regarding genetic discrimination have changed over time by comparing our findings to those of previous studies investigating this topic, and to compare CGPs knowledge and attitudes regarding anti-genetic discrimination laws to that of primary care providers (PCPs). The PCP data were obtained from an unpublished study conducted at City of Hope National Medical Center. A 39 question, anonymous, internet-based survey was conducted of the National Society of Genetic Counselors Familial Cancer Special Interest Group. One hundred and fifty three responses were obtained (34% response rate). The mean total knowledge score of CGPs regarding anti-genetic discrimination laws was significantly greater than that of PCPs ($p<0.001$). A higher percentage of CGPs in this study than in a previous study said that if they were to undergo genetic testing, they would bill their insurance for the cost of genetic testing. The majority of CGPs (94%) perceived the current risk of genetic discrimination to be low, very low, or theoretical and 64% expressed confidence in the current federal anti-genetic discrimination legislation. These results show that CGPs have a higher level of knowledge regarding anti-genetic discrimination laws than PCPs, that concern about genetic discrimination has decreased among CGPs since earlier studies, and that the majority of participants have confidence in current legislation and perceive the risk of genetic discrimination to be low to theoretical.

Association of Interleukin-1 beta (IL1B) Gene and Risk of Intracranial Hemorrhage in Brain Arteriovenous Malformation Patients. *P.G. Hysi[1], H. Kim[1], L. Pawlikowska[1], C. McCullough[4], J. Zaroff[5], D. Marchuk[6], M. Lawton[2], P-Y. Kwok[3, 7], W.L. Young[1]* 1) Center for Cerebrovascular Research, Department of Anesthesia and Perioperative Care, UCSF, San Francisco, CA; 2) Departments of Neurological Surgery, UCSF, San Francisco,CA; 3) Cardiovascular Research Institute, UCSF, San Francisco, CA; 4) Departments of Epidemiology and Biostatistics, UCSF,San Francisco,CA; 5) Cardiology Department, San Francisco, CA Kaiser Permanente San Francisco, CA; 6) Department of Molecular Genetics and Microbiology, Duke University Medical Center, Durham, NC; 7) Cardiovascular Research Institute, UCSF, San Francisco, CA.

Polymorphisms in the proinflammatory cytokine interleukin-1 beta (IL1B) gene have been associated with increased risk of brain ischemic injury and subarachnoid hemorrhage. IL1B expression levels are also upregulated in primary intracerebral hemorrhage patients. To determine if genetic variants in IL1B are associated with intracranial hemorrhage (ICH) in the clinical course of brain arteriovenous malformation (BAVM) patients, we genotyped two promoter SNPs (-511C>T and -31T>C) and one synonymous coding SNP in exon 5 (+3953C>T) in 414 BAVM patients. Kaplan-Meier survival analysis censoring patients at first treatment, death or last follow-up, and Cox regression analysis adjusting for age, white race, and gender effects were performed. BAVM patients with the -31 CC genotype (HR=2.8, 95%CI=1.2-6.7, p=0.02) or -511 TT genotype (HR=2.7, 95%CI=1.1-6.6, p=0.03) had a greater risk of subsequent ICH compared to reference genotypes, whereas the +3953C>T SNP was not associated with ICH in the clinical course. These promoter polymorphisms were in strong linkage disequilibrium (r2=0.95) and were also associated with AVM susceptibility among Caucasians. The -511 C>T SNP has been shown to influence IL1B protein production in vitro and the -31 T>C SNP lies in a TATA box transcription initiation site. Our data suggest that functional promoter variants in IL1B may play a role in ICH and BAVM pathogenesis, and warrants further investigation.

The frequency and distribution of normal copy number variants (CNVs) in subjects with an autism spectrum disorder (ASD) and/or idiopathic intellectual disability (ID). *C. Fawcett[1, 6], Y. Qiao[1, 2, 6], C. Harvard[1, 6], C. Tyson[1, 6], X. Liu[3, 6], JJA. Holden[3, 4, 5, 6], MES. Lewis[2, 6], E. Rajcan-Separovic[1, 6]* 1) Dept Pathology, and; 2) Medical Genetics, UBC, Vancouver, Canada; 3) Dept Psychiatry, and; 4) Physiology, Queens Univ, Kingston, Canada; 5) Autism Research Program, Kingston; 6) ASD-Canadian American Research Consortium (www.autismresearch.com).

Copy number variants (CNVs) have been shown to be widely distributed throughout the genome of neurodevelopmentally normal individuals using high resolution techniques including array CGH. However, the nature and significance of the CNVs remain unknown. Using commercial 1 MB array CGH, we assessed the frequency and type of known CNVs in 90 ASD and 84 ID subjects and compared them to the reported findings in the normal population (http://projects.tcag.ca/variation) as well as our own cohort of 27 control subjects. For the top 5 recurrent clones (each 10% in frequency), 4 of them (RP11-259N12: 1p13.3, RP11-100C24: 13q21.1, RP11-125A5: 14q12, and RP11-79F15: 19p13.2) were shared between the two patient groups and no significant difference in frequency was found, while clone RP11-88L18 (5p15.1) was more prevalent in the ASD and clone RP11-9H12 (9q32) in the ID group. The total frequency of each of the top 5 clones in both patient groups was within the range observed for these clones amongst unaffected individuals. No correlation was found between the type of CNV (gain or loss) for the top 5 clones in each group, except for clone RP11-88L18, which was seen 10 times more often as a loss than a gain only in the ASD group. RP11-125A5 was previously reported to have a high frequency of variation in neoplasia (50% compared to 10% reference), suggesting increased genomic instability associated with the disorder. Our study has found no difference in the frequency or type of copy number for the 4 of the 5 most common CNVs observed to date in our studies of ASD and ID subjects, suggesting that their link to these neurobiologic disorders is unlikely. Additional studies on RP11-88L18 are warranted to determine the significance of the prevalent loss of this region in ASD.

Large scale clinical application of QF-PCR for Rapid Prenatal Diagnosis of Common Chromosome Aneuploidies.

V. Cirigliano[1,2], G. Voglino[3], A. Marongiu[3], E. Ordoñez[1,2], A. Plaja[1], C. Fuster[2], M. Adinolfi[4] 1) General Lab, Barcelona, Spain; 2) Biologia Celular. Universitat Autònoma de Barcelona Bellaterra, Spain; 3) Promea-Day Surgery Turin Italy; 4) University College London U.K.

Rapid prenatal diagnoses of common aneuploidies can be performed using microsatellites amplified by Quantitative Fluorescent PCR (QF-PCR). The assay was introduced as preliminary investigation to remove parental anxiety while waiting for the results of cytogenetic analysis. Main advantages of the molecular assay are its low cost, speed and automation allowing large scale application. We developed a highly informative QF-PCR assay that was applied to systematically screen 38.000 consecutive prenatal samples with results issued within 24 hours. The most common referral indications were raised biochemical risk (32%) and advanced maternal age (30%), 6% of these cases were also associated with increased nucal translucency; parental anxiety generated 22% of samples and abnormal ultrasound findings were present in 7 % of fetuses. All samples were also tested by conventional cytogenetic analysis and results compared. In most cases a normal chromosome complement was correctly assessed by QF-PCR without false positive results. All 1278 non mosaic aneuploidies involving chromosomes 21, 18 and 13 were identified with 100% sensitivity and specificity. Several cases of partial trisomies and chromosome mosaicisms could also be detected. The assay proved efficient and reliable allowing early termination of affected pregnancies without waiting for cytogenetic analysis. Despite being deliberately targeted to investigate only disorders affecting three autosomes (21, 18 and 13) and the two sex chromosomes, we show that QF-PCR can detect the great majority of chromosome abnormalities in a few hours after sampling. Our results raise the possibility of reducing the load of conventional prenatal cytogenetics if all pregnancies are also monitored by careful application of biochemical and ultrasound tests in the first trimester. In countries where large scale cytogenetics is hampered by its cost and lack of technical expertise QF-PCR may be used as the only prenatal diagnostic test.

X-Linked Mental Retardation Snyder-Robinson Type, second report in a Mexican family. *L.E. Becerra[1,3], G. Castañeda-Cisneros[2,3], J.E. García-Ortíz[1,3], J. Sánchez-Corona[2,3]* 1) Division de Genética, CIBO, IMSS, Guadalajara, Jalisco, Mexico; 2) División de Medicina Molecular, CIBO, IMSS, Guadalajara, Jalisco, México; 3) Doctorado en Genética Humana, CUCS-UdeG, Guadalajara, Jalisco, México.

Snyder and Robinson syndrome (OMIM 309583) is defined as a X-linked mental retardation syndrome with characteristic habitus (marfanoid), diminished muscle bulk, osteoporosis, facial asymmetry, a prominent lower lip, nasal voice, narrow or cleft palate, and long, thin fingers and toes; in some an unsteady gait, nonspecific movement disorder, and seizures. By linkage analysis was identified the related gene on Xp21.3-p22.12(spermine synthase gene). Here we described a Mexican family with Snyder-Robinson syndrome (SRS) with two individuals aged 28 and 21 year-old, respectively, born from healthy parents (at present mother 47 and father 60 year-old, respectively). They showed psychomotor development delay, thin habitus, facial asymmetry with prominent lower lip (more evident in younger brother), thoracic kyphoscoliosis, thin finger and toes, osteoporosis, and fractures (the older was more affected). In both: normal karyotype, negative molecular X-fragile test, lower bone density (-3.22 SD), and lower platelet count. X-ray studies shows: normal cranial computed axial tomography; thickened calvarium; lower bone density, long and thin tubular bones with thin cortex, the older had thoracic kyphoscoliosis, and asymmetric bent femur. The differential diagnosis included: Lujan-Fryns syndrome (OMIM 309520) tshares thin habitus, mental retardation, speech defects, X-linked recessive inheritance, but macrocephaly, long and triangular face, delayed skeletal maturation, hypoplasia of corpus callosum and heart anomalies are not recorded in SRS; Fragoso syndrome (OMIM 248770) shares thin habitus, lower bone density, scoliosis, hypotonia and mental retardation but facial asymmetry, prominent lower lip, and fractures are not referred, and its inheritance is recessive; Martin-Bell syndrome (OMIM 309550) sharing mental retardation, X-linked inheritance, but not macrocephaly, heart anomalies, and the molecular studies were negative.

Pharmacogenomic Testing of CYP450 2C9, VKORC1 and Thrombophilic Factor II and Factor V using the Warfarin Sensitivity-Resistance Panel the INFINITI Analyzer. *P. Hujsak, Y. Fu* R&D, AutoGenomics, Inc, Carlsbad, CA.

Warfarin targets the vitamin K epoxide reductase complex 1 (VKORC1) enzyme and affects the down stream proteins in Vitamin K metabolic cascade. Warfarin is metabolized mainly in humans by Cytochrome P450 2C9 (CYP450 2C9). Effective warfarin dosing has been correlated with genetic variants of both enzymes. Thrombophilic Factor II and Factor V mutations could affect Warfarin dosing of patients because of increase in blood clotting. Therefore, identifying an individuals genotype of these four enzymes may help determine initial Warfarin therapy levels and long term International Normalized Ratio (INR), thus ensuring maximum safety. We have developed a multiplex Warfarin-Sensitivity-Resistance (WSRP) pharmacogenetic assay for genotyping VKORC1, CYP450 2C9, Factor II, and Factor V using the BioFilmChip and the INFINITI Analyzer. Multiple alleles in each DNA sample are analyzed in a single tube by PCR amplification (off line), followed directly by Detection Primer Extension (DPE) using the INFINITI Analyzer. The INFINITI Analyzer performs SNP analysis by hybridizing the DPE product to universal molecular OligoZip immobilized on the BioFilmChip. For the VKORC1 enzyme, we are testing non-coding SNPs: C381T, C861A, G3673A, T5808G, G6853C and G9041A, and coding SNPs: G5396C, G5417T, T5445C, A5483G, G6642A and T8798G. For CYP450 2C9, the following SNPs are being tested: C430T (*2), A1075C (*3), C1080G (*5), and 818delA (*6). Our comprehensive panel also includes testing for Factor II G20210A and Factor V G1691A (Leiden) are also tested. Results obtained from 150 different samples using the WSR-P test correlated well with the standard known methods such as sequencing. This robust assay for genotyping VKORC1 coding and non-coding regions, and detecting mutations in the CYP450 2C9, Factor II and Factor V genes in individuals could be potentially useful in managing Warfarin therapy safely and effectively, and may account for differences in ethnic populations.

Perennial challenges in genetic screening policy-making. *A. Andermann[1,2], I. Blancquaert[1,3], S. Beauchamp[1]* 1) Agence dévaluation des technologies et des modes dintervention en sante (AETMIS), Montreal, Canada; 2) McGill University, Montreal, Canada; 3) Université de Montréal, Montreal, Canada.

INTRODUCTION: Genetic screening policy-making is highly complex and deals with many sensitive issues on multiple levels. A systematic approach is therefore needed to promote greater transparency and accountability. OBJECTIVES: As part of a longer process in the development of a decision guide for genetic screening policy-making that included a series of literature reviews and consultations, local and international experts were consulted to determine whether a draft of the guide was considered useful and how well it addressed challenges in genetic screening policy-making. METHODS: Self-completion questionnaires and a copy of the draft decision guide were sent to 66 local and international experts and high-ranking officials in the fields of population-based screening, public health and genetics as well as 51 stakeholders who had been involved in previous consultations. Reminders were sent to non-respondents. Data was analyzed using thematic coding and validated using an inter-judges technique. RESULTS: With an overall response rate of 29% (n=34/117), it was considered that the decision guide is an improvement over existing lists of criteria. In particular, the decision guide attempts to address and make explicit many of the perennial challenges in genetic screening policy-making, including: 1) the lack of evidence with regard to rare diseases, 2) balancing individual-level and population-level concerns, 3) ensuring the protection of individuals and communities, and 4) ultimately reaching consensus as to whether the benefits outweigh the risks of screening. CONCLUSIONS: Although it may not be possible to entirely resolve all perennial issues associated with genetic screening policy-making, the decision guide encourages documentation of evidence, trade-offs, and reasoning underpinning recommendations, thus promoting greater transparency, and allowing decisions to be revisited over time.

Clinical Presentation of Newly or Rarely Described Chromosomal Rearrangements. *J. Alfardan, G. Scharer, J. Thomas, R. Gallagher, D. Manchester, A. Tsai* UCHSC, TCH, Department of Pediatrics, Division of Genetics, Denver, CO.

Introduction: We describe 16 patients referred to our genetic service for developmental delays and/or congenital anomalies over a 6 month period and diagnosed with new or rare chromosomal rearrangements. Most of the rearrangements have not been described. Testing included HRC, FISH and/or DNA array and parental testing. **Patients 1 and 2:** 8 yo girl presented at birth with ASD, dysmorphy and global delays. HRC/FISH showed a small dup 7p22.1-22.2. Her mother has the same rearrangement but showed a milder phenotype. Presentation resembles larger dup 7p. We suggest that 7p22.1-22.2, specifically 7p22.1, is a dup 7p critical region. **Patient 3:** 6 yo boy with global delays and dysmorphy. DNA array showed del 13q32.3-33.1 and included ZIC2 gene. **Patients 4, 5 and 6:** 3 and 6 yo sisters with global delays and dysmorphy. Their mother had early developmental delays. The three have del 16q24.2-24.2 detected by DNA array. **Patients 7 and 8:** 6 yo boy with global delays and seizures. DNA array showed dup 5p13.2. His mother, who had normal development, has the same duplication. **Patients 9, 10 and 11:**(Pt 9 and 10) are unrelated 15 yo girl and 5 yo boy with dysmorphy and global delays. Mother (pt 11) of the 5 yo had multiple miscarriages, dysmorphy and cognitive impairment. HRC for those patients showed del 8q21.12-21.3. **Patient 12:** 1 week old boy with TOF, dysmorphy, and club foot. HRC showed del 9q34.2. **Patients 13 and 14:** 1 yo boy with developmental delays whose DNA array showed dup 8p23.3. His father also tested positive but had normal early development. **Patients 15 and 16:** 1 day old girl with dilated aortic arch, dysmorphy and hypotonia. Her mother had two miscarriages and reported early learning disabilities. Both have del 4q35.2-35.2. **Results:** We documented several newly/rarely reported chromosomal rearrangements. While some are de novo, others familial. Of the latter, some parents showed similar phenotype while others reportedly normal. **Conclusion:** We recommend DNA array for patients with developmental delays and/or congenital malformations as a first or second tier genetic testing. If a parent is also positive, this does not automatically indicate a polymorphism.

Evaluation of the limitations of detection of BAC aCGH using quantitative PCR and oligo array hybridization.

W. Bi[1], K. Li[2], C. Chen[2], S.W. Cheung[1] 1) Dept Molec & Human Genetics, Baylor Col Medicine, Houston, TX; 2) Applied Biosystems, 850 Lincoln Center Dr., Foster City, CA 94404.

Array-based comparative genomic hybridization (aCGH) is a powerful tool for detection of genomic imbalance and has been successfully implemented in molecular cytogenetic evaluation of genetic diseases. Targeted BAC/PAC arrays have been developed for clinical diagnosis at Baylor College of Medicine. As a standard practice, the copy number changes are identified by aCGH and subsequent confirmatory FISH studies are performed. The routine cutoff is set at +/- 0.2 for the log ratio and < 0.05 for the T-statistics permutation based p-value; however, there are occasional data points near this value whose significance is ambiguous. We have examined five such cases with potential changes by BAC arrays not confirmed by FISH. Three Taqman quantitative PCR assays were designed for each BAC with RNaseP as an active reference and the copy numbers were determined by relative quantification. These cases were further studied using a focused 44K oligonucleotide-based BAC emulation microarray with 20-30 oligos for each BAC clone as a second method for comparison. The results of qPCR analysis for all 15 assays were consistent with the results of the oligo aCGH analysis. Case 1 had a putative gain detected by a single clone in BAC aCGH. A duplication was detected by about 60% of the BAC clone; this partial coverage likely contributed to no changes detected in FISH. Case 2 had a potential deletion indicated by two adjacent clones in BAC aCGH. We found a deletion detected by 40% of one of the clones; the second clone included a copy number variation within an 80 kb region, which may have contributed to the marginal hybridization value. No changes were observed in the remaining three cases, suggesting that the potential gains with a single clone in BAC aCGH were weak false positive signals. We conclude that the causes for the inconsistency between BAC aCGH and FISH analysis include gains or losses detected by part of a BAC clone or other technical limitations of BAC aCGH. Our data also indicate that the focused oligo array enables a higher resolution and better accuracy than the BAC array.

Application of high resolution genomic analysis to define clonal relationships between synchronous lung tumors.
J.M. Campbell, T.P. Buys, J. Chae, C. MacAulay, S. Lam, W.L.. Lam BC Cancer Agency, Vancouver, BC, CANADA.

Background: Lung cancer is the leading cause of cancer death worldwide. Because pulmonary metastases and multiple independent primary tumors are staged and managed differently in the clinic, determining the clonal relationship between tumors found in the same patient is essential for proper patient management. While most molecular analyses of suspected cases of multiple primary lung tumors (MPLTs) have relied on the status of specific genetic markers, critical genetic events (e.g. loss of chromosome arm 3p) could have occurred as independent events and do not truly reflect clonal expansion. Objectives: To assess clonal origins of multiple lung tumors from the same patient using the boundaries of multiple segmental genetic alterations for use as signature markers for clonality. To define key genetic alterations in lung tumorigenesis and disease progression by their independent emergence in each of the lung tumors from a given case. Study Design: Patients presenting with multiple lung tumors were identified and DNA was extracted from microdissected tumor cells. These DNA samples were then profiled by tiling path array CGH. SeeGH visualization software was then used to define segmental DNA alterations and chromosomal breakpoints. Results: Alignment of genomic profiles identified multiple shared and unique segmental alterations in tumors from the same patient. Shared chromosomal breakpoints in the tumors suggested a clonal relationship. Genomic changes unique to each tumor suggested subsequent tumor evolution (i.e. independent alterations). Although alteration boundaries for some regions did differ between tumors from the same patient, some of these unique alterations encompassed similar tracts of the genome, suggesting independent alteration of the same genes. Genomic determinations of clonality were contrasted with clinical determination of multiple primaries or intra-pulmonary metastases. Conclusion: We demonstrate the application of genomic profiles to delineate clonality of lung tumors from the same patient through the identification of shared breakpoints. This is an effective means of establishing the clonal relationship between such tumors.

Cis regulation of gene expression is an important target for selection in the human genome. *S. Kudaravalli[1], B.E. Stranger[2], E.T. Dermitzakis*[2], J.K. Pritchard*[1]* 1) Dept Human Genetics, University of Chicago, Chicago, IL; 2) Population and Comparative Genomics, Sanger Institute, Hinxton, Cambridge, UK.

*Joint supervision.

Previous studies have used genome-wide genotype data from the International HapMap project with genome-wide expression data to identify SNPs that are associated with gene expression differences in lymphoblastoid cell lines (e.g. Stranger et al, 2007). In this study we find SNPs showing haplotype-based signals for selection (Voight et al, 2006) are significantly more likely to be associated with cis gene expression differences than are matched control SNPs. This effect remains highly significant even after controlling for various confounding factors and is observed in all three HapMap population groups. Our results argue that selection on gene expression is an important and widespread mode of human adaptation.

An interdisciplinary approach to genetic screening policy-making. *I. Blancquaert[1,2], A. Andermann[1,3], S. Beauchamp[1]* 1) Agence dévaluation des technologies et des modes dintervention en sante (AETMIS), Montreal, Canada; 2) Université de Montréal, Montreal, Canada; 3) McGill University, Montreal, Canada.

INTRODUCTION: Decision-making with regard to population-based genetic screening programs is highly complex. Judging the utility of screening, which entails an evaluation of whether the benefits outweigh the risks, requires that a large range of factors are taken into consideration. OBJECTIVES: In developing a decision guide to support policy-makers faced with difficult decisions regarding the introduction or expansion of population-based genetic screening, a consultative process was used which sought to integrate the views of stakeholders as well as experts from a number of relevant disciplines. METHODS: Two rounds of consultations with local stakeholders and with local and international experts in the fields of population-based screening, public health and genetics led to the transformation of an initial list of 20 criteria, synthesized from over 54 published lists of criteria, into a more elaborate decision guide. RESULTS: The decision guide was structured according to the logic of the decision-making process that emerged from the consultations, which involves three nested decision nodes. Some considerations (e.g. scientific, ethical, legal, social, organizational, economic, political, etc.) are more relevant at specific stages in the decision-making process, and therefore, are more prominent in certain nodes of the decision guide. Although multiple types of expertise need to be called upon during this process, different disciplines have different perspectives, methodologies, and vocabularies which stem from different paradigms. Thus, an interdisciplinary approach also raises many challenges. CONCLUSIONS: Genetic screening policy-making requires the input of many different types of evidence and expertise. This led to the production of an interdisciplinary decision guide which has the advantage of making explicit the broad range of issues involved, articulating the different considerations according to the logic of the decision-making process, highlighting trade-offs and promoting a dialogue between different stakeholder groups.

Fabry Disease: Identification and Structural Analysis of 34 Novel -Galactosidase A Mutations Causing Fabry Disease. *D. Kwan[1], M.D. Rudelli[1], D. Germain[2], S.C. Garman[3], M.E. Grace[1], I. Nazarenko[1], R. Dobrovolny[1], M. Yasuda[1], R.J. Desnick[1]* 1) Department of Genetics & Genomic Sciences, Mount Sinai School Medicine, New York, NY 10029; 2) Assistance Publique-Hopitaux de Paris, Paris, France; 3) Department of Biochemistry and Molecular Biology, University of Massachusetts, Amherst, MA 01003.

Fabry disease, an X-linked recessive inborn error of glycosphingolipid metabolism, results from the deficient activity of the lysosomal enzyme, -galactosidase A (-Gal A). Here we report 34 novel lesions in the -Gal A gene causing Fabry disease. These include 16 missense (M1V, M42R, G43S, E48D, W81C, A121P, V124D, G132E, K168N, Y207C, I242F, F295C, D299G, G328E, G373R, P389R), four nonsense (Q212X, Q283X, W340X, W399X), one splicing defect (IVS4-3C>G), seven small deletions (c.402delT, c.646delT, c.722delG, c.732delC, c.807delG, c.1086del13, c.1145delGCTTC), three small insertions (c. 265dupCT, c.723dupT, c.996insC), one 26 bp deletion beginning at cDNA nucleotide 57, one complex mutation (D55V/Q57L), and one complex rearrangement (c.281delG/c.283delTGGA). Of the missense mutations, K168N and Y207C occurred at the active site. Transient expression of six missense mutations revealed that E48D, V124D, Y207C, D299G, G373R, and P389R had residual activity ranging from ~6 to 17% of expressed wildtype activity. The effect of each missense mutation on the 3D structure of the enzyme was also analyzed. These studies further define the molecular heterogeneity of the -Gal A mutations in Fabry disease and provide insight into -Gal A structure-function relationships.

Simplification of methodology for multi-channel Bayesian analysis in complex sibship risk assessment. *R. Best, A.C. Edens* Dept Obstetrics/Gynecology, Univ South Carolina Sch Med, Columbia, SC.

The use of Bayes' theorem in genetic counseling for X-linked recessive disorders allows for the integration of family history information across multiple generations as well as laboratory test studies, resulting in patient-specific risk estimates that include as much relevant information as possible. We present a clinical practice case involving Duchenne muscular dystrophy that includes a proband and three maternal aunts, each with relevant conditional information. We discuss the practical difficulties of increasing the number of channels of calculation with multiple generations and complex sibships and offer some simplifications to make the calculations more manageable. For complex sibships, the calculation table can be split into additional channels to accommodate multiple siblings with conditional information. To reduce the total number of calculations, channels can be eliminated when the mutations rate (?) enters the channel more than once. This approach has practical future applications, as it allows clinicians to be more efficient when performing Bayesian calculations.

Creation of maternally inherited mouse models of mitochondrial cardiomyopathy and directional mitochondrial DNA (mtDNA) segregation by introduction of a homoplasmic mtDNA COI missense mutation and a linked heteroplasmic ND6 frameshift mutation into the female mouse germ line. *W. Fan[1], K. Waymire[1], P. Li[2], N. Narula[3], P.E. Coskun[1], M.A. Vannan[2], C. Rocher[1, 4], J. Narula[2], G. MacGregor[1], D.C. Wallace[1]* 1) MAMMAG, University of California, Irvine, Irvine, CA; 2) Medicine, University of California, Irvine, Irvine, CA; 3) Pathology, University of California, Irvine, Irvine, CA; 4) INSERM, U. Bordeaux 2, Bordeaux, France.

We have created the first mouse models of maternally inherited mitochondrial myopathy and cardiomyopathy caused by a missense mutation and of directional segregation of a heteroplasmic mtDNA frameshift mutation. A mtDNA was isolated from cultured mouse cells that was homoplasmic for a COI T6589C (V421A) missense mutation and an ND6 13885insC frameshift mutation. This mtDNA was introduced into the mouse germ line via cybrid transfer into rhodamine 6G-treated female embryonic stem (mES) cells generating an ES cell homoplasmic for the COI mutation in which 4% of the mtDNAs contained a 13885insCdelT ND6 reversion. One chimeric mother produced a female offspring whose mtDNA was homoplasmic for the COI mutation and heteroplasmic for the ND6 mutation (47% ND6 13885insC + 53% 13885insCdelT). This mouse developed mild myopathy and cardiomyopathy and had a partial complex I + IV defect. The frameshift mtDNA was directionally lost within the first three generations, decreasing successively from 47 to 14 to 6 to 0% ND6 13885insC. The resulting homoplasmic COI T6589C + 13885insCdelT mutant mice had a 37%-48% complex IV deficiency in brain, heart, liver, and skeletal muscle and increased heart mitochondrial proliferation, disordered mitochondrial distribution, and cristae-lysis. Echo cardiograms revealed that these animals developed a hypertrophic cardiomyopathy associated with a 26% increase in left ventricular wall thickness, a 30% decrease in left ventricular diastolic internal dimension, a 39% decrease in circumferential strain, and a 74% decrease in radial strain. This stable maternally inherited mouse model now opens new avenues for studying the pathophysiology and therapeutic of mitochondrial disease.

Whole Genome Association Study of Response to Citalopram in the STAR*D Sample. *H.A. Garriock[1], J.B. Kraft[1], E.J. Peters[1], G.D. Jenkins[2], M.S. Reinalda[2], P.J. McGrath[3], S.L. Slager[2], S.P. Hamilton[1]* 1) Department of Psychiatry and Institute for Human Genetics, University of California, San Francisco, CA; 2) Division of Biostatistics, Mayo Clinic College of Medicine, Rochester, MN; 3) New York State Psychiatric Institute and Columbia University, New York City, NY.

Background: Inter-individual variability in response to antidepressants is thought to be influenced at least in part by DNA variation. To date, candidate gene approaches to antidepressant response have led to results of marginal impact. We have thus undertaken a genome-wide association study to look for novel genetic determinants of antidepressant response in a large clinical sample. Methods: We used a subset of subjects enrolled in the antidepressant trial Sequenced Treatment Alternatives to Relieve Depression (STAR*D). The number of subjects giving DNA was 1,953 and thus represents our sample in its entirety. Our citalopram response phenotypes included response (50% reduction in QIDS-SR), remission, and drug tolerance. In a two-stage design, we genotyped part of the sample for 590,000 SNPs (N=831), and carried out a replication analysis in the remaining sample (N=835). Results: Markers were tested for association using Armitage trend test and results were ordered on the basis of the p-value. In our most highly powered discovery sample (white, non-hispanic) and combined across the three phenotypes, we observed about 185 markers with p-values less than 0.0001, with associated dominant odds ratios for SNP with MAF >0.05 ranging from 1.58-13.4. Assessment of our replication sample is underway. Conclusions: Results from the first stage of the study must still be confirmed in the validation stage. Data from the first stage of our study have implicated a large number of previously unconsidered loci involved in antidepressant response.

A Comprehensive Whole Genome Analysis Panel Containing over 1M SNPs. *M. Eberle[1], S.S. Murray[2], K.A. Viaud[1], D. Peiffer[1], L. Zhou[3], P.C. Ng[4], K. Kuhn[1], R. Shen[1], L.M. Galver[1]* 1) Illumina Inc; 2) Scripps Genomic Medicine; 3) Prognosis Biosciences; 4) Craig Venter Institute.

Whole genome association studies are a powerful tool for detecting loci associated with complex diseases. A comprehensive whole genome panel must include markers for even coverage of the genome and tag SNPs for maximum genomic coverage and power. We have constructed a whole-genome panel containing over one million SNPs in addition to non-polymorphic probes for this purpose. SNP loci were chosen from both the HapMap and NCBI SNP databases while probes were designed in SNP-poor regions for detection of copy number variation (CNV). This panel utilizes the Infinium assay that allows interrogation of a large number of markers efficiently and accurately on a single slide (Steemers et al., 2006). We have maximized genomic coverage for this panel by selecting tag SNPs from the HapMap data for all 4 populations. Approximately 94%, 93% and 73% of HapMap Phase II variation is captured at an r2 0.8 in the Caucasian (CEU), Han Chinese/Japanese (CHB/JPT) and Yoruba (YRI) populations, respectively. Alternatively, coverage can be measured by examining the power to detect risk alleles under various disease models and sample sizes. We explored a wide range of disease risks and study designs to estimate the power of this panel for detecting risk alleles associated with complex diseases. Results show that in European and Asian populations these SNPs provide ~90-95% of the power that could be achieved by genotyping all ~2.2 million common (MAF > 5%) SNPs in the HapMap database in the same number of samples. There are approximately 400,000 gene-centric SNPs in this panel that map within 10kb of a gene region and cover greater than 99% of RefSeq genes at an average density of 6 SNPs per 10kb. Approximately 25,000 of these SNPs are non-synonymous. Additionally there are greater than 6,000 SNPs and indels in the gene-rich MHC region chosen from a high-density MHC map (deBakker et al., 2006), and 10,000 SNPs located within more than 200 known ADME genes. Markers were also added to maximize coverage of published and novel CNV regions as well as achieve even spacing across the genome.

Cervical intraepithelial neoplasia and factors in chromatin remodelling: A comprehensive serial analysis of gene expression. *J.Y. Kennett, A. Shadeo, R. Chari, C. MacAulay, W.L. Lam* Cancer Genetics, BC Cancer Research Centre, Vancouver, B.C., Canada.

Cervical cancer affects approximately 500,000 women worldwide each year with highest rates found in developing countries. Cervical intraepithelial neoplasia (CIN) is a precursor lesion to cervical cancer and can be further described as CIN I, CIN II and CIN III (mild, moderate and severe dysplasia, respectively). Most CIN I lesions spontaneously regress to normal cervical epithelia however CIN III lesions are much more likely to progress to cervical cancer if left untreated. CIN II may be a critical junction in disease development. Social, clinical and genetic factors indicate that frontline monitoring will continue to play an important role in cervical cancer prevention and improved methods for detection and biological markers are needed. A thorough understanding of genetic events in precancerous cervical intraepithelial neoplasia is required to delineate important causal events in cervical cancer. In this study we have analyzed the transcriptome across sixteen cases (CIN I, CIN II, CIN III and normal cervical epithelium) using an unbiased long serial analysis of gene expression (L-SAGE) method. In total, sixteen L-SAGE libraries were sequenced to 2,481,387 tags, establishing the largest SAGE data collection for cervical tissue worldwide. We identified 108 tags increased in frequency in CIN III and 138 tags decreased and overall observed 246 tags differentially expressed between normal cervical tissue and CIN III. Biological functions most influenced by these genes include cell death, cell growth/proliferation and cellular movement. In evaluation of expression differences between normal and CIN lesions, we identified two gene networks targeted. Several of these genes directly or indirectly involve chromatin remodelling or the SWI/SNF ATPase chromatin remodelling complex. Further, these disruptions may be targeted to the critical stage of moderate dysplasia (CIN II) and provide candidate markers for screening at this junction.

Large scale transcriptomic analysis of *ACVR2A*, a pre-eclampsia positional candidate gene. *M.P. Johnson[1], J.E. Curran[1], J. Kent Jr.[1], H.H.H. Göring[1], T.D. Dyer[1], R. Austgulen[2], S.A. Cole[1], J.W. MacCluer[1], S.P. Brennecke[3], J. Blangero[1], E.K. Moses[1]* 1) Department of Genetics, Southwest Foundation for Biomedical Research, San Antonio, TX, USA; 2) Faculty of Medicine, Department of Cancer Research and Molecular Medicine, Norwegian University of Science and Technology, Trondheim, Norway; 3) Department of Perinatal Medicine and the University of Melbourne Department of Obstetrics & Gynaecology, Royal Womens Hospital, Carlton, Australia.

We have previously identified three putative pre-eclampsia/eclampsia (PE/E) susceptibility quantitative trait loci (QTLs) on chromosomes 2q, 5q and 13q in a cohort of Australian/New Zealand (Aus/NZ) families. Comprehensive interrogation of the chromosome 2q QTL has implicated the *ACVR2A* gene as a plausible PE/E susceptibility candidate. In this study we now report a novel integrative genomic approach to assist us further with the genetic dissection of these PE/E susceptibility QTLs that utilizes a unique dataset of whole-genome lymphocyte transcriptional profiles from 1,240 individuals in large extended Mexican American families of the San Antonio Family Heart Study (SAFHS). A linkage-based genome-wide scan of *ACVR2A* transcript levels in this dataset identified a putative *trans*-acting QTL on chromosome 5q (LOD 3.7 at 123cM). This putative *trans*-acting QTL in Mexican Americans lies in very close proximity to our PE/E susceptibility QTL on chromosome 5q at 121cM in Aus/NZ families. In an attempt to identify the putative *trans*-acting gene at the 5q QTL we examined the genetic correlations of expression levels between the *ACVR2A* transcript and all transcripts residing under our 5q 1-LOD support interval (~117cM - 133cM). There were 12 transcripts significantly genetically correlated with *ACVR2A* (FDR 0.05). Members of the SAFHS are now being genotyped using Illuminas humanhap550 beadchip for which the gene centric SNP data under the putative 5q *trans*-acting QTL will be interrogated against *ACVR2A* expression levels. This integrative genomic approach may provide a valuable means to genetically dissect complex human disorders such as PE/E.

Applications of next generation sequencing using stepwise cycled ligation. *G. Costa, C. Lee, L. Apone, J. Stuart, J. Warner, R. David, A. Sheridan, S. Ranade, J. Ichikawa, K. McKernan* Genetic Analysis, Applied Biosystems, Beverly, MA.

The SOLiD sequencing system uses stepwise cycled ligation and is being developed for high throughput DNA sequencing. In this novel system, short fragment DNA populations are amplified onto 1-micron beads, enriched and randomly deposited at high density onto glass slides. The DNA bead arrays are then placed into a dual automated flow cell where 4-color, fluorescently-labeled octameric probes are delivered serially and serve to interrogate known template positions on DNA strands. Current enhancements to the SOLiD system have included the development of library construction methods that afford genome sequencing of short fragment (1 x <50 bp) and mate-paired (2 x 25 bp) DNA libraries. Consistent improvements have been made in total sequence throughput by enhanced read length and base calls, higher bead density and optimized ligation biochemistry. Taken together, recent improvements have demonstrated performance of >2 Gb per single tag (fragment library) and up to 4 Gb per dual tag (mate-pair library) per instrument run. Results presented will highlight a number of collaborative projects directed at the sequencing of microbial, fungal and human genomes. Sequencing applications have included directed resequencing of human cancer-based amplicon libraries, whole genome sequencing of microbial and fungal genomes, and transcriptome analyses.

Introduction of prkar1a -/- Mouse Embryonic Fibroblasts in Nude Mice Leads to Tumor Formation: Expression profiling reveals consistent alterations in Cell Cycle Regulation Genes. *S.A. Boikos, C. Giatzakis, A. Robinson-White, K. Tsang, H.P. Hsiao, F. Wen, Y. Patronas, M. Nesterova, C. Stratakis* SEGEN, DEB, NICHD, NIH, Bethesda, MD, USA, 20892-1103.

PRKAR1A-inactivating mutations cause primary pigmented nodular adrenocortical disease, Carney complex, a multiple neoplasia syndrome, and sporadic endocrine tumors. R1a, is the main regulator of cAMP-dependent PKA a pathway that when activated leads to inhibition of growth and/or proliferation in several cell lines. Enhanced expression of R1a has also been shown in several human cancer tissues and cell lines. In order to investigate the mechanisms, regulation of Prkar1a gene and the interraction with other genes, we established a model using Mouse Embryonic Fibroblasts (derived from the heterozygote knockout prkar1a +/- mouse) grown in athymic nude mice. In order to identify genes regulated by Prkar1a, gene expression was assessed by oligonucleotide microoarrays in 4 groups: Prkar1a+/-, Prkar1a-/- not selected in soft agar, Prkar1a-/- selected in soft agar and RNA pool from tumors grown in the nude mice. We used the Illumina s Sentrix HumanRef-8 Expression BeadChip. Z-transformation for normalization was performed on each Illumina sample/array. We used the Ct model for the statistical analysis of real time. Using a cut-off of /=2 times, we identified a total of 156 genes that had altered expression in any of the above 4 groups. Confirmation of the microarray data was done for selected genes by real-time PCR; the latter confirmed significant up-regulation of Cdkn2c, Cdkn2a, Cdkn1b and Cdkn2b, while Cyclin D2 was significantly down-regulated. We conclude that cell cycle regulation genes appear to have a crucial role in prkar1a-related tumorigenesis in mice, consistent with similar studies in human tissues. Ongoing protein and proliferation assays using siRNA on genes controlling the cell cycle aim at further investigating the interaction of these genes with the PKA signaling and related pathways.

Selection underlies most doublet somatic EGFR mutations in lung cancer: about 1/3 occur at five amino acid pairs. *Z. Chen, j. feng, j. saldivar, D. Gu, A. Bolkholt, S. Sommer* Molec Gen & Molec Diagnosis, City of Hope Natl Med Ctr, Duarte, CA.

Doublet mutations are generally not well characterized. We find that doublet mutations were present at high frequency and on one allele of EGFR tyrosine kinase (TK) domain in lung cancers. Sequencing of 470kb elsewhere in the EGFR gene did not demonstrate any additional somatic mutations, the doublets were not obiously associated with tumor hypermutability. When doublets from the literature were added, a total of 94 doublets became available for analysis. The frequency of doublets overall is 5.6%, which is seven-fold greater than that observed in normal somatic tissue in mouse. All characterized doublet mutations are in cis. About half of all doublet mutations contain one or two of 12 distinct missense mutations at five amino acids: E709, G719, S768, T790, and L861. These 12 missense mutations are uncommonly or never been reported in singlets. Moreover, when the common L858 target is included, more than one third of EGFR doublet mutations occur at one of five pairs of missense mutations: G719/E709, G719/S768, G719/L861, L858/E709, and L858/T790. While analysis of the frequency of silent mutations in doublets is consistent with a random and hitchhiker mutation in spontaneous somatic mouse doublets in normal tissue and for p53 doublets in human lung cancer, that is not the case for EGFR mutations. Curiously, the frequency of doublets is decreased in smokers despite high mutagen exposure from cigarette. We conclude that most EGFR doublet mutations arise by sequential functional selection.

Low Serum Testosterone in Men with Marfan Syndrome. *M. Burchett[1], B.F. Griswold[2], L. Sloper[2], C.A. Francomano[3], S. Basaria[4], N.B. McDonnell[2]* 1) Centre Col, Danville, KY; 2) LCI, NIA/NIH, Baltimore, MD; 3) GBMC, Baltimore, MD; 4) CRB, NIA/NIH, Baltimore, MD.

Marfan syndrome is a heritable disorder of connective tissue associated with cardiovascular and skeletal, and ocular abnormalities. Abnormalities of sex hormones in Marfan syndrome have not been noted previously. In six consecutive adult male subjects with Marfan syndrome, ages 25-52, enrolled at the National Institutes of Health, serum total testosterone values below the age norms were detected in research based testing. The lowest value was 155 ng/dL in a 31 year old man. Steroid hormone binding globulin (SHGB) was not elevated in any of the subjects. The subjects had normal sexual development and infertility was not noted. All subjects had decreased muscularity, a feature noted commonly in Marfan syndrome, as well as osteroporosis or osteopenia. One subject had suffered two vertebral compression fractures. Investigation of the pituitary axis in the Marfan syndrome cohort is ongoing in the study. Replacement therapy with exogenous testosterone was not initiated due to concern for cardiovascular consequences such as increase in blood pressure and progression of aortic root enlargement. Low serum sex hormones in Marfan syndrome may be a contributor to reduced bone density and increased fracture risk.

The Molecular Etiology of Peters anomaly, Microcornea, and Cataracts, in Family R0023, A Newfoundland Family. *L. Doucette, J. Green, B. Fernandez, T.L. Young* Discipline of Genetics, Faculty of Medicine, Memorial University of Newfoundland, St. John's, NL, Canada.

Introduction A Newfoundland family R0023 exhibits an autosomal dominant form of anterior segment dysgenesis, a disorder of the anterior eye segment. In this family, one individual is afflicted with Peters anomaly, a rare disorder characterized by iris-lens, lens-cornea adhesions, and corneal opacities, and is considered one of the most severe phenotypes of anterior segment dysgenesis. Other affected individuals exhibit microcornea, or congenital cataracts, less severe phenotypes of this disorder. Due to the Mendelian pattern of autosomal dominant inheritance seen in this family, we believe that this varying phenotype in affected relatives is caused by mutation of a single gene involved in the early stages of anterior segment development. Both genomic and cDNA will be obtained from affected family members to directly sequence 5 genes associated with Peters anomaly and anterior segment dysgenesis (namely PAX6, PITX2, PITX3, FOXC1, and CYP1B1). If causative mutations are not found in these 5 functional candidate genes a genome wide scan will be performed in order to determine the molecular etiology of Peters anomaly with cataracts and microcornea in this Newfoundland family. To date, the coding and untranslated regions and their intron/exon boundaries of 4 of these 5 genes (PAX6, PITX2, PITX3, and FOXC1) have been directly sequenced in 7 selected individuals from this family (5 affected, 2 unaffected). A number of SNPs have been identified at this point, but no causative mutations have been found in these four genes.

Optimal methods to map quantitative trait loci using extreme trait values. *D. Covarrubias[1,2], S.M. Leal[1]* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Statistics, Rice University, Houston, TX.

For mapping quantitative trait loci, one effective study design is to select a subset of individuals with extreme high and low quantitative trait (QT) values. This study design has been implemented to increase power while reducing the number of individuals genotyped or sequenced, and was recently used to identify genes for HDL cholesterol (Cohen et al. 2004) and cardiovascular disease (Arking et al. 2006). There are several frameworks for extreme QT sampling which can be used: phenotyping study subjects until a set sample size of individuals meeting a QT criterion are obtained, or using an existing sample and analyzing only a subset of individuals based upon a QT threshold. For this study, we examined the latter sampling framework for a variety of genetic variances, allele frequencies and sample sizes. Thresholds which optimize power were determined when the QT was dichotomized. Additionally, type I and II error was evaluated for parametric (ANOVA, linear regression, Cochran-Armitage test for trend, Fisher exact test) and non-parametric (Kruskal-Wallis) statistical tests. For the analysis of QTs, the highest power is obtained when the entire sample is analyzed and the power decreases with increasing extreme QT sampling. Additionally, for ANOVA and linear regression, type I error inflates with increasing extreme QT sampling. When the QT is dichotomized, using only those individuals with the highest and lowest QT values, the optimal power is obtained when ~50% of the total sample is analyzed. For this situation, usually the Fisher exact test is most powerful and uniformly controls type I error. If thresholds > 25% are used for sampling, the Kruskal-Wallis test is more powerful than the Fisher exact test and also controls type I error.

Power-based tag SNP selection using efficient power evaluation. *B. Han[1], H. Kang[1], E. Eskin[2]* 1) Dept Computer Sci, Univ California, San Diego, La Jolla, CA; 2) Dept Computer Sci, Univ California, Los Angeles, Los Angeles, CA.

Discovering statistical correlation between genetic variation and clinical traits through genetic association studies is an important method for identifying causal variation. Since fully resequencing is practically infeasible, genetic association studies take advantage of local correlation structure (or linkage disequilibrium) between single nucleotide polymorphisms (or SNPs) by selecting a subset of SNPs to be genotyped (tag SNPs). While many current association studies are performed using commercially available high-throughput genotyping products that define a set of tag SNPs, choosing tag SNPs remains as an important problem for both custom follow-up studies as well as designing the high-throughput genotyping products themselves. The most widely used tag SNP selection method uses a criteria based on r^2, or the correlation between SNPs. However, tag SNPs chosen based on a r^2 criterion are not necessarily the tags chosen to maximize the statistical power of an association study. We propose a flexible study design framework that chooses SNPs to maximize the statistical power of an association study. Our method both obtains a tag set as well as measures the statistical power of this tag set through empirical simulations for a wide range of individuals. Empirical simulations based on HapMap reference data support that our method gains considerable amount of power compared to the traditional r^2 based method, or significantly reduces the number of individuals given the desired power of the study. Using our method, we designed a 500k microarray, which has superior power to Affymetrix 500k or Illumina 550k microarray. In addition, our design framework provides an efficient method to empirically evaluate genome-wide power for a wide range of number of individuals. The implementation of our method is publicly available via web server.

Ancestry block correction: A new method to correct for stratification in genome-wide association studies in admixed populations. *J. Estrada-Gil[1], I. Silva-Zolezzi[1], A. Hidalgo-Miranda[1], J. Fernadnez-Lopez[1], E. Hernandez-Lemuz[1], R. Goya-Ogarrio[1], I. Pe'er[2], G. Jimenez-Sanchez[1]* 1) National Institute of Genomic Medicine, Mexico; 2) School of Engineering & Applied Science, Columbia University, NY.

Genome-wide association studies (GWAS) have emerged as a powerful approach to identify genetic variants related to common diseases such as age-related macular degeneration and diabetes. Association studies in admixed populations may show spurious results due to population stratification. An approach to correct this effect is to estimate and include individual admixture proportions in the analysis. However, for individuals of admixed ancestry this correction may be of limited benefit since their chromosomes consist of mosaics of blocks derived from ancestral populations. We propose a new method that includes calculations of ancestry block proportions. To compare performance between using individual admixture and ancestry block corrections, we analyzed over 100,000 SNPs in 300 individuals from six different regions of Mexico. Admixture proportions were inferred using 3 sets of Ancestry Informative Markers (AIMs) (2824 with 0.3, 1479 with 0.5 and 127 with 0.7), and ancestry blocks with all markers. Using these data, we simulated three scenarios for GWAS: 1) A model without phenotype; 2) A monogenic model with full penetrance exemplified by the lactase persistence phenotype and, 3) Phenotype with incomplete penetrance. In the first simulation, 100 spurious associations were corrected using either method. In the second scenario, 2 spurious associations (p=3.6E-8 and p=1.2E-7) were corrected by means of ancestry blocks (p=1.3E-2 and p=5.7E-6) but not by individual admixture (p=1.4E-6 and p=1.E-7). For the third model, 64 spurious associations were detected (mean p=4.5E-8). Association p-values for these 64 signals were less significant using ancestry block correction (mean p=0.241) than using individual admixture correction (mean p=0.034). Our results show that in admixed populations, ancestry block analysis may provide better correction for population stratification with a potential benefit for GWAS.

Identification of *NRG3* (neuregulin 3) as a quantitative trait locus for the positive symptoms of schizophrenia. *P. Chen[1], D. Avramopoulos[2], J. McGrath[2], V.K. Lasseter[2], G. Nestadt[2], M.D. Fallin[3], A. Pulver[2], D. Valle[1]* 1) Inst Genetic Medicine, Johns Hopkins Sch Medicine, Baltimore, MD; 2) Dept Psychiatry; 3) Dept Epidemiology, School of Public Health.

Schizophrenia (SZ) is a complex disorder with a strong genetic component. Our previous genomewide linkage scan on families of Ashkenazi Jewish (AJ) descent (Fallin *et al*. Am J Hum Genet, 2003) showed the strongest linkage signal at chromosome 10q22 (NPL score: 4.27, P=0.00002). To further narrow down the susceptibility gene(s), we obtained a SNP-based fine mapping study with 1536 SNPs across the 12.5 Mb region. All subjects are of AJ background and were analyzed as 305 trios in family-based or 458 cases and 487 controls in population-based study. We used the UNPHASED statistic package (Dudbridge, Genet Epidemiol, 2003). The phenotypes for analysis included the disease status (either affected or non-affected) and 9 quantitative traits (factors) derived from the 73 items of our consensus diagnostic ratings and direct assessment interviews (unpublished data) using the principal component factor analysis method. This 9 factor model is statistically supported and yields a number of factors consistent with other dimensional studies in the literature. Using the positive symptoms factor (e.g. thought insertion, delusions of influence, somatic hallucinations) as the quantitative trait, we found strong evidence of association at 3 nearby SNPs (rs10883866, rs10748842 and rs6584400) which are in strong linkage disequilibrium (LD) with each other. Our best P value from TDT analysis was 0.0000025 and the best P value from population-based association study was 0.000022. These 3 SNPs are located in a 13 kb interval in the first intron of *NRG3*, with an underlying LD block covering the proximal promoter, exon 1 and a part of intron 1 (total ~160 kb). *NRG3* is primarily expressed in the CNS and is one of 3 paralogs of *NRG1*, a gene strongly implicated in SZ in Celtic populations (Stefansson *et al*. Am J Hum Genet, 2002). These biological properties and our linkage and association results strongly implicate NRG3 as a candidate gene for SZ and justify functional and sequencing studies that are currently underway.

A regulatory code controlling gene expression during heart development. *F.E. Arimura[1], I. Ovcharenko[2], M.A. Nobrega[1]* 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Computational Biology Branch, National Center for Biotechnology Information, NIH, Bethesda, MD.

Identifying biologically active transcriptional noncoding elements in mammalian genomes and understanding the combinations of sequence signatures that are necessary and sufficient to confer quantitative, temporal- and tissue-specific expression in vertebrates represents one of the greatest challenges in genome biology. It is unclear if groups of genes that are co-expressed in a tissue or coordinately respond to certain stimuli share a cis-regulatory code underlying this concerted expression. To investigate whether the complex orchestration of gene expression during heart development is controlled by a common regulatory code, we combined whole genome alignments, gene expression profiling in developing hearts and pattern analysis of DNA binding motifs to identify putative heart-specific regulatory elements in the mouse genome. A list of 450 putative heart enhancers sharing common DNA motifs was generated, and we tested 27 of these elements, randomly selected, in a newly developed zebrafish transgenic reporter assay. A total of 11 elements (40.7%) demonstrated heart-specific expression in developing fish embryos. To assess the false discovery rate of this strategy, 52 elements in the vicinity of genes expressed during heart development were also tested, and none drove reporter expression in the developing fish. We also tested in zebrafish 17 mammalian heart enhancers previously identified using transgenic mice. 13 (76.5%) of these elements reproduced the expression pattern in fish hearts, demonstrating the feasibility of using zebrafish transgenics to test mammalian sequences. Together, these results indicate that our predicted heart enhancers likely share a common code of DNA binding motifs. Further experimentation is under way to improve the predictive power of the method and refinement of the specific DNA motifs.

Exposure to Secondhand Smoke and TGF1 SNPs Interact to Decrease Lung Function in Cystic Fibrosis. *J.M. Collaco, L.L. Vanscoy, S. Blackman, A. Bowers, K. Naughton, J. Ellen, G.R. Cutting* Dept of Pediatrics and Institute of Genetic Medicine, Johns Hopkins, Baltimore, MD.

A major challenge for human genetics is to identify gene-environment interactions that adversely affect health. Using patients enrolled in the U.S. Cystic Fibrosis (CF) Twin and Sibling Study, we determined if exposure to secondhand smoke (SHS) in the home affected lung function and whether SHS exposure modulated the effect of variants in TGF1, a modifier of CF lung function. Lung disease severity was defined using forced expiratory volume in 1 second (FEV1), a quantitative measure correlated with survival. To facilitate comparison of patients, lung function measures were converted to disease-specific percentiles. The best CF-specific %ile for FEV1 within the last year was used as a cross-sectional measure. Lifetime average CF-specific %ile for FEV1 was used as a longitudinal measure. Exposure to secondhand smoke was defined as any history of cigarette smoking in the home based on parental report. Cross-sectional lung function measures differed (p=0.001) between patients exposed (mean =0.63; 95%CI: 0.59-0.67; n=211) compared to patients not exposed to SHS (mean=0.70; 95%CI: 0.68-0.73; n=500). Longitudinal lung function measures also differed (p=0.017) between patients exposed (mean=0.551; 95%CI: 0.51-0.59; n=161) compared to patients not exposed to SHS (mean=0.60; 95%CI: 0.58-0.62; n=502). All patients were typed for rs1800469 (-509) and rs1982073 (codon 10), the two TGF1 SNPs associated with severe CF lung disease. Patients homozygous for the -509 T allele who were SHS-exposed had lower (p=0.004) longitudinal lung function measures (0.47 0.27; n=22) than non-exposed patients (0.67 0.24; n=44). Similarly, patients homozygous for the codon 10 C allele who were SHS-exposed had lower (p=0.002) lung function than non-exposed patients. SHS exposure did not affect lung function in patients with other -509 or codon 10 genotypes and lung function in non-exposed patients was similar regardless of -509 or codon 10 genotype. These data demonstrate that exposure to second hand smoke dramatically alters the modifier effect of the TGF1 genotype upon CF lung disease severity.

Neural Restrictive Silencer Factor (NRSF) and Choline Acethyltransferase (CHAT) expression in cerebral tissue of Alzheimer's disease patients. *R.E. González-Castañeda[1], V.J. Sánchez-González[1], A. Barba-González[1], E. Martínez-Cano[1], S. Sustersick-Castro[1], O. González-Perez[2], K. Solorza-Camacho[1], A. Jimenez-Delgado[1], A. Miranda-Riestra[1], F. Pacheco-Moises[3], V. Loera-Castañeda[4], G. Ortiz[1]* 1) Laboratorio de Enfermedades neurodegenerativas, Centro de Investigación Biomédica de Occidente, Division de Neurociencias, CIBO (IMSS), México; 2) Departamento de Neurociencias, Centro Universitario de Ciencias de la Salud, U de G, México; 3) Departamento de Química, Centro Universitario de Ciencias Exactas e Ingeniería, U de G,Mexico; 4) CIIDIR-IPN, Unidad Durango, México.

Background:Decreased choline acetyltransferase (ChAT) brain levels is one of the main biochemical disorders in Alzheimer's Disease (AD). Recent data show that the ChAT gene can be regulated by a neural restrictive silencer factor (NRSF). Objective. To evaluate ChAT and NRSF genetic and protein expression in frontal, temporal, enthorrinal and parietal cortices of AD patients. Methods. A total of 4 patients with AD and 4 without dementia were studied. Cerebral tissue was obtained and processed by the guanidine isothiocyanate method for RNA extraction. ChAT and NRSF expression was determined by reverse transcription-polymerase chain reaction (RT-PCR) and Western blotting. Results. Global levels of ChAT gene expression were decreased by 39% in AD patients as compared to the control group ($p<0.05$, U test), whereas ChAT protein levels decreased only by 17% ($p=0.02$). Compared to the control group, NRSF gene expression was increased by 86% in the AD group ($p=0.001$). On the other side, NRSF protein levels were increased by 57% ($p>0.05$). Conclusion. Greater NRSF protein levels determine low ChAT gene expression levels in AD patients.

CHOPPY - A Copy Number Detection Platform Using Illumina Genotyping Data. *X. Gai, J.C. Perin, E. Rappaport, J. Glessner, S.F.A Grant, H. Harkonarson, T.H. Shaikh, P.S. White* Children's Hospital of Philadelphia, Philadelphia, PA.

The Illuminas HumanHap550 beadchip provides an unprecedented surveillance of the human genome with an average intermarker distance of approximately 6kb. The data can also be examined for chromosomal copy number variations (CNVs), potentially allowing the detection of CNVs of only a few kb. However, identification of copy number changes with Illumina supplied BeadStudio software mostly relies upon visual inspection of the Log R Ratio plot and the B Allele Frequency plot. The process is effective only for the detection of larger CNVs and is inefficient for larger number of samples. We have developed a software platform (CHOPPY) for automatic and batch analysis of the CNVs. CHOPPY was designed for large-scale and high-throughput CNV analysis and consists of three major components: CHOPPY.R for command line data analysis, a CHOPPY database for storing CNVs, and a Web interface called Copy Number Querier (CNQ) for querying and assessing the putative CNVs. The CHOPPY web interface is integrated with a local installation of the UCSC Genome Browser. CNVs can be presented either as an annotation track or in a tabular format for a given patient or cohort, along with other relevant annotations. This provides a convenient setup for interpreting the biological and clinical significance of any observed copy number change. In general, over 90% of known CNVs 20 SNPs or larger, deletions or duplications, can be consistently detected with CHOPPY. For the cleaner data sets, the percentage can be as high as 90% for deletions spanning as few as 4 SNPs. The false discovery rate is estimated to be less than 1% for all identified CNVs that cover at least 4 SNPs. This is supported by the experimental validations of two small duplications and a 4 SNP deletion of of10kb in size. CHOPPY was used to identify 31 unique CNVs, spanning as few as 4 SNPs, in a complete trio. Out of the 15 CNVs found in the probands genome, 13 were inherited. This high percentage argues strongly for CHOPPYs performance in terms of both the false positive rate and the false negative rate. We are currently validating performance on CNVs as small as 2 SNPs.

Mitochondrial DNA Mutations Found in Native Central and South American Samples Provide Evidence for Mitochondrial Adaptation to New Environments. *O. Derbeneva, K. Von Hasseln, M. Brandon, M. Lvova, D.C. Wallace* MAMMAG, University of California, Irvine, Irvine, CA.

Human mitochondrial DNA (mtDNA) lineages (haplogroups, hplgrs) show striking geographic associations. This led us to hypothesize that ancient mtDNA mutations which altered the mitochondrial OXPHOS energy allocation between ATP production and heat generation (coupling efficiency) permitted humans to adapt to new climatic zones. Analysis of mtDNA sequences revealed that the mtDNA COI gene is variable in the tropics, the cytochrome b gene is variable in the temperate zone, and the ATP6 gene is variable in the arctic (Mishmar et al., 2003, PNAS 100:171-176). The mtDNA hplgrs A2, C1, and D1 arose in Siberia and subsequently cross the Bering land bridge to colonize the Americas. Therefore, these cold adapted Siberian mtDNAs had to readapt to the tropical conditions of Central and South America. To determine if these mtDNA lineages acquired new mtDNA mutations permitting topical survival, we sequenced 91 A2, C1 and D1 mtDNAs from 9 South and Central American Amerindian tribes. Both novel and recurrent polypeptide, tRNA & rRNA, and control region mutations were found to have been acquired as the Siberian mtDNAs became established in the tropics. The ratio of non-synonymous to synonymous variants was found to be 2.5 times higher at the base of the branches of the tropic D1 tree than at the ends consistent with early adaptive selection. Furthermore, missense mutations were elevated 1.5-3 fold in the ATP6 and COII genes relative to arctic and non-arctic mtDNAs, and many of the acquired missense mutations had previously been observed in other populations on different mtDNA hplgrs, e.g. nucleotide (nt) 4216 previously found in European hplgrs T & J; nt 13708 in J; nt 5460 in W, Q1, Q2; nt 1719 in I & X; nt 1888 in T; nt 15924 in L; etc. Such convergent evolution can only be explained by adaptive selection. Thus, Siberian mtDNA lineages A2, C1, and D1 acquired adaptive mutations as they migrated into tropical America, thus proving that mtDNA variation has permitted human adaptation to new environments.

An unusual duplication 3q syndrome phenotype in a patient with der(22)t(3;22)(q26.3;p13). *R. Habibian[1], A. Hajianpour[1], L. Dong[1], R. Tefft[2], L.M. Randolph[3], L. Drugan[1], M.J. Hajianpour[4]* 1) Cytogenetics Laboratory, Genzyme Genetics, Monrovia, CA; 2) White Memorial Hospital, LA, CA; 3) Children Hospital of Los Angeles, CA; 4) Gene Trek Genetics, Burbank, CA.

We present a newborn baby boy with dup(3q) syndrome and phenotypic features similar to Cornelia de Lange syndrome (CdLS). He was born at 36 weeks of gestation to a 23-year-old, G2, P1 mother by C-section delivery due to fetal distress. Gestational history is remarkable for polyhydramnios and IUGR. Clinical findings included microcephaly, dysplastic right ear, with left anotia and atresia of left ear canal, bushy eyebrows, prominent maxilla with flat face, long philtrum, and depressed nasal bridge with anteverted nares, thin vermilion border of upper lip, downturned corners of mouth, micrognathia and bifid uvula. He had hypertrichosis, VSD, ASD, septal hypertrophy, mild hepatomegaly, micropenis with hypospadias and cryptorchidism, and clinodactyly of fifth fingers. His thumbs and great toes were broadened at the tips, and his nails were narrow and hyperconvex. He later developed hypoglycemia, hepatosplenomegaly, ascites and thrombocytopenia. These findings are also seen in neonatal hemochromatosis, mannosidosis and transaldolase deficiency. The latter may present with facial features similar to CdLS. An extensive metabolic workup was performed. Mannosidosis was ruled out. His ferritin level was 3300 (normal 22-322) and his iron level was 164 (normal 40-100). Pseudomonas grew from his endotracheal tube later, and he had Klebsiella sepsis. Gastrografin barium enema showed a possible microcolon. The baby died before completion of work-up for the above mentioned conditions. The chromosome analysis revealed 46,XY,der(22)t(3;22)(q26.3;p13) indicating a partial trisomy for 3q26.3 to 3qter. Duplication 3q syndrome shows phenotypic overlap with Cornelia de Lange syndrome (CdLS), which has been mapped to 5p13.1. However, hepatosplenomegaly, ascites, hypoglycemia and thrombocytopenia are not reported in duplication 3q syndrome. His high ferritin and iron studies indicated possible neonatal hemochromatosis, but liver biopsy could not be completed due to his precarious condition and then death.

Clinical application of whole genome oligonucleotide array CGH demonstrates markedly improved sensitivity in detecting unbalanced chromosomal anomalies involved in human disease. *J. Compton, S. Bale, Y. Shevchenko, G. Richard* GeneDx, Gaithersburg, MD.

Oligonucleotide array comparative genomic hybridization (oligo aCGH) in microarray format has been used previously only in the research setting to detect unbalanced chromosomal anomalies. Encouraged by research results, we have tested the hypothesis that whole genome oligo aCGH analysis can significantly improve detection of disease-related anomalies as implemented in a clinical diagnostic laboratory. Here we report outcomes using a custom-designed 44,000 probe microarray with a near-uniform probe spacing of 80 kb across the genome except in large repetitive regions, and only 5 kb spacing in over 100 clinically significant regions or other locations of interest (e.g. sub-telomeres). Likely clinically-relevant gains or losses were confirmed by qPCR, microsatellite marker, or FISH analysis. At the time of writing, 119 specimens have been analyzed, of which 21 were positive; an overall positive yield of 17.6%. Among the 35 cases reported with normal G-band karyotype, 7 had positive findings (20%). Interestingly, 3 positive results were also obtained among the 35 cases submitted with previous negative findings from BAC-based targeted aCGH analysis, which suggests improved detection sensitivity of 10% using oligo aCGH compared to BAC-based aCGH. One patient with two separate balanced translocations by G-banding harbored a large interstitial deletion on another chromosome. In counterpoint, two patients with normal aCGH results were subsequently found to have mutations in single genes by sequence analysis, illustrating that clinical pathology and mutational spectrum of known disease genes should be used to guide the choice of diagnostic methodology. Our present data demonstrate that oligo aCGH will provide a significantly higher diagnostic yield compared to other cytogenetic methods. The high resolution possible with oligo aCGH provided a marked improvement in the detection of clinically-relevant chromosomal anomalies, yielded a more precise definition of breakpoints and boundaries, and refined interpretation of translocations that appeared balanced by karyotype analysis.

Joint genome-wide analysis of 3200 Crohn's disease patients documents more than 20 significant associations.
M.J. Daly on behalf of Crohn's Disease GWA Meta-analysis Working Group

Genome-wide association studies (GWAS) in Crohns disease (CD) published as of June 2007 have defined unequivocal evidence of 9 novel, replicating loci, increasing the total number of confirmed risk factors from 2 to 11. It is clear from the published data, however, that the loci identified to date constitute only a minority of the overall heritability, and that power in the individual studies was quite low to identify even loci that were later confirmed. Thus, to further gene discovery from these efforts, we have embarked on a joint analysis and coordinated replication study of top results. The combined study begins with a meta-analysis of the three published scans: 1748 cases/2938 controls (Wellcome Trust Case Control Consortium - UK) - Affymetrix 500K, 946 cases/977 controls (NIDDK IBD Genetics Consortium - North America) - Illumina HumanHap 300K, 547 CD cases/928 controls (Belgium/France) - Illumina HumanHap 300K. We have combined the existing genotype data with imputed genotypes predicted via statistical models of known haplotypes from the HapMap project to enable a joint analysis of roughly 3200 cases and 4800 controls on the superset of ~750,000 SNPs contained on one or both genotyping platforms. This combined data set offers substantially increased power to detect genes of modest effect - a 20% risk allele with an OR of 1.2 has only a 6% chance of achieving a p.0001 in a "typical" 1000 case/1000 control GWAS, but a 78% chance of doing so in the combined study. The initial meta-analysis convincingly confirms all replicated published loci (including established older associations at NOD2 and IBD5 and all recently reported hits such as IL23R, ATG16L1, IRGM, NKX2-3), 9 of which have p 10^{-8}. Importantly, the meta-analysis has revealed more than 30 additional loci with p 10^{-5}. Very few such results are expected by chance and, as the bulk of the distribution indicates no systematic inflation ($_{GC}$<1.1), the majority of these likely constitute novel risk factors. The results of a coordinated replication effort in independent samples will be reported, providing a dramatically augmented picture of the genetic architecture of Crohns disease.

Model for disclosure of research genetic testing results. *S. Adam[1], D. Avard[4], P. Birch[1], P. Eydoux[3], B. Knoppers[4], S. Langlois[1], M.A. Marra[2], J. Samuel[4], J.M. Friedman[1]* 1) Dept Med Genet, Univ BC; 2) Genome Sci Ctr, BC Cancer Agency; 3) Dept Path & Lab Med, Univ BC. (1-3 Vancouver, BC); 4) Centre de recherche en droit public, Univ of Montreal, Que.

Genetic research in children raises many ethical concerns, especially if clinical implications of the results are difficult to interpret. We have recently conducted a study of array genomic hybridization (AGH) in children with mental retardation (MR) of unknown etiology despite clinical genetics evaluation and conventional cytogenetic analysis. Although the families (and their referring clinicians) were informed that our research results may not be clinically interpretable, identifying a precise cause for the childs MR was almost always the major reason for study participation. We found potentially pathogenic but previously unreported de novo submicroscopic CNVs in approximately 15% of the first 200 patients. In response to repeated requests to provide our research results to the families, we developed a model for disclosure of research AGH results that integrates the research, clinical and laboratory teams. Our disclosure process involves the collection of fresh blood samples and confirmation of the research result by a clinical laboratory using an established clinical method. Typically, locus-specific FISH is done with a probe chosen on the basis of the AGH findings. Thereafter, the research team consults with the familys geneticist and genetic counsellor regarding the limitations and interpretation of the findings. Considerations include the occurrence of similar CNVs or cytogenetic abnormalities in reported cases and available databases, the presence of apparently benign CNVs in the region, the genetic content, and genotype-phenotype correlations. The degree of uncertainty associated with interpretation of the CNV as pathogenic for the childs MR is explicitly considered. The family is then offered genetic counselling by the clinical geneticist and genetic counsellor who enrolled the child in the study. As clinical applications of new genetic technologies are developed, a comprehensive model for disclosure of research results to families participating in clinical studies will be critical.

Gaucher disease therapeutic biomarker: Dried blood spot assays for chitotriosidase genotype and enzyme activity. *M.E. Grace, M. Balwani, R.J. Desnick* Department of Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York, NY.

Gaucher disease (GD), due to the deficient activity of acid -glucosidase, is the most prevalent lysosomal storage disease. The enzymatic defect results in the progressive accumulation of glycosylceramide (GL-1), primarily in the monocyte/macrophage system throughout the body. Due to the macrophage involvement, GD patients have high levels of plasma chitotriosidase, an enzyme secreted by activated macrophages. CHITO activities in untreated GD patients typically are ~600-fold greater than those in normal controls, and generally, are correlated with disease severity. Plasma CHITO activity has proven useful for monitoring disease severity and the effectiveness of various therapies for GD. The CHITO genotype is key to interpreting plasma CHITO levels in patients, as there are common low activity (G102S) (Grace et al. Hum Mut, Epub 2007) and null (dup24) alleles in ~50% and ~40% of patients, respectively. To facilitate CHITO genotyping and activity assays, a dried blood spot (DBS) assay was developed. The DBS provided a source of DNA for genotyping. The enzyme assay was performed by incubating a 2 mm DBS (equivalent to ~1.4 L blood) with substrate for 2 hr at 37C with shaking. There was excellent correlation between the direct plasma and DBS assays over a range of 50 to ~1000 nmol/h/mL. In a test of 30 blinded GD samples, two samples with no activity in the DBS assay were homozygous for the dup24 null allele. The sample with the lowest plasma activity (22 nmol/h/mL) had the lowest mean DBS activity (52 nmol/h/mL). Analogously, the sample with the highest plasma activity (917 nmol/h/mL) had the highest mean DBS activity (860 nmol/h/mL). Replicate assays over a two month time period demonstrated the stability of CHITO activity on the filter paper. These studies demonstrated the feasibility of offering CHITO enzymatic and DNA analyses by DBS for initial evaluation and periodic monitoring.

Graphical synthesis of association results and neighboring linkage disequilibrium. *E. Jorgenson, M. Kvale, J.S. Witte* Epidemiology & Biostatistics, Univ California, San Francisco, San Francisco, CA.

Promising findings from association studies are commonly presented with two distinct figures: one giving results of the association study, and the other indicating linkage disequilibrium between genetic markers in the region(s) of interest. For example, a number of recent genome-wide association studies have presented their most compelling results in this manner. Usually, this means plotting p-values on a negative log base 10 scale and displaying a linkage disequilibrium map beneath those results. Ideally, these results would be combined together, and indicate how linkage disequilibrium affects the observed association signal and help localize the causal variant(s).

Here we present a method for displaying both association results and linkage disequilibrium between genetic markers in the same figure. Using this method, we are able to plot both the association results and the expected association results for each genetic marker conditional on their linkage disequilibrium with other markers in the region. It is then possible to test whether the association result for a given maker significantly exceeds the expected association due to linkage disequilibrium with other markers. Software that can efficiently handle dense genotype data over large regions is available on our website.

Association of gene SCL11A1 with Rheumatoid Arthritis in a Mexican population. *E.R. Ochoa-Martínez[1,5], M.P. Casillas-Avila[4], L. González-López[3], E.A. Aguilar-Chávez[3], I.J. Gámez-Nava[1], V.M. Anguiano-Alvarez[4], I.P. Dávalos-Rodríguez[1], M. Salazar-Páramo[2], L. Sandoval-Ramírez[1]* 1) División de Genética, Centro de Investigación Biomédica de Occidente, CMNO, IMSS, Guadalajara Jalisco Mexico; 2) Hospital de Especialidades, CMNO, IMSS; 3) Hospital General Regional No 110 IMSS; 4) Doctorado en Genética Humana, Centro Universitario de Ciencias de la Salud; 5) Centro Universitario de Ciencias Biológicas y Agropecuarias, Universidad de Guadalajara, Guadalajara, Jalisco, Mexico.

The SLC11A1 gene codifies for macrophage to a natural resistant protein 1, it has been considered as a candidate gene for autoimmune diseases susceptibility. This suggests that SLC11A1 is a candidate gene for autoimmune diseases genetic susceptibility, like Rheumatoid Arthritis (RA) and infections that involve macrophage response. Objective: To determine if there is an association between 823CT, D543N, 1729+55del4 polymorphisms and Rheumatoid Arthritis susceptibility. The polymorphisms were analyzed in 109 healthy individuals as control and 148 RA patients diagnosed according to the ARA (American Rheumatology Association), this patients are from IMSS Guadalajara, Jalisco. Genotypes analyses were made by PCR-RFLP technique, using primers and enzymes described by Liu et al (1995). The enzymatic digestion products, were solved with electrophoresis of poliacrilamide gels (29:1) final concentration at 6%, and were dyed with silver nitrate (AgNO3). The allelic frequencies of 823CT indicate a statistically significant difference (p= 2.9x10-4 OR= 0.45 (IC 95% 0.29 - 0.71)). Comparing genotype frequency between patients and control was significant to the CC variant (p= 1.8x10-4 OR 0.37) CT (p= 1.8x10-3 OR 2.33), but not significant for TT (p= 0.14 OR 2.32) in 823CT. The D543N and 1729+55del4 polymorphisms can not be associated as a susceptibility factor to Rheumatoid Arthritis, because genotypes and allelic frequencies were similar for both groups. Statistical analysis of 823CT polymorphism between controls and patients suggest that this polymorphism is associated with susceptibility to Rheumatoid Arthritis, specifying that the C allele confers protection to RA in Mexican population.

Transcription Factor 7-Like 2 *(TCF7L2)* interacts with Arachidonate 5-Lipoxegenase *(5-LO)* to decrease fasting insulin (FI) in Mexican Americans (MA). *M.H. Black[1], J. Hartiala[1,2], A. Xiang[1], E. Trigo[3], M. Kawakubo[1], J. Lawrence[4], T.A. Buchanan[3], R.M. Watanabe[1], H. Allayee[1,2]* 1) Dept of Prev Med, Keck Schl of Med of USC, Los Angeles, CA; 2) Inst for Genetic Med, Keck Schl of Med of USC, Los Angeles, CA; 3) Dept of Med, Keck Schl of Med of USC, Los Angeles, CA; 4) Kaiser Permanente, Pasadena, CA.

5-LO, which generates pro-inflammatory leukotrines, has been implicated in atherogenesis and has recently been shown to play a role in adiposity and insulin homeostasis. *5-LO* -/- mice are obese and have lower insulin secretion versus wild type mice. Genome-wide studies have established *TCF7L2* as a susceptibility gene for type 2 diabetes (T2D). As both *TCF7L2* and *5-LO* are involved in Wnt signaling, we hypothesized that interaction between *TCF7L2* and *5-LO* may be associated with FI in humans. To test this hypothesis, we genotyped *TCF7L2* rs7903146 and the *5-LO* promoter-repeat variant in 143 MA families from the BetaGene study. Participants were phenotyped with oral and intravenous glucose tolerance tests. We report data from 672 subjects (41% male, 59% female) with mean age 34.09.1 yrs and BMI 29.36.0 kg/m^2. Variant interaction was tested for association with T2D-related traits using a likelihood ratio test under a variance components framework, adjusting for age and sex. Given functional data showing increasing *5-LO* expression with decreasing repeat size, we assumed an additive genetic model for *5-LO*. rs7903146 was tested under a dominant genetic model due to low minor allele frequency. Interaction between rs7903146 and *5-LO* promoter repeats was significantly associated with FI (p=0.038). Among *TCF7L2* CC subjects (n=413), FI decreased by ~1 U/ml with decreasing *5-LO* repeat length. In contrast, among *TCF7L2* T carriers (n=259), those with at least one *5-LO* 3 repeat had FI levels more than twice that of subjects with *5-LO* 4 or 5 repeats. This decrease in FI with increasing number of *5-LO* repeats among *TCF7L2* T carriers is consistent with reduced insulin observed in *5-LO* -/- mice. These results suggest that variation in *5-LO* and *TCF7L2* play an interdependent role, possibly through Wnt signaling mechanisms, in regulating FI levels in MA.

Paternal X-linked gene(s) associated with increased risk of autism spectrum disorder in females. *N. Gharani, R.A. Zimmerman, B.J. Smith, S. Buyske, D.M. Waterworth, L.M. Brzustowicz* Dept Genetics, Rutgers Univ, Piscataway, NJ.

Autism is a serious neurodevelopmental disorder with a complex genetic basis. Males are at least four times more likely to be affected than females, suggesting a role for X-linked genetic and/ or epigenetic features in the etiology of the disease. One of the epigenetic processes that regulate X-chromosome gene expression in females is X-chromosome inactivation (XCI). We hypothesized that skewing of XCI may play a role in autism by modulate the threshold of risk in female members of autism families. To explore this possibility we investigated the XCI pattern of 337 ASD affected and unaffected female members from 145 autism families using a standard published technique that examines differential methylation of the Androgen Receptor gene on active and inactive X-chromosomes. Of the 337 samples assayed for XCI patterns, 40 were uninformative (homozygous for the CAG repeat). Our data in 297 informative individuals demonstrates skewed XCI in both affected and unaffected females with as many as 42% of samples showing a skewing ratio of >80:20, which is significantly higher ($P < 0.0001$) than 9% observed in the normal female population. Since XCI skewing is observed in both affected and unaffected individuals we have investigated the parental origin of the active X-chromosome in 129 informative ASD affected probands and unaffected siblings (for whom parental origin of the X could be unequivocally assigned). This analysis has shown a higher proportion of affecteds (74%) in the group with a predominantly paternal active X-chromosome compared to ~50% of those with skewing towards a maternal active X-chromosome (Fishers exact $P=0.007$; OR=2.80, 95% C.I. 1.34, 5.83). Individuals are ~3 times more likely to be affected if there was skewing towards a paternal rather than maternal active X-chromosome. These data implicate a paternal X-chromosome in the risk of autism in females, suggesting a role for imprinted gene(s). These results support the hypothesis that variable expression at critical X-linked imprinted gene(s) alter an individuals threshold of risk for ASD and that skewed XCI is the mechanism by which this threshold is altered in females.

Sequential phenotype/genotype FISH assay targeting rare tumor cells using archived bone marrow smears and paraffin embedded tissue sections. *V. Bedell[1], S.J. Forman[2], K. Gaal[3], V. Pullarkat[2], L.M. Weiss[3], G. Somlo[2], S. Wilcyznski[3], M.L. Slovak[1]* 1) Cytogenetics, City of Hope, Duarte, CA; 2) Hematology & Hematopoietic Cell Transplantation, City of Hope, Duarte, CA; 3) Anatomic Pathology, City of Hope, Duarte, CA.

Interphase fluorescent in situ hybridization (FISH) is the standard cytogenetic assay to detect specific clonal karyotypic aberrations in formalin-fixed paraffin-embedded tissue (PET). Direct correlation with immunophenotype or morphology in focal disease or infrequent cell types is rarely performed because the procedure is labor-intensive and usually requires extensive troubleshooting. We examined various archived leukemic bone marrow smears and paraffin embedded tissue, many of which were second opinion or consult cases, either to help the clinician have a better picture of the evolution of a patients hematologic malignancy or to assess a specific genetic target, such as IGH@ or ERBB2, in samples with low tumor burden. We present a sequential FISH-based technique that utilizes the identical bone marrow smears or PET sections evaluated by a pathologist to target rare tumor cells; specifically plasma cells, mast cells, or leukemic blasts in 11 archived bone marrow smears and CD20 positive cells in 21 lymphomas. Thirty-two breast tumors were also analyzed. Successful hybridization was achieved in 62/64(97%)samples. The two unsuccessful samples were not evaluable by our current automated system configuration. Seven blinded control sections were all concordant (5 negative/2 positive). Cutoff limits were determined independently for each FISH probe used, and ranged from 2-5%. The method was applicable with various probes, both commercially available and homebrew, in specimens ranging in age from one month to 14 years. The methodology is straightforward, using uncomplicated pretreatment and hybridization conditions. Basic equipment, attached to an automated image analyzer with image capture software, records the location of targeted cells for genotypic/phenotypic correlation. This assay is reliable and reproducible on test samples regardless of specimen age, probe design, tissue type or referring institution.

A *cis*-regulatory map of the human embryonic stem cell genome. *R.D. Hawkins[1, 2], G. Hon[1, 2], J.E. Antosiewicz[3], J.A. Thomson[3], B. Ren[1, 2]* 1) Laboratory of Gene Regulation, Ludwig Institute for Cancer Research, La Jolla, CA; 2) Department of Cellular and Molecular Medicine, UCSD School of Medicine, La Jolla, CA; 3) The Wisconsin National Primate Research Center, University of Wisconsin-Madison, Madison, WI.

The self-renewal capacity and pluripotency of embryonic stem cells (ESC) depend on the complex interactions between transcription factors and genomic regulatory sequences in these cells. Our ability to exploit the human embryonic stem cells for therapeutic purposes is currently limited by an incomplete understanding of the *cis*-regulatory elements in the human genome. As a first step towards elucidating the mechanisms of self-renewal and cell fate commitment by human ESC, we have systematically identified and characterized the promoters, enhancers and insulator elements in the human genome in undifferentiated human ESC and in differentiated ESC after BMP4 treatment. We accomplish this by locating the genomic binding sites of specific histone modifications and the insulator binding protein CTCF in these cells using ChIP-chip analysis and genome tiling microarrays. We find that the patterns of insulator protein binding to DNA and chromatin modifications at promoters are nearly invariant before and after differentiation. By contrast, the chromatin modifications at enhancers undergo significant changes during this process. We identified specific enhancers that correspond to genes involved in self-renewal as well as differentiation and development. We find that a single gene is often driven by multiple enhancers, and that the effect of multiple enhancers is generally additive. This genome-wide map of *cis*-regulatory elements will provide insights on the regulatory mechanism for stem cell maintenance and differentiation.

A novel presentation of twins with an interstitial 11q deletion and discordant phenotype. *R. Arvon[1], S. Madan-Kheterpal[2], S. Emery[1], U. Surti[1]* 1) Magee Womens Hospital of University of Pittsburgh Medical Center, Pittsburgh, Pa; 2) The Children's Hospital of Pittsburgh of University of Pittsburgh Medical Center, Pittsburgh, Pa.

We report a case of twins who both inherited an unbalanced rearrangement from their father, a balanced insertional carrier, and who exhibit clearly different phenotypes. A 32 year old G 2 P 1 with a dichorionic/diamniotic twin pregnancy presented at 32 wks after twin A was diagnosed with a congenital diaphragmatic hernia (CDH). The father of the subjects mentioned that he had a balanced chromosomal rearrangement found when his mother underwent an amniocentesis for advanced maternal age in 1977. Both the ultrasound exam and fetal MRI of twin A confirmed a left-sided CDH as well as a single umbilical artery (SUA) and micrognathia. The ultrasound exam of twin B revealed normal anatomy. We obtained a blood sample from the father and an amniocentesis was performed on each twin. The father was found to be a balanced carrier of an insertion of 11q into 5p 46,XY,ins(5;11)(p13.1;q14.2q23.1) assumed to be de novo because he reported that his parents had normal karyotypes. Chromosomal analysis of the amniotic fluid of both twins revealed partial monosomy of 11q 46,XY,del(11)(q14.2q23.1)pat at 650 bands. The mother went into premature labor and delivered both twins at 32 wks . Twin A expired within a few hours after birth and autopsy confirmed a left-sided CDH with abdominal organs in the left chest as well as a SUA and micrognathia. At birth, twin B was noted to have bilateral talipes equinovarus and appeared dysmorphic. The prominent features were micrognathia, down slanting palpebral fissures, mild hypertelorism and posteriorly rotated and simple ears. Chromosomal analysis at 650 bands performed post-natally confirmed the karyotype in both twins 46,XY,del(11)(q14.2q23.1)pat. At present, zygosity testing of both subjects to help determine the reason for the discrepancy in the phenotypes is pending. Partial monosomy of 11q has been previously reported, however not with the same break points as our subjects and the discrepancy in the phenotypes of the twins was unexpected, making this case unique.

Haplotypes 5 and 3 of the globin cluster genes in two Mexican Amerindian populations. *M. Casas-Castañeda[1], M.T. Magaña[2,3], L. Sandoval[2,3], A.R. Villalobos-Arambula[4], F.J. Perea[2,3], B. Ibarra[2,3]* 1) Instituto de Ciencias Biologicas, Universidad Autonoma de Guadalajara, Guadalajara, Guadalajara, Mexico; 2) Division de Genética Centro de Investigacion Biomedica Occidente Inst Mex del Seguro Social Guadalajara Mexico; 3) Doctorado en Genetica Humana Universidad de Guadalajara Guadalajara, Mexico; 4) Centro Universitario de Ciencias Biologicas y Agropecuarias Universidad de Guadalajara Guadalajara Mexico.

In this work we analyzed ten polymorphisms of the -globin genes, in two Mexican native populations, Purepechas and Tarahumaras, with the aim of determining the 5'and 3'haplotypes (Hps) and the relationship with the reported populations. Five sites (Hinc II-, Hind III-G, Hind III-A, Hinc II-5'and Hinc II-3') to the 5 Hp and five (Exon 1 nucleotide 16, intron 1 nucleotides 46, 74 and 81, and Hinf I-) to the 3 Hp. Six sites were identified by RFLP's and four by sequencing. The results were compared with the previously studied populations. 5' Hp: In Purepechas we found 8 different Hps, the three most common were 1 (72.3%), 11 (10.3%) and 2 (8.3%). In Tarahumaras we observed 7 distinct haplotypes, with 1 (79.4%), 14 (8.7%) and 5 (5.1%) having the highest frequencies. The genetic and nucleotide diversity in both populations showed mean values respect to 32 reported populations. In the genetic distances, only Tarahumaras did not show significant differences with Huichols and Koreans. 3' Hp: The Purepechas revealed 7 different Hp and 6 the Tarahumaras; C, A and B1 were the more frequent in both populations. We found three news 3'Hps, CTGCT in both populations, GTTCT in Purepechas and GTGCA in Tarahumaras. The diversity values are similar in the 10 analyzed populations, in agreement with the location of the 5 studied polymorphisms, since they are intragenic and then more conserved. Both populations did not display differences with Asian populations (Sumatra and Mongolia); in addition Tarahumaras also was similar to Nuu-Chah-Nult Amerindians.

Identification of a ciliary protein as a novel contributor to sporadic heterotaxia. *E.E. Davis[1], J.W. Belmont[2], H. Omran[3], N. Katsanis[1]* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore MD 21205, USA; 2) Department of Molecular and Human Genetics and Division of Cardiology, Department of Pediatrics, Baylor College of Medicine, Houston, Texas, USA; 3) Department of Pediatrics and Adolescent Medicine, University Hospital Freiburg, Freiburg, Germany.

Heterotaxia is defined as the spectrum of birth defects where asymmetric left-right (LR) patterning is perturbed; typical manifestations include cardiovascular, gastrointestinal, pulmonary, and genitourinary anomalies. Despite its frequent occurrence in the population (as high as 1:500 live births), the genetic basis for heterotaxias remains largely unknown. It has been shown that defects in cilia in the embryonic node can cause a constellation of phenotypes including LR determination defects, as in the case of Kartagener syndrome, or, less frequently, in Bardet-Biedl syndrome, we hypothesized that mutations in ciliary protein-encoding genes could contribute to sporadic heterotaxia. To explore this possibility, we took advantage of a recently defined integrated ciliary proteome to screen a series of known and novel ciliary genes in a panel of heterotaxia patients. For one transcript, CP007, we have found both nonsense and missense mutations in highly conserved amino acids in ~2% of patients. To confirm the pathogenic potential of the missense variants, we pursued a functional analysis in zebrafish, where we have measured the ability of mutant mRNA to rescue LR-determination defects caused by cp007 suppression; our preliminary data suggest that some of the cp007 mutations compromise but do not completely abrogate the function of the CP007 protein and support the potential role of this transcript in sporadic heterotaxias. Overall, our data suggest that partial loss of ciliary function predisposes to LR determination defects in humans and that evaluation of additional ciliary genes will expand our appreciation of the total mutational load in this phenotype. Finally, the implementation of an in vivo model to evaluate all variants found represents an indispensable tool that will likely be important in the emerging medical resequencing era.

High Resolution Measurements of Copy Number Variant Regions. *A. Ben-Dor[1], N. Sampas[1], A. Tsalenko[1], A. Scheffer-Wong[1], S. Dallaire[2], J. Tchinda[2,3], P. Tsang[1], A. Yamada[1], Z. Yakhini[1], G.H. Perry[2], C. Lee[2,3], S. Laderman[1], L. Bruhn[1]* 1) Agilent Technologies, Santa Clara, CA; 2) Brigham & Women's Hospital, Boston, MA; 3) Harvard Medical School, Boston, MA.

Genomic copy number variations (CNVs) are a major source of genetic differences between individuals. Technological improvements for the discovery and characterization of CNVs will advance our understanding of their prevalence, complexity, and association with disease-related phenotypes. In order to detect CNVs that encompass a wide range of sizes and complexities, we have developed a database of ~16 million 60mer probe sequences that cover the non-repeat masked portion of the genome at an average spacing of 100bp. These probes were selected according to stringent thermodynamic and sequence characteristics. In addition, we developed an efficient algorithmic workflow for the analysis and visualization of CNV data that includes a statistically robust approach for calling CNV intervals in individual samples as well as methods for grouping per-sample variants into CNV regions (CNVRs). We evaluated the performance of the platform by profiling DNA samples from healthy individuals, e.g. from the Hapmap set, using custom 244K feature arrays with probes focused on candidate CNVRs. CNV we detected with multiple consecutive probes range from <200bp to several Mbp, and exhibit a large spectrum of complexities, from simple CNVRs with virtually no variation in size between individuals to very complex regions (i.e. the HLA region on Chr6). Moreover, we are able to detect many regions with clearly distinct copy number states in different individuals. To estimate reproducibility rates we performed three independent measurements comparing two DNA samples previously profiled in various studies (NA15510 vs. NA10851) using a two array set comprising 470,143 probes encompassing 2192 known CNV regions. On average, 420 multi-probe CNV were called in each sample. These CNV were highly reproducible (8% false-positive rate, and 5% false-negative rate). In addition, the boundaries of the regions were called very consistently; more than 85% of the boundaries were mapped to within single probe resolution.

Genetic variants associated with myocardial infarction (MI) risk in five ethnic groups: the INTERHEART genetics study. *J.C. Engert[1], C. Xie[2], A. Montpetit[3], D. Serre[3], B. Keavney[4], H. Cordell[4], M. McQueen[2], S. Yusuf[2], T.J. Hudson[1,3], S.S. Anand[2] for the INTERHEART genetics investigators* 1) Depts. of Medicine and Human Genetics, McGill Univ., Montreal, QC; 2) McMaster Univ., Population Health Res Inst., Hamilton Health Sciences, Hamilton, ON; 3) McGill Univ. & Genome Quebec Innovation Centre, Montreal, QC; 4) Univ. of Newcastle upon Tyne, Newcastle-upon-Tyne, UK.

The INTERHEART case-control study showed that 9 modifiable risk factors (tobacco, diabetes, hypertension, dyslipidemia, abdominal obesity, physical inactivity, psychosocial stress, low fruit and vegetable intake, and no alcohol consumption) account for > 90% of the population attributable risk for MI globally. We investigated the association between candidate gene SNPs and MI and risk factors for MI in 8,034 individuals from 5 ethnic groups. Samples from individuals of South Asian, Arab, Iranian, Nepalese and European origin were genotyped for 1,536 tagging and other SNPs in 103 candidate genes. 1,442 SNPs were polymorphic and in HWE in all 5 ethnic groups. We used a staged design in which 1,344 of these SNPs were first assessed versus the MI risk factor(s) with which they were hypothesized to be associated. SNPs significantly associated with a risk factor (after adjusting for age, sex and ethnic group, and correcting for multiple testing) were passed to stage 2 and tested in an additive model versus MI. Cases and controls were matched by ethnic group, sex and age (+/- 5 years). An empirical p value was determined using permutation testing in stage 2. Fifteen SNPs passed stage 1 testing: 12 SNPs were associated with Apo B/A ratio, 2 SNPs with alcohol intake, and 1 SNP with fruit and vegetable intake. Three SNPs from two lipid related loci (ApoE and LDLR) were associated with MI in 5 ethnic groups. Notably, all 3 associated SNPs were protective alleles. The ApoE SNP (rs7412) is the one that defines isoform 2 and it had an odds ratio of 0.78 (95% CI: 0.70-0.89) and a p-value of 0.0004. The LDLR SNPs were both intronic: rs1433099 had an OR of 0.90 (95% CI: 0.84-0.96) and a p-value of 0.002 and rs6511720 had an OR of 0.86 (95% CI: 0.77-0.95) and a p-value of 0.004.

Interactions involving nitric oxide synthase genes and environmental risk factors in Parkinson's disease. *D.B. Hancock[1], E.R. Martin[2], J.M. Vance[2], W.K. Scott[2]* 1) Duke University, Durham, NC; 2) University of Miami, Miami, FL.

Nitric oxide synthase (NOS) genes (*NOS1*, *NOS2A*, and *NOS3*) are biological candidate genes for Parkinsons disease (PD), as excess nitric oxide (NO) levels are associated with dopaminergic neuronal depletion in the substantia nigra. NO levels may also be influenced by the putative PD risk factors cigarette smoking, caffeine, nonsteroidal anti-inflammatory drugs, and pesticides. Thus, combinations of NOS-related genetic and environmental factors might be important in the etiology of PD. We genotyped 27 *NOS1* coding and tagging SNPs, 18 *NOS2A* SNPs, and 5 *NOS3* SNPs in 337 families with no history of PD (337 cases, 389 relative and other unrelated controls) and examined allelic associations with PD using the Association in the Presence of Linkage (APL) test and the Pedigree Disequilibrium Test (PDT). In those with environmental risk factor data (163 cases and 178 controls), interactions between the risk or minor allele of each SNP and exposure history of each risk factor (ever vs. never) were assessed with generalized estimating equations. Significant associations were found for the *NOS1* SNPs rs3782218, rs11068447, rs7295972, rs2293052, rs12829185, rs3741475, and rs2682826 (p=0.00083-0.046) and the *NOS2A* SNPs rs2072324, rs944725, rs12944039, rs2248814, rs2297516, rs1060826, and rs2255929 (p=0.0000040-0.047) using APL and/or PDT in at least one of three family subsets, in which the case reported an age-at-onset less than 40, 45, or 50 years old. There were no significant associations of *NOS3* SNPs with PD. Significant interactions ($p<0.05$) between pesticides and two of the *NOS1* SNPs (rs12829185 and rs2682826) and between smoking and two of the *NOS2A* SNPs (rs2248814 and rs1060826) were detected. These data support *NOS1* and *NOS2A* as genetic risk factors for PD and demonstrate that their interactions with established environmental PD risk factors may influence susceptibility to PD development.

First prenatal detection of maternal uniparental disomy (UPD) of chromosome 6 and rescue of trisomy 6. *M. Haag[1], L. Beischel[2], J. Rokeach[3], D. Wallace[3], J. Knops[1], K. O'Connor[1], J. Johnson[2], J. Ibrahim[4]* 1) Genzyme Genetics,Santa Fe,NM; 2) Shodair Genetics Laboratory,Helena,MT; 3) Monmouth Medical Group,Long Branch,NJ; 4) Genetics,St. Josephs Regional Medical Center,Paterson,NJ.

Uniparental disomy (UPD) can result from a meiotic or postzygotic nondisjunction event followed by trisomy rescue and is of concern when trisomy mosaicism is detected during routine prenatal diagnosis. Characteristic phenotypes resulting from UPD are emerging along with better understanding of novel mechanisms of gene expression, such as imprinting. In well documented cases of UPD 6 that are paternal in origin there has been a strong association with transient neonatal diabetes due to abnormal expression of an imprinted gene. However, maternal UPD 6 is a very rare finding and no consistent phenotypic picture has yet emerged. We report here a case of maternal UPD 6 that was ascertained through trisomy 6 mosaicism observed in cultured chorionic villi from a 45 year old patient. Trisomy 6 was not detected in a follow-up amniocentesis. Analysis of DNA polymorphisms for chromosome 6 in amniocytes and parental samples showed markers which lacked an allele of obligate paternal origin. All loci were homozygous in the amniocytes, consistent with maternal uniparental isodisomy 6. DNA marker analysis confirmed paternity. The pregnancy was monitored by serial ultrasounds and IUGR was detected at 29 weeks. Other fetal parameters were within normal limits. The patient delivered at 33 weeks with no further fetal complications noted. Full trisomy 6 is apparently lethal to human development, reported only in fetal demise. One third of trisomy rescue for chromosome 6 results in UPD, which is compatible with development to term. Almost all cases of UPD 6 (maternal and paternal) exhibit isodisomy consistent with rescue of a meiosis II error. Reports of maternal UPD 6 have shown an association with intrauterine growth retardation (IUGR). This case offers the first example of prenatal detection of maternal uniparental isodisomy 6, associated with IUGR and early delivery, but an otherwise favorable outcome, indicating that the trisomic cells were most likely confined to the placenta.

LDLR polymorphisms, cholesterol and Alzheimers disease. *S. Estus[1], H. Zhu[1], F. Zou[2], J. Lok[2], S. Younkin[2], A.K. Manning[3], K.E. Grear[1], I.F. Ling[1], H.M. Tucker[1], J.F. Simpson[1], J. Kelly[4], D. Bennett[4], L.A. Cupples[3], S.G. Younkin[2]*
1) Physiology, University of Kentucky, Lexington, KY; 2) Neurosciences, Mayo Clinic, Jacksonville, FL; 3) Biostatistics, University of Boston, Boston, MA; 4) ADC, Rush University Medical Center, Chicago, IL.

Functional SNPs within the low-density lipoprotein receptor (LDLR) represent powerful investigative tools. Here, we focus on cholesterol homeostasis because LDLR mutations cause familial hypercholesterolemia and on Alzheimers disease (AD) because LDLR is a receptor for apoE, alleles of which modulate AD risk. Our first SNP of interest, rs688, neutralizes a putative LDLR exon 12 splicing enhancer and associates with decreased exon inclusion in vivo in a gender-dependent fashion; in vitro minigene studies establish rs688 as a functional SNP. We hypothesize the rs688 minor allele decreases LDLR function because the LDLR isoform lacking exon 12 encodes a truncated, non-functional receptor. The second SNP of interest is rs2738464 within the LDLR 3UTR, the minor allele of which we associated with increased LDLR mRNA by comparing LDLR allelic expression in heterozygous individuals; we hypothesize the rs2738464 minor allele enhances LDLR function. We evaluated these SNPs for association with cholesterol homeostasis in the Framingham Offspring Study and with AD in several case-control series. The minor allele of rs688 associates with modest but significant increases in LDL (7 mg/dl) and total cholesterol (5 mg/dl) in women (adjusted values, p0.05) but not men; this gender difference reflects rs688 association with splicing efficiency in the female but not male liver. Preliminary analyses indicate that the rs688 minor allele associates with increased AD odds in men (OR of 1.48, 95% CI of 1.13-1.96, p=0.005, recessive model, n=1,535), but not women, reflecting its association with decreased splicing in the human male brain. Preliminary analyses indicate that rs2738464 associates with lower LDL and total cholesterol in men and women. Evaluation of rs2738464 with AD is on-going. In summary, these studies suggest that LDLR variants may contribute to cholesterol homeostasis and risk for AD in a gender-dependent fashion.

The telomeric protein TRF2 and Nijmegen Breakage syndrome protein NBS1 modulate the association of the ataxia-telangiectasia protein ATM with DNA damage. *P. Bradshaw[1], W. Wang[1], D.J. Stavropoulos[1,2], M.S. Meyn[1,2]*
1) Genetics & Genome Biology, Hospital for Sick Children, Toronto, ON, Canada; 2) Molecular & Medical Genetics, Univ of Toronto, Toronto, ON, Canada.

Eukaryotes use complex networks to respond to as few as 2-4 induced double-strand breaks (DSBs) in genomic DNA. The ATM protein kinase plays a key role in the major human DSB response network by associating with damaged chromatin, then activating DNA repair, cell cycle checkpoints, and other damage responses. To better understand the ATM response, we used laser microbeam irradiation to induce DNA damage in human fibroblasts then followed the localization of endogenous ATM and GFP-tagged ATM to photo-induced DNA damage. We find that endogenous ATM rapidly forms foci that, unlike H2AX, tightly colocalize with damaged DNA. GFP-ATM localizes to photo induced DNA damage within 3-5 seconds post irradiation and GFP-ATM accumulation plateaus within 2 minutes post-irradiation. In cells deficient for NBS1, a member of the MRN DSB sensing complex, GFP-ATM does not associate with damaged DNA in the first minute post-irradiation. In contrast, mutating the ATM 1981 phosphorylation site from serine to alanine delayed but did not block accumulation of GFP-ATM at damaged DNA. The telomeric ends of chromosomes normally do not trigger DNA damage responses, in part due to the telomeric protein TRF2. We find that TRF2 and TRF1 associate as rapidly as ATM with photo-induced DNA damage in non-telomeric DNA and that TRF2 over-expression impairs phosphorylation of ATM, H2AX and p53 following ionizing radiation. Additionally, over-expression of a DsRed-tagged TRF2, but not TRF1, attenuates GFP-ATM accumulation at DNA damage. Our data indicate that a functional MRN complex is required for ATM recruitment to damage sites, and optimal accumulation of ATM at damaged DNA may require phosphorylation at serine 1981. In contrast, interactions with TRF2 appear to dampen the ATM response to DSBs, supporting a model in which TRF2 interactions with ATM promote local repair of non-telomeric DNA damage while inhibiting ATM-dependent activation of global DNA damage responses such as cell cycle checkpoints and apoptosis.

THALIDOMIDE THERAPY IN A PATIENT WITH THALASSEMIA MAJOR. *L. Aguilar Lopez[1], J.L. Delgado-Lamas[1], B. Rubio[1], F.J. Perea[2,3], B. Ibarra[2,3]* 1) Servicio de Hematologia, Hospital de Especialidades UMAE, CMNO, IMSS, Guadalajara, Mexico; 2) Division de Genetica, Centro de Investigacion Biomedica de Occidente, CMNO, IMSS Guadalajara Mexico; 3) Doctorado en Genética Humana, Universidad de Guadalajara, Guadalajara, Mexico.

The thalassemia is characterized by a deficiency or absence of globin chains. The homozygote state (Thalassemia Major), has high blood transfusion requirements since early age. We describe a 21 years old women with Thalassemia Major diagnosed at 5 months of age. In 1997, the biochemical studies showed high HbF levels (62.3%) and HbA2 of 3.61%, the genotype was identified as -28 A-C/Cd 39 T-C. She had chronic blood transfusions, every 2 or 3 months, with an iron overload. She was splenectomized at the age of five years. She had received chelation therapy (Desferoxamina) with different time intervals. Her hemoglobin levels without transfusion were as low as 2.9 g/dL. The patient was received at the hematology service of the Hospital de Especialidades in Dcember 2001 with 4.0 g/dL, when she initiated the thalidomide therapy (100 mg per day), the first hemoglobin increase was observed after three moths to 7 g/dL, since then she has the thalidomide therapy uninterruptedly and never was transfused again with hemoglobin levels between 7.6 to 10.6 g/dL and almost 100% of HbF. She is at present in good health conditions with hemoglobin values of 10.2 g/dL. To our knowledge this is the first report of a Thalassemia Major patient treated with thalidomide with such a great results at the hemoglobin levels and general good health conditions. The molecular and physiological effects of the thalidomide must be deeply investigated, since it is know the angiogenic effect in cancer, the benefic effect in thalassemic patients could be mediated by its gene modulator effect however the true mechanism require to be investigated.

Population-based WGA studies of cigarette smoking reveal novel genes for nicotine dependence. *W. Berrettini[1,2], X. Yuan[2], K. Song[2], D. Waterworth[2], H. Chilcoat[2], P. Vollenweider[3], G. Waeber[3], M. Preisig[3], P. Muglia[2], F. Tozzi[2], V. Mooser[2]* 1) Dept Psychiatry, Univ Pennsylvania, Philadelphia, PA; 2) GSK R&D, Upper Merion, PA, Research Triangle Park, NC and Verona, Italy; 3) CHUV University Hospital Lausanne Switzerland.

BACKGROUND: Cigarette smoking, a major risk factor for lung and cardiovascular diseases, is the single largest preventable source of morbidity and mortality in North America and Europe. Twin and adoption studies indicate that a majority of risk for nicotine dependence (ND) is genetic. The goal of the present study was to find novel genes associated with ND, in an effort to identify new drug targets for this addiction. METHODS: We conducted WGA analyses of cigarettes-per-day (CPD) as a quantitative trait in a cross-sectional population-based sample of 5641 European-origin subjects from the city of Lausanne, Switzerland, and in a second sample of ~974 European-origin persons, selected for the presence or absence of dyslipidemia. Genotyping was done with Affymetrix 500K chips. Finally, CPD analysis of ~ 8000 individuals of European origin were also completed for selected candidate genes. RESULTS: Combined analysis of the two datasets revealed ~ 20 genes (and 561 SNPs) containing one or more alleles which were nominally significant ($p < 0.05$) for CPD in both samples, with the same allele identified as conferring ND risk. These 20 genes included CHRNA3 ($p = 0.00007$), identified as a ND risk gene ($p = 0.0003$) by Saccone et al (HMG 16:36, 2007). Three additional genes were also nominally significant both in the present two studies ($p < 0.003$) and in the one ND WGA study published (Bierut et al, HMG 16:24, 2007, $p < 0.02$). Analyses of CPD in ~ 8000 additional individuals of European origin confirmed CHRNA3 ($p = 0.0000026$) as a risk allele for this quantitative trait of CPD. CONCLUSION: This comprehensive approach implicates several genes identified in one previous WGA study of ND. A more precise phenotypic definition of ND using specific questionnaires is currently ongoing which is expected to provide additional insight into genetic deteminants of ND.

Long range haplotype diversity analysis and Haplotype sharing between the Mexican Mestizo and the European, Asian and African Populations. *A. Hidalgo, J. Estrada-Gil, L. Uribe-Figueroa, I. Silva-Zolezzi, A. Contreras, G. Jimenez-Sanchez* National Institute of Genomic Medicine, Mexico.

Given the history of the Mexican Mestizo population, resulting from the admixure of Amerindian, Spaniards and to a lesser extent Africans, we are evaluating genomic variability in our population and comparing it with other populations. Phase I of the Mexican Genome Diversity Project (MGDP), genotyped 300 Mestizos from six states of the country (Guanajuato, Guerrero, Sonora, Veracruz, Yucatan and Zacatecas) using the Affymetrix 100K array. Long range haplotype diversity (LRHD) and haplotype sharing (HS) were compared between the Mestizos and populations of the International HapMap. Data was phased using FastPhase v1.1.4, LRHD was calculated in 1 Mb windows, and the frequency of the haplotypes was averaged and compared to the percentage of chromosomes represented by those haplotypes. HS was assessed by comparing haplotypes frequencies of five SNPs(~100 kb). LRHD analysis showed that 67.8 haplotypes per megabase capture 95% of the chromosomes in the Mexicans, while 92.6, 82.2 and 69.4 are necessary to achieve this coverage in the YRI, CEU and JPT-CHB populations, respectively. Haplotype sharing indicated that 64% of the haplotypes (5% minor allele frequency) from the YRI are present in the Mexicans, as well as 74% from the JPT-CHB and 80% from the CEU. The Asian-CEU combination shared 93% of the haplotypes and 96% of the combined haplotypes from the four HapMap populations were present in the Mexicans. Our results indicate that data from the International HapMap can be used in the Mexican population. However the highest power can only be obtained using the combination of the four populations. The remaining 4% of the haplotypes, not represented in the HapMap data, might be derived from the Amerindian component in the admixture that led to the modern Mexican Mestizos. To increase genomic resolution in our population, we are increasing coverage to over 1 million SNPs. In addition, and we are including Amerindian samples in our study. These results will contribute to strengthen resources for association studies in Mexican populations.

Integrated genotyping of SNPs and copy number variation using Affymetrix array technology. *J.M. Korn[1,2,3,4], F. Kuruvilla[3,4], A. Wysoker[3], E. Hubbell[5], S. Cawley[5], S.A. McCarroll[3,4], M.J. Daly[3,4], D. Altshuler[3,4]* 1) Biophysics, Harvard University, Boston, MA; 2) The Harvard-MIT Division of Health Sciences and Technology, Cambridge, MA; 3) Broad Institute of MIT and Harvard, Cambridge, MA; 4) Massachusetts General Hospital, Boston, MA; 5) Affymetrix, Inc., Santa Clara, CA.

Typically, whole genome association studies have treated SNPs as simple biallelic systems. However, a significant percentage of the genome is present at variable copy number, creating myriad possibilities beyond the canonical genotypes of AA, AB, and BB at SNPs in these regions, and impressing the importance of analyzing copy number variation alongside SNPs in studies of genetic variability. Joint analysis allows for high-resolution mapping of CNVs, unbiased estimates of SNP allele frequency, and clarification of chromosomal abnormalities ambiguous from SNP genotypes alone. The resulting SNP-CNV map is valuable for both case-control association and pedigree-based studies. We present two linked algorithms for integrated SNP genotyping and copy number analysis: Birdseed, a 2D Gaussian Mixture Model for SNP genotyping, and a novel HMM to detect copy number that seamlessly integrates both the SNP and non-polymoprhic probes on Affymetrix's SNP 6.0 array. Several customizations exploiting common features of SNPs ensure highly accurate genotyping. Birdseed achieves a 99.6% call rate and 99.7% concordance for the 270 HapMap samples. Imputation of copy-normal and copy-variant clusters not fit by the model allows for recovery of rare genotypes that can otherwise be lost. Imputed 1-copy cluster means were validated on chrX, and are accurate with 5% error. An in-silico gender mixing experiment simulated heterozygous deletions of varying sizes. For deletions spanning 3, 5, and 10 probes (corresponding to 5kb, 8kb, and 17kb on average) we discover 39%, 76%, and 84% of the events with 1 probe tolerance. Allowing a breakpoint error of 5 probes, we recover 96% of deletions spanning at least 10 probes. Together, these algorithms allow for accurate genotyping of SNPs both within and outside CNVs, and high resolution detection of deletions and duplications.

Drosophila NnaD mutant flies model mouse purkinje cell degeneration (pcd) and implicate mitochondrial dysfunction in Nna recessive phenotypes. *S.M. Jackson[1], G. Dunn[1], S.L. Baccam[1], L.J. Pallanck[2], A.R. La Spada[1]* 1) Dept Laboratory Medicine, Univ Washington, Seattle, WA; 2) Dept Genome Sci, Univ Washington, Seattle, WA.

The Purkinje cell degeneration (pcd) mouse is a unique recessive model of neurodegeneration, as pcd mice undergo dramatic postnatal degeneration of Purkinje cells and retinal photoreceptors, yielding a phenotype of ataxia, blindness, and male sterility. The causal gene for pcd is Nna1, encoding a protein (Nna1) that contains putative carboxypeptidase and ATP/GTP binding domains. How loss of Nna1 leads to neurodegeneration remains unclear. Analysis of Drosophila genome sequence revealed a single orthologue of mouse Nna1 (CG32627; NnaD) located on the Drosophila X chromosome. Overall, NnaD is 48% similar and 25% identical to Nna1; however, conservation is much higher in the carboxypeptidase domain (42% similar and 59% identical). To define the normal function of Nna1 and understand the implications of Nna1 loss-of-function, we studied NnaD with a Drosphila strain carrying a P-element insertion ($NnaD^{PL90}$) at the NnaD locus, a mutation that reduces NnaD expression to 10% of normal. Most $NnaD^{PL90}$ hemizygotes die during the larval stage of development, although ~30-40% survive to adulthood. $NnaD^{PL90}$ males have reduced lifespans (17d vs 40d), are sterile, and go blind. The sterility of $NnaD^{PL90}$ hemizygotes results from defective spermatid individualization, and was associated with apoptotic activation, as evidenced by increased activity of the executioner caspase Drice. Examination of $NnaD^{PL90}$ mutants revealed blindness due to progressive retinal degeneration. Ultrastructural analysis of degenerating retinae showed strikingly abnormal mitochondrial morphologies. All phenotypes of $NnaD^{PL90}$ mutants were rescued by ectopic expression of NnaD, confirming that these phenotypes derive from loss of NnaD. Our findings suggest that loss of NnaD in Drosophila recapitulates pcd phenotypes seen in mice lacking Nna1, and that loss of NnaD - Nna1 produces disease pathology by affecting mitochondrial function, pinpointing mitochondria as a likely target for other cerebellar and retinal degenerative processes.

The relationship between cleft lip and palate and methylation of an IAP transposon insertion at Wnt9b in the A/WySn mouse model. *D.M. Juriloff[1], M.J. Harris[1], L. Gagnier[2], D.L. Mager[1,2]* 1) Dept Medical Genetics, U British Columbia, Vancouver, BC, Canada; 2) Terry Fox Laboratory, BC Cancer Agency, Vancouver, BC, Canada.

The A/WySn mouse strain has a high frequency of cleft lip and palate (CLP) of complex genetic etiology. It is a very good model for human CLP, a common birth defect with complex etiology that is poorly understood. Previously, the CLP of A/WySn was shown to be caused by the joint effect of two unlinked recessive loci, clf1 and clf2, and a very strong maternal effect of the A/WySn strain; clf1 is a malfunction of the Wnt9b gene, caused by the insertion of an IAP transposon 6.6 kb 3 of the gene (hereafter, Wnt9b-IAP). Complex inheritance patterns for other mutations due to IAP insertions are due to parental effects on methylation of their IAP. Therefore, we have examined the relationship between phenotype and methylation of this individual inserted IAP in this model. Methylation of the 5LTR of the IAP was assessed by COBRA assay and validated by bisulfite sequencing in some cases; faces of E12 embryos, or heads of E11.5 embryos were used. A/WySn embryos with normal faces showed consistent methylation of 50% (n=10), whereas CLP littermates were consistently lower, at 0-5% (n=12). In order to detect parent-of-origin effects on methylation of the IAP, various crosses were used to produce the compound mutant, Wnt9b-IAP/Wnt9b-null, which has a high risk of CLP and has received the Wnt9b-IAP mutation from one known parent. Consistently across several experiments, phenotypically normal compound-mutant embryos had IAP methylation levels of 40-60% (n=29), whereas their CLP littermates had 0-10% (n=7). In normal embryos, the IAP from A/WySn mothers tended to be less methylated (40-55%) than the IAP from A/WySn sires (50-60%). However, nearly all CLP (with near 0% methylation) was associated with maternally-derived IAPs, and this indicates that for this IAP the population of maternal gametes as a group must be less methylated than their paternal counterpart. In summary, the complexity of heredity of CLP in the A/WySn mouse model is due to epigenetics and points to similar mechanisms in human.

High-resolution genetic characterization of 51 unique human populations from the Human Genome Diversity Project. *D. Absher[1], J. Li[1], H. Tang[2], S. Ramachandran[3], A. Southwick[1], G. Barsh[2], M.W. Feldman[3], L. Cavalli-Sforza[2], R.M. Myers[1,2]* 1) Stanford Human Genome Center, Palo Alto, CA; 2) Dept Genetics, Stanford University, Palo Alto, CA; 3) Dept Biological Sciences, Stanford University, Palo Alto, CA.

The Human Genome Diversity Project (HGDP) began fifteen years ago as an attempt to characterize genetic diversity in a worldwide collection of humans, and to study the history and geography of mutation, drift and selection in human populations. The HGDP samples include more than 1,050 individuals from 51 unique populations distributed globally and have been studied previously by using microsatellite markers and a few thousand SNPs. To characterize further this valuable resource, we performed the first high-resolution genetic study of the HGDP collection, where we genotyped 660,000 SNPs in 1,043 of the individuals with the Illumina Infinium platform. The extensive genomic coverage of this panel revealed fine structures both between and within populations at an unprecedented resolution. Principal component analyses clearly delineated sub-populations that were indistinguishable in previous studies, for example, between the southern and northern Han Chinese. Estimates of genetic distance from these data allowed us to refine genetic relationship trees down to the individual level. Furthermore, clustering analysis at the individual level recapitulates the continental clusters previously constructed with microsatellite markers, and generates intriguing hypotheses regarding migratory and admixture history of human populations. Finally, we analyzed the genotyping intensity data for evidence of copy number variation (CNV) and identified many examples of population-specific CNVs. We believe these data and analyses will serve as a valuable resource for both population studies of human diversity as well as disease association studies in diverse ethnic backgrounds.

Inhibition of caspase-7 proteolytic cleavage of ataxin-7 markedly ameliorates polyglutamine neurotoxicity in SCA7 transgenic mice. *S.J. Guyenet[1], A. Lin[2], B.L. Sopher[1], S.K. Custer[1], J.E. Young[1], L.M. Ellerby[2], A.R. La Spada[1]*
1) Dept Laboratory Medicine, Univ Washington, Seattle, WA; 2) Buck Institute for Ageing Research, Novato, CA.

Spinocerebellar ataxia type 7 (SCA7) is a dominantly inherited neurodegenerative disease caused by a CAG repeat expansion located in the 5 coding region of the ataxin-7 gene. The CAG repeat expansion encodes an abnormally long glutamine tract that is expressed in the ataxin-7 protein, rendering it toxic. Neuronal loss and gliosis occur in the retina, cerebellum, and associated brainstem structures. This leads to progressive blindness and a debilitating lack of coordination. Neuronal intranuclear inclusions, composed of truncated ataxin-7, accumulate in many brain regions. Among the polyglutamine diseases, Huntingtons disease, SCA3, SBMA, DRPLA and SCA7 all exhibit proteolytic cleavage that exacerbates aggregation and toxicity. Ataxin-7 contains a predicted caspase cleavage site at an aspartic acid residue at position 266, and we have shown that caspase-7 can cleave the ataxin-7 protein at this site. Furthermore, cleavage-resistant polyglutamine-expanded ataxin-7 is less toxic than wild-type ataxin-7 in vitro. To test the hypothesis that caspase-7 cleavage of ataxin-7 contributes to SCA7 disease pathogenesis, we generated SCA7 transgenic mice with or without a point mutation (D266N) targeted to this site. After confirming that we had derived independent SCA7 transgenic lines with comparable levels of transgene expression, we evaluated the biochemical and phenotypic features of the SCA7-92Q-D266N mice. In contrast to SCA7-92Q-wt mice, ataxin-7 protein expressed by SCA7-92Q-D266N mice is resistant to proteolytic cleavage by caspase-7. Based upon behavioral phenotyping, survival, and histopathology analysis, SCA7-92Q-D266N mice display a markedly attenuated neurodegenerative phenotype in comparison to SCA7-92Q-wt mice. Our findings indicate that caspase-7-mediated proteolytic cleavage of ataxin-7 constitutes a key step in the SCA7 pathogenic cascade, and provides a rational target for directed therapy development for this currently untreatable disorder.

Mixed Inbred Gne$^{M712T/M712T}$ Mice Show Increased Survival, Attenuated Kidney Disease, and Altered NeuGc/NeuAc Profile. *D. Darvish[1, 2], Y. Valles[1], S. Darvish[1, 2], J. Orozco[2], O. Scremin[2], G. Lawson[3], B. Darvish[2]* 1) HIBM Research Group, Inc, Encino, CA; 2) VA Greater Los Angeles(VA-GLA / UCLA), Los Angeles, CA; 3) UCLA, Los Angeles, CA.

Recessive form of Hereditary Inclusion Body Myopathy (HIBM, IBM2 - MIM:600737) is an adult onset muscle wasting disorders that is caused by hypomorphic GNE, the rate-limiting enzyme of sialic acid biosynthesis. Unlike human patients, mice bearing the Gne$^{M712T/M712T}$ genotype in B6 background strain suffer severe glomerular hematuria, incomplete podocyte development, and do not survive beyond the first few days of life. We back-crossed heterozygous mice (Gne$^{M712T/+}$) of B6 strain with FVB strain mice. In FVB;B6 mixed inbred background (N1), the homozygous mice show attenuated glomerular disease and survive longer (n=12, 18.213.3 weeks). Wildtype, heterozygous, and homozygous mice were used for phenotype analysis. Functional motor evaluation included Rotarod treadmill, exercise induced creatine kinase elevation, and grip strength. Large difference in strength or endurance, which could be attributed to the genotype of the mice, was excluded in all tests. Laboratory workup included complete blood count (CBC), chemistry panel, and liver enzymes. The only notable abnormality was that homozygous mice show increased BUN (45.218.6mg/dL, ref range 12-28). Histology shows varying levels glomerular disease in every homozygous mouse without exception. Sia levels, normalized to protein concentration, were measured in liver, kidney, muscle, and serum. Paradoxically, the homozygous mice showed increased total Sia levels in serum (2x control). Additionally, the NeuGc:NeuAc ratios were slightly shifted in homozygous mice, which seems to be attributed to higher levels of NeuGc in muscle and higher levels of NeuAc in serum. Although kidney disease is attenuated and survival is improved in mixed inbred background (FVB;B6), Gne$^{M712T/M712T}$ mice do not show reduced muscle strength/endurance. Increase in serum Sia levels may be caused by altered glomerular filtration. This paradoxical increase in serum Sia may contribute to Sia pools of muscle, and exert a potential beneficial effect.

Cytogenetic features associated with FLT3 abnormalities in acute myeloid leukemia (AML). *A. Block[1], S.N.J. Sait[1], S. Kakati[1], P. Starostik[2], M. Barcos[3], G. Deeb[3], M. Wetzler[4], E.S. Wang[4]* 1) Clinical Cytogenetics Lab, Roswell Park Cancer Inst, Buffalo, NY; 2) Molecular Diagnostics Lab, Roswell Park Cancer Inst, Buffalo, NY; 3) Department of Pathology, Roswell Park Cancer Inst, Buffalo, NY; 4) Department of Medicine, Roswell Park Cancer Inst, Buffalo, NY.

Accumulation of acquired genetic alterations and epigenetic changes in hematopoietic progenitor cells have been implicated in the development of acute myeloid leukemia (AML). Molecular analyses have associated the fms-related tyrosine kinase 3 (FLT3) gene with multistep pathogenesis in AML. In order to evaluate the cytogenetic contribution to the genomic instability in FLT3-positive AML, we identified 29 AML patients (pts) treated at our institution with either FLT3 internal tandem duplication (FLT-ITD; 16 female, 8 male) or missense mutations of the aspartic acid 835 of the kinase domain (D835; 1 female, 4 male). Median age was 58 years (range 22-89). FLT3 mutations were found at diagnosis in 10 pts and at relapse in 19 pts. Median overall survival from FLT3+ AML diagnosis was 6.0 months. FAB morphological classification included M1, M2, M4, M5a and M5b. Karyotypic abnormalities (abn) at diagnosis were described in 7/24 pts with FLT3-ITD and 3/5 pts with D835. Cytogenetically abnormal cases displayed extensive ITD expansion as compared to cytogenetically normal cases. 7/19 karyotypically normal AML at diagnosis later developed clonal abn at relapse. Using CALGB hierarchical criteria, no pts were observed with "favorable" cytogenetic abn. Recurrent intermediate and unfavorable risk abn included +8, +11, t(6;11), t(9;11), 11q23 abn and del(7q). Complex karyotypes (≥3 abn) were observed in 6 pts. Most structural abn did not involve recurring breakpoints. Further identification of prognostic factors in this group of pts may optimize treatment and more precisely predict patient outcome.

The Pompe Registry: Centralized Data Collection to Track the Natural Course of Pompe Disease. *L. Case[1], P. Kishnani[2], A. van der Ploeg[3]* 1) Community and Family Medicine, Duke University Medical Center, Durham, NC; 2) Genetics, Duke University Medical Center, Durham, NC; 3) Genetics and Metabolism, Erasmus Medical Center, Rotterdam, NL.

Background: Pompe disease is a rare, progressive, and often fatal muscle disease due to a deficiency of lysosomal acid--glucosidase. The disease manifests as a clinical spectrum that varies with respect to age at onset, rate of disease progression, and extent of organ involvement. **Methods**: A global, observational Registry was developed to collect anonymous, longitudinal data on Pompe patients. **Preliminary Results**: As of March 9, 2007, 305 patients from 18 countries have been enrolled. The majority (75.4 %) are Caucasian. 20.3% (62/305) are infants, with rapidly progressive cardiorespiratory disease and death by one year; median age of diagnosis was 5.6 months. 68.9% (210/305) are older, typically with progressive skeletal/respiratory muscle weakness and longer survival; median age of diagnosis was 33.1 years. Age of onset was unspecified in 10.8% of patients. The median age at first recorded symptom was 3.5 months for infants and 26.4 years for adults. Of the patients genotyped, 60.6 (63/104) expressed the IVS1-13TG mutation. 99 patients are currently reported as receiving enzyme replacement therapy. **Conclusion**: Preliminary Registry data show that the (median) range of time from symptom onset to diagnosis represents a significant lag as consistent with published literature, suggesting the need for greater disease awareness The overall objective of the Pompe Registry is to increase disease understanding across patient phenotypes/genotypes, medical disciplines and regional disease management norms and monitor the impact of treatment and other disease support methods over time.

Association of tag SNPs in neuronal UCPs with cranial-cervical dystonia. *J. Jamiyansuren[1,2], R. Kaji[1], K. Maeda[1], K. Yasuno[3,4], S. Matsumoto[1], S. Makino[2], G. Tamiya[2]* 1) Department of Neurology and Neuroscience, Tokushima University Graduate School of Medicine, Tokushima 770-8503, Japan; 2) Division of Human Molecular Genetics, Department of Neurology and Neuroscience, Tokushima University Graduate School of Medicine, Tokushima 770-8503, Japan; 3) Department of Molecular Life Science, Tokai University School of Medicine, Isehara, Kanagawa 259-1193, Japan; 4) Core Research for Evolutional Science and Technology (CREST), Japan Science and Technology Agency, Kawaguchi, Saitama 332-0012, Japan.

Dystonia is a syndrome characterized by sustained muscle contractions, producing twisting, repetitive, and patterned movements, or abnormal postures. We performed a case-control study in sporadic cranial-cervical dystonia (CCD) in Japan using tag SNP markers in the mitochondrial uncoupling protein genes, *UCP2*, *UCP4* and *BMCP1/UCP5* that are expressed in various brain tissues and may exert a neuroprotective effect against increased oxidative stress and calcium dysregulation. We found modest associations between CCD and some tag SNPs in *UCPs*, all of which were statistically significant even after correcting for multiple comparisons. Moreover, we investigated the synergistic interaction between *UCPs* in CCD by using the multifactor dimensionality reduction (MDR) method and the logistic regression analysis. Our findings suggest that neuronal *UCPs* have a modest but important involvement in the genetic etiology of CCD as well as schizophrenia we have previously reported. This is the first report of the association between CCD and neuronal *UCPs*.

Chromatin accessibility is associated with recombination hotspots of genomic rearrangements. *M.O. Dorschner[1], M.A. Weaver[2], A. Haydock[2], J. Goldy[2], K. Lee[2], S. Vong[2], F. Neri[2], A. Shafer[2], P. Sabo[2], J.A. Stamatoyannopoulos[1,2]* 1) Department of Medicine , University of Washington, Seattle, WA; 2) Department of Genome Sciences, University of Washington, Seattle, WA.

Despite our ability to identify and delineate genomic rearrangements, our understanding of the underlying molecular mechanisms that cause them lags behind. Many studies have implied that chromatin structure plays a role in mediating rearrangements, however few provide evidence to support their hypotheses. Our lab has generated detailed in vivo chromatin profiles of the human genome from many cell types using several high-throughput genome-scale technologies. These assays detect DNase I hypersensitive sites (DHSs) which coincide with active functional elements. Recently, we examined these chromatin accessibility data to determine if DHSs are located in close proximity to known recombination hotspots, in particular, those associated with genomic disorders and transclocations. Our analysis yielded several remarkable findings: 1) DHSs are collocated with recombination hotspots, even within segmental duplications known to mediate large rearrangements such a those causing Neurofibromatosis Type I, Charcot-Marie-Tooth, Smith-Magenis syndrome, Williams Beuren syndrome and many other genomic disorders; 2) DHSs are found at both meiotic and mitotic breakpoint clusters, including translocations involving IGHA1 and BCR; 3) all recombination hotspots were found within regions of open chromatin and 4) the terminal ends and subfragments of segmental duplications are often delineated by DHSs. These findings have major implications for the study of chromatin structure and its impact on recombination. A comprehensive map of DHSs will provide investigators with information to facilitate the localization of rearrangement breakpoints, particularly those found within segmental duplications. We hypothesize that variation in chromatin structure at recombination hotspots predisposes individuals to rearrangement. Such predispositions may be valuable when predicting genetic disease risk. Analysis of chromatin structure has the potential to further our understanding of the molecular pathogenesis of genomic rearrangements.

Bronchiectasis and Mycobacterium Avium Complex(MAC) infection is associated with Hereditary Disorders of Connective Tissue. *B. Griswold[1], L. Sloper[1], C.A. Francomano[2], N.B. McDonnell[1]* 1) LCI, NIA, Baltimore, MD; 2) GBMC, Baltimore, MD.

Bronchiectasis is an abnormal stretching and enlarging of the respiratory passages and may predispose the patients to respiratory infections. A previous study noted a relationship between bronchiectasis and the presence of scoliosis, however did not discuss the role of heritable disorders of connective tissue (HDCT). In a cohort of 95 patients with Ehlers-Danlos syndrome (EDS) enrolled at a natural history study of HDCT at the National Institutes of Health, we identified four patients with bronchiectasis and infection with Mycobacterium avium complex (MAC) in the setting of intact immune function. The organism was identified by specimens obtained during bronchoscopy. MAC consists of two speciesM. avium and M. intracellulare, and is found in water supplies, house dust, soil, farm animals, birds, and cigarette components. It rarely causes pathology in the immunocompetent host. Two of the subjects were women, ages 39 and 50, with hypermobility type of EDS and Marfanoid body habitus, mild scoliosis and dolicocephaly. The third patient was a 50 year old woman with classical EDS, with atrophic scars, doughy skin and joint hypermobility and no evidence of scoliosis. The fourth patient was a teenage boy with hypermobile EDS, stretchy skin without atrophic scars. He had congenital stenosis of the lumbar spine, however, did not have scoliosis. Two patients were diagnosed with bronchiectasis and MAC prior to enrollment in the study, and the others developed the infection during the follow-up period.

CNV INTEGRATOR: A new automated tool for processing, annotating and visualizing Copy Number Variations. *R. Goya, A. Hidalgo, L. Uribe, J. Fernandez, G. Jimenez-Sanchez* National Institute of Genomic Medicine, Mexico.

Copy number variation (CNV) represents an important source of variation in the genome. Copy number analysis has become of key importance in biology and medicine. Current technology allows high-throughput generation of CNV data. However, definition of basic statistics derived from large amount of samples, such as determination of minimal overlapping regions, CNV prevalence and mining of gene content in the regions is a time consuming task. To facilitate CNV analysis, we have generated CNV INTEGRATOR, a new automated mining tool that uses text tables containing array probe identifiers, their physical position in the human genome and CNV data. We analyzed CNVs in 300 individuals from the Mexican Genome Diversity Project genotyped with the 500K SNP genotyping set from Affymetrix. Copy number was evaluated using Affymetrixs CNAT 4.0.1 and DChip. A set of 30 randomly selected females was used as a reference set in each case. Text tables with copy number information from all the samples were exported from both platforms and processed using CNV INTEGRATOR. This tool consists of 1) a mysql database condensing CNV data; 2) a Perl-based pipeline to process the data, and 3) a web front-end using PHP for user interaction. The database is screened for continuous sets of altered SNPs with changes in copy number, grouping them into regions, defining the minimum regions of overlap and indicating the prevalence of these changes. This process concludes with a web-based report containing the total number of CNVs, percentages of deletions and amplifications, average number of changes per sample, the shortest and longest alteration and a summary table displaying all changes above a user-determined threshold. The report also includes a graphical representation of the overlapping regions, their sizes, and a list of genes they contain and SNPs involved. In addition, it includes pertinent links to genome browsers. To increase the CNV resolution in our population, we are currently including data generated with the Illumina 550K array from the same sample. In summary, this new bioinformatic tool will improve our ability for CNV data mining using data from different sources.

Deletions of the MEN1 gene are more common than previously thought. *P.J. Bridge[1], T.L. Gillan[1], M.E. Phillips[1], D. Gilchrist[2], A.M. Innes[1], J.S. Parboosingh[1]* 1) Molecular Diagnostic Laboratory, Alberta Children's Hospital, Calgary, AB, Canada; 2) Department of Medical Genetics, University of Alberta, Edmonton, AB, Canada.

Multiple endocrine neoplasia type I (MEN1) is an AD inherited cancer syndrome characterized by multiple endocrine tumours in the parathyroid, pituitary and gastro-entero-pancreatic tract. Clinical diagnosis of MEN1 is made by the presence of at least two MEN1-related tumours. MEN1 is associated with germline mutations in the MEN1 tumour suppressor gene located on chromosome 11q13. To date over 400 MEN1 mutations have been described, the majority of which result in premature protein truncation due to frameshift, nonsense or splice site mutations. MEN1 mutations are detected in 80-90% of probands with a positive family history. No genotype/phenotype correlations have been observed although considerable effort has been made. Mutations in the MEN1 gene have also been identified in sporadic MEN1-associated tumours. In the Molecular Diagnostic Laboratory (MDL) we perform a comprehensive screen of the MEN1 gene using sequence analysis and the more recently implemented MLPA analysis. With this combined approach, we detect at least 95% of MEN1 germline mutations segregating in families. Eighty-seven families have been submitted for mutation screening; all patients had either a personal or family history of MEN1-associated symptoms. The first forty probands of putative MEN1 families were screened by sequencing alone while 47 probands were screened by both sequencing and MLPA analysis. Pathogenic mutations were identified in nineteen families and consisted of: 5 nonsense mutations, 3 missense mutations, 2 splice site mutations, 5 small deletions, 1 insertion and 3 large deletions. Interestingly, since the implementation of MLPA in spring 2006, the presence of three large deletions segregating in MEN1 families suggests that large deletions of the MEN1 gene may be more common than originally reported. In our sample of 19 MEN1 mutation positives, based on clinical and pedigree information provided with the requisition, they were equally likely to have a positive family history or a negative family history.

complex Segmental Duplication Superstructure found on Human Chromosome 17q. *D. Chen[1], V. Leppä[2], T. Miettinen[3], A. Palotie[3, 4], L. Peltonen[2, 4], J. Saarela[2]* 1) Dept Human Genetics, Univ California, Los Angeles, Los Angeles, CA, USA; 2) National Public Health Institute, Helsinki, Finland; 3) Finnish Genome Center, University of Helsinki, Helsinki, Finland; 4) The Broad Institute of MIT and Harvard, Cambridge, MA, USA.

Human Chromosome 17 is enriched for a variety of human neoplasia, genetic diseases and polymorphic structural variations. The underlying cause of such observations is chromosomal instability. In has been proposed that chromosome 17 is significantly enriched with segmental duplications. A major mechanism resulting in chromosomal instability is the non-allelic homologous recombination between 2 highly similar genomic sequences. To characterize segmental duplication on chromosome 17, we conducted genome-wide sequence alignment using expressed transcripts mapped within the previously identified duplicated domains on 17q22-24. The analysis identified a segmental duplicated superstructure (SDS) on the 17q arm. The superstructure consisted of 13 discrete genomic domains and shared significant sequence homology. A similar structure was also found on the sytentic chimpanzee chromosome. In addition, the segmental duplicated structure is found to enrich with retrotransposable sequence element. Analysis of the genomic sequences of the duplication domains revealed the most highly copied sequences to be retrotransposable sequence elements. Twelve retrotransposable mRNAs and their sequence copies were found almost exclusively within the SDS, both in the human 17q and the chimpanzee 19q. The highest numbers of sequence alignments were observed with two transcripts, AK125814 and AK125932. Interestingly, the AK125814 transcript was found to be expressed in 5/6 healthy human and two chimpanzee PBMC samples. Sequencing of the rt-PCR products showed that AK125814 was preferentially expressed from one of the duplicated locations, which varied between individuals. The complex duplication architecture on 17q may predispose to chromosomal instability via NAHR and possibly lead to disease causing copy number variations. Furthermore, the structure served a template in which accelerated chromosomal evolution can occur.

Locus for autosomal dominant keratoconus identified on chromosome 13. *B.A. Bejjani[1], D. Winters[1], M. Rydzanicz[1], A. Molinari[2], J.A. Pitarque[2], K.L. Mackay[1], K. Lee[3], R.A. Lewis[3], S.M. Leal[3], M. Gajecka[1]* 1) Health Research & Education Center, Washington State Univ, Spokane, WA; 2) Hospital Metropolitano, Quito, Ecuador; 3) Baylor College of Medicine, Houston, TX.

Keratoconus (KC) is a non-inflammatory thinning and anterior protrusion of the cornea that results in steepening and distortion of the cornea, altered refractive powers, and altered visual acuity. We identified and investigated an Ecuadorian cohort in which KC without other ocular or systemic features is transmitted as an autosomal dominant trait with incomplete penetrance. We sequenced the coding exons for the KC candidate genes, VSX1 and SOD1 in affected individuals from these Ecuadorian families and in ethnically matched controls and excluded VSX1 and SOD1 as candidate genes for KC in this population. Next, we performed a genome-wide linkage analysis on 18 Ecuadorian families (77 affected individuals, 67 unaffected and 11 individuals with unknown status) using fluorescent markers with an average spacing of 5 cM, spanning the genome. We excluded previously defined KC loci on chromosomes 2p24, 3p14-q13, 5q14.3-q21.1, 15q and 16q22.3-q23.1. One of the largest families (KC-014) had 22 available DNA samples, of which 11 samples were from individuals affected with KC. A new locus was identified on chromosome 13 for family KC-014 with a maximum 2-point LOD score of 2.8 and multipoint NLP score of 9.9.

NTS promoter variants are associated with body mass index. *N. Kavaslar[1], N. Ahituv[2], T. Naing[1], S. Hebert[1], H. Doelle[1], R. Dent[1], A. Stewart[1], R. Roberts[1], L. Pennacchio[2], R. McPherson[1]* 1) University of Ottawa Heart Institute, Ottawa, ON, Canada; 2) Lawrence Berkeley National Laboratory, Berkeley, CA.

Neurotensin (NTS) is a brain-gut peptide with a role in appetite regulation. NTS levels are known to be decreased in obese subjects and to increase after bariatric surgery. The NTS gene has four exons and spans 8.7kb on chr12q21. To determine whether variants in the NTS gene are associated with obesity, we resequenced the exons and intron-exon boundaries in 378 lean (av BMI 19.4kg/m2) and 379 obese (av BMI 49.0kg/m2) subjects matched for age and sex. We identified a total of 5 nonsynonymous novel coding variants and 10 noncoding SNPs. Of these 15 variants, only two showed a difference in frequency between obese and lean cohorts: rs1800832 is located 3 bp upstream of the translation start site and 84% of the subjects (both cohorts combined) who are homozygous for the rare G allele of this SNP are lean ($p<0.001$), whereas the variant -23G/A is novel and unique to the obese population (1.6%, $p=0.014$). A third 5 variant, rs2234762, showed a small difference in minor allele frequency between the two cohorts (0.236 in obese and 0.246 in lean). In silico analysis suggested a functional role for the promoter variants rs1800832 and rs2234762, since they result in loss of a PPAR/RXR site and gain of an HBP1 site, respectively. We analysed these two common SNPs with 2000bp and 500bp constructs using the dual luciferase assay in two cell lines. The promoter activity of constructs containing the rare allele was decreased by 10-14% (ns). Using data from the Affymetrix 500K genotyping assay, we analysed six SNPs in the 20kb vicinity of the NTS gene in a cohort of 1622 subjects enrolled in the Ottawa Heart Study. Three SNPs upstream and one SNP downstream of the NTS gene showed an association with BMI in men (n=1032; rs4143239, $p=0.019$; rs11117064, $p=0.021$; rs11117060, $p=0.030$; rs12314274, $p=0.023$; adjusted for age). Our results indicate that variants in regulatory regions of the NTS gene have a modest role in body weight regulation, in accord with the hypothesis that multiple rare alleles in the coding and noncoding regions of candidate genes contribute to the complex phenotype of obesity.

Detection of multi-locus genetic interaction in aspirin-intolerant asthma with multifactor-dimensionality reduction analysis. *S.H. Kim[1], H.H. Jeong[2], H.Y. Lee[1], M.K. Kim[2], B.Y. Cho[1], J.S. Lee[3], K.B. Wee[2], H.S. Park[1]* 1) Department of Allergy and Rheumatology, Ajou University School of Medicine, Suwon, Suwon, Korea; 2) Department of Infromation & Communication, Ajou University; 3) Department of mathmatics, Ajou University.

Background and objective: Aspirin-intolerant asthma (AIA) is a common phenotype of aspirin hypersensitivity and affects about 10~20% of asthmatic patients. Recently, the single gene polymorphism associated with the AIA susceptibility has been investigated, but identification of multi-locus single nucleotide polymorphism (SNP) set in association with the susceptibility has not been investigated Subjects and methods: In this study, we selected 23 SNPs in 13 candidate genes for 94 asthmatics with aspirin hypersensitivity (AIA) and 152 asthmatics without aspirin hypersensitivity (aspirin-tolerant asthma, ATA) and genotyped each SNP by a primer extension method. Multi-locus genetic interactions were examined with multifactor-dimensionality reduction (MDR) to test all multi-locus SNP combinations for the efficient prediction of AIA. Result: Through a MDR analysis, we identified four-locus gene-gene interaction models that predict AIA disease risk among asthmatic patients with 65.16 % balanced accuracy and a cross-validation consistency of 70 %. Conclusion: These results suggest that significant epistatic effect of four-locus genetic interaction may exist in the susceptibility for AIA in asthmatic patients which may be a useful in vitro method to diagnose the AIA with acceptable sensitivity.

Duplication 17p13.3 detected by array CGH. *V. Jaswaney, J. Tepperberg, P. Papenhausen, B. Wilford, I. Gadi* Lab Dir/Cytogenetics, Laboratory Corp America, Res Triangle Park, NC.

We report 4 patients with an apparent 17p13.3 duplication and three patients with a 17p13.3 deletion using a PerkElmer constitutional BAC array. These patients were submitted for array CGH analysis for developmental delay, learning difficulties, mental retardation or other birth defects. It is reported that many of the microduplications are not associated with a severe phenotype as compared to microdeletions which are well characterized in literature. Duplications in normal individuals appear to represent a benign variant. Three of the four patients had duplications of multiple bac clones and 1 was a duplication of a single bac. Theoretically, an unbalanced meiotic recombination should result in a deletion or duplication with an equal frequency. FISH is an excellent targeted tool to identify specific microdeletions however, microduplications may not be apparent by G-banding or by interphase FISH. Confirmation of a bac microdeletion or microduplication by FISH may not be necessary and can be identified by the increased sensitivity of the array, and the density and redundancy of the bac clones within the constitutional array. Microduplications detected by the recent advances in genome analysis using array based techniques will increase our understanding of the clinical pathology associated with specific duplications. Parental studies are pending to determine whether the origin of the duplication is de novo or familial. The apparent extent of DNA duplication observed and details of clinical presentation of each of these patients will be presented.

Mice lacking the kinase domain of the Src protein develop osteopetrosis and lack incisors. *E. Ivakine[1], R. Zirngibl[2], C. Jung[1, 2], J. Aubin[2], R. McInnes[1, 2]* 1) Program in Developmental and Stem Cell Biology, Hospital for Sick Children Research Institute, Toronto, ON, Canada; 2) Department of Molecular and Medical Genetics, University of Toronto, Toronto, ON, Canada.

The protein tyrosine kinase Src participates in diverse biological processes ranging from cell growth and differentiation to signaling and adhesion. It is expressed in a large variety of tissues with highest levels in brain, platelets and osteoclasts. Mice with a targeted disruption of the *Src* gene develop severe osteopetrosis due to impaired osteoclast function. The Src 60 kDa protein has a modular structure with a unique domain, and SH2, SH3 and kinase domains. However, whether the kinase domain is essential for osteoclast function has been controversial (Genes & Dev. 11:2835, 1997 vs JBC 279: 17660, 2004). Here we describe the positional cloning and characterization of a novel spontaneous *Src* gene allele (*Src*^{thl}). An insertion of a C nucleotide into *Src* exon 12 leads to a frameshift and a premature stop codon. The mutation predicts a deletion of 1/2 of the kinase domain, and immunoblots of *Src*$^{thl/thl}$ brain lysates identify a truncated 37kDa Src protein. At birth, *Src*$^{thl/thl}$ mice appear normal, but by 12 days of age can be easily identified by their small size, lack of incisors and variable numbers of molar teeth (usually 1-2 are absent). 65% of *Src*$^{thl/thl}$ mice maintained on a mashed food diet survive up to 6 months of age; the remainder die from as yet unidentified causes. Importantly, all the *Src*$^{thl/thl}$ mice have increased bone mineral density by 8 weeks of age and develop severe osteopetrosis indistinguishable from *Src*-null mice. We conclude, therefore, that the kinase function of *Src* is indeed essential for bone remodeling and that the lack of the kinase activity causes osteopetrosis in mice. Given the pleiotropic roles of the Src protein, this novel *Src* allele will facilitate studies that distingish between kinase-dependent and kinase-independent functions of the Src protein in a range of biological processes.

TaqMan Drug Metabolism Genotyping Assay Panels on TaqMan Low Density Arrays. *T. Hartshorne, J. Au-Young, T. Ceccardi, R. Padilla, J. Ziegle* Molecular Biology, Genomics; Applied Biosystems, Foster City, CA.

TaqMan Low Density Arrays from Applied Biosystems are 384 well micro fluidic cards that offer a convenient and easy to use platform for running panels of TaqMan Gene Expression Assays. The arrays are pre-loaded with assays, which greatly simplifies the experimental workflow, eliminates the need for liquid-handling robots, and facilitates high reproducibility of results. Investigators engaged in pharmacogenetic research often need to repeatedly screen a given set of Drug Metabolism Enzyme (DME) polymorphisms. To determine if TaqMan Arrays could be used with panels of TaqMan DME Genotyping Assays, we conducted benchmark tests to compare the performance of genotyping assays on TaqMan Arrays and on conventional 384 well plate platforms. Two arrays were tested: these had the configuration of 48 assays spotted 8 times and contained a total of 91 distinct TaqMan Validated SNP and DME Genotyping Assays. One array contained 48 DME assays to Cytochrome P450 SNPs in CYP2D6, CYP2C9 and CYP2C19 genes, many of which were challenging targets for assay design due to the presence of pseudogenes and copy number variations. 45 African American and 45 Caucasian Coriell genomic DNA samples were run on the arrays and the resulting genotyping data was compared to data from assay validation studies run on 384 well plates. Assay performance was found to be equivalent between platforms: all assays tested on arrays performed well (100% pass rate), and call rates and call accuracy were > 99 % in 3 separate experiments. Data from both arrays and 384 well plates was analyzed using Autocaller Software (in development). This interactive software tool enables overlaying and viewing cluster plots from multiple plates or arrays for easy analysis and editing of genotyping data. TaqMan Low Density Arrays could offer a simple workflow and accurate genotyping platform for routine, reliable and cost-effective pharmacogenetic screening of DME polymorphisms.

The Face of Feingold: Two Three-Generation Families with ODED Syndrome. *W. Al-Hertani[1], H. van Bokhoven[2], G.E. Graham[1]* 1) Department of Genetics, Childrens Hospital of Eastern Ontario & University of Ottawa, Ottawa, Ontario, Canada; 2) Department of Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands.

Feingold (ODED) syndrome is an autosomal dominant condition characterized by microcephaly, variable cognitive disability, short stature, esophageal and duodenal atresias and hypoplasia, brachymesophalangy and syndactyly of the digits. The syndrome is caused by mutations in MYCN (2p24.1) and to date there is no evidence for genetic heterogeneity. Here we present six affected individuals (a daughter, mother and maternal grandmother in two unrelated families) with molecularly proven diagnoses. In family A the diagnosis was suggested by the presence of TEF in both mother and daughter and supported by the presence of microcephaly, facial findings and typical digital findings. In contrast, the diagnosis in family B was made on the basis of facial features without a history of intestinal atresia or typical limb findings in the proband. The salient facial characteristics in our patients include short, upslanting palpebral fissures, bilateral epicanthus (which may resolve with outgrowth of the nasal root) and an impression of hypotelorism in adulthood. The face of Feingold syndrome has not been emphasized in the literature despite its utility in establishing the diagnosis, particularly in the absence of gastrointestinal atresias and obvious extremity findings such as moderate or marked syndactyly. The women in our families also draw attention to the presence of tapered fingers and a large sandal gap in addition to the generalized brachymesophalangy, clinodactyly of the index finger and thumb hypoplasia already recognized as characteristic. Our families also confirm that the cognitive phenotype in Feingold syndrome can be normal, reinforcing a recent suggestion that microcephaly-digital abnormalities-normal intelligence is probably not a distinct condition. In both of our families cognition was normal in the grandmothers and sub-normal in the daughters and granddaughters, possibly reflecting ascertainment bias.

Association analysis RANKL/RANK/OPG genes with cross-sectional geometry at the femoral neck in Caucasian families. *H.W. Deng[1,2,3,4], H. Shen[1], D.H. Xiong[3], R.R. Recker[3], C. Papasian[1], Y.J. Liu[1]* 1) Orthopedic Surg/Basic Med Sci, Univ Missouri, Kansas City, Kansas City, MO; 2) School of Life Science and Technology, Xi'an Jiaotong University, Xi'an , Shaanxi 710049, P. R. China; 3) Osteoporosis Research Center, Creighton University, Omaha, NE 68131, USA; 4) College of Life Sciences, Hunan Normal University, Changsha, Hunan 410081, P. R. China.

The molecular mechanisms underlying the crosstalk between stromal/osteoblast cells and hematopoietic cells have recently been elucidated by finding a new cytokine system, which is composed of a ligand - RANKL; its specific receptor - RANK; and its decoy receptor - OPG. Bone geometry, in addition to bone mineral density (BMD), is a key factor in bone strength, which is the ultimate intrinsic determinant of fracture risk. In this study, we aimed to investigate if the polymorphisms in the RANKL, RANK, and OPG genes contribute to variation in bone geometry, and if there exist gene-gene interactions among these three genes that are involved in a functional pathway. We performed family-based association analyses by genotyping 41 SNPs (an average density of one SNP per 4kb) in a sample of 405 Caucasian nuclear families comprising 1873 subjects. We conducted analyses using single SNP- and haplotype-based association test (FBAT) for association with five hip geometric variables, namely, cross-sectional diameter (CSA), cortical thickness (CT), endocortical diameter (ED), sectional modulus (Z), and buckling ratio (BR). In addition, we performed gene-gene interaction analyses using multianalytic approaches such as the restricted partition method (RPM) and a newly developed LD-based statistic to detect gene-gene interaction between two unlinked loci. The most significant associations were found between RANKL and CSA, CT and BR (P = 0.02 - 0.002). Haplotype analyses further supported the association observed in single SNP analyses. Significant gene-gene interactions were also observed among the OPG, RANK and RANKL genes. Our findings suggest that genetic variants in genes involved in the RANKL/RANK/OPG bone remodeling pathway are strongly associated with variation in bone geometry.

Is Ménières disease associated with polymorphisms in KCNE1 or KCNE3 in the United States? *C.A. Campbell[1, 2], C.C. Della Santina[3], N.B. Smith[3], J.P. Carey[3], L.B. Minor[3], R.J.H. Smith[1,2]* 1) Dept of Otolaryngology, University of Iowa, Iowa City, IA; 2) Interdepartmental PhD Program in Genetics, University of Iowa, Iowa City, IA; 3) Dept of Otolaryngology, Dept of Biomedical Engineering, and Dept of Neuroscience, The Johns Hopkins University, Baltimore, MD.

Ménières disease (MD) is a complex disorder of unknown etiology characterized by the symptoms of vertigo, sensorineural hearing loss and tinnitus. Incidence in Caucasians is 1-2 per 10,000 and in the Japanese, 35-160 per 1,000,000 (Morrison 1995). Although candidate genes studies focused on COCH (coagulation factor C homology), ATQ1 (antiquitin) and AQP2 (aquaporin 2) have been unsuccessful in identifying disease-causing allele variants of these genes, Doi and colleagues have reported that two single nucleotide polymorphisms (SNPs) in KCNE1 and KCNE3 are associated with MD in Japanese patients (Doi et al. 2005). These two genes encode potassium channels that are expressed in the stria vascularis and endolymphatic sac, respectively. Their role in ion transport and their expression pattern suggest that they may be important in inner ear homeostasis. To establish whether a similar association exists in the Caucasian MD population, we sequenced the coding regions and exon-intron boundaries of both genes in ~150 persons with MD and compared results to 168 ethnically matched CEPH controls, and a second control group of 150 Caucasians. Neither of the two reported SNPs were significantly associated with MD when compared to the CEPH control population. Population stratification was evaluated for the two control populations using an LCT promoter SNP (rs4988235), and 22 STRP markers spaced throughout the genome. Comparison of the population stratification results will be presented. In addition, the results from the second Caucasian control population candidate gene association study will be presented.

High-density linkage screen identifies potential dementia loci in the Amish. *L. Jiang[1], J.L. McCauley[1], P.J. Gallins[2], N. Schnetz-Boutaud[1], A.E. Crunk[1], L.L. McFarland[1], D. Fuzzell[1], C. Knebusch[1], M. Creason[2], L. Caywood[2], C.E. Jackson[3], W.K. Scott[2], M.A. Pericak-Vance[2], J.L. Haines[1]* 1) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN; 2) University of Miami School of Medicine, Miami, FL; 3) Scott & White, Temple, TX.

Although a role for the *APOE* gene in late-onset Alzheimers disease (AD) is apparent, it accounts for less than half of the susceptibility and thus other genetic variations are likely to be involved. Genetic heterogeneity is a major complicating factor hindering further gene identification in AD, as is evident with the recent findings implicating a role for the *SORL1* gene in AD risk. To minimize heterogeneity, we have been collecting individuals with dementia from the genetically isolated Amish populations in Ohio and Indiana. We have assessed over 1550 individuals who have consented to participate. Through use of the Anabaptist Genealogy Database (AGDB) and its query software PedHunter, we interrogated the family structure of our sample using kinship coefficients. Subsequently, we used the GREFFA program to construct sub-pedigrees, clustering individuals based on kinship scores 0.0156 (second-cousins), from our complex multi-generational extended Amish pedigree (n=4,220 over 11 generations). We have undertaken a whole-genome SNP linkage screen (Illumina Linkage Panel IVb) using 672 Amish individuals (103 with AD) within 21 sub-pedigrees ranging in total size from 18 to 157 individuals. We performed 2-pt linkage analysis using both dominant and recessive models, on 5,645 SNPs using the Superlink program. Preliminary analysis found 150 SNPs with lod scores 1.0. Suggestive linkage to AD was found for 13 SNPs across 12 independent loci (2-pt lod scores 2.0: 1q, 2p, 2q, 3q, 4q, 5q, 6q, 7q, 14q, 18q, 20p, and 21q). Two SNPs in strong linkage disequilibrium, on 5q give our highest lod scores (3.88 and 3.72 recessive; 2.41 and 2.65 dominant), in a region independently suggested to be linked to AD. These results provide evidence for multiple AD risk genes with our strongest result providing additional evidence for a novel gene at chromosome 5q.

Analysis of a neuregulin 1 missense mutation in families of Mexican and Central American origin. *A. Davelos Baines[1, 2], A. Figueroa[1, 2], C. Walss-Bass[1, 3], R. Salazar[4], A. Dassori[3], J. Peters[3], A. Ontiveros[5], H. Nicolini[6], R. Mendoza[7], M. Escamilla[1, 3], H. Raventos[4]* 1) South Texas Medical Genetics Group, UTHSCSA, Edinburg, TX; 2) UTPA, Edinburg, TX; 3) UTHSCSA, San Antonio, TX; 4) Universidad de Costa Rica, San Pedro, Costa Rica; 5) INFOSAME, Monterrey, Mexico; 6) Medical and Family Research Group, Carracci, Mexico D.F; 7) David Geffen School of Medicine at UCLA, Torrence, CA.

A missense mutation (Val to Leu) in exon 11 of the neuregulin 1 gene has been associated with schizophrenia in a population from the Central Valley of Costa Rica (CVCR). DNA genotyping and association studies were performed for 793 individuals with psychosis (536 of whom had a diagnosis of schizophrenia) from families of Mexican and Central American origin. Association analysis by the Family Based Association Test (FBAT) revealed that the missense mutation was transmitted more often than expected to affected persons, but the association was not significant in this sample ($p = 0.28$ for psychosis and $p=0.47$ for schizophrenia). A previous finding of an association of a missense mutation in the neuregulin 1 gene was not replicated in this independent sample of Hispanic individuals. Further analyses of samples from different populations should be conducted to determine the prevalence of this mutation and its relation to schizophrenia spectrum disorders.

Clinical practice protocols for 3-methylcrotonyl CoA carboxylase (3-MCC) deficiency. *G.L. Arnold[1], D.D. Koeberl[2], B. A. Barshop[3], B.K. Burton[4], S. Cederbaum[5], A. Feigenbaum[6], C.O. Harding[7], D. Kronn[8], D. Matern[9], J.B. Gibson[10], C.L. Garganta[11], N. Braverman[12], N. Longo[13], S.G. Kahler[14], the 3-MCC working group* 1) U Rochester, Rochester NY; 2) Duke U Med Ctr, Durham NC; 3) UCSD, San Diego CA; 4) Children's Mem Hosp, Chicago IL; 5) UCLA, Los Angeles CA; 6) Hosp for Sick Children, Toronto, Ontario; 7) Oregon Health & Science U, Portland OR; 8) NY Med College, Valhalla NY; 9) Mayo Med Ctr, Rochester MN; 10) U Texas HSC, San Antonio TX; 11) Tufts-NEMC, Boston MA; 12) Johns Hopkins Med Ctr, Baltimore MD; 13) U Utah Med Ctr, Salt Lake City UT; 14) UAMS, Little Rock AR.

3-MCC deficiency is among the most common inborn errors of metabolism identified on expanded newborn screening (1:35,000 births). However, evidence based guidelines for diagnosis and management of this disorder are lacking. Using the traditional Delphi method, a panel of 15 experts in inborn errors of metabolism was convened to develop consensus based clinical practice guidelines for the diagnosis and management of 3-MCC screen positive infants and their mothers.

Panelists reviewed the initial evaluation of the screen positive infant mother dyad, diagnostic guidelines, and management of diagnosed patients. The panel agreed on biotinidase, acylcarnitine profile, organic acid and plasma carnitine analyses for screen positive infants, organic acid and plasma acylcarnitine profile for the mother and an expanded panel of tests for ill appearing infants. Follow-up testing is commonly inconclusive; the clinician may consider re-testing in one month (for liver maturity), or after weaning (in a breast fed infant when mother has elevated 3-MCC metabolites). Final diagnosis can be made on metabolite levels alone in some cases, but lymphocyte assay is recommended in most cases (fibroblast assay if lymphocyte assay is not diagnostic). Treatment recommendations include prevention of catabolic stress by avoidance of fasting, and carnitine supplementation especially in deficient or symptomatic individuals. Formal data are unavailable regarding the role of leucine restricted diets or supplemental use of biotin or glycine. [Recommendations Grade D (case report/series or expert opinion based)].

Identification of functional pathways of the immune and hematological systems important to bone health using transcriptional profiling in a nonhuman primate. *L.M. Havill[1], J.M. Proffitt[1], J.C. Charlesworth[1], M.P. Johnson[1], J.E. Curran[1], E.K. Moses[1], J. Blangero[1], C. Brugnara[2], O.S. Platt[2], M.C. Mahaney[1]* 1) Genetics, SFBR, San Antonio, TX; 2) Laboratory Medicine, Harvard University School of Medicine, Cambridge, MA.

Recent research suggests that components of the immune and hematological systems contribute to variation in bone health. Studies of bone mineral density (BMD), a measure of bone fracture resistance, unequivocally show that this trait, and hence, osteoporosis risk, has a strong genetic basis. Many of the genes associated with BMD are also pivotal to immune function and hematopoiesis. We used genome-wide transcriptional profiles to identify functional networks of genes likely to be important to normal variation in BMD in the baboon, an established primate model for human bone maintenance and turnover. We used the Illumina Human Sentrix-6 BeadChip micro-array to interrogate RNA from stored lymphocytes of 495 baboons (Papio hamadryas). Transcript levels were regressed against BMD assessed by DXA at the ultradistal radius (trabecular bone) and the radius shaft (cortical bone). We identified ~500 transcripts showing nominally significant correlations to BMD as genes of interest. We used Ingenuity Pathways Analysis version 5.0 (Ingenuity Systems, www.ingenuity.com) to overlay these genes/gene products onto a global molecular network developed from literature-reported connectivity recorded in the Ingenuity Pathways Knowledge Base, allowing for the characterization of immune and hematological system-related functional networks represented amongst the genes of interest. Several functional pathways were common to the results for both sites, though the genes implicating these pathways were not entirely redundant between sites. Immune system functions in common to both traits involve cell growth, generation and morphology. Those for the hematological system involve cell binding, generation, migration and morphology. Our results support a role of immune and hematological system-related genes in normal variation in an osteoporosis risk factor, and may provide insight into the mechanisms underlying their role in bone health.

***LPIN2* variations in psoriasis.** *H. El-Shanti[1], P.J. Ferguson[1], C. Madison[1], S. Leal[2], L.Y. Tan[1], T. Helms[1]* 1) University of Iowa, Iowa City, IA; 2) Baylor College of Medicine, Houston, TX.

STATEMENT OF PURPOSE: One approach to the identification of genes involved in a complex disorder is to examine the involvement of a candidate gene - identified due to its physiologic role or its causal role in a monogenic disorder of a similar phenotype - by genotyping for polymorphisms within the gene and performing association studies. Majeed syndrome is an autosomal recessive disorder characterized by chronic recurrent multifocal osteomyelitis, congenital dyserythropoietic anemia and an inflammatory dermatosis. Some of the carriers have psoriasis. We showed that homozygous mutations in *LPIN2* are responsible for Majeed syndrome. Furthermore, *LPIN2* is located within a psoriasis susceptibility locus. We hypothesize that *LPIN2* is the gene that predisposes to psoriasis at this locus. METHODS: We performed a case-control association study of 78 individuals with psoriasis and 44 controls. Genotyping was performed on 8 tag SNPs within *LPIN2* utilizing Taqman assays. Subsequently, the exons and splice sites of *LPIN2* were sequenced to identify variations in coding regions and splice sites. Further analysis utilizing techniques to detect large deletions or duplications within the genomic structure of *LPIN2* are ongoing. RESULTS: Preliminary assessment of the case-control association study did not reveal significant results; likely due to small numbers in our cohort. Sequencing revealed 3 coding variants that were present in affected individuals and not present in controls. The three variants are A331S, P348L and L504F. Conservation across species suggest that A331S and L504F may be significant. The variant A331S was not found in a large cohort of controls (CEPH-Human Diversity Panel). CONCLUSION: Although we have not demonstrated an association of *LPIN2* and psoriasis in our case-control association study, we have detected coding variations in at least one individual that is probably significant. Given Kryukov et al.s recent data suggesting that most rare missense alleles are deleterious in humans, these variants need to be studied in further detail and in a larger cohort to determine their significance in the etiology of psoriasis.

Circulating endothelial progenitor cells are elevated in pulmonary arterial hypertension and show distinct expression profiles consistent with increased endothelial lineage commitment. *M.A. Aldred[1], K. Asosingh[2], S.C. Erzurum[2]* 1) Genomic Medicine Institute, and; 2) Department of Pathobiology, Cleveland Clinic Lerner Research Institute, Cleveland, OH.

Pulmonary arterial hypertension (PAH) is a serious progressive lung vascular disorder characterized by proliferation and migration of endothelial and smooth muscle cells, leading to narrowing of precapillary pulmonary arteries and a sustained elevation of mean pulmonary artery pressure. Mutations of the *BMPR2* gene underlie most familial cases and 20-25% of sporadic PAH. However, the penetrance averages only 20%; one of the biggest challenges is thus to identify early markers of disease in asymptomatic carriers. Vascular repair has traditionally been thought to occur through resident cell populations, but recently the role of bone marrow-derived circulating stem cells has become apparent. Circulating endothelial progenitor cells (EPCs) are crucial to the process of vasculogenesis, homing to damaged tissues and incorporating into existing endothelium to form new vessels. We hypothesized that EPC dysfunction might contribute to proliferative vascular disorders such as PAH. EPCs were isolated from peripheral blood samples from 14 PAH patients and 9 controls. FACS analysis demonstrated significantly more EPCs in patients than controls and a correlation with mean pulmonary artery pressure. *In vitro* endothelial cell colony forming assays (CFU-EC) yielded 10-fold more colonies in PAH patients, indicating greater commitment to the endothelial cell lineage. Expression microarray analysis on CFU-EC from 10 patients and controls confirmed that CFU-EC express endothelial and angiogenic markers, such as Endoglin and VEGF. Furthermore, our data suggest that a subset of these genes are differentially expressed in PAH and may correlate with *BMPR2* mutation status. Genes in lipid and hypoxia pathways were also dysregulated in PAH CFU-EC. Our data suggest that EPCs from PAH patients have increased endothelial lineage commitment and may play a role in disease pathogenesis. With further characterization of CFU-EC gene expression, EPCs may have utility as markers of early PAH in asymptomatic mutation carriers.

The impact of haplotype Size, diversity and frequency on haplotype blocking inference. *C.H. Chen[1], C.C. Chang[1], S. Shete[2], C.S.J. Fann[1]* 1) Intitute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 2) Dept of Epidemiology, The University of Texas M. D. Anderson Cancer Center.

While direct molecular haplotyping technologies are timing and costly, statistical algorithms to estimate haplotypes based on genotype data have been proposed to facilitate genetic analysis. Most methods estimate haplotypes and haplotype frequency within a pre-determined halotype block (segment). However, the boundaries of haplotype blocks change when sample size, marker density, and ethnicity of the genotype data vary. It is essential to examine the stability of the estimated haplotype block. In this study, we defined a block similarity index to quantify the difference among haplotype block estimates based on various data sets. To initiate the robustness of the block boundaries, we conducted a simulation based on the genotype data of MHC region from the YRI and CHB samples of the HapMap project. The first step was to determine haplotype blocks by inter-markers LD measure D'. Haplotypes and haplotype frequencies were estimated within each haplotype block. Haploview was used to carry out the above calculation. The estimated haplotypes and their frequencies were then used to simulate genotype data using SimPed. Next, the simulated genotype data were analyzed using Haploview as in the first step. Finally, the block similarity index was used computed to compare the haplotype blocking of the original and simulated data sets. A decay of the block similarity index suggested an instability of the estimated haplotype block. In addition, block length and haplotype diversity were also considered in the comparison. Our results showed that the use of different cutoffs of D', (0.5, 0.6, 0.7), had little impact on defining block boundaries. For blocks with lower haplotype diversity, the block similarity index was higher when the block length increased and lower for shorter blocks. However, for blocks with high haplotype diversity, the trend held if the number of haplotypes is small. In summary, the robustness of a haplotype block, in terms of the block similarity index, was related to its block length, number of haplotyes, and haplotype diversity.

Unique interstitial 3p duplication in a patient with multiple congenital anomalies. *E.M. James[1], K.R. Schmidt[1], U. Surti[2], L.A. Gole[2]* 1) Medical Genetics, Children's Hospital of Pittsburgh, Pittsburgh, PA; 2) Pittsburgh Cytogenetics Laboratory, Magee-Womens Hospital, Pittsburgh, PA.

Here we report on a ten-year-old female patient with a duplication of 3(p23p25) identified by karyotype. Although duplication of the entire p-arm of chromosome 3 and terminal duplications of 3p have been well-characterized, literature review has not identified any other cases of this specific interstitial duplication. Our patients clinical features include tetralogy of Fallot, cortical dysplasia with pachygyria/polymicrogyria, mental retardation, and minor dysmorphic features including a square face, full cheeks, and hypertelorism. She developed seizures at two years. At the age of ten years, she uses only a few words and signs but does communicate using a picture board. Several other patients have been described in the past with overlapping duplications, including two related patients with partial trisomy 3p and congenital heart disease, psychomotor retardation, and similar facial features. She is similar to another patient with an overlapping 3p duplication in her speech delay, mental retardation, and psychomotor retardation. A fourth patient with a terminal deletion of 3p with a slight overlap at 3p25 had mental retardation, hypotonia, and mild dysmorphic features. Fifteen other patients have been reported with terminal duplications of 3p. Ten of fifteen had congenital heart defects. Several had cleft lip with or without cleft palate. Our patient differs from those previously reported in that she has the smallest duplicated area, and she is the first reported with documented structural abnormalities of the brain. Narrowing the duplicated area should help to delineate genes within this area important in cardiac and brain malformations.

Increasing Power in Association Studies using Prior Information. *E. Eskin* Dept Computer Sci, Univ California, Los Angeles, Los Angeles, CA.

The availability of whole genome human variation reference sets such as those provided by the International HapMap project provide an opportunity to incorporate various types of genomic data as prior information in genetic association studies. We present an approach for incorporating this information by revisiting how we perform multiple hypothesis correction. In a traditional association study, in order to correct for multiple hypothesis testing, the significance threshold at each marker, t, is set to control the total false positive rate. In our framework, we vary the threshold at each marker t_i and use these thresholds to incorporate prior information. We present a numerical procedure for solving for thresholds that maximize association study power using prior information. We present the results of benchmark simulation experiments using the HapMap data which demonstrate a significant increase in association study power under this framework. We provide a webserver for performing association studies using our method and provide thresholds optimized for the the Affymetrix 500k and Illumina HumanHap 550 chips.

A Long-Range Haplotype of the SREBF1 Gene is Common in Europeans and Shows Signs of Recent Positive Selection. *S.D. Bailey[1], G. Paré[2], A. Montpetit[2], T.J. Hudson[1,2,3], D. Gaudet[4], J.C. Engert[1,3]* 1) Department of Human Genetics, McGill University, Montreal, Quebéc, Canada; 2) McGill University and Genome Quebéc Innovation Centre, Montreal, Quebéc, Canada; 3) Department of Medicine, McGill University, Montreal, Quebéc, Canada; 4) Dyslipidemia, Diabetes and Atherosclerosis Group and Community Genomics Research Centre, Université de Montreal and Chicoutimi Hospital, Quebéc, Canada.

The sterol regulatory element-binding transcription factor 1 (SREBF1) plays a pivotal role in cholesterol and lipid homeostasis. Genetic variation at the SREBF1 gene locus has been associated with obesity and type 2 diabetes. In order to capture common variation at the SREBF1 locus, we have genotyped 11 tagging single nucleotide polymorphisms (tSNPs) in 51 populations from the human diversity panel and a large French Canadian sample from the Saguenay-Lac St-Jean region region of Quebéc. Eight of the tSNPs passed quality control in all populations and were used in subsequent analysis. In the European derived populations and the HapMap CEU sample, we identified a common haplotype that spans the entire length, of the SREBF1 gene (~42.5kb). This eight SNP haplotype is the most prevalent haplotype in the European populations analyzed (except for Sardinia) (frequency range = 0.375-0.717). The second most frequent haplotype in all of these samples had the alternate allele at every SNP site (Yin Yang haplotypes)(1). This was the most common haplotype in the HapMap Asian samples (allele frequency = 0.829). In all populations the two Yin Yang haplotypes accounted for > 86% of the alleles. Of the eight SNPs comprising the haplotype, five alleles are ancestral and three alleles are derived. Two of the eight tSNPs were found to have an integrated haplotype score (iHS) of greater than 2 in the HapMap CEU sample, which is indicative of recent positive selection (2). This haplotype represents just a portion of a frequent haplotype (allele frequency = 0.517) that spans a ~250kb block of linkage disequilibrium and contains 98 SNPs with MAFs >0.05 in the HapMap CEU sample.1. Zhang J, et al. Am J Hum Genet 73:1073-1081, 2003; 2. Voight BF, et al. PLoS Biol 4:e72, 2006.

Development of a clinical array CGH test for identification of genomic imbalances in hematological malignancies. *S. Gunn[1], M.E. Gorre[1], B. Tirtorahardjo[1], X.T. Reveles[2], R.S. Robetorye[2], P. Cottter[1], M.S. Mohammed[1]*
1) Combimatrix Molecular Diagnostics, Irvine, CA; 2) UT Health Science Center, San Antonio, TX.

Chromosomal imbalances are a hallmark of many hematological malignancies and specific recurrent changes in genomic copy number have been shown to correlate with disease severity. As these correlations become established, their translation into clinical tests will enable prognosis and risk-adapted treatment decisions at diagnosis. Commercial FISH panels have recently become available for the diagnosis of select hematological cancers including chronic lymphocytic leukemia (CLL) and acute lymphocytic leukemia (ALL). However, effective use of these tests can be complicated by the need to culture often slowly-dividing cells as well as to assume inclusion of the appropriate probe in a 5-8 probe panel. Although array CGH (aCGH) testing is becoming more common in clinical diagnostic practice, clinical application has largely been limited to diagnosis of constitutional versus acquired abnormalities. Here we describe an aCGH test designed to interrogate all CLL prognostic loci assayed by commercial FISH panels and genomic regions implicated in publications for several hematological disorders, all within a backbone of generic whole genome coverage. The arrays were developed and manufactured in-house and consist of two sets of 887 BAC clones printed in triplicate on a single slide for dye-swapped reactions. We tested the ability of the array to correctly detect and identify chromosomal imbalances using isolated genomic DNA from 21 clinical leukemic peripheral blood samples with known abnormal cytogenetic results by karyotyping, FISH, or commercial research microarrays. Previously identified imbalances were detected by the array in 21/21 samples. In 6 samples, abnormalities not previously documented by cytogenetics or FISH, such as cryptic loss of 14q32.33, were found in addition to the expected changes. By combining the coverage of well-defined loci implicated in hematological disease risk groups with the global genome perspective of an array, this new test offers the most comprehensive and efficient method of genomic imbalance assessment for risk-adapted treatment of leukemia patients.

Handedness and APOE Genotype in School-Aged Children. *C.S. Bloss[1], D.C. Delis[2, 3], M.W. Bondi[2, 3], D.P. Salmon[4]* 1) University of California, San Diego and San Diego State University Joint Doctoral Program in Clinical Psychology, CA; 2) Veterans Affairs San Diego Healthcare System, CA; 3) Department of Psychiatry, University of California, San Diego, School of Medicine, CA; 4) Department of Neurosciences, University of California, San Diego, School of Medicine, CA.

Recent developmental studies have found evidence for an advantageous effect of the 4 allele of the apolipoprotein E gene (APOE) during human prenatal, perinatal, and infancy periods of life, and possibly a detrimental effect of the 2 allele. To further explore the role of APOE genotype in early brain development, hand dominance, which can be an indicator of early atypical brain and/or cognitive development, was assessed in a sample of school-aged children. A total of 147 children enrolled at a public school reported their hand dominance for writing and underwent buccal swab testing to determine their APOE genotype. A chi-square test was used to determine whether hand dominance differed as a function of APOE genotype. Notably, a significantly higher percentage of 2-positive children were left-hand dominant for writing (29.2%) versus 3/3 homozygote (8.8%) and 4-positive (6.1%) children ($p < .05$). This finding raises the possibility that the 2 allele may be associated with factors that give rise to atypical hemispheric dominance and/or that it may serve as a risk factor for certain disorders found to be more prevalent in left-handed individuals (e.g., developmental learning disorders). While the 2 allele may serve as a risk factor with respect to early brain development, thereby contributing to its relatively low prevalence in the population, it appears to have protective properties against the development of certain disorders later in life, such as Alzheimers disease.

Global Analysis of Four Neural Tube Defect LongSAGE Libraries to Identify Anencephaly and Spina Bifida Candidate Genes. *A. Dellinger[1], S. Thomas[2], P.-T. Xu[1], H. Etchevers[2], M. Vekemans[2], J.R. Gilbert[3], M.C. Speer[1]* 1) Center of Human Genetics, Duke University Medical Center, Durham, NC; 2) INSERM U781, Hôpital Necker- Enfants Malades, Paris, France; 3) Miami Institute for Human Genomics, University of Miami School of Medicine, Miami, FL.

Neural tube defects (NTDs) are complex birth defects including anencephaly and spina bifida. Genetic contribution to NTD risk is well-established, yet major genes have not been identified. Evaluation of differential expression by LongSAGE (Serial Analysis of Gene Expression) can identify candidate genes. We made 4 LongSAGE libraries from caudal (CAU) and rostral (ROS) ends of normal microdissected human neural tube tissue at closure (Carnegie Stage 12) and post-closure (Carnegie Stage 13). (See Xu et al., this meeting). We hypothesize gene expression differences in library comparisons between ROS12 and ROS13 may identify candidate anencephaly risk genes; between CAU12 and CAU13 may identify candidate spina bifida risk genes; and between CAU and ROS may identify genes influencing the development of anencephaly vs. spina bifida.

P-values for tags in comparisons between stages and between CAU and ROS were computed using ^{2} or Fisher exact tests. 3294 genes had p .05. Eliminating tags mapped to multiple genes left 2061 genes, with more genes in comparisons between stages (885 and 1086) than between CAU and ROS (70 and 293). To identify subsets of candidate risk genes we used genomic convergence, incorporating the 2061 genes with: linkage analysis in NTD families (236 genes); NTD pathway analysis (folic acid, retinol, Wnt signaling, cytokines) using KEGG, GO, and interaction databases (94 genes); and genes from known NTD mouse models (41 genes). CAU12 vs CAU13 has more pathway and linkage genes than ROS12 vs ROS13, including folate pathway genes DHFR (up in 13), FOLR1 (down), TYMS (up), and RBP1 (up). Folate and retinol pathway genes indicate a decrease in folic and retinoic acid levels, respectively, from stage 12 to stage 13. These data provide a rich source for the identification of lesion-specific candidate genes for neural tube defects.

Haplotype diversity in the angiotensinogen and Beta-1 adrenergic receptor in Mexican Mestizo populations. *E. Balam, K. Carrillo, A. Contreras, L. Alfaro, G. Jimenez-Sanchez* National Institute of Genomic Medicine, Mexico.

Cardiovascular diseases are the leading cause of death in Mexico. Genetic variation in B_1-adrenergic receptor *ADRB1*and angiotensinogen *AGT*genes, influence the risk for cardiovascular disease. Here we describe the haplotype structure of 7 SNPs in *ADRB1*and 5 SNPs in *AGT*in Mexican Mestizo populations, and we compare them with other populations including those from International HapMap Project. We obtained genomic DNA from Mexican Mestizo blood simples. Volunteers were from 6 geographically distant states in Mexico: Zacatecas (ZAC), Sonora (SON), Yucatan (YUC), Veracruz (VER), Guerrero (GRO) and Guanajuato (GTO). We genotyped 5 polymorphisms in AGT: -218GA (rs5049), -20AC (rs5050), -6GA (rs5051), 3889CT (rs4762) and 4072CT (rs699); and 7 polimorphisms in ADRB1: 145AG (1801252), 1165CG (1801253), (rs7093444), (rs2429511), (rs3813720), (rs2183378), (rs7919873) in 184 individuals from each population (n=1,104) using direct allelic discrimination with TaqMan probes on a 7900HT RT-PCR System (AB, USA). Haplotypes blocks founded in AGT gene in 6 Mexican Mestizo populations showns differences among mestizo populations, basically populations in the North of the country (SON and ZAC) preserves strong LD on 4 SNPs (rs699, rs 4762, 5051, 5050) with D'97 and r^2 0.8. Two SNPs in the regulatory regions (rs699 and rs4762) showns strong LD with those in coding regions (rs 5051 and 5050); the Mestizo Populations located at south of country showns low degree of LD between SNPs at regulatory region and codin region with D' 0.8 and R^2 0.8. Comparison between haplotype blocks from Mexican Mestizo populations (SON and ZAC) and International HapMap populations (CEU, CHB, JPT and YRI) showns at these loci, shows that only in Mexican Mestizo populations is founded strong LD between SNPs in regulatory region and coding regions. Our data support the notion that some Mestizo populations in Mexico conserve haplotype blocks at these genes (*AGT*and *ADRB1*) that differ from those in other populations, that could be important issue in the genomic medicine.

New genome-wide platform for discovery and genotyping of copy number variants reveals much higher number of common CNVs in human genome. *J. Gulcher[1], D. Gudbjartsson[1], A. Jonasdottir[1], A. Gylfason[1], A. Baker[1], G. Masson[1], A. Karason[1], A. Jonasdottir[1], A. Olafsdottir[1], S. Reynisdottir[1], S. Gudjonsson[1], D. Peiffer[2], K. Viaud[2], L. Galver[2], L. Zhou[2], K. Kuhn[2], R. Shen[2], S. Murray[2], U. Thorsteinsdottir[1], K. Stefansson[1]* 1) deCODE genetics, Reykjavik, Iceland; 2) Illumina, San Diego, CA.

CNVs may be an important source of disease-associated variations.We designed the CNV features on the Illumina Human CNV12,CNV370, and 1M BeadChips, which target 4 categories of segments that we predicted were more likely to have common structural variation:1)the unSNPable genome- defined as gaps of 15kb in human HapMap map or gaps 5kb with more than one HapMap SNP failure due to HWE or inheritance issues,2)segmental duplications-duplicons 100 bases or greater within 3 Mb,3) megasatellites-tandem repeats 500 base unit length,4)numerous gaps in the MHC. In total 14,000 segments were targeted for intensity measurements using 55,000 SNPs or probes of invariant bases(2/3 were SNPs to facilitate phasing),most not covered by current SNP platforms.The 11,000 segments not in the Database of Genomic Variants comprise 7% of the genome. Although the Affymetrix 6.0 has 1M extra probes for CNV analysis,7000 of our 11,000 novel segments are missed. Our hypothesis was that these segments are more likely to contain CNVs than the SNPable genome, and that CNVs in these segments are likely to have higher non-wildtype allelic frequencies. We have now run 3 HapMap plates along with 100 sets of trios. Normalized intensities of probes within megasatellites correlated well with copy number precisely defined by restriction fragment lengths on Southern blotting. Twenty-one novel common CNVs predicted by our CNV algorithm were tested by Southern blot and kinetic PCR- all 21 were polymorphic as predicted demonstrating high specificity of the platform. We find at least an order of magnitude increase in the number of common CNVs found within this 7% of the genome with non-wild-type frequency greater than 2% beyond those found using arrays or BACs covering the 93% of the genome.Many CNVs correlate to expression in peripheral leukocytes of genes near the CNV. .

Characterization of the structural aberrations and mutations of the RCCX module in patients with Congenital Adrenal Hyperplasia and Ehlers-Danlos syndromes. *W. Chen[1], J. Yang[1], M. Berk[2], C. VanRyzin[2], D. Merke[2], N.B. McDonnell[1]* 1) Lab Clinical Investigation, NIA/NIH, Baltimore, MD; 2) NICHD/NIH, Bethesda, MD.

The gene2 encoding 21-hydroxylase (CYP21A2) and Tenascin-X (TNXB) are located within the HLA complex on chromosome 6, in a region of high gene density termed the RCCX module. The region has multiple pseudogenes as well as tandem repeat sequences that promote misalignment during meiosis leading to complex gene rearrangements, deletions and gene conversion events. CYP21A2 mutations cause Congenital Adrenal Hyperplasia (CAH) and TNX deficiency has been proposed as a cause of hypermobile Ehlers-Danlos syndrome (EDS). We investigated the structure of the RCCX module in a cohort of CAH patients seen at the National Institute of Child Health and Development, and in Ehlers-Danlos patients seen at the National Institute on Aging. Southern blotting, PCR-based detection of deletions, and direct sequencing of exons of interest were utilized. A novel heterozygous 30 kB TNXB deletion that did not extend into CYP21A2 was found in a family with hypermobile form of EDS. CYP21A2 deletions were detected in 30% of the subjects in the CAH cohort, 25% of those subjects had a deletion extending into TNXB. Unusual haplotypes including three CAH probands with triplication of CYP21A2, and a sibling pair with a deletion of TNXB and triplication of CYP21A2 were identified through Southern Blot analysis. A novel mutation in a CAH family with joint hypermobility was detected in exon 8 of TNXB (c.G3452>A Arg1151His). This mutation involves the highly conserved fibronectin type III repeat in TNXB which is known to be involved in collagen fibrillogenesis, and was not seen in control subjects.

Contiguous gene deletion of 16q24.3 in an individual with venous malformations, distichiasis and other anomalies. *M.G. Butler[1], S.L. Dagenais[1], J.L. Garcia-Perez[1], J.W. Innis[1,2], T.W. Glover[1,2]* 1) Human Genetics, University of Michigan, Ann Arbor, MI; 2) Pediatrics, University of Michigan, Ann Arbor, MI.

Varicose veins and distichiasis, or growth of accessory eyelashes from the Meibomian glands, occur together in lymphedema-distichiasis syndrome (LD). LD is an autosomal dominant syndrome also characterized by pubertal onset of bilateral lower extremity edema. A 12 year-old female presented with a subset of LD features including distichiasis and severe varicose veins, but without lymphedema. She also had microcephaly and mental retardation, features not typically associated with LD. Additional members of the probands family had distachiasis and less severe varicose veins. Our lab demonstrated that mutations in the forkhead transcription factor FOXC2 cause LD, but cases without FOXC2 mutations have been reported. Mutational screening of FOXC2 failed to identify mutations in the proband, but chromosomal microarray identified a deletion of BAC clone RP11-106D4 located ~ 750 kb telomeric to the FOXC2 locus on chromosome 16. The deletion was also identified in 3 affected family members but was not present in 1 unaffected relative. The RP11-106D4 clone rarely varied in over 800 unrelated samples tested previously. The presence of the deletion was confirmed by FISH using an overlapping BAC clone RP11-178L8. Using a combination of techniques, we cloned the breakpoints of the deletion. It spans 260 kb on 16q24.3 including three genes: FBXO31 (F-box Protein 31), MAP1LC3B (microtubule-associated protein 1 light chain 3 beta), and ZCCHC14 (zinc finger, CCHC domain containing 14) and extends into a conserved gene desert distal to FOXC2. We studied the expression pattern of each deleted gene in mouse embryos using in situ hybridization. Fbxo31 is expressed strongly in the eyelid, surrounding blood vessels, and kidney, which are also sites of Foxc2 expression. Map1lc3B is expressed in the stomach, and Zcchc14 is expressed in the ear and skull. Based on expression analysis, deletion of FBXO31 could be the cause of varicose veins and distichiasis in this family, although deletion of a long range FOXC2 enhancer element cannot be ruled out. *FOXC2FBXO31MAP1LC3BZCCHC14*.

Chromosome-Wide Methylation Analysis Gives New Insights on the Effectiveness of DNA Promoter Methylation in Transcriptional Repression in Melanoma Cells Compared to Normal Melanocytes. *Y. Koga[1], M. Pelizzola[2], A. Molinaro[2], M. Krauthammer[3], S. Ariyan[4], D. Narayan[4], R. Halaban[5], S.M. Weissman[1]* 1) Departments of Genetics; 2) Epidemiology; 3) Pathology; 4) Surgery; 5) Dermatology, Yale University School of Medicine, New Haven, CT.

Altered gene expression due to aberrant modifications of chromatin is involved in tumorigenesis and maintenance of the malignant phenotype. One such process involves methylation/demethylation of cytosine at cytosine-guanine (CpG) pair rich islands in promoter regions of genes. We, therefore, examined genome-wide DNA promoter methylation coupled with gene expression analysis to determine melanoma specific epigenetic profiles and identify epigenomic markers in melanoma development. The methylcytosine immunoprecipitation method known as MeDIP (Weber et al., 2005) was adapted to enrich for methylated DNA. MeDIP coupled with DNA hybridization to microarrays was employed to generate methylation profiles in normal melanocytes compared to melanoma cells. The DNA methylation profiles were compared to global gene expression studies in these cells. A preliminary analysis of the entire X-chromosome demonstrated complexity of DNA methylation patterns across the different coding and non-coding genomic regions. DNA from melanoma cells was hypermethylated in the upstream, 5'UTR and coding exon regions compared to normal melanocytes. Bioinformatic analysis showed that hypermethylation of high CpG content (CpGr0.4), in upstream and 5'UTR regions appeared to be highly indicative of transcriptional repression. DNA methylation profiles combined with gene expression analysis highlighted several interesting regions of specific hyper/de-methylation in melanoma cells. Bisulfite sequencing of specific regions confirmed the MeDIP results and showed strong correlation between DNA methylation and gene expression. Our studies demonstrate that novel insights can be derived from global DNA methylation and gene expression analyses that can be the basis for predicting epigenomic markers in melanoma.

Regional differences in SNPs associated with susceptibility to pulmonary tuberculosis in Mexican mestizo populations. *I. Aguilar-Delfin, C. Rangel-Escareño, J. Estrada-Gil, R. Goya, G. Jimenez-Sanchez* National Institute of Genomic Medicine, Mexico.

Most individuals within the Mexican population are considered mestizo, having originated from the admixture of Amerindian groups with Spaniards and, to a lesser extent, Africans. This complex admixture process has resulted in genetic differences between geographical regions. The purpose of this study was to assess the existence of regional differences in Mexican mestizo populations in polymorphisms associated with susceptibility to pulmonary tuberculosis (PTB), analyzing individual genotypes as well as higher order interactions i.e. combinatorial genotypic categories. We called our method **C**ombinatorial **G**enotype **B**ins (CGBs) which also ranks PTB risk scores according to a probability matrix using the reported ORs for individual SNPs. Among the functional polymorphisms known to influence susceptibility to PTB we selected ***MCP1, IL10, IL12RB1*** and ***SLC11a1*** and used Taqman to genotype *MCP1-2518A>G* (rs1024611), *IL10-1082A>G* (rs1800896), *IL12RB1-111A>T* and *SLC11A1+1627G>A* (rs17235409) in 1,150 healthy mestizos from six different states. Results show that *MCP1-2518* GG genotype has a higher frequency in Mexican mestizos (0.276 0.073 CI 0.195-0.368) compared to Europeans and Africans (0.017) suggesting that the G allele may have been contributed by Amerindian populations. The state of Sonora exhibits a significantly lower frequency of GG genotype (0.150) compared to the rest of the states (0.302 0.043, CI 0.208 - 0.378; F_{ST} $p<0.001$) and also exhibits the lowest Amerindian contribution in the 100 kb genomic region that contains *MCP1*. The higher-order analysis showed that 3 of the CGBs corresponding to bins with high and moderate PTB risk scores have frequency differences between Mexican mestizos and a subset of 50 individuals with significantly higher Amerindian ancestral component. Overall, the results support the existence of regional differences in genomic determinants associated with susceptibility to PTB in Mexican mestizos which could have resulted from heterogeneity in the proportion of Amerindian ancestry.

Clinical and Molecular Features of Mitochondrial DNA depletion due to Mutations in Deoxyguanosine Kinase.

Lipson[3], H. Vallance[8], F. Scaglia[1], L.-J. Wong[1] 1) Dept M & H Gen, Baylor C M, Houston, TX; 2) David Gladstone Inst at UCSF, San Francisco;; 3) Kaiser Permanente, Sacramento, Ca;; 4) Children's Hospital Philadelphia, Philidelphia, PA;; 5) Stanford University SoM, Stanford, CA;; 6) Massachusetts General, Boston, MA;; 7) University of Utah, Salt Lake City, Utah;; 8) University of BC, Vancouver, B.C., Canada; 9) Childrens Hospital Bambino Gesu, Rome, Italy;.

Background

Deoxyguanosine kinase (*DGK*) is a nuclear gene that along with *thymidine kinase-2* salvages deoxyribonucleotides (dNTPs) for mtDNA synthesis. Deficiency of either of these causes a mitochondrial depeletion syndrome.

Methods

We have undertaken a retrospective analysis of two centers 9 Kindreds representing 16 mutations, 13 of which are unpublished. These are compared with previously published cases to establish genotype/phenotype.

Results

DGK mutations are associated with both isolated hepatic and hepato-cerebral forms. In all patients in our series hepatocerebral disease was associated with an abnormal newborn screen, early onset of nystagmus and early death. Conversely, the absence of a neurological phenotype is predictive of long term survival independent of liver transplantation. The N46S mutation is associated with isolated hepatic disease in all ethnicities.

Conclusions

Mitochondrial depletion caused by mutations in *DGK* should be considered in children with hepatic dysfunction or cholestasis even without neurological findings Full gene sequencing is warranted if *DGK* deficiency is suspected.

Candidate Genes for Asthma and Atopy. *D. Daley[1], M. Lemire[2], P.D. P.D. Paré[1], A.J. Sanford[1], A.L. Kozyrskyj[3], C. Laprise[4], Y. Bosse[2], A. Motpetit[2], A. Becker[3], D. Zamar[1], B. Tripp[1], J. He[1], K. Tremblay[4], A. James[5], A.W. Musk[5], L.J. Palmer[6], T.J. Hudson[2]* 1) University of British Columbia; 2) McGill University and Genome Quebec Innovation Centre; 3) University of Manitoba; 4) University of Quebec at Chicoutimi; 5) Sir Charles Gairdner Hospital; 6) University of Western Australia.

To better understand the development of asthma and allergic diseases, we conducted a genetic association study combining the power and resources of 4 study populations: 1) a high risk birth cohort the Canadian Asthma Primary Prevention Study(CAPPS), 2) a population-based birth cohort of children from the Study of Asthma Genes and Environment (SAGE), 3) a French Canadian founder population the Saguenay-Lac St. Jean Quebec family based sample (SLSJ) and 4) a population based sample from the town of Busselton Australia the Busselton Health Study population. We examined candidate genes with the same set of 1536 single-nucleotide polymorphisms (SNPs), a common genotyping platform, and stringent standardized phenotypes. Our panel comprised candidate genes associated with asthma and allergic phenotypes (asthma, atopy, atopic asthma, and airway hyperresponsiveness) with strong biologic plausibility and/or prior evidence for association. For a full list of genes and SNPs see *http://genapha.icapture.ubc.ca/.* For each gene a maximally informative set of SNPs was selected and genotyped using the Illumina GoldenGate assay. Genetic analysis was carried out using Family Based Tests of Association (TDT for the family based samples CAPPS (549 families), SAGE (723 families), and SLSJ (260 families)) and logistic/linear regression as appropriate for the Busselton Health Study (800 cases and 800 controls) with correction for the number of SNPs and phenotypes tested. Preliminary population genetic information including LD plots and allele frequencies by cohort and ethnicity can be found at *http://genapha.icapture.ubc.ca/*. Preliminary findings have identified associations with IL13 (asthma, atopy, and atopic asthma), IL18, and IFNGR2 (atopy) in the combined analysis of the CAPPS, SAGE and SLSJ cohorts. Analysis is ongoing and updated results are forthcoming.

Development of a disease severity scoring system for patients with Pompe disease. *E.H. Giannini[1], D.L. Marsden[2]*
1) Rheumatology, Cincinnati Children's Hospital, Cincinnati, OH; 2) Genzyme Corporation, Cambridge, MA.

Background: A Disease Severity Scoring Index (DS3) assesses the burden of disease severity in a patient and can compare patients with the same disease. It can distinguish between separate organ system scores and overall scores, allowing for comparison within organ systems. The clinical progress of a patient or the response to treatment can be followed. It is particularly useful in rare, heterogeneous diseases. A system is being developed for Pompe Disease, a rare autosomal recessive neuromuscular disorder due to a deficiency of lysosomal enzyme acid--glucosidase (GAA), which results in accumulation of glycogen in cardiac, skeletal and smooth muscle. Clinical phenotype ranges from severe, rapidly progressive disease in infants, to slower, more heterogeneous disease in children and adults. Enzyme replacement treatment (ERT) with recombinant GAA, Myozyme, is now available. **Methods:** A panel of Pompe experts was assembled to identify critical health domains. A Delphi group of physicians was consulted to capture standard medical practice(s) for severity measurement within each critical domain. Selected domains were: Cardiac, Respiratory, Proximal Muscle, Physician Reported Outcomes and Patient Reported Outcomes. Within each domain, 1-2 clinical assessments were identified. **Results:** To test this preliminary model, 9 cases from the Pompe Registry representing a severity spectrum were scored, and compared to results from a blinded small expert group assessment of the same cases using the Clinical Global Impression (CGI) Severity scale, yielding a 0.93 coefficient of correlation, indicating preliminary DS3 consistency with expert opinion, confirming DS3 validity, reliability and relevance. Validation will be completed by comparing DS3 results with the expert Delphi group opinion for multiple patient cases at multiple time points. **Conclusion:** Preliminary results indicate the Pompe DS3 model will help standardize disease terminology, highlight key clinical assessments to quantify disease severity. Ultimately this tool will evolve into a universal disease staging system where specific medical interventions may be recommended.

S-nitrosoglutathione Reductase and $_2$-Adrenergic Receptor Gene-Gene Interaction is Associated with Asthma in Latinos. *S. Choudhry[1], L.G. Que[2], L. Liu[1], C. Eng[1], S. Nazario[3], J. Casal[3], A. Torres[3], J. Salas[4], R. Chapela[4], J. Rodriguez-Santana[5], P.C. Avila[6], W. Rodriguez-Cintron[3], E.G. Burchard[1]* 1) University of California, San Francisco, CA; 2) Duke University, Durham, NC; 3) VAMC, San Juan, PR; 4) INER, Mexico City, Distrito Federal, Mexico; 5) Pediatric Pulmonary Program, San Juan, PR; 6) Northwestern University, Chicago, IL.

S-nitrosoglutathione (GSNO), an endogenous bronchodilator present in airway lining fluid (ALF) of healthy subjects, is depleted from ALF of subjects with asthma. GSNO reductase (GSNOR) is the enzyme that metabolizes S-nitrosothiols in vivo. Deletion of the GSNOR gene protected mice from experimental asthma and $_2$-receptor desensitization to $_2$-agonists. We hypothesized that genetic variants in the GSNOR gene may be associated with asthma. We also reasoned that there may be biological interactions between GSNOR and $_2$-adrenergic receptor ($_2$AR), which modulate response to bronchodilators. To test our hypotheses we performed family-based and gene-gene interaction analyses in Puerto Rican (n=386) and Mexican (n=300) trios with asthma. Five SNPs, one in the promoter region and four in the 3 UTR, were tested for association with asthma and related phenotypes. Family-based analyses demonstrated that several GSNOR SNPs, including the SNP in the promoter region ($p = 0.05$) and 3 SNPs in the 3 UTR ($p = 0.03$ to 0.008), and haplotype ($p = 0.02$) were significantly associated with asthma in Puerto Ricans. No association between GSNOR SNPs and asthma was found in Mexicans. However, we found evidence of GSNOR-$_2$AR interaction and its association with bronchodilator response in both Mexican and Puerto Rican asthmatics (combined $p = 0.001$). Our data suggest a genetic association of GSNOR with asthma diagnosis and a GSNOR-$_2$AR gene-gene interaction associated with bronchodilator response. These results further implicate GSNO in asthma pathogenesis and bronchodilator responsiveness.

Clonal chromosome evolution in a patient with germ cell cancer and treatment-related MDS. *D. Boles[1], D. King[1], J. Parker[1], B. Carstarphen[1], C. Stollmack[1], S. Chai[2], S. McClure[3]* 1) Cytogenetics Laboratory, Presbyterian Reference Laboratory, Charlotte, NC; 2) Carolinas Cancer Care, Charlotte, NC; 3) Presbyterian Pathology Group, Presbyterian Hospital, Charlotte, NC.

Therapy-related AML/myelodysplastic syndrome is a frequent finding in patients with germ cell tumors after chemotherapy that includes etoposide or ifosfamide. Our patient is a 24 year old male with a history of germ cell tumor and rhabdomyosarcoma who developed therapy related MDS/AML after separate treatments with BEP (bleomycin, etopside, cisplatin) and TIP (paclitaxel, ifosfamide, cisplatin). Standard G-band analysis of unstimulated 24 hour bone marrow cultures revealed two abnormal subclones: 47,XY,+iso(12)(p10), a common finding in germ cell cancers, and 48,XY,+8,+iso(12)(p10). The iso(12)(p10) was confirmed by FISH. The final karyotype was: 47,XY,+iso(12)(p10)[3]/48,idem,+8[15].ish i(12)(p10)(TELx4,AML1x2)[8/8].nuc ish(TELx4,AML1x2)[195/344],(TEL,AML1)x2[107/344]. Trisomy 8 is a frequent abnormality in patients with therapy-related MDS; however, the co-occurence of iso(12)(p10) and trisomy 8 in the same cells is unusual. The probable evolution of this cancer is that cells with iso(12)(p10) as the sole abnormality, and presumably derived from a primordial germ cell, then acquired an extra copy of chromosome 8 (an AML/MDS marker). The hematopoietic process that would result in this karyotype is unclear but cumulative genetic defects in a stem cell with myeloid potential are suggested.

Further SNP mapping of 10q26 supports strong association of rs11200638 in the HTRA1 promoter to age-related macular degeneration. *D. Gibbs[1], Z. Yang[1], D.J. Cameron[1], C. Stratton[1], A. DeWan[2], J. Hoh[2], K. Zhang[1]* 1) Department of Ophthalmology and Visual Sciences, University of Utah, Salt Lake City, UT; 2) Department of Epidemiology and Public Health, Yale University, New Have, CT.

Purpose: Age related macular degeneration (AMD) is the leading cause of blindness in the developed world. While this disease is known to have a genetic basis, few genes have been consistently implicated. One locus at chromosome 10q26 has been shown in multiple independent studies to confer risk. Recently a SNP in the 10q region in a transcription factor binding site of the promoter of HTRA1 gene was described as a causal variant for AMD. The purpose of this study is to investigate addition variants in chromosome 10q26 in order to refine understanding of the region. Methods: Using DNA extracted from peripheral blood leukocytes, additional single nucleotide polymorphisms (SNPs) were genotyped by PCR and the SNPSHOT method on an ABI 3130xl Sequencer. A Utah cohort, of 546 AMD patients, was genotyped for addition SNPs in chromosome 10q26 and allele frequencies were compared to 294 age and ethnicity matched normal controls by lab personnel blinded to case/control status. Results: We genotyped 18 single nucleotide polymorphisms (SNPs) in the 10q26 region encompassing the genes PLEKHA1, ARMS2 (formerly LOC387715), and HTRA1. Many variants throughout this region were associated with AMD but rs11200638 was the most significantly associated polymorphism with a chi-squared test for trend p-value of 5.3X10-15. Conclusions: From this comparative data the HTRA1 promoter SNP rs11200638 still remains the most significantly associated SNP with AMD. These findings do not exclude the possibility that there may be multiple causal variants. However rs11200638 remains the best candidate presented thus far.

Early experience with intrathecal rhIDU for spinal cord compression in MPS I patients. *P. Dickson[1], V. Muñoz-Rojas[2], R. Giugliani[2], D. Naylor[3], A. Chen[3], M. Passage[1], S. Le[1], A. Victoroff[1], A. Mlikotic[4]* 1) Dept Pediatrics, Harbor-UCLA Medical Ctr, Torrance, CA; 2) Medical Genetics Service, Hospital de Clínicas de Porto Alegre, Porto Alegre, RS, Brazil; 3) Dept Neurology, Harbor-UCLA Medical Ctr. Torrance, CA; 4) Dept Radiology, Harbor-UCLA Med Ctr. Torrance, CA.

Intrathecal enzyme replacement therapy with recombinant human -L-iduronidase (rhIDU) reduces brain glycosaminoglycan (GAG) levels to normal and spinal meninges GAG levels by 57-70% in treated MPS I dogs.[1] Three patients with MPS I (Hurler-Scheie and Scheie types) and spinal cord compression age 13-39 y received 1.74 mg IT rhIDU monthly for 3-6 doses. One subject was enrolled in an ongoing clinical trial of IT rhIDU; two were treated off-study. One off-study patient was reported previously.[2] All subjects showed improvements in the signs and symptoms of spinal cord compression. Improvements included reduction in lower extremity pain in 2/2 subjects, improvement in numbness/tingling in 2/2 subjects, newfound ability to move the right leg in 1, improvement of pain and temperature asymmetries in 2/2, improved strength and range of motion in 1, and disappearance of ankle clonus in 1. MRI and evoked potentials did not change. Six-minute walk test improved for 1 subject and decreased for 1 subject; the third subject is non-ambulatory. IT rhIDU was well-tolerated by the subjects. There was one SAE (pneumonia), felt unlikely to be related to IT rhIDU. Other related AE were mild and/or self-limited. A CSF leukocytosis developed in 1 subject (peak 37 WBC) with no meningeal signs and responded to oral steroids. The subject also experienced elevation of CSF opening pressure which resolved. All CSF anti-iduronidase antibody titers were < 1 OD unit/l. IT rhIDU appears to alleviate some of the signs and symptoms of spinal cord compression and is well-tolerated by subjects. Further study is needed, and a clinical trial is underway.

The dysmorphologic features of a newborn following an abdominal pregnancy. *C.G. Abarquez[1,2], M.L. Alcausin[1,2], C.D. Padilla[1,2], E.M.C. Cutiongco-de la Paz[1,2]* 1) Institute of Human Genetics, National Institutes of Health, Manila, Philippines; 2) Section of Genetics, Department of Pediatrics Philippine General Hospital, Manila, Philippines.

Abdominal pregnancy is an implantation of an ectopic gestational sac in the peritoneal cavity. It is a rare occurrence and has an incidence of 1 per 11,000 pregnancies but may be more common or less frequent depending on race and country. Abdominal pregnancy is considered advanced if it survives beyond 20 weeks of gestation. It exceptionally reaches term but delivery of a live infant is rare. A high incidence of fetal deformations and mortality has been frequently reported. A deformation sequence occurs when an abnormal mechanical force produces several related deformations. We report a case of a live dysmorphic newborn with an estimated gestation of 40 weeks following an advanced primary abdominal pregnancy. The abdomen, being an abnormal site for fetal development contributed to the pressure deformities noted. The findings of a segmental atelectasis on radiograph, facial asymmetry, torticollis and the clubfeet were secondary to the external abdominal constraint. It is important to detect dysmorphism and malformations because these impact on the overall prognosis and will allow interventions that will prevent, anticipate or treat complications.

BIMBAM: Bayesian IMputation Based Association Mapping. *Y. Guan, M. Stephens* Human Genetics, University of Chicago, Chicago, IL.

To briefly explain the rationale for imputation-based methods, consider the "tag-SNP"; design for association studies, where SNPs are first identified (eg by resequencing) in a panel of individuals, and then a subset of these SNPs ("tags") are typed in the study sample. The imputation-based approach exploits the fact that tag SNPs are often good predictors for the other (non-tag) SNPs, to first "impute" the genotypes of all individuals at all non-tag SNPs, and then assesses the strength of the association between the imputed genotypes and the phenotype. The idea is that this both improves power to detect associations, and interpretability of results (by assessing which SNPs, both tag and non-tag, are the best candidates for causally affecting the phenotype). Imputation-based methods should also be helpful in combining data from multiple studies that have typed different SNPs in the same region (eg genome-wide scans using different genotyping platforms). Here, the idea is to use known patterns of correlation among the two sets of markers (eg from the HapMap data) to impute genotypes at all markers in all individuals, allowing the data from both studies to be used when assessing correlation between phenotype and each marker. We distribute a software package BIMBAM (Bayesian IMputation Based Association Mapping). Bimbam computes both single-SNP Bayes Factors (BFs) for each SNP, and, optionally, multi-SNP BFs for combinations of SNPs. The latter allows one to assess the potential that multiple SNPs in a data sets are combining to influence phenotype, and is intended for use in small genomic regions (e.g. candidate genes). The imputation is performed using the algorithm used in fastPHASE. BIMBAM can handle quantitative phenotype, where BFs are computed using the prior D2 from Servin and Stephens (2007). Bayesian logit regression based approach has been developed to handle case/control phenotype and will be integrated into BIMBAM shortly.

Frequent pathogenic and apparently benign *de novo* copy number variants detected by 500K GeneChip array genomic hybridization in children with idiopathic mental retardation. *J.M. Friedman[1,2], S. Adam[1], L. Armstrong[3], C. Boerkoel[3], S. Chan[4], D. Chai[3], A.D. Delaney[4], W.T. Gibson[3], S. Langlois[2,3], E. Lemyre[5], B. McGillivray[2,3], J. Michaud[5], M. Patel[3], H. Qian[4], G. Rouleau[5], M. Van Allen[3], S.-L. Yong[3], F. Zahir[1,2], P. Eydoux[3], M. Marra[2,4]* 1) Medical Genetics Research Unit, Child & Family Res Inst, Vancouver, Canada; 2) Dept of Medical Genetics, U of British Columbia, Vancouver, Canada; 3) Childrens & Womens Hosp, Vancouver, Canada; 4) Genome Sciences Ctr, BC Cancer Agency, Vancouver, Canada; 5) Centre de Recherche, CHU Sainte-Justine, Montréal, Canada.

We are using 500K GeneChip array genomic hybridization to screen for novel pathogenic copy number variants (CNVs) in children with mental retardation (MR) and normal cytogenetic studies. We found *de novo* CNVs in at least 16 (18%) of 90 children with idiopathic MR studied. There were 7 duplications and 11 deletions, including two unbalanced translocations, ranging in size from 89 kb to 11.1 Mb.

At least 3 of the *de novo* CNVs found in these children are unlikely to be pathogenic for their MR. One child had a 107 kb deletion of 14q11.2, but fosmid FISH showed some cells with 2 copies, some cells with 1 copy, and some cells with no copies of the affected region. This genomic region contains many T-cell receptor alpha V genes, and it is likely that the deletion occurred somatically. A second child had a 166 kb duplication of a different genomic segment in 14q11.2. The region contains multiple olfactory receptor loci but no other annotated genes and is frequently involved in polymorphic (presumably benign) gain CNVs. A third child had an 89 kb deletion of 6p21.33p22.1 within the HLA region. Polymorphic loss CNVs of this genomic segment are frequently observed in normal populations.

Array genomic hybridization with high-density oligonucleotide chips can detect CNVs smaller than 100 kb in children with idiopathic MR, but many of these genomic alterations may not be pathogenic even if they have arisen *de novo*.

Differential allele frequencies in drug-related SNPs in the Mexican population. *A. Contreras, I. Silva-Zolezzi, LA. Alfaro, G. Jimenez-Sanchez* National Institute of Genomic Medicine, Mexico.

Genetic variation influence how humans respond to commonly used drugs. There is growing evidence showing that ethnic origin contributes to drug response. Most of the Mexican population results from admixture of any of 65 ethnic groups with Spanish, and in a lesser extent, Africans. To better understand drug-related SNPs distribution in the Mexican population, we genotyped seven SNPs known to influence drug response: *ADCY9* 2316AG (Albuterol and Budesonide), *CRHR1* 30864GT (Budesonide), *MDR1* 3435CT (Carbamazepine), *MDR1* 2677GT (Paclitaxel), *5-HT2C* -759CT (Risperidone, Olanzepine), *5-HT2A* 4472GA (Citalopram) and *PDE6A* 22620AT (Fluoxetine) in 300 Mexican Mestizos from six different states: Guerrero, Guanajuato, Sonora, Veracruz, Yucatan and Zacatecas. Our results showed the following allele frequencies: *ADCY9* 2316AG, G 0.226 (0.170-0.322) and GG 0.054 (0.034-0.071); *CRHR1* 30864GT, T 0.221 (0.157-0.371) and TT 0.050 (0.000-0.168); *MDR1* 3435CT, T 0.459 (0.368-0.553) and TT 0.195 (0.000-0.332); *MDR1* 2677GT, T 0.459 (0.370-0.555) and TT 0.211 (0.137-0.349); *5-HT2C* -759CT, T 0.185 (0.102-0.281) and TT 0.104 (0.067-0.237); *5-HT2A* 4472GA, A 0.269 (0.204-0.366) and AA 0.067 (0.000-0.189); *PDE6A* 22620AT, T 0.183 (0.134-0.366) and TT 0.003 (0.000-0.157). Allele distribution in Mexico showed significant differences between some states (p0.05). Moreover, comparative analysis with other world populations evidenced different allele frequencies, examples include *MDR1* 2677GT (MEX 0.46 vs YRI 0.0), *ADCY9* 2316AG (MEX 0.23 vs CEU 0.40), and *PDE6A* 22620AT (MEX 0.18 vs CHB 0.02). Our results indicate that these analyses will be of relevance to better design pharmacogenomic studies in Mexico, contributing to a more rational use of drugs in Mexican populations.

Interaction of Genotype, Homocysteine and Vitamin Levels on Migraine. *L. Griffiths, R. Lea, N. Colson, S. Quinlan*
Genomics Res Ctr, Sch Med Sci, Griffith Univ Gold Coast, Southport, Australia.

Studies in our laboratory have investigated a number of vascular related genes to determine their involvement in migraine. These studies have identified a role for the methylene tetrahydrofolate reductase (MTHFR) gene in migraine, with our studies and others implicating the C677T variant in migraine, in particular migraine with aura (MA) susceptibility. The TT genotype of this variant which is associated with MA, is also associated with decreased MTHFR enzyme and elevated plasma homocysteine levels. High homocysteine levels have been associated with various vascular related disorders, but an increase in dietary vitamin B and folate levels can have an important effect reducing these levels. To determine the effects of vitamin supplementation on homocysteine levels and disease symptoms in migraine we are conducting a pilot trial. 53 MA patients were randomised to receive vitamin (folic acid, B6 and B12) supplementation over a 3 month period, with assessment at baseline for plasma homocysteine levels, folate and vitamin status and C677T genotype. The vitamin treatment was within maximum daily dosages, was well tolerated and no adverse events were recorded. For the total patient group, baseline homocysteine levels were negatively correlated with folate ($P=0.001$), vitamin B12 ($P=0.006$) and vitamin B6 ($P =0.034$) with only minor variation between the treatment and placebo groups observed ($P>0.1$). Mean homocysteine was also similar in the two groups at baseline ($P = 0.95$) and baseline levels of vitamins between C677T genotype groups were not statistically significant ($P>0.05$). The mean homocysteine level was ~16% higher in the TT genotype group compared to CT/CC ($P=0.09$). After 3 months of vitamin supplementation the treatment group showed a mean reduction in homocysteine of 39% ($P < 0.0001$), whilst the placebo group showed no change ($P > 0.05$). The results indicate that vitamin supplementation has a marked effect on homocysteine levels in MA patients and suggest that this response is modified by MTHFR C677T genotype. Also subjective information received from patients has indicated a noticeable reduction in migraine severity, frequency and duration.

Examination of Candidate Genes for an Autosomal Recessive Syndrome of Epilepsy, Ataxia and Tremors. *A. Buhr[1], A. Daoud[2], A. Saadoon[2], S. Chen[1], R. Spiegel[1], H. El-Shanti[1]* 1) University of Iowa, Iowa City, IA; 2) Jordan University of Science and Technology, Irbid, Jordan.

STATEMENT OF PURPOSE: Gene discovery in epilepsy has been progressing rapidly in the past decade, but mutations are often found in single families with autosomal dominant epilepsy with very limited application of this knowledge to the sporadic forms. Autosomal recessive epilepsy has traditionally been resistant to gene mapping and identification because families are usually small and are not sufficient for linkage analysis. However, gene discovery in autosomal recessive epilepsy may provide insight into a new class of genes that play a role in sporadic idiopathic generalized epilepsy. We have identified a large inbred family with an autosomal recessive syndrome of ataxia, epilepsy and tremors. We mapped the gene to the pericentromeric region of chromosome 12 by homozygosity mapping. Within this region, we identified 10 to 15 candidate genes, but were able to exclude most of them by direct sequencing. METHODS Mutation detection in candidate genes was approached by direct sequencing of gene exons and splice sites and evaluation of identified variants by calculating population allele frequency of variants. We are currently exploring the role of mutational mechanisms other than point mutations in these candidate genes. RESULTS We selected the following outstanding candidate genes for our preliminary pass based on their function or their expression pattern: *ASB8, LRRK2, SLC38A2, SLC2A13, NELL2, FLJ20489, GLT8D3, ALG10, ALG10B*. Of the possible 117 exons to sequence, all but 16 were thoroughly completed. We found no etiologic mutations in those exons. We also examined *LRRK2* for exonic deletions or duplication. CONCLUSIONS We were able to preliminarily exclude the previously mentioned candidate genes from being responsible for the neurologic disorder in our family. These genes were evaluated for point mutations and small deletions or duplications, which we did not find. We are currently expanding our candidate gene list and exploring other mechanisms beyond point mutations and small deletions or duplications in these and other genes.

Functional polymorphisms of FPR1 gene and aggressive periodontitis in Japanese. *T. Gunji[1,2], Y. Onouchi[2], T. Nagasawa[1], H. Watanabe[1], H. Kobayashi[1], S. Arakawa[1], K. Noguchi[1], A. Hata[2], Y. Izumi[1], I. Ishikawa[3]* 1) Periodontology, Department of Hard Tissue Engineering, Tokyo Medical and Dental University Graduate School, Tokyo, Japan; 2) Laboratory for Gastrointestinal Disease, SNP Research Center, RIKEN, Yokohama Institute, Yokohama, Japan; 3) Institute of Advanced Biomedical Engineering and Science, Tokyo Womens Medical University, Tokyo, Japan.

Aggressive periodontitis (AgP) is a severe type of periodontitis with possible familial aggregation that causes rapid alveolar bone destruction in individuals without any systemic disorders. Formyl peptide receptor 1 (FPR1) is a chemotactic G protein-coupled receptor that is expressed on the surface of polymorphonuclear neutrophils (PMNs) and other phagocytes. FPR1 of PMNs in AgP patients is reported to be defective and a role of FPR1 Single Nucleotide Polymorphisms (SNPs) in AgP progression was suggested, but these results have not yet been fully confirmed. The purpose of this study is to investigate the possible role of FPR1 in AgP in Japanese.

To examine whether polymorphisms in *FPR1* gene are associated with AgP, we performed an association study with 38 AgP patients and 373 controls using 30 variations identified by sequencing the 21.1 kb gene region. Three SNPs showed a significant association with AgP (chi squared test, $p < 0.05$). Among them, the susceptible allele of the SNP which was located in approximately 10kb upstream of the gene decreased activity of transcriptional regulation in *vitro*. Haplotype association analysis with this SNP and a non synonymous SNP in Exon 2 (Asn > Lys) revealed that one haplotype was significantly represented in AgP patients ($p = 0.035$).

In conclusion, our result suggested that structurally and transcriptionaly altered FPR1 function might be relevant to the risk for AgP in Japanese.

Global gene expression analysis using 7081 publicly available microarrays identifies 26 novel genes selectively expressed in fetal cartilage. *V. Funari[1], A. Day[2], D. Krakow[1, 2], S. Nelson[2], D. Cohn[1, 2]* 1) Medical Genetics Institute, Cedars-Sinai Medical Ctr, 8700 Beverly Blvd, Los Angeles, CA; 2) Department of Human Genetics, David Geffen School of Medicine at UCLA, Los Angeles, CA.

Cartilage plays a fundamental role in the development, function and maintenance of the human skeleton and mutations in many genes selectively expressed in cartilage are associated with skeletal dysplasia phenotypes. To identify new genes which may play important roles in human skeletogenesis, microarray analysis was used to identify 90 uncharacterized or unannotated genes that were expressed at least 5-fold higher in fetal cartilage than in normal non-cartilage tissues. These genes were then further evaluated for their global gene expression patterns in 7081 publicly available microarrays. An approach was developed to determine which of these genes exhibited null or minimal expression with little variation within non-cartilage tissues, hypothesized to represent cartilage selective genes. 26 of the 90 novel genes exhibited the least variation in gene expression among non-cartilage tissues, and displayed expression patterns similar to a set of cartilage-selective control genes. All 26 genes were significantly down-regulated in cultured de-differentiated chondrocytes, indicating that these genes in part characterized the differentiated state of cartilage. Analysis of regional expression within the cartilage growth plate demonstrated that two of the genes, LOC200118 and C10ORF49, were down-regulated in the hypertrophic zone. In addition, orthologous proteins have been identified in other vertebrates, consistent with an evolutionarily conserved biological role. The protein structure of LOC200118 suggests it is a transcription factor, while C10orf49 encodes a protein predicted to contain a signal peptide and a protein-protein interaction domain suggesting it may interact with other proteins within the extracellular matrix. This study indicates that the cartilage transcriptome contains a rich resource of novel genes likely to have roles in skeletal development. These genes also represent novel candidate disease genes for inherited skeletal disorders.

Treatment of MPS I dogs from birth with intrathecal and intravenous rhIDU. *N.M. Ellinwood[1], E.M. Snella[1], J. Jens[1], K.L. Kline[2], J. Parkes[2], J. Wengert[2], M. Passage[3], S. Le[3], P. Dickson[3]* 1) Dept Animal Sci, Iowa St Univ, Ames, IA; 2) Dept Vet Clin Sci, Iowa St Univ, Ames, IA; 3) Dept Pediatrics, LA Biomed at Harbor-UCLA, Torrance, CA.

Introduction: Recombinant human -L-iduronidase (rhIDU) is used as enzyme replacement therapy for mucopolysaccharidosis (MPS) I. Antibodies develop in treated patients that may reduce the efficacy of treatment. Previous research in gene therapy has shown natural tolerance in MPS I mice treated from birth.[1] **Methods:** MPS I dogs received 0.58 mg/kg/week IV rhIDU (n=5) or 2.0 mg/kg/week (n=1). Two low dose IV dogs received 1.74 mg rhIDU every three months via intrathecal injection (n=2). Serum samples for specific, anti-iduronidase IgG antibodies were analyzed by ELISA. **Results:** The pups were treated beginning at age 1 day (n=2), 4-8 days (n=3), and 25 days (n=1). Two pups infused on the first day of life (when natural pup mortality is high) died following one treatment. No adverse events occurred in the dogs treated after 4 days of age. After 10-24 weeks of treatment, serum anti-iduronidase antibody levels were < 1 OD unit/ul in all treated pups (tolerance cut-off is 20 OD units/ul). No immune suppressive therapy was used in the pups. In contrast, 8 adult normal and MPS I dogs receiving IV rhIDU developed a mean antibody titer of 149 OD units/ul (range 60.2-377.9) after 12 weeks of treatment.[2] Treated pups also had a more normal appearance to the cranium and had less toe-splaying than untreated littermates. **Conclusion:** MPS I pups beginning IV rhIDU treatment between 4 and 25 days of age did not develop anti-iduronidase antibodies after 10-25 weeks of treatment, consistent with immune tolerance to therapy. This may have important implications for MPS I patients beginning treatment early in life.

Spine abnormalities is correlated with back pain in young persons with Ehlers-Danlos Syndromes. *S. Bangura[1], B.F. Griswold[1], L. Sloper[1], R. Raza[3], C.A. Francomano[2], N.B. McDonnell[1]* 1) LCI, NIA/NIH, Baltimore, MD; 2) GBMC, Baltimore, MD; 3) Harbor Hospital, Baltimore, MD.

The Ehlers-Danlos syndromes (EDS) are a heterogeneous group of hereditary disorders of connective tissue characterized by joint, skin and vascular abnormalities. Joint laxity, dislocations and chronic pain are commonly recognized features of EDS in young persons, however, the correlation of pain with spinal pathology has not been studied systematically. We investigated abnormalities of the spine in 26 consecutive subjects younger than 25 with a diagnosis of hypermobile or classical EDS enrolled in a natural history study of hereditary disorders of connective tissue at the National Institutes of Health. The age range was 12-25, and there were 14 females and 12 males. Magnetic Resonance Imaging (MRI) of the lumbar spine was obtained in all subjects, and additional limited thoracic and cervical studies were obtained on some of the subjects. In 15 of these young patients, abnormal signal was detected in lumbar discs, with eccentric placement or diminished size of nucleus pulposus. Degenerative disc disease, bulging or herniated discs, and facet joint athrosis was present in at least one level in 20/25 patients. Two patients have severe lumbar spinal stenosis. Dural ectasia was associated with the presence of Marfanoid body habitus and scoliosis, however none of the patients have cardiac or ocular findings that suggested the diagnosis of Marfan syndrome. Schmorls nodes were seen in all male subjects. All subjects with spinal pathology had complaints of back/neck pain. The results suggest that MRI investigations are likely to identify spinal pathology in young EDS patients who have significant back or neck pain.

Inferring selection intensity and allele age from haplotype structure. *H. Chen, M. Slatkin* Department of Integrative Biology,University of California, Berkeley, CA.

It is a challenging task to infer selection coefficient and allele age from population genetic data. Here we present a method that can efficiently estimate selection coefficient from the haplotype structure around the vicinity of the segregating selected allele. A subdivided population model with varying population sizes is used to model the historical frequency trajectories of the selected allele. Given the trajectories and the selected mutant position, the genealogies of the haplotypes are modeled with random mutation, coalescent and recombination events. The importance sampling algorithms are adopted to explore both frequency trajectories and gene genealogies consistent with the sample. By the simulation data, we demonstrate that the method can estimate the selection intensity for moderate selection. We also applied the method to a real data set G6PD. The proposed method is highlighted in handling haplotype data from recombination regions and from populations with exponential growth or other arbitrary histories.

Treatment of Pompe Disease with the Pharmacological Chaperone AT2220: Mechanistic Studies and Phase 1 Clinical Results. *J.J. Flanagan, X. Wu, A.C. Powe, R. Khanna, R. Soska, W. Liang, E.R. Benjamin, D. Palling, S. Sitaraman, B.A. Wustman, K.J. Valenzano, D.J. Lockhart, H.V. Do* Amicus Therapeutics, Cranbury, NJ.

Pompe disease is a genetic disorder caused by mutations in acid -glucosidase (GAA). GAA deficiency leads to lysosomal glycogen accumulation and results in progressive skeletal muscle weakness, reduced cardiac function, respiratory insufficiency, and CNS impairment. GAA is synthesized as a precursor glycoprotein and requires protein and carbohydrate processing to yield the mature lysosomal enzyme. We are developing a new therapeutic approach for the treatment of genetic disorders by using small molecules called pharmacological chaperones to selectively bind and stabilize mutant proteins. In this study, we show that the pharmacological chaperone AT2220 (1-deoxynojirimycin HCl) significantly increases GAA specific activity in patient-derived fibroblasts. Using transient expression in COS7 cells, multiple GAA missense mutations showed increased activity in response to AT2220. Moreover, all responsive GAA mutations showed improved processing which is indicative of increased protein trafficking. Administration of AT2220 to wild-type mice increased GAA activity in multiple tissues affected in Pompe disease. In cardiac and skeletal muscles from these animals, GAA processing also improved after AT2220 treatment. The above results indicate that AT2220 increases protein trafficking, processing and cellular activity for wild-type GAA and a number of GAA missense mutations. AT2220 was evaluated in two Phase 1 clinical trials. In a single ascending dose study, 32 individuals received oral doses of 50, 150, 300, or 600 mg AT2220 or placebo. AT2220 was shown to be highly orally bioavailable, with linear pharmacokinetics and a plasma half-life of 7 to 8 hours. In a multiple ascending dose study, 24 individuals received oral doses of 50, 150, or 450 mg/day AT2220 or placebo for 7 days. In both studies, there were no drug-related serious adverse events and the drug was generally well tolerated. Collectively, these data indicate that AT2220 merits further evaluation as a treatment for Pompe disease.

GENETIC/NUTRIENT DETERMINANTS OF CONGENITAL HEART DEFECTS IN THE INUIT OF NUNAVUT. *L. Arbour[1], G. Osborne[2], R. Rupps[1], M. Forth[2], M. Nowdluk[2], L. Field[1], R. Rozen[3]* 1) Dept of Medical Genetics, University of British Columbia, Vanouver, BC, Canada; 2) Dept of Health and Social Services, Iqaluit, Nunavut; 3) Dept of Human Genetics and Pediatrics, McGill University, Montreal,Quebec.

There is suggestion that not only neural tube defects (NTDs) but other anomalies, such as heart defects, might be reduced with folic acid, either with multivitamin use or grain fortification. Folate has been long considered a nutrient of concern in Northern communities where the availability and preference for folate rich foods is lower than in the south. Although NTDs are not more frequent in Nunavut, septal heart defects were documented to be increased by nearly 4 times (ICD-9 745) prefortification. Methods: To explore determinants of the increased rate of septal heart defects Inuit mothers of children with and without heart defects were invited to participate in a case-control study evaluating nutrient intake, pregnancy exposures, RBC folate, serum cobalamin, homocysteine, and six functional polymorphisms for genes important in folate metabolism and uptake (MTHFR A222V and E429A, MTRR I22M, RFC-1 H27R, BHMT R239Q, MTHFD1 R653Q). Results: 61 children with isolated heart defects and their mothers (n=60) with 58 community matched controls participated. There were no differences in RBC folate (953 Vs 957 nmol/L p=.94), serum cobalamin (380 Vs 354 pmol/L p= 0.35), and homocysteine (8.8 Vs. 8.9 mol/L p=0.93) between mothers of cases and controls. There was no difference in alcohol (20%) and cigarette use (80%) in pregnancy. No women were taking multivites at conception nor at the time of this study. However, RFC-1 H27R was more common in cases (OR 3.2 CI 1.1-9.2 p=.03) and in mothers of cases (3.9 CI 1.43-10.9 p=.01) than controls. Although the allele frequency was low for MTHFR A222V, this variant was also increased in cases (p=.04) alone. Conclusion: Previously implicated in infants with heart defects, RFC-1, a gene important in cellular transport of folate may contribute to the multifactorial etiology of septal heart defects in this population. Further study is underway to determine if heart defects have decreased since folic acid fortification was commenced.

Effectiveness of intrathecal rhIDU in deep brain structures in MPS I dogs. *A. Chen[1], M. Passage[2], S. Le[2], C. Vogler[3], P. Dickson[2]* 1) Neurology, Harbor-UCLA Med. Ctr., Torrance, CA; 2) Pediatrics, LA Biomed at Harbor-UCLA, Torrance, CA; 3) Pathology, St. Louis Univ. School of Med., St. Louis, MO.

Introduction: Intrathecal (IT) recombinant human -L-iduronidase (rhIDU) has been shown to reduce mean brain glycosaminoglycans (GAGs) to normal levels in MPS I dogs.[1] In this study, we examined functional neuroanatomical regions including deep structures following treatment with IT rhIDU.
Methods: MPS I dogs were treated monthly with 3-4 doses of 1.08 mg IT rhIDU (n=5). Normal dogs (n=5) and untreated MPS I dogs (n=2) were also studied. Sections 0.5 - 1 cm^3 were evaluated from superficial neuroanatomical regions (rostral forebrain and cerebellum), from deeper structures (hippocampal formation, basal ganglia/thalamus), and from brainstem. Samples were assayed for GAG using an Alcian blue dye binding method.
Results: Superficial regions: rostral forebrain GAG was 2.360.543 g/mg in normal dogs; 8.051.07 g/mg untreated MPS I dogs; 3.510.660 g/mg, monthly IT-treated MPS I dogs. Cerebellum: 2.670.327 g/mg, normal; 7.590.658 g/mg, untreated MPS I dogs; 3.950.849 g/mg, IT-treated. Deep regions: basal ganglia: 3.510.599 g/mg, normal; 5.40 g/mg (n=1), untreated; 4.760.903 g/mg, IT-treated. Hippocampal formation: 3.300.396 g/mg, normal; 5.930.170 g/mg, untreated; 3.910.391 g/mg, IT-treated. Brainstem: 3.731.10 g/mg, normal; 6.492.14 g/mg untreated , 5.360.740 g/mg IT-treated. Pathology is pending.
Conclusion: GAG storage in untreated MPS I dogs was similar among different functional neuroanatomical regions. GAG storage reduction with IT rhIDU was better (48-56%) in the superficial regions of the brain, as compared to deeper regions and brainstem (12-34%). There may be regional differences in the efficacy of IT rhIDU in the MPS I dog brain.

Inherited Metabolic Disorders Clinic Referral Patterns. *J.M. DeLuca, A.R. Siegel, E. Blakely, T. Marchetti, G.L. Arnold* Pediatrics, University of Rochester, Rochester, NY.

The determinants of access to Inherited Metabolic Disease (IMD) clinics have not been adequately characterized. This pilot study was developed in order to evaluate referral patterns and improve access to services. We retrospectively reviewed the charts of 120 new patients referred to the IMD clinic at the Golisano Children's Hospital between January 2005 and December 2006.

Referral sources included: primary providers (43%), NY state newborn screening (NBS) program (47%), and others (10%). Reasons for referral included: suspected metabolic abnormalities (20%), abnormal biochemical lab results (10%), failure to thrive (6%), developmental delay (6%), hypoglycemia (3%), and other indications (such as evaluation for affected relatives, multiple congenital anomalies, and dysmorphic features). Fourteen of 57 NBS referrals were positive. Of the 63 non-NBS referrals, 12 (19%) received formal diagnoses including Niemann-Pick Type A, Angelman syndrome, peroxisomal disease, neurofibromatosis type 1 and others. In addition, 31 patients (50%) require ongoing management for recurrent hypoglycemic episodes or persistent biochemical abnormalities. Excluding newborn screens, the median interval from onset of symptoms to clinic visit was 1 year; the median age at the time of visit was 2 years. There was no correlation between patient age and length of interval between symptom onset and referral. Thirty-five of these patients were evaluated by other specialties prior to the initial clinic visit including: developmental pediatrics, cardiology, neurology, and other services.

The substantial percentage of patients receiving diagnoses and ongoing clinical management suggests that patients might benefit from earlier referral to IMD clinics. These data will form the basis for an educational outreach initiative for health care providers to encourage earlier referral for patients suspected of having metabolic disorders.

ACTA2 mutations cause diverse and diffuse vascular diseases, including aortic aneurysms, premature coronary artery disease and Moyamoya disease. *D. Guo[1], H. Pannu[1], V. Tran-fadulu[1], C. Papke[1], N. Avidan[1], S. Bourgeois[1], R. Yu[2], A. Estrera[1], H. Safi[1], P. Tung[1], L.. Buja[1], S. Scherer[3], C. Raman[1], S. Shete[2], D. Milewicz[1]* 1) Univ Texas/Houston Medical School, Houston, TX; 2) Univ Texas/MD Anderson Cancer Center, Houston, TX; 3) Baylor College of Medicine, Houston, TX.

ACTA2 encodes smooth muscle cell (SMC) alpha-actin, a contractile protein that is the most abundant protein in vascular SMCs. A large family with autosomal dominant inheritance of thoracic aortic aneurysm and dissection (TAAD) was use to map and identify a mutation in ACTA2 (R149C) as the cause of TAAD. All individuals examined with ACTA2 mutations also had marked livedo reticularis (LR, rash due to dermal capillary occlusion); segregation of LR alone with the ACTA2 mutation yielded a LOD of 5.85. Six ACTA2 + members did not have TAAD, but rather premature coronary artery disease (CAD < 55 yrs). Sequencing of ACTA2 in 97 TAAD families identified mutations in 14 families that segregated with TAAD and premature CAD (R149C was present in 4 families); no ACTA2 SNPs were found in 196 controls. Three unrelated families with R258C/H ACTA2 mutations had 6 members with strokes < 30 yrs, with 4 diagnosed with Moyamoya disease (MMD, strokes due to carotid artery occlusion). Six families had unique ACTA2 mutations. ACTA2 mutations segregated with TAAD (LOD score 4.14) and premature CAD (combined TAAD and CAD, LOD score 8.5). Also, ACTA2 + family members were more likely to have premature CAD than ACTA2 - members ($p < 10\text{-}4$). Aortic pathology showed medial degeneration and the unique finding of focal occlusion of capillaries due to SMC hyperplasia. SMCs from ACTA2 mutation patients had little to no alpha-actin filaments compared to control SMCs. Therefore, ACTA2 mutations cause TAAD, premature CAD and strokes, MMD, and LR. The diversity of vascular diseases imparted by a mutation in a single gene alters our understanding and approach to identifying the genetic basis of vascular diseases.

Genome wide identification of transcriptional start sites in human cancer cell lines with SOLiD sequencing technology. *S. Hashimoto[1], K. Matsushima[1], S. Morishita[2], R.C. Nutter[3]* 1) Graduate school of Medicine, The University of Tokyo, Tokyo, Japan; 2) 2Department of Computational Biology, Graduate School of Frontier Sciences, The University of Tokyo, Japan; 3) Applied Biosystems, Foster City, CA.

Genomic and full-length cDNA sequences provide opportunities for understanding human gene expression. Although the established functional genomic technologies, for example, DNA array and SAGE, can identify coding and noncoding RNA transcripts, identification of genes across the whole genome is still problematic. We and others have developed high-throughput methods, such as 5'SAGE that enable genome-wide identification of transcription start sites (TSSs) and that allow quantification of mRNA transcripts. Determination of the TSS would be the first step in identifying the promoter region, which pivotally regulates transcription of the gene. Although the TSS of most genes show heterogeneity, this may reflect physiological, developmental, and pathological states of the particular cells or tissues. The use of these methods markedly facilitates identification of full-length protein-coding and noncoding RNAs, and also of their promoter regions. We have recently improved these methods for the newest sequencing method, Oligonucleotide ligation and detection(SOLiD) technology, so called 5'end-SOLiD. An important factor in tumor development seems to be the epigenetic effects on tumor suppressor genes. Because of its ability to suppress tumor cell proliferation, angiogenesis, and inflammation, the epigenetic drug such as histone deacetylase (HDAC) inhibitor is currently in clinical trials. However, how epigenetic drugs mediate its effects is poorly understood. To assess the effects of epigenetic drugs, the gene expression by 5'end-SOLiD in colon cancer cell lines treated with epigenetically affecting agents, 5-aza-2'-deoxycytidine, a potent inhibitor of DNA methylation and trichostatin A, a HDAC inhibitor was investigated. Epigenetic modification induced not only the change of expression of the cell cycle progression-associated genes in human colon cancer cells but also the gene expression with aberrant start sites.

Association of HTRA1 polymorphism and bilateral neovascular age-related macular degeneration. *H. Chen[1,2,3], Z. Yang[1,2], D. Gibbs[1,2], C. Olson[1,2], J. Harmon[1,2], Z. Tong[1,2], S. Tang[3], K. Zhang[1,2]* 1) Ophthalmology, University of Utah, Salt Lake City, UT; 2) Human Molecular Biology and Genetics, University of Utah, Salt Lake City, UT; 3) Zhongshan Ophthalmic Center, Sun Yat-sen University, Guangzhou, China.

PURPOSE: Age-related macular degeneration (AMD) is a leading cause of irreversible blindness in elderly people. Recently, a single nucleotide polymorphism (SNP), rs11200638, in the promoter of the HTRA1 gene was found to be associated with wet and dry form of AMD. The purpose of this study is to investigate the association of rs11200638 SNP with bilateral and unilateral wet AMD. METHODS: AMD patients and age matched controls were enrolled and genotyped for the rs11200638 polymorphism. AMD patients were classified as bilateral wet AMD, unilateral wet AMD, bilateral dry AMD and unilateral dry AMD. Wet AMD eyes were also classified according to choroidal neovascularization subtype including classic, occult and mixed choroidal neovascularization. Allele frequencies and genotype frequencies were compared among different phenotype groups by a chi square test. Odds ratios (ORs) and 95% confidential intervals were calculated to estimate risk. RESULTS: The A allele and AA genotype at the SNP rs11200638 of HTRA1, were significantly more prevalent in bilateral wet AMD patients than unilateral wet AMD patients (p=0.04 and 0.03 respectively, chi square test). The homozygote OR of binocular wet AMD(12.41; 95% CI, 5.70-27.03) was 1.95 fold greater than that of monocular wet AMD (6.36; 95% CI, 2.98-13.55). The same trend was seen in dry AMD. There is no significant difference of allele or genotype frequencies among the subtypes of choroidal neovascularization. CONCLUSIONS: The SNP rs11200638 in the promoter of HTRA1 was associated with bilaterality of AMD. The risk allele A conferred higher risk to binocular AMD than monocular AMD. This is consistent with the role of HTRA1 in the pathogenesis. Further study on HTRA1 will provide insight into pathogenesis of AMD.

Genome-wide association scans in cohorts from Sardinia and Finland identify a locus for fasting glucose levels.

W.M. Chen[1], A.U. Jackson[1], A. Scuteri[2,6], M.R. Erdos[3], M. Uda[4], W.L. Duren[1], S. Sanna[1,4], H.M. Stringham[1], A. Mulas[4], H. Shen[5], L.J. Scott[1], S. Najjar[6], A.R. Shuldiner[5], J. Tuomilehto[7], E. Lakatta[6], R.N. Bergman[8], D. Schlessinger[6], M. Boehnke[1], G.R. Abecasis[1], R.M. Watanabe[8] 1) Biostats, U of Michigan, Ann Arbor, MI; 2) Operativa Geriatria, INRCA, Rome, Italy; 3) National Human Genome Research Institute, Bethesda, MD; 4) Istituto di neurogenetica e neurofarmacologia, CNR, Cagliari, Italy; 5) U of Maryland, Baltimore, MD; 6) National Institute on Aging, Baltimore, MD; 7) Public Health Institute of Finland, Finland; 8) School of Medicine of USC, LA, CA.

Fasting glucose levels are a function of glucose production and utilization. Glucose is tightly regulated within a narrow range and dysfunction of this regulation can lead to type 2 diabetes. We carried out two independent genome-wide association (GWA) scans for fasting glucose levels: a scan of 4,305 Sardinians in large pedigrees from the ProgeNIA study genotyped using the Affymetrix 500K chip set and a scan of 1,256 mostly unrelated nondiabetic Finnish individuals from the FUSION study genotyped on the Illumina HumanHap300 chip. In both GWA scans, an additive genetic model was used to test for association between fasting glucose levels and SNPs, adjusting for familiality and covariates including sex, age, and age^2. To minimize the impact of outliers and skewed distribution on the association testing, quantile normalization was applied to each trait prior to GWA scans. Analysis of our two GWA scans identified a SNP that is strongly associated in both the ProgeNIA ($p = 4.0 \times 10^{-7}$) and FUSION ($p = 1.9 \times 10^{-3}$) studies, and achieves clear genome-wide significance in our two-study meta-analysis ($p = 2.8 \times 10^{-9}$). This SNP is located within 10kb of a gene that encodes an enzyme involved in the release of glucose into bloodstream. To confirm and follow-up the signal, we currently are genotyping additional SNPs in the region and following up in additional samples. Preliminary replication analysis on 973 Finish individuals and 451 Amish individuals are promising, showing a significant result in the same direction ($p = 6.5 \times 10^{-5}$ for replication data only and 1.1×10^{-12} for combined data).

Serum proteins of tumor free and tumor bearing Xiphophorus. *A. Islam* Ophthalmology, Schepens Eye Resaerch Institute, HMS, Boston, MA.

Comparative blood serum protein analysis of tumor bearing and tumor free Xiphophorus helleri was investigated by using native-PAGE (Poly Acrylamide Gel Electrophoresis). For comparative analysis, the serum proteins e.g. albumin, transferrin, globulins, and lipoproteids bands were analyzed. These 4 proteins spectra have a diversification in constructions, which showed in different polymorphic peaks in between the normal or tumor free (tf) and tumor bearing (tb) Xiphophorus species. The globulin and transferrin fractions have distinct polymorphism in the affected and non-affected animals. The serum proteins analysis of tf and tb Xiphophorus showed that the globulin fractions were depressed in normal and have found declining peaks in the acute and tumor bearing melanoma formed fish. Tumor free fish have up rising peaks of globulin and transferrin spectra in comparison to Xtb type. The albumin peaks of both tf and tb fish showed more or less similar peaks with a molecular weight of 65 kDa. In tumor bearing species, lipoproteids peaks were variable and higher than the tumor free Xiphophorus (Xtf). The protein variations between tf and tb animals which were in inbred lines interpret different aspects and functions of blood serums. The result could be an ideal material to compare and identify immunity and physiology of diseased and non-diseased populations in relation to different proteins combinations. The protein markers of Poeciliidae could be used as a cancer marker for human.

Further delineation of regions of dosage imbalance in rearrangements of 1p36: patient with choanal atresia, cataracts, severe mental retardation. *E. Chen[1,2], X. Li[1], E. Obolensky[2]* 1) Kaiser Permanente, San Jose, CA; 2) and Oakland, CA.

The 1p36 deletion syndrome is recognized as the most common terminal deletion syndrome. However, few cases of 1p36 duplications have been reported and genotype-phenotype correlations are emerging. One case of isolated duplication 1p36.3 has been associated with growth delay, metopic synostosis, blepharophimosis, ASD, rectal stenosis, 2-3 toe syndactylies, mild delays. It has been proposed that a deleted chromosome 1 undergoes multiple breakage-fusion-bridge cycles and inversions to produce a chromosome arm with a complex rearrangement. A region of overlap is thought that, when triplicated is associated with craniosynostosis, and when deleted is associated with large, late-closing anterior fontanels. Overexpression or haploinsufficiency of MMP 23A and B genes has been proposed as possible candidate genes. We describe a male with an apparently de novo cytogenetically visible duplication of 1p36.31p36.33. FISH studies show that the critical region for the 1p36 deletion syndrome (p58) is duplicated. D1Z2 and TEL1p probes are also duplicated. He has congenital cataracts, blepharophimosis, choanal atresia, dysmorphisms, transient hypogammaglobulinemia, severe growth and developmental delays, but no craniosynostosis. Targeted BAC aCGH (Signature Genomics) detected a duplication and a deletion in the 1p36.3 region. BAC whole genome array (UCSF, 1.4 Mb resolution) detected an additional duplication in the 1p36.11-p36.33 region. Oligonucleotide aCGH (Agilent Technologies, 44K) further defined three regions of rearrangements: a duplication of distal 1p36.32-p36.33, a deletion of adjacent 1p36.32p36.32, and an 11 Mb duplication of proximal 1p35.3-p36.21. The distal duplication region contains the putative gene for epilepsy, KCNAB2, and the MMP 23A and B genes, whereas the proximally duplicated region contains putative genes for congenital cataracts. This is the first patient with choanal atresia, transient hypogammaglobulinemia of infancy, and congenital cataracts associated with 1p36 duplication/deletion. Comparison of our data with other studies will provide insights into genotype-phenotype correlations, gene dosage, and positional effects.

Comparison of background relatedness by analysis of the distribution of homozygous segments in the four ethnic groups of the HapMap Phase II dataset. *T.A. Johnson[1,2], T. Tsunoda[1]* 1) Laboratory for Medical Informatics, SNP Research Center, RIKEN Yokohama Institute, Yokohama, Japan; 2) Tokyo Medical and Dental University, Department of Bioinformatics, Medical Research Institute, Tokyo, Japan.

Relatedness exists as a continuum from that observed between family members, to that which distinguishes geographically isolated populations, to that seen between members of a particular ethnic group, and on to that which makes us all human. Mapping of loci identitical-by-descent in closely related individuals has been extremely important for interrogation of rare but highly penetrant Mendelian diseases, while toward the middle of the relatedness spectrum, that seen within ethnic populations, such phenomena as linkage disequilibrium and haplotype-block structure has provided researchers with some of the tools to examine common disease on a population-wide basis. One extreme example of this background relatedness has been the discovery of extended runs of homozygous loci, some on the order of megabases, in population genetic data. We explored this on a finer scale using release 22 of the HapMap Phase II dataset by detecting all homozygous segments across the 270 individuals sampled from the Yoruba (YRI), Caucasian (CEU), Chinese (CHB), and Japanese (JPT) populations. To filter out uninformative segments while allowing for inter-population comparison, we calculated a homozygosity probability score (HPS), which is the product of the lowest observed homozygosity from the four ethnic groups of each locus in a detected segment. For segments with HPS<=0.01, the average total basepair length of segments on autosomes was 0.85E+09, 1.13E+09, 1.23E+09, and 1.24E+09, for individuals from the YRI, CEU, CHB, and JPT groups, respectively. To examine background relatedness coming from relatively more recent ancestors, we examined segments >130 kb which showed the average total basepair length of segments on autosomes was 1.34E+08, 3.54E+08, 4.46E+08, and 4.62E+08, for individuals from the YRI, CEU, CHB, and JPT groups, respectively. To further compare levels of background relatedness, we will provide maps of the genome-wide binned coverage of extended homozygosity for each population.

Mapping copy-number variation at high resolution and determining the exact breakpoint sequence by a combination of high-resolution CGH (HR-CGH) and vectorette-PCR. *F. Grubert[1], A.E. Urban[1], J.O. Korbel[1], M. Kasowski[1], R. Haraksingh[1], J. Korenberg[2], B.S. Emanuel[3], M. Gerstein[1], M. Snyder[1], S.M. Weissman[1]* 1) Yale University, New Haven, CT; 2) Mount Sinai Hospital, Los Angeles,CA; 3) Children's Hospital of Philadelphia, PA.

Copy-Number Variation (CNV) and Copy-Number Polymorphisms (CNP) are being found to be a pervasive architectural feature of the human genome and are expected to contribute significantly to phenotypic variation both in the healthy individual and in disease states. Array-CGH, the dominant methodology to determine CNV, has a typical predictive resolution of about 50 kb. CNV below that horizon will be missed as will be the actual breakpoint-sequence of the variant or aberration. We have developed HR-CGH based on high-density oligonucleotide tiling microarrays [Urban, Korbel et al. PNAS 2006; Korbel, Urban et al. PNAS 2007]. Maskless Synthesis arrays with 385 000 oligomers are constructed to represent the non-repetitive part of the genomic sequence of entire chromosomes at a tiling density of typically 1 oligomer/~100bp or better. The ratio of signal intensities from control and experimental channel are processed by our /BreakPtr/ algorithm, which predicts copy-number changes and their dosages and breakpoints while screening out false-positive calls caused by cross-hybridization. Predictions are validated with vectorette-PCR and direct sequencing of the resulting amplicons, making cloning superfluous. Using this approach we have studied CNVs, CNPs and aberrations, and their breakpoints, using oligonucleotide tiling arrays representing chromosomes 21, 22 and X, respectively. We probed the corresponding arrays with samples from probands with Down Syndrome and partial trisomy 21, Velo-Cardio-Facial Syndrome (VCFS) and from the HapMap panel. We have detected, cataloged and verified variations from 3 Mb to smaller than 1kb in size. In several cases we were already successful in determining the exact breakpoint sequence.

Differential distribution of type 2 diabetes-related polymorphisms in Mexican Mestizo and indigenous populations. *L. del Bosque-Plata, J. Fernandez-Lopez, E. Hernandez-Lemus, M. Arrieta-Gonzalez, K. Carrillo-Sanchez, A. Inchaustegui, C. Rangel, I. Silva-Zolezzi, J. Estrada-Gil, G. Jimenez-Sanchez* National Institute of Genomic Medicine, Mexico.

Most of the Mexican population results from admixture of any of 65 ethnic groups, with Spanish, and in a lesser extent Africans. To explore whether this population origin have influenced T2D-associated allele frequencies in our population, we analyzed SNPs in 13 genes previously associated with T2D in at least two studies with a p 0.01. We analyzed 1,104 samples from the Mexican Genomic Diversity Project, from six states of Mexico: Yucatan, Guanajuato, Guerrero, Sonora, Veracruz, and Zacatecas. In addition, we analyzed samples from five Amerindian groups: 60 Mazatecan (MT), 34 Nahua (ST) (San Luis Potosí), 60 Purepecha (Pu), 25 Nahua (XV) (Veracruz), and 62 Otomi (OT). We compared allele frequencies with those of the international HapMap populations. The following SNPs of T2D-associated genes were genotyped using TaqMan *KCNJ11* (rs5219), *PPARG* (rs1801282), *HNF4A* (rs2144908), *SLC2A1* (rs841853), *CAPN10* (rs3792267), *TCF7L2* (rs7903146), *ADIPOQ* (rs2666729), *PTPN1* (rs914458), *GCK* (rs3757840), *LMNA* (rs4641), *SLC30A8* (rs13266634), *HHEX* (rs1111875), *EXT2* (rs3740878). Results were tested for HWE, allele and genotype frequency differences were calculated by Fisher exact test and Fst. This comparative analysis show SNPs with small variation within mestizos between regions as in the case of *CAPN10*, *PTPN1* , and others with differences of more than 10% as in the case of *PPARG* , *SLC2A1* , *HNF4A* , *ADIPOQ* and *TCLF7L2* ; in some cases a marked frequency variation between the Amerindian groups: The allele frequencies of the SNPs *HNF4A* rs2144908 (XV 08-Pu 28;Mestizo:Gue 39-Son 55); HapMap:CEU 81;HCB 51,JPT 57YRI 93) and *TCF7L2* rs7895340 are lower in all the Amerindian groups(MT.05-ST.11) from those in mestizo groups (Yuc .15-Son .26) and from those reported in the Hap Map populations (CEU 25,HCB 02,JPT 02,YRI 29). Our results show a wide range of MAFs in T2D-associated SNPs, making evident that our complex population history may have implications.

Genotype-by-diet interaction analysis of paraoxonase 1 reveals a QTL on chromosome 17. *V.P. Diego, H.H.H. Goring, D.L. Rainwater, S.A. Cole, T.D. Dyer, J.T. Williams, J.W. MacCluer, M.C. Mahaney, J. Blangero* Dept Genetics, SW Foundation Biomed Res, San Antonio, TX.

It is increasingly appreciated that the macronutrient component of the diet has profound effects on the processes of oxidative stress and subclinical, chronic inflammatory stress. Experimental work has shown that saturated and unsaturated fatty acids have reciprocal effects on the gene expression of key players in oxidative stress and inflammation, such as the components of the toll-like receptor signaling pathway. We therefore sought to perform genotype-by-diet interaction (GDI) analyses of a biomarker of oxidative stress and inflammation under dichotomized saturated (SFAT) and unsaturated (UFAT) fatty acid intake environments in Mexican American families participating in the San Antonio Family Heart Study. For preliminary GDI analyses, we analyzed paraoxonase 1 (PON1), a novel biomarker of inflammation and oxidative stress. For the SFAT environment, we found a suggestive linkage signal (corrected (for degrees of freedom) LOD score = 2.76) on chromosome 12 at 17 cM. For the UFAT environment, we found one significant and one suggestive linkage signal on chromosome 17 at 64 cM and chromosome 12 at 22 cM (corrected LOD scores = 3.00 and 2.90, respectively). The only evidence of GDI at a QTL was found on chromosome 17 at 64 cM ($p = 0.00669$). Earlier analyses by our group have detected QTLs of significant effect at the structural location on chromosome 7q21-q22 and at chromosome 12 in the vicinity of current results. The current report, in addition, gives significant evidence of a QTL on chromosome 17 when taking into account the effects of unsaturated fatty acid intake. It is noteworthy that under standard linkage analysis (i.e., no interaction effects) there is only suggestive evidence of a QTL whereas the incorporation of dietary environment provides significant evidence of a QTL. Moreover, the GDI pattern exhibited at the chromosome 17 locus has a sensible biological interpretation. We conclude that GDI modeling can help to identify and localize QTLs, and aid in understanding underlying biological processes.

DNA Copy Number Variation in Normal Dogs. *C.E. Alvarez[1], W.K. Chen[1], L.J. Rush[2], J.D. Swartz[1]* 1) Molecular and Human Genetics, Columbus Children's Research Institute & The Ohio State University College of Medicine, Columbus, OH; 2) Department of Veterinary Biosciences, The Ohio State University, Columbus, OH.

Domestic dogs, Canis lupus familiaris, are a subspecies of the wolf, Canis lupus. They have co-evolved with humans for over 15,000 years. In the last 150 years, hundreds of pure breeds were created by selection of mostly morphological and behavioral traits. The existence of so many isolated, but related, populations makes them attractive for genetic studies. Moreover, the majority of the hundreds of diseases described in dogs are similar to ones in humans. These include diverse cancers, heart disease and many sensory or neurological disorders. Consistent with their histories of rapid selection and common population bottlenecks, specific dog breeds are predisposed to certain diseases, suggesting that a limited number of risk alleles are responsible. New tools have spawned a new era of dog genetics. Here we report on the normal DNA Copy Number Variation (CNV) of dogs. In normal humans, thousands of gene-spanning CNV regions (CNVrs) have been identified and some have strong roles in disease predisposition. We conducted CNV discovery in a small panel of normal pure bred dogs that represent the four classes of breeds: ancient/Asian, mastiff, herding and hunting. We quantified CNV by Comparative Genome Hybridization on a high resolution whole genome microarray (isothermal long-oligonucleotides at <5 kb mean spacing; Nimblegen). Selected regions were validated by other hybridization and PCR-based methods. We identified 155 variants - spanning 50 CNVrs - at high confidence. The mean number of CNVrs per animal was 17, similar to that reported for mouse (using the mouse version of the same array platform). Cluster analysis of all CNV regions showed that different breeds generally group together within their breed classes, indicating that a significant portion of this genetic variation has been evolutionarily transmitted from the founders of the four breed classes. The CNV regions generally affect multiple genes, as in humans and mice. We thus suspect that CNV contributes to breed-specific traits of dogs, including breed-specific disease predisposition.

Genome-Wide Association for Late-Onset Alzheimer Disease (LOAD) Confirms Risk locus on Chromosome 12.

G. Beecham[1], E. Martin[1], Y.-J. Li[2], R. Carney[1], M. Slifer[1], J. Gilbert[1], J. Haines[3], M. Pericak-Vance[1] 1) MIHG, University of Miami, Miller School of Medicine, Miami FL; 2) CHG, Duke University, Durham NC; 3) CHGR, Vanderbilt University, Nashville NC.

The heritability of late-onset Alzheimer disease (LOAD) is ~80%. Despite its strong genetic component, only apolipoprotein E (APOE) has been consistently associated with LOAD. While APOE has a strong effect on LOAD, the risk allele is neither necessary nor sufficient for LOAD. At most, APOE accounts for half of the genetic component of LOAD and the risk allele is not even present in a third of LOAD cases. To identify the remaining risk loci, we performed a genome-wide association (GWA) study for LOAD. Data was generated using the Illumina Infinium platform on 518 cases and 531 controls for 550,000 SNPs. All cases met NINDS-ADRDA criteria for probable or possible AD and all controls were cognitively normal on MMSE exams. The data were analyzed for population substructure using STRUCTURE and Eigenstrat, and numerous quality control tests were used to ensure the integrity of the data. We tested for association using Armitages Trend test. SNPs on chromosomes 1, 2, 12, 13, 14, and 19 have P-values <0.00001, uncorrected, suggesting multiple regions that need to be investigated in more detail. Not surprisingly, three SNPs in APOE exceeded a genome-wide association FDR of 0.20, and served as positive controls. Most importantly, one additional SNP on chromosome 12 also exceeded this threshold (FDR = 0.172). The Chromosome 12 SNP, RS11610206 (~46Mb), lies within a very narrow linkage peak (LOD score 4.2) that we recently reported using a completely independent dataset. Two potential candidates (45-47Mb) are AMIGO2 involved in neuronal survival and SENP1, involved in the processing of SUMO family genes. The convergence of the previous linkage and current association data provide overwhelming evidence for a risk allele near this SNP.

ENU-induced, targeted and sporadic mutations reveal a critical role for *Prdm16* during mouse and human craniofacial development. *B.C. Bjork[1], A.R. Vieira[2], S.W. Davis[3], S.A. Camper[3], J.C. Murray[2], D.R. Beier[1]* 1) Div Genetics, Brigham & Women's Hospital, Boston, MA; 2) Dept. Pediatrics, Univ. of Iowa, Iowa City, IA; 3) Depts. Human Genetics and Internal Medicine, Univ. of Michigan, Ann Arbor, MI.

Our ongoing recessive ENU mutagenesis screen generates phenotypes that model human birth defects, such as clefting. The *cleft palate only 1 (cpo1)* mutation is an excellent model of nonsyndromic clefting.

The *cpo1* mutant is a hypomorphic allele caused by a mutation that reduces splicing efficiency to the 7th exon of the zinc finger transcription factor *Prdm16*. Mutant palate shelves fail to elevate. Skeletal preparations, histology and palate culture show that this failure is due to physical obstruction by the tongue. *Prdm16* expression in palate epithelium and mesenchyme, craniofacial and tongue musculature and developing craniofacial cartilage is consistent with it playing a critical role during palatogenesis. We confirmed the etiology of *Prdm16* in *cpo1* mutants with the observation that homozygous mutants carrying a gene trap allele of *Prdm16* have a cleft palate and consistent pattern of *LacZ* expression.

Previously, we identified 3 potential etiologic missense mutations in *PRDM16* in a screen of 200 NSCL/P cases from Iowa and the Philippines. Since isoforms of the *PRDM16* paralog *MDS/EVI-1* are known to inhibit TGF signaling, we utilized a TGF-responsive luciferase reporter to show that *Prdm16* isoforms similarly inhibit TGF signaling. One human missense mutation significantly impairs this function.

Expression analysis of TGF pathway genes in *cpo1* embryos to identify interacting proteins and downstream targets is ongoing. We have generated a targeted conditional gene trap allele of *Prdm16* that will allow us to further our study of *Prdm16* during mouse development. Finally, we are developing a general *Sleeping Beauty*-mediated RNAi transgenesis strategy to rapidly validate positionally cloned ENU mutations.

KCNQ1 V205M missense mutation causes LQTS in a Northern Canadian community. *J. Eldstrom[1], S. Rezazadeh[1], R. Rupps[2], S. Sanatani[3], B. Casey[4], G. Tibbits[5], D. Fedida[1], L. Arbour[2]* 1) Dept of Anesthesiology, UBC Vancouver, BC, Canada; 2) Departments of Medical Genetics,; 3) Pediatrics, and; 4) Pathology, University of British Columbia, Vancouver, BC; 5) Department of Kinesiology, Simon Fraser University, Burnaby, BC, Canada.

Eight known genes are responsible for hereditary Long QT syndrome (LQTS), an autosomal dominant condition predisposing to arrhythmia and risk of sudden death. Usually rare (about 1 in 7,000), it was brought to our attention that at least 40 people were considered affected with 200 relatives at risk, all from the same semi-isolated community. Two distantly related affected women were screened for mutations. A novel missense mutation, V205M in the S3 transmembrane region of the KCNQ1 channel, the -subunit for the slow delayed rectifier potassium channel, *Iks*, was confirmed in both. To verify pathogenesis, wild type (Wt) KCNQ1 and subunit KCNE1 for *Iks* were expressed in mammalian cells and compared to those with a V205M construct. Similar surface expression of the channels was evident, but with a depolarizing shift in the V1/2 of activation in the mutant channels. Furthermore, a slowing of channel activation (294 85 ms, n=5; and 878 124 ms, n=4; for Wt and V205M channels, respectively, at +70 mV), and an acceleration of deactivation (53 3.6 ms, n=5; and 14 3.5, n=4; for Wt and V205M channels, at -100 mV) was evident. Using a ventricular action potential voltage clamp protocol applied at 3 Hz, Wt channels, but not V205M channels, accumulated in the open state, resulting in large outward IKs currents only for Wt channels. The outward ionic charge through heteromultimeric WT/mutant channels during the action potential clamp was reduced by more than 75% suggesting a functional dominant negative effect of the V205M mutation at high heart rates. Conclusions: The changes in IKs kinetics produced by the V205M mutation are expected to decrease current and reduce the repolarization reserve during the cardiac ventricular action potential, with increased susceptibility to initiation of arrhythmias, especially during periods of high sympathetic drive. Genotyping is underway for the remainder of those at risk.

Identifying Gaps in Residency Training: Distressing Results from the Dictation Station. *G.E. Graham[1], S. Langlois[2]* 1) Children's Hospital of Eastern Ontario and University of Ottawa, ON; 2) BC Women and Children's Hospital and University of British Columbia, Vancouver, BC.

Like most specialist physicians, Clinical Geneticists rely almost exclusively on letters to communicate our assessment, treatment and follow-up plans to other health care providers. Since we often write directly to patients to summarize complex and crucial information (an unusual practice in other medical disciplines), we depend on letters to a greater extent than most. Despite this, letter-writing skills are rarely taught in a formal sense and dictation skills are almost never taught. While there has been some attention drawn to written communication since the introduction of the RCPSC CanMEDS 2000 framework and the explicit identification of the Communicator role, most Canadian Medical Genetics residents are not being taught the principles of good consult letter writing and to our knowledge none are being taught effective dictation skills. In the context of an OSCE exam and with advance consent from participants, we asked 10 residents to dictate the physical examination on a fictitious patient with a recognizable syndrome using clinical measurements and a facial photograph. The tapes were transcribed verbatim and the transcripts scored by a clinical geneticist who was blinded to the identity and training level of the dictating resident. A senior clinical geneticist who was unaware of the study completed the same dictation to help establish criteria by which the residents transcripts could be evaluated. We found the majority of residents to have poor dictation skills as measured by clarity, verbal fluency, organization, use of punctuation and efficiency (words/sec playback). There was only a loose correlation between the quality of the dictation as judged by these indicators and the training level of the resident, suggesting that residents do not acquire sufficient skills by practice alone. This pilot project, while performed in an artificial circumstance with a small number of residents, has convinced us that a formal study of resident dictation skills that includes a teaching intervention and pre-/post-intervention evaluation is warranted.

Massively Parallel cDNA Resequencing For Transcriptome Analysis. *Z. Chen, B.L. Merriman, Y. Lee, B. O'connor, S.F. Nelson* Dept Human Genetics, Univ California, Los Angeles, Los Angeles, CA.

The new massively parallel resequencing technologies are well suited to gene expression profiling and transcriptome analysis. By adopting suitable methodologies, it is possible to simultaneously do basic transcript counting for quantitative gene expression analysis, as well as resequence transcripts to detect alternative splice variants, allelic expression differences, and coding sequence mutations. Here we investigate the viability of these various goals within the context of resequencing a large number of tumor cDNA libraries using the Solexa massively parallel sequencing technology, which allows us to sequence cDNA libraries with a depth of up to ~100,000,000 36-mer reads. We also consider important related issues such as the impact of protocols for cDNA library generation and specifics of the sequencing protocol on the quality of the resulting data.

Single nucleotide polymorphisms and comparative sequence analysis of the *TNFA* gene in a pedigreed colony of vervet monkeys (*Chlorocebus aethiops*). *S.B. Gray, T.D. Howard, C.D. Langefeld, G.A. Hawkins, A.F. Diallo, J.D. Wagner* Pathology/Comparative Medicine, Wake Forest University School of Medicine, Winston-Salem, NC.

Single nucleotide polymorphisms (SNPs) in the human *TNFA* gene have been associated with differential *TNFA* expression or susceptibility to various complex diseases. Vervet monkeys are becoming an important animal model for such complex diseases as obesity, Type 2 diabetes, and atherosclerosis. At present, there is little genetic information available for the vervet. This study represents one step toward further genetically characterizing the vervet in order to refine it as a robust animal model. This data will also permit future association studies and facilitate phylogenetic analyses. *TNFA* is a candidate gene that is putatively involved in an inflammatory cascade involving obesity and its comorbidities. We have sequenced the promoter, exons and intronic regions of the *TNFA* gene in 265 individuals from a pedigreed colony of vervet monkeys, which is currently in the 5th-7th generation, with 24 original matrilines. This resulted in a contiguous sequence of ~4 kb. These 265 individuals were previously phenotypically characterized for obesity and associated risk factors, most of which were shown to be significantly heritable. Sequencing revealed a total of 11 SNPs, with 5 in the promoter region, 4 in the intronic regions, and 2 in the 3/5 untranslated region, and minor allele frequencies between 0.08 and 0.40. An intronic tetranucleotide repeat polymorphism was also detected. Comparisons of the vervet *TNFA* gene sequence with that of humans and rhesus macaques indicated 93.6% and 98.4% sequence identity, respectively. A comparative sequence map of the *TNFA* gene, reported herein, for humans, vervets, and rhesus monkeys, illustrates that the number and relative position of SNPs is similar among all 3 species. This sequence data will contribute to refining the vervet model of complex polygenic disease, allow future association studies, facilitate phylogenetic analyses, and represents the first report, to our knowledge, of *TNFA* or any other cytokine gene sequence data for the vervet monkey.

Total leukonychia and sebaceous cysts in a novel family: are the acoustic neurinomas of the index case in relation with the disease? *C. Jeanpetit[1], G. Morin[1], C. Desenclos[2], S. Olschwang[3], N. Levy[4], M. Mathieu[1]* 1) Clinical Genetics Unit, Amiens University Hospital, Amiens, France; 2) Neurosurgery Service, Amiens University Hospital, Amiens, France; 3) Paoli Calmette Institute, Marseille, France; 4) Medical Genetics Service, Marseille, France.

This French family of five generations demonstrates total leukonychia and multiple sebaceous cysts. Six members are affected, five women and one boy. The index case, a 41-year-old woman, was initially addressed for bilateral acoustic neurinomas, resembling neurofibromatosis type II. .Her physical examination revealed leukonychia of fingers and toes and multiple sebaceous cysts of the scalp. Among the five related affected persons nobody demonstrates neurinoma. The association of total leukonychia and sebaceous cysts is a rare disease, first reported by Bauer in 1920, in a large family of nineteen affected persons with leukonychia, and seventeen with sebaceous cysts. In 1975, Gorlin and Bushkel described a family of five boys with leukonychia, four with sebaceous cysts, three with renal stones and one with acute pancreatitis. In 1986, another family with eleven individuals was reported by Friedel, inconstantly associated with trichilemnal cysts and ciliary dystrophy. In 1997, Slee published the observation of one affected mother with pancreatitis and her daughter. The etiopathogeny of this disease is completely unknown. The mode of inheritance appears autosomal dominant in all the reported families. But no analysis for localisation has been made in this apparently benign disease and no candidate gene is really evocated. However, several cases of pancreatitis and renal stones suggest the possibility of complications. To our knowledge, the acoustic neurinomas or other tumours have never been reported. This argument and the absence of this complication in the other five affected members of our family suggest a different disease. But the screening of the NF2 gene of the index case failed to find a mutation.

Leptin Gene Polymorphism Is Associated with Breast Cancer In Obese Postmenopausal Women. *B.A. Bhavani[1], M. Madhupoornima[2], Ammena[3]* 1) Genetics, kasturba gandhi degree college, Secunderabad, Andhra pradesh, India; 2) 2. Department of Biochemistry, Bhavans degree and PG College for women, secunderabad, Andhra Pradesh, India; 3) 3. Department of Biotechnology, Lyola degree and PG college, Secunderabad Andhra Pradesh, India.

Leptin is an adipocyte-derived hormone that regulates food intake and energy expenditure. Recent functional studies have suggested a direct effect of leptin on menopausal status and breast cancer. In this study we examined the genetic association of the leptin gene polymorphism with obesity, postmenopausal status and risk for breast cancer in postmenopausal woman. A highly polymorphic tetranucleotide repeat polymorphism in the 3'-flanking region of the leptin gene was examined. The alleles of the polymorphism consisted of two groups with different size distributions: a shorter one (class I) and a longer one (class II). The frequency of class I/class I genotype was much higher in postmenopausal woman than in premenopausal woman. (13.5% vs. 3.4%; P = 0.0027). Further postmenopausal woman with breast cancer were observed to have high frequency of class I/class I genotype as compared to postmenopausal woman without breast cancer (OR- 2.56, CI 1.256-4.892, $p<0.05$). Significant difference in body mass index was observed with different genotypes in postmenopausal woman ($p<0.05$). The leptin gene polymorphism was associated with obesity and postmenopausal status. These data together with recent functional data on the direct effect of leptin onmenopausal status suggest that the leptin gene and its product, leptin, are an attractive target for studies on the mechanisms of menopausal changes and for the development of methods for the prediction, prevention, and therapy for menopausal changes and breast cancer.

Expanding the clinical phenotype of the 3q29 microdeletion syndrome and characterization of the reciprocal microduplication. *B. Ballif[1], J. Coppinger[1], G. Gowans[2], J. Hersh[3], S. Madan-Khetarpal[4], K. Schmidt[4], R. Tervo[5], L. Escobar[6], C. Friedrich[7], M. McDonald[8], J. Ming[9], E. Zackai[9], B.A. Bejjani[1], L.G. Shaffer[1]* 1) Signature Genomic Laboratories, Spokane, WA; 2) Weisskopf Child Evaluation Center, Louisville, KY; 3) University of Louisville, KY; 4) Children's Hospital of Pittsburgh, PA; 5) Gillette Children's Specialty Healthcare, St. Paul, MN; 6) St. Vincent Children's Hospital, Indianapolis IN; 7) University of Mississippi Medical Center, Jackson, MS; 8) Duke University Medical Center, Durham, NC; 9) Childrens Hospital of Philadelphia, PA.

Interstitial deletions of 3q29 have been recently described as a novel microdeletion syndrome mediated by nonallelic homologous recombination between low-copy repeats resulting in an 1.5 Mb common-sized deletion. Given the molecular mechanism causing the deletion, the reciprocal duplication is anticipated to occur with equal frequency. To our knowledge, the duplication has not been reported in the literature. We have analyzed 13,000 cases by array CGH using a targeted BAC microarray which includes a high-resolution, near-tiling-path coverage of the most distal 5 Mb of 3q29. Among these cases, we have identified 12 patients with microdeletions of 3q29 including one family with a mildly affected mother and two affected children. We have also identified 14 patients with duplications of 3q29, five of which appear to be the reciprocal duplication product of the 3q29 microdeletion and nine with duplications that flank, span, or partially overlap the common deletion region. Examination of eight 3q29 microdeletion patients revealed variable clinical presentations but identified some common features not previously appreciated. The clinical features of seven 3q29 duplication cases were also examined and, like 3q29 microdeletions, were found to be variable with few common features. Furthermore, de novo and inherited abnormalities were found in both the microdeletion and microduplication cohorts illustrating the need for parental samples to fully characterize these abnormalities. Our report demonstrates that array CGH is especially suited to identify chromosome abnormalities with unclear or variable presentations.

Construction of a SNP Chip Containing 94 Candidate Genes for Schizophrenia and Schizophrenia-Related Phenotypes. *T.A. Greenwood[1], G.A. Light[1], M.F. Green[2], R.E. Gur[3], K.H. Nuechterlein[2], A. Olincy[4], L.J. Seidman[5], D.W. Tsuang[6], N.J. Schork[1,7], D.R. Weinberger[8], D.L. Braff[1]* 1) Dept of Psychiatry, Univ of California, San Diego, La Jolla, CA; 2) Dept of Psychiatry and Biobehavioral Sciences, Univ of California, Los Angeles, Los Angeles, CA; 3) Dept of Psychiatry, Univ of Pennsylvania, Philadelphia, PA; 4) Dept of Psychiatry, Univ of Colorado Health Sciences Center, Denver, CO; 5) Dept of Psychiatry, Harvard Medical School, Boston, MA; 6) Department of Psychiatry and Behavioral Sciences, Univ of Washington Seattle, WA; 7) Scripps Genomic Medicine, San Diego, CA; 8) Clinical Brain Disorder Branch, Genes, Cognition, and Psychosis Program, National Institute of Mental Health, National Institutes of Health, Bethesda, MD.

We have constructed a gene chip containing 1536 SNPs in 94 genes of relevance to schizophrenia that were chosen based on knowledge of biological systems, as well as an extensive review of published association and linkage studies. Many of these genes have also been reputed to be involved in P50 suppression, prepulse inhibition, neurocognitive functioning, brain development, and bipolar disorder. These genes cluster into several pathways, including cell signal transduction, amino acid metabolism, and glutamate, serotonin, dopamine, and GABA receptor signaling. In order to efficiently interrogate these genes, we have chosen to make primary use of Caucasian haplotype-tagging SNPs. Of the 1427 tagging SNPs that were selected for 89 of the genes, many also had reported associations in the literature, and 18 were nonsynonymous cSNPs. For the 5 genes for which tagging SNPs were not available, 29 SNPs were chosen for even coverage. We have also included an additional 80 SNPs that were reported to be associated with schizophrenia in the literature, many of which had been replicated by separate groups, and 10 of which were nonsynonymous cSNPs. Our preliminary analyses of three neurophysiological and nine neurocognitive endophenotypes for schizophrenia using the SNPs from this chip in a sample of 140 families have provided many interesting associations. This gene chip may be of interest to many groups studying schizophrenia and related phenotypes.

A possible Role for the PTPN11 gene in Sex Determination. *M.T. Thomas[1], J.J. Jessen[1], S.K. Keating[2], D.C. Chitayat[1]* 1) Department of Obstetrics and Gynecology, Mount Sinai Hospital, Toronto, Ontario, Canada; 2) Department of Laboratory Medicine and pathobiology, Mount Sinai Hospital.

The SH2 domain-containing protein-tyrosine phosphatase PTPN11(Shp2) has a major role in normal organogenesis and is an essential component of signaling pathways. A germline gain of function mutation is known to be associated with Noonan syndrome as well as in different malignancies. However, to the best of our knowledge, there have been no report regarding the role of PTPN11 gene in sex determination. We report a case of abnormal sex determination in association with a germline mutation in the PTPN11 gene. Case Report: The mother was a 41-year-old G2P0TA1L0 woman of Jamaican descent and her partner was 45 years old and of the same descent. The couple was healthy and non-consanguineous. The pregnancy was complicated with fetal ultrasound finding of polyhydramnios and cystic hygroma detected at 12.3 weeks gestation. CVS was done subsequently and was 46, XX. Repeat fetal ultrasound at 15.7 weeks gestation showed oligohydramnios, hydrops fetalis, a large cystic hygroma, bilateral club feet and left genu recurvatum. The stomach and bladder could not be seen, the left ventricle was smaller than the right and there was a query AVSD. The mother developed a mirror image at 17 weeks gestation and delivery was induced. The autopsy showed IUGR, facial dysmorphism, low set ears and ambiguous genitalia with normal testes. No prostatic tissue was identified and a possible rudimentary uterus between the bladder and the rectum. There was bilateral club feet, pulmonary hypoplasia, AVSD and absent thymus. DNA analysis for PTPN11 showed a heterozygous CA nucleotide change in exon 13 of the PTPN11 gene denoted T7507K. This mutation has not been reported previously. FISH analysis for SRY and 22q11.2, were negative. Parental mutation analysis failed to identify this mutation in them. Our patient had normal female genotype, normal testes, ambiguous genitalia and absent Wolffian duct derivatives in the absence of SRY gene and in association with a germline mutation in the PTPN11 gene. This raises a possible important role for the PTPN11 gene in sex determination.

Short Telomeres in a case of acrogeria. *R. Drouin, O. Samassekou* Service of Genetics, Department of Pediatrics, Faculty of Medicine and Health Sciences, Universite de Sherbrooke, Sherbrooke, PQ, Canada.

Telomeres play a major role in the biology of cancer and aging. Changes in telomere homeostasis during premature aging syndromes, specifically the reduction of their length, have been reported. We report the case of 4 years old girl, first child of her family (she has a younger brother), who presented the following clinical manifestations: The facial features include micrognathia, alopecia, and prominent scalp veins; a short stature; growth delay; and thin and wrinkled skin. Besides these morphological abnormalities, she had an atrium septal defect. A diagnosis of acrogeria was proposed. Blood samples and skin biopsies were obtained from each member of the family. Regular blood and fibroblast cultures were set up to perform cytogenetic studies. Conventional cytogenetic studies and FISH (fluorescence in situ hybridization) using subtelomeric probes were performed on the lymphocyte culture and no chromosomal abnormalities were found. The same results were obtained for her parents and brother. The quantitative FISH technique was carried out on the metaphases of each member of her family. Ten metaphases of each individual were analyzed by measuring the signal intensity on each arm of the chromosomes. This signal intensity is proportional to the telomere length. The Q-FISH analysis showed a dramatically reduced telomere length of the patient when compared to her brother or even to her parents. Compared to all other members of her family, when analyzing each telomere length individually, the pattern of telomere length distribution was different. The Telomere Restriction Fragment (TRF) analysis, which assessed the average telomere length of the whole genome, confirmed the short telomere length observed by the Q-FISH. The sequencing of LMNA (lamin A) gene did not revealed any mutations, excluding the progeria diagnosis. Fibroblasts of all members of the family are cultured and the telomere length is assessed at every two or three passages. Further molecular studies will be needed to identify the gene responsible for this disease.

Genetic dissection of idiopathic generalized epilepsy: SNP discovery and genotyping in genes encoding ion channels in case and control populations. *R.A. Gibbs[1,2], D.A. Wheeler[1], A. Goldman[3], D.M. Muzny[1], S.E. Scherer[1], C. Davis[3], J.L. Noebels[3]* 1) Hum Genome Seq Ctr, Baylor College Medicine, Houston, TX 77030; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX 77030; 3) Department of Neurology, Baylor College of Medicine, Houston TX.

Epilepsy is the second most common neurological disorder, with a life-time prevalence of approximately 1-3% world-wide. Since mutations in ion channel genes account for the vast majority of rare inherited forms of idiopathic epilepsy they could be an equally important cause of the much more common, sporadic forms of the disorder. To investigate this problem, we are resequencing the exons of 240 ion channel genes in patients and matched controls. To date, we have generated sequence data across 2950 exons sampled from 256 patients and 54 controls. The study has produced over 4800 novel markers, 20% of which cause non-synonymous protein coding changes (nsSNP). From an initial set of SNPs we chose 1500 markers for a genotyping panel. The panel included 290 novel nsSNPs and putative splice variants from our study and an additional 503 nsSNPs and splice junction variants from dbSNP. We have tested 100 cases and 200 Caucasian controls in a first round of genotyping. A broad allele frequency spectrum was observed with over 50% of the polymorphic sites found at frequencies less than 5% but as yet no statistically significant associations have emerged. The project has also discovered termination mutations in 14 genes, nearly half of which have already been validated by an independent sequencing technology (pyrosequencing). These mutations are confined to cases in all but 2 of the genes, although the sample size of controls is still small. One of these genes, CLCN2, is also implicated in Mendelian forms of epilepsy. These findings are of great interest given the large number of spontaneous termination mutations in SCN1A, which are found in cases of severe myoclonic epilepsy of infancy. We are now focusing attention on the other nsSNPs found in these genes.

Coverage and power for genetic association studies using near-complete variation data from candidate genes.
T.R. Bhangale, M.J. Rieder, D.A. Nickerson Department of Genome Sciences, University of Washington Seattle, Seattle, WA.

Recent studies show that the HapMap captures most of the common variation and that SNPs derived from HapMap on the commercial genome-wide arrays provide promising coverage and power for association studies. Most evaluations of coverage and power have been based on using the Phase II HapMap data and SNPs in the ten ENCODE regions as the reference. We have used a near complete variation data set from SeattleSNPs, generated by resequencing of 24 Yoruban (YRI) and 23 CEPH (CEU) individuals from the HapMap panel, across 76 candidate genes, to evaluate the performances of the Phase II HapMap, and SNPs on the latest commercial arrays. Only 44% (YRI) and 48% (CEU) of relatively high frequency SNPs (minor allele frequency or MAF 0.3) were found in the HapMap. HapMap SNPs also revealed differences in the coverage for the two populations. While 84% of common (MAF 0.05) SNPs were captured at r2 0.8 in CEU, the coverage in YRI was 70%. These estimates are lower than previous estimates using the ENCODE regions. Coverage of the common variation in SeattleSNPs by the commercial arrays was also considerably lower than that using HapMap as the reference. For example, for the Illumina 650K array, the estimates were: 44% (YRI) and 74% (CEU) for SeattleSNPs and 68% (YRI) and 90% (CEU) for HapMap. By extending a recently described haplotype-sampling approach for power evaluation, using more flexible disease model specifications, we quantified power over a range of effect sizes and common allele frequencies. Overall, the power estimates for HapMap and the arrays were found to be lower in YRI compared to CEU. Despite the differences in the coverage values, at higher effect sizes and in additive models, the power estimates of most arrays were quite similar to those of HapMap in CEU. In YRI and at lower effect sizes, however, the arrays and the overall HapMap variation were found to provide considerably lower power at the sample sizes on the order of 1,000.

Urinary globotriaosylceramide excretion correlates with the genotype in children and adults with Fabry disease.

C. Auray-Blais[1], D. Cyr[1], A. Ntwari[1], M.L. West[2], J. Cox-Brinkman[3], D.G. Bichet[4], D.P. Germain[5], R. Laframboise[6], S.B. Melançon[4], T. Stockley[7], J.T.R. Clarke[1], R. Drouin[1] 1) Dept Pediatrics, Service of Genetics, Université de Sherbrooke,Sherbrooke, Qc, Canada; 2) Halifax, NS, Canada; 3) Amsterdam, The Netherlands; 4) Montreal, Qc, Canada; 5) Paris, France; 6) Québec, Qc, Canada; 7) Toronto, Ont, Canada.

Background: Fabry disease is a complex, multisystemic and clinically heterogeneous disease, with elevated urinary excretion of globotriaosylceramide (Gb3), the principal substrate of the deficient enzyme alpha-galactosidase A. Our first aim was to develop and validate a simple and rapid multiplex Gb3/creatinine methodology using liquid chromatography-tandem mass spectrometry (LC-MS/MS) analysis of urine samples collected on filter paper. The second aim was to evaluate the relationship between urinary Gb3/creatinine excretion and the genotype of children and adult patients with FD. **Methods**: The analysis of Gb3/creatinine was developed and validated for use with a short multiplex LC-MS/MS run of 2.6 minutes. We studied the relationship between the urinary levels of total Gb3/creatinine excretion and four types of mutations in the *GLA* gene (missense, nonsense, frameshift, and splice-site defects) in 32 children and 78 adult patients with FD. **Results**: The mean recoveries of Gb3 and creatinine from the urine filter paper standards were 91% and 97%, respectively with good precision, reproducibility, and linearity. The statistical analysis using the independent variables of sex, age, types of mutations and treatment showed that the mutation factor is statistically significant ($p = 0.0006$). This means that the levels of urinary excretion of Gb3/creatinine in children and adults with Fabry disease are directly related to the type of mutation. The same correlation has been found for the sex ($p < 0.0001$) and treatment ($p = 0.0005$). **Conclusions**: We found a highly significant correlation between the urinary excretion levels of Gb3 and the types of mutations in adults and children with Fabry disease. The results also indicate that the urinary excretion of this specific glycosphingolipid biomarker is directly related to sex and treatment, but not age.

Chromosomal and molecular signatures oligodendrogliome. *M. Gadji[1], D. Fortin[2], A.-M. Tsanaclis[3], R. Drouin[1]* 1) Genetics - Dept of Pediatrics, Faculty of Medicine and Health Sciences, Sherbrooke, Quebec, Canada; 2) Service of neurosurgery, Department of Surgery, Faculty of Medicine and Health Sciences, Université de Sherbrooke, Sherbrooke, Quebec, Canada; 3) Department of Pathology, Faculty of Medicine and Health Sciences, Université de Sherbrooke, Sherbrooke, Quebec, Canada.

The pathogenesis of oligodendrogliomas is largely unknown. Combined loss of chromosome arms 1p and 19q has proven to be a powerful predictor of chemotherapeutic response and survival in oligodendrogliomas. The mechanism of this dual chromosomal arm loss is unexplained. Recently, two studies using cytogenetic analysis of cultured low grade oligodendroglial tumours, showed a chromosomal translocation of 1p and 19q [t(1,19)(q10;p10)], arguing to the combined loss on 1p/19q was mediated by this translocation. However, this translocation was indicated in 12% of tumours without 1p/19q deletion. We prospectively studied the oligodendroglial tumours diagnosed at the CHUS using cytogenetic and molecular genetic techniques. To date, eighteen cases composed of 7 anaplastic olidendrogliomas, 5 anaplastic oligoastrocytomas, 5 oligodendrogliomas and 1 primary neuroectodermal tumor were studied using biopsy samples after surgical resection. Thirteen cases were successfully cultured and GTG banding was performed. The karyotypes of 5 cases displayed 3 normal karyotypes, one hypotriploidy karyotype and one with a translocation between chromosome 1q and chromosome 7p [t(1;7)(q10;p10)]. To study the 1p/19q deletion status of our patients, we used fluorescent in situ hybridization technique (FISH) using specific commercial probes for chromosomes 1 and 19. To define the length of the deletions and genes related, we will use LOH (Loss Of Heterozygosity) screening with microsatellite markers specific to chromosome 1 and chromosome 19. The combination of karyotyping and molecular investigations will allow us to define a new mechanism of codeletion of chromosomal arms 1p and 19q.

Identification of commonly aberrant genomic regions using high resolution oligo array CGH of FFPE breast cancer samples. *C. Carmack[1], R. Davis[2], A. De Witte[1], B. Poirier[2], E. Lin[1], A. Borowski[2], J. Ghosh[1], J. Gao[1], S. Giles[1], E. LeProust[1], D. Amorese[1], D. Roberts[1], S. Shams[3], J. Gregg[2]* 1) Agilent Technologies, Santa Clara, CA; 2) University of California Davis Medical Center, Sacramento, CA; 3) BioDiscovery, Inc. El Segundo, CA.

Background: A number of published studies have suggested that DNA copy number can be an important therapy determinant for cancer. Perhaps the best example of the importance of copy number to cancer therapy is the effectiveness of Trastuzumab (antibody to Her2/neu) in the treatment of breast tumors with amplifications in the EGFR family member ERBB2. While it is anticipated that copy number determination may also aid in the discovery of potential therapeutic targets, it is still unclear where the genomic regions are and what further prognostic or diagnostic information they may provide for breast cancer.

Material and Methods: We have designed two Comparative Genomic Hybridization (CGH) arrays. The first is a whole genome array consisting of 244,000 in situ synthesized 60-mer oligonucleotides spanning the entire human genome with an average genomic distance between probes of ~12 Kbp. A second array, containing 44,000 features was specifically designed to focus on chromosome 17 with an average probe spacing of 1kb across the chromosome and ~400bp through the region encompassing ERBB2 (17q21.2-q21.3), ~30k probes and ~8k probes respectively. Using these arrays, we performed an analysis of copy number changes in breast carcinomas and in breast carcinoma cell lines. We defined the smallest commonly amplified regions in cases with amplification at ERBB2. We also define and classify other common aberrations including amplification at 1p and deletion at 16q.

Results and Discussion: Using both whole genome and focused array data, we define several common aberrations in breast cancer samples. Further, patient chromosomal/gene copy number determinations are analyzed with respect to their ERBB2 and Estrogen Receptor protein levels, clinical classification, and outcome.

The molecular pathophysiology of Borjeson Forssman Lehman Syndrome. *M.A. Corbett[1], L. Vandeleur[1], J. Crawford[1], C. Wilkinson[2], C. Shoubridge[1], E. Parkinson-Lawrence[3], D. Brooks[3], L.S. Nguyen[1], W. Just[4], J. Gecz[1,5]* 1) Department of Genetic Medicine, Women's and Children's Hospital, North Adelaide, Australia; 2) School of Mathematical Sciences, The University of Adelaide, Adelaide, Australia; 3) Division of Health Sciences, School of Pharmacy and Medical Sciences, City East Campus, The University of South Australia,Adelaide, Australia; 4) Department of Human Genetics, University Clinic Ulm, Ulm, Germany; 5) Department of Paediatrics, University of Adelaide, Adelaide, Australia.

Mutations in PHF6 cause Borjeson-Forssman-Lehmann Syndrome (BFLS), a syndromic form of X-linked mental retardation. The main clinical features of BFLS are intellectual disability, truncal obesity with gynecomastia, hypogonadism and large ears. To date there are 12 different PHF6 mutations known in 19 unrelated BFLS families and isolated cases. PHF6 is a ubiquitously expressed nucleolar protein, which has four nuclear localisation sequences and two PHD-like zinc finger motifs. To elucidate the role of PHF6 in the cell and in BFLS we performed microarray gene expression profiling on lymphoblastic cell lines (LCL) from six BFLS patients. We observed significant changes in RNA processing, DNA replication and the cell cycle genes, consistent with cellular processes of the nucleolus. We also noted that two unrelated patients with a recurrent c.1024 C>T, p.R342X mutation had significantly reduced levels of PHF6 transcript, due to nonsense mediated decay of the predominant PHF6 transcript (PHF6a) but not of an alternate transcript (PHF6b). PHF6a and PHF6b differ by the alternative exclusion or inclusion of a 330bp sequence in the 3UTR. Examination of PHF6 expression in different tissues detected increased amounts of PHF6b in the brain compared to PHF6a levels. We showed by luciferase reporter assay that the 330bp 3UTR sequence in PHF6b increases expression. Thus PHF6 expression can be regulated post-trancriptionally. We detected variable levels of PHF6 protein in LCL of patients with BFLS, including low levels of the truncated p.R342X mutant. All cases of BFLS are similar, thus we predict that PHF6 has a single functional domain that is disrupted by any mutation in the protein.

Dissecting the role of Ofd1 in limb development and skeletal patterning. *S.B. Bimonte[1], L.Q. Quagliata[1], R.T. Tammaro[1], B.F. Franco[1,2]* 1) Telethon Institute of Genetics and Medicine, TIGEM, Naples, Italy; 2) Department of Pediatrics, Federico II University of Naples, Italy.

OFD type 1 syndrome is a genetic disorder characterized by oral, facial and digital anomalies, due to dysfunction of primary cilia. We have generated a mouse model for OFD1 syndrome. Ofd14-5/+ females displayed craniofacial abnormalities and a skeletal phenotype which included polydactyly of both limbs and shortened long bones. To bypass the problem of the embryonic male and perinathal female lethality, we have developed a mouse model in which the Ofd1 gene has been specifically inactivated in the limbs by crossing the Ofd1fl with the CrePrx1 transgenic mice, which specifically express the Cre recombinase in the early limb bud mesenchyme. Ofd14-5/+;CrePrx1 and Ofd14-5;CrePrx1 mutants were viable and displayed only limb and skeletal abnormalities. The strongest phenotype was observed in Ofd14-5;CrePrx1 males. Malformations include severe polydactyly with 7 to 9 digits and lack of normal digit identity, shortening of bones, fusion of synovial joints, disorganization of the growth plate and delay in endochondral ossification. Whole mount RNA in situ studies on limb buds from Ofd14-5/+;CrePrx1 and Ofd14-5;CrePrx1 embryos at E11.5 revealed that the domain of expression of Hoxd12, Hoxd13, Gremlin and dHand was abnormally extended anteriorly in the limb buds of the male mutants starting from E11.5. Western blotting analysis indicates a reduction of the Gli3R (Gli3-83) repressor form suggesting that Ofd1, as already shown for IFT proteins, is implicated in the control of the transcription activities of Gli proteins. Preliminary analysis of mutants indicate deregulation of Ihh, an increase of chondrocytes proliferation, absence of an organized growth plate, reduction in the bone mineralization and lack/reduction of bone collar. Our data indicate that Ofd1 plays an important role in the determination of the correct digit number and could be involved in the chondrocytes differentiation from hypertrophic chondrocytes to osteoblasts and in the periosteal ossification. Our experiment are now aimed to understand which are the molecular steps underlying these functions.

A randomised controlled trial of aspirin and resistant starch to prevent colorectal neoplasia in Lynch Syndrome: The CAPP2 Study. *J. Burn[1], D.T. Bishop[2], J-P. Mecklin[3], F. Macrae[4], G. Moeslein[5], S. Olschwang[6], M.L.S. Bisgaard[7], R. Ramesar[8], F. Elliott[2], G. Barker[1], J. Jass[9], H.T. Lynch[10], J. Mathers[1]* 1) Inst Human Genetics & Human Nutrition Research Centre, Newcastle University,UK; 2) Inst of Molecular Medicine, Leeds University, UK; 3) Jyvaskyla Central Hospital, Finland; 4) Royal Melbourne Hospital, Australia; 5) St. Josefs Hospital, Bochum-Linden, Germany; 6) Institut Paoli Calmettes, Marseille, France; 7) University of Copenhagen, Copenhagen, Denmark; 8) University of Cape Town, Observatory, South Africa; 9) Dept of Cellular Pathology, St. Mark's Hospital, London, UK; 10) Hereditary Cancer Inst. Creighton University, Omaha, USA.

There is strong epidemiological evidence in favour of aspirin and resistant starch being protective against colorectal cancer. We randomised 1009 eligible carriers of mismatch repair gene defects at risk of Lynch Syndrome (HNPCC), from 43 centres worldwide, in a factorial design to receive 600mg enteric coated aspirin or placebo and 30 grams of non-GM resistant starch (Novelose) or placebo for up to 4 years. 937 started treatment. 191 withdrew without an exit colonoscopy being recorded. The average duration of therapy among the 735 participants analysed was 29 months (range 7.4 to 74.4). A total of 141 participants developed colonic neoplasia including 22 carcinomas. This exceeded the number of events predicted on power anlaysis to be needed to detect an effect equivalent to epidemiological predictions. The numbers in each randomisation group were equal. The results of this genetically targeted trial, the largest to date and the first in Lynch syndrome, are currently under publication embargo. They will help determine chemoprevention in HNPCC families and patients with sporadic MSI high tumours. We have now proven that people who are at high risk of genetic disease are willing to participate in long term chemoprevention/dietary trials, are compliant and contribute a high level of statistical power. Geneticists should become more involved in development of disease prevention strategies. (New Engl. J. Med. submitted).

WHOLE GENOME ANALYSIS IDENTIFIES A SUSCEPTIBILITY LOCUS TO HIV-1. *S. Deutsch[1], C. Loeuillet[2], A. Ciuffi[2], D. Robyr[1], M. Munoz[2], P. Taffé[3], M. Rotger[2], J.S. Beckmann[4], S.E. Antonarakis[1], A. Telenti[2]* 1) Genetic Medicine and Development, University of Geneva, Switzerland; 2) Institute of Microbiology, University of Lausanne, Switzerland; 3) Swiss HIV Cohort Study Data Center, Lausanne, Switzerland; 4) Medical Genetics, University of Lausanne, Switzerland.

Susceptibility to lentiviral infection (including HIV) is a quantitative trait that is influenced by genetic variability of the host. To identify loci underlying this trait we established an in vitro approach in lymphoblastoid cells (LCLs), based on a lentiviral GFP reporter system. We phenotyped 198 LCLs from 15 three-generation CEPH families to calculate heritability and perform quantitative linkage (QTL) analysis. Heritability calculations showed that the phenotype has a strong genetic component with a h2r of 0.53. QTL analysis using variance components, led to the identification of a significant locus on chromosome 8q (p=2E-04). The empirical significance of the locus was confirmed by performing simulation studies. To further dissect the locus, we phenotyped 57 LCLs from the CEU HapMap collection, and performed an association analysis using tag SNPs in a 3Mb region around the marker with the highest LOD-score. This resulted in the identification of a single intergenic SNP (p=7.7E-05) that remained significant after correction for multiple testing. To confirm the association, we infected CD4 cells from 128 healthy blood donors with replicating HIV. Individuals heterozygous for the SNP were on average 57% more susceptible to infection than non-carriers (p=0.02). In addition, we genotyped 496 HIV positive individuals that were followed up for 7 years without anti-retroviral treatment to determine whether the genotype had an effect on disease progression. Carriers of the SNP showed increased levels of viremia (p=0.009) and a faster depletion of CD4 cells (p=0.046) compared to non-carriers. Since the SNP is located in an intergenic region, we performed a 3C experiment to detect potential interactions with genes within a 100 Kb region. Our data identify a novel locus on chromosome 8 that modulates HIV susceptibility in vitro and in vivo and provide candidates genes that might underlie this biological effect.

Gene-wide association study on ABCB1/MDR1 polymorphisms and colorectal cancer risk. *D. Campa[1,2], B. Pardini[2,3], P. Vodicka[3], S. Wilkening[1], K. Hemminki[1,4], R. Barale[2], F. Canzian[1]* 1) German Cancer Research Center(DKFZ), Heidelberg, Germany; 2) Department of Biology, University of Pisa, Pisa, Italy; 3) Institute of Experimental Medicine, Academy of Sciences of the Czech Republic, Prague, Czech Republic; 4) Department of Biosciences at Novum, Karolinska Institute, Huddinge, Sweden.

Transporters are the gatekeepers for all cells and organelles, controlling uptake and efflux of a large variety of compounds such as sugars, amino acids, nucleotides, inorganic ions xenobiotics , including toxins, carcinogens, and drugs. Among ABC transporters, ABCB1, is the best known member of the family. Its expression in the human intestine increases from proximal to distal, resulting in the higher expression levels in the colon. ABCB1 is involved in the excretion of several carcinogens from the gut into the intestinal lumen. The aim of the present work was to study the impact of genetic variants of ABCB1 gene on risk of colorectal cancer, with particular attention to the role of putatively functional variants that have been previously shown to be associated with cancer risk, such as C3435T and S892A polymorphisms within ABCB1. In order to study exhaustively genetic variation of ABCB1 gene, we have followed a hybrid functional/tagging approach. Genotype data from the most recent release of the HapMap project have been downloaded. All polymorphisms with minor allele frequency 5% in HapMap Caucasians have been included. We performed a case-control study on 690 cases and 590 controls of Czech origin. We found that carriers of the T allele of ABCB1 G2677T polymorphism had an increased risk of colorectal cancer. In conclusion this findings suggest that variants impairing ABCB1 activity would lead to an increased colorectal-cancer risk due to a decreased toxin/carcinogen clearance trough the body.

Data Sharing - A good idea in principle? *J.S. Kaye* Ethox Centre, University of Oxford, Radcliffe Infirmary, Woodstock Road, Oxford.

The scientific benefits of sharing sequence data are well established. This has lead to considerable investment by funding bodies, to establish new genomic resources that can be used by all, but also to develop the means to link and share existing collections. The initial data- sharing principles were articulated in the Bermuda Principles 1996, and more recently the Fort Lauderdale Tripartite-Agreement 2003. Both of these documents relate to sequence information. Since then, data sharing policies have been put in place by major funding bodies, such as the NIH, the European Commission, and the MRC (UK) as a requirement of funding, which apply to all types of data generated through the research process. The rationale behind such initiatives is to utilize publicly-funded research data to its fullest extent, by opening up such collections to other researchers, thereby reducing unnecessary duplication of data-sets, enabling new lines of enquiry and speeding up the process of knowledge production. The basic principle is that all data should be shared, unless controllers of datasets can establish good reasons why this should not be so. These requirements have implications for the present practice such as how to protect the privacy rights of the research participants; standardise procedures; ensure trust between researchers; fair acknowledgement of use of the resource; and the apportionment of intellectual property rights. Using Europe as a case study, the purpose of this paper is to outline some of the legal obstacles and issues that arise out of the push by funders to share samples and data, in order to hi-light areas of the law that need development and require further policy consideration.

Investigation the effect of Iron accumulation on different parts mtDNA of Iranian patients comparing with normal mtDNA. *S. EtemadAhari[1], S. Kasraie[1], M. Moin[2], M. Houshmand[1], M. Shafa Shariat Panahi[1]* 1) Dept Molecular Medical Gen, NIGEB, Tehran, Iran; 2) Immunology,Asthma & Allergy Research Institute, Tehran,Ian.

Friedreich's ataxia (FRDA)1 is the most common inherited ataxia. Clinically, Friedreich's ataxia is characterized by multiple symptoms including progressive gait and limb ataxia, dysarthria, diabetes mellitus, and hypertrophic cardiomyopathy. There is much evidence to suggest that FRDA results from mitochondrial iron accumulation leading to cellular damage and death by the production of toxic free radicals by Fenton chemistry.Presence of free radicals in mitochondria of patients with FRDA motive us to investigate different parts of mtDNA in 20Iranian FRDA patients, by PCR and automated DNA sequencing and compare it with normal mtDNA to find any probable point mutation that can be adjunctin the pathogenesis of FRDA.

ELUCIDATION OF THE RMRP PATHOGENESIS IN CARTILAGE HAIR HYPOPLASIA. *P. Hermanns[1], K. Reicherter[1], A. Bertuch[2], B. Lee[3,4], B. Zabel[1]* 1) pediatric genetics section, Centre for Pediatric & Youth Medicine, Freiburg, Baden-Württembe, Germany; 2) Pediatrics-Hematology & Oncology, Texas Childrens Feigin Center, Houston, TX, USA; 3) Baylor College of Medicine, Houston, TX, USA; 4) Howard Huges Medical Institute Houston, TX, USA.

CHH is an autosomal recessive disease chracterized by dwarfism, fine, sparse hair, deficient cellular immunity and predisposition to malignancy. CHH is caused by mutations in RMRP, which is the RNA component of a ribonucleoprotein complex. Yeast studies suggest its involvement in several cellular processes. Mutations include promoter insertions and duplications that are exclusively located between the TATA box and the transcription start site. Also point mutations and small insertions and deletions spread out through the entire RMRP transcript have been identified. In vitro studies show that promoter duplications found in CHH patients cause a hypomorphic allele affecting RMRP transcription. qRT-PCR analysis of patient lymphoblasts revealed a 7-fold decrease in RMRP RNA level. RMRP mutations introduced into the yeast ortholog NME1 neither altered mitochondrial function nor, affected mitochondrial content in a CHH patient fibroblast cell line. The 70A>G causes an alteration in rRNA processing and microarray studies performed with two patients suggest that RMRP mutation is associated with significant up-regulation of several cytokines and cell cycle regulatory genes. These data suggest that alteration of ribosomal processing leads to altered cytokine signaling and cell cycle progression in terminally differentiated cell types involved in CHH pathogenesis, i.e., lymphocytic and chondrocytic lineages. Additionally, preliminary studies suggest that RMRP might be regulated by miRNAs. To elucidate this further a miRNA microarray will be performed with total RNA isolated from whole blood of CHH patients, who have two identified mutations. This result will be compared to an expression profiling performed with sample of the same patients. This way we expect to identify differentially regulated miRNAs and their target genes in CHH patients compared to normal controls, thus gaining more insights in the pathogenic mechanisms in CHH.

Development and Validation of New Molecular Diagnostic Assays for the Jak2 V617F Screening and Quantification. *O. Biglia[1], J.P. LeCouedic[2], S. Hermouet[3], F. Hermitte[1], N. Maroc[1]* 1) Ipsogen, Marseille, France; 2) INSERM U790-Institut Gustave Roussy, Villejuif, France; 3) Laboratoire d'Hématologie & INSERM U601, CHU Nantes, France.

JAK2 V617F is an acquired mutation found in > 95% of patients with polycythemia vera (PV), and in > 50% of patients with essential thrombocythemia (ET) and chronic idiopathic myelofibrosis (CIMF). The discovery of this mutation has profoundly modified the diagnosis of Ph- (BCR-ABL negative) Myeloproliferative Disorders (MPD). Using different technologies, often multi step and time consuming, variable incidences of this mutation in each pathology subtypes have been reported. Those variations are mainly due to a great heterogeneity in the technologies used and sometimes to their poor sensitivity, highlighting the needs for a simple, standardized, accurate and sensitive assay. We developed two assays: Jak2 MutaScreen assay, based on TaqMan allelic discrimination, is dedicated to Jak2 mutation screening on DNA samples at the time of diagnosis, while Jak2 MutaQuant assay is an allele specific RQ-PCR and is dedicated to mutation load quantification on follow-up samples. We performed a multi centre performance evaluation of our Jak2 MutaScreen genotyping assay. Multi centre study in 14 labs on 7 different apparatus (ABI-prism, LightCycler, iCycler) on 296 MPD samples demonstrated 98.65% correlation with technologies used at diagnosis. Parallel internal validation on 142 samples allowed identifying 13% more mutated cases than direct sequencing method. We will also present analytical validation of both assays, inter and intra-laboratory reproducibility, and technology performance comparison (sequencing versus Jak2 MutaScreen, Jak2 MutaScreen + Reference Scale versus Jak2 MutaQuant). Sensitivity, dynamic range and inter platform capability of Jak2 MutaScreen assay are compatible with a wide use for highly accurate and sensitive detection of JAK2 V617F mutation at diagnosis. Jak2 MutaQuant provides a tool for the monitoring of minimal residual disease in clinical research studies; clinical utility of this test will have to be addressed in multicentric prospective clinical trials.

Identifying Disease-causing Non-coding Mutations by Medical Sequencing. *T. Hefferon[1], S.Q. Lee-Lin[1], J. Idol[1], V. Maduro[1], S. Terry[2], A. Sharp[3], E.D. Green[1], NIH Intramural Sequencing Center* 1) NHGRI, NIH, Bethesda, MD; 2) PXE Int'l, Washington, DC; 3) Dept. Genome Sciences, U. Washington, Seattle, WA.

The comparison of genome sequences from diverse vertebrate species has enabled the identification of highly conserved regions that are under negative selection. Having resisted mutation over evolutionary time, such regions are likely to contain functional genomic elements that are important for the survival of organisms. We are using a comparative genomics approach to identify highly conserved non-coding regions in and around known human disease genes, and then screening those regions by medical sequencing for possible disease-causing mutations. In two related projects, we are studying patients with cystic fibrosis (CF) or pseudoxanthoma elasticum (PXE). The genomic regions encompassing both genes mutated in these disorders (*CFTR* and *ABCC6*, respectively) have been sequenced in multiple species, allowing the identification of multi-species conserved sequences (MCSs). We are using a medical-sequencing approach to screen DNA samples from patients where one or both mutations remain unidentified after rigorous screening of coding, splice, and promoter regions; since these patients do not appear to have two coding mutations, they may carry disease-causing changes in non-coding functional sequences. We have found multiple variants in both genes, and are following them up with further studies to define their possible functional roles. Our *CFTR* studies are being aided by the rich data sets for the corresponding genomic regions generated by the ENCODE project; these data are providing important insights about the possible function of the conserved non-coding regions being examined. Meanwhile, our *ABCC6* studies are complicated by the presence of two partial pseudogenes in the genomic region of interest, which are products of segmental duplications; this raises the possibility that copy-number changes may account for the disease in some patients. Together, these projects illustrate the complexities associated with the search for disease-causing mutations in some genetic diseases and the important interface between comparative genomics and medical sequencing in human genetics studies.

Infantile Neuronal Ceroid Lipofuscinosis (CLN8)in a child with dicentric isochromosome 8 due to a mitotic recombination event. *P. Chakraborty[1,3], L. Pham[2], D. Bulman[2], J. Michaud[1, 3], P. Humphreys[1], M.T. Geraghty[1,3]* 1) Children's Hospital of Eastern Ontario, Ottawa; 2) Ottawa Health Research Institute; 3) Dept of Pathology, University of Ottawa, Canada.

We report a girl with an isodicentric chromosome 8 [45, XX, psu dic (8;8) (p23;p23)]. She presented with global developmental delay in infancy, and developed a seizure disorder at 4 years of age and regressed developmentally in all spheres. At age 8, she had roving eye movements, continuous myoclonic jerks, and a spastic quadraparesis. CT scans showed cerebral atrophy with ventriculomegaly and she died at 11 years of age. Autopsy showed severe cerebral atrophy and storage of autofluorescent material in neurons and several extraneural organs, and membrane bound fingerprint and curvilinear inclusions. This suggested the diagnosis of a Neuronal Ceroid Lipofuscinosis (NCL). NCL's are a clincally and genetically heterogeneous group of lysosomal storage disorders causing blindness, seizures and neurodegeneration. The NCL's have been classified clinically by age at presentation, and more recently genetically by the gene involved. Northern epilepsy in the Finnish population and the Turkish variant of late infantile neuronal ceroid lipofuscinosis are known to be caused by mutations of the CLN8 gene located on the chromosome 8p23. FISH analysis using a CLN8 probe revealed homozygous deletion of this locus. Performing PCRs from the tip of chromosome 8 towards the centromere confirmed the homozygous deletion of CLN8, as well as of ZNF596 and LOC157693 (both telomeric to CLN8). MYOM2, coding for the sarcomeric myomesin M-protein 2, was absent in the patient (who did not have any phenotypic muscle defects). Microsatellite markers spanning chromosome 8 were examined in both maternal and patient DNA. Non-maternal alleles were detected suggesting that the translocation is a result of a mitotic recombination event. In conclusion, this is the first report of a dicentric chromosome 8 resulting from a post-zygotic recombination event causing homozygous deletion of CLN8 and NCL. Homozygous knockout of MYOM2 was also present without any evident muscle pathology.

The molecular analysis of apparently balanced chromosome translocations in two unrelated patients with hypogonadotropic hypogonadism. *H.G. Kim[1], K. Norris[2], A.S. Kulharya[2], L.C. Layman[1]* 1) Section of Reprod Endocrinol & Genet, Dept OB/GYN, Inst Molec Med Genet, Medical College of Georgia, Augusta, GA; 2) Depts. Pathology and Pediatrics, Medical College of Georgia, Augusta, GA.

Patients with idiopathic hypogonadotropic hypogonadism (IHH) present with absent puberty due to a hypothalamic-pituitary defect, and may be either normosmic (nIHH) or anosmic (Kallmann syndrome). Although mutations in genes such as FGFR1, KAL1, and GNRHR constitute the most commonly encountered etiology in IHH, the molecular basis for most patients remains unknown. Apparently balanced chromosomal rearrangements found in some patients may actually disrupt a gene at the breakpoint, thereby aiding in identification of the causative gene. We have characterized translocations in two unrelated IHH patientsone a 46,XY,t(10;12)(q26.3;q13.1) in a male with Kallmann syndrome, and the other a mos46,XY,t(3;12)(p13;p13)[18]/46,XY[3] in a male with normosmic IHH and cerebellar ataxia. The 10q26 breakpoint has been reported previously in a Kallmann syndrome patient with monosomy 10q26 and in several cases of translocations involving urogenital anomalies and hypogenitalism. In our patient, the 10q26 translocation breakpoint maps proximal to BAC clone RP11-95I16 and that of 12q13.1 was narrowed to 4.3 Mb between RP11-88L2 and RP11-204C20. In the second patient with the mosaic 3;12 translocation, homogeneous lymphoblastoid cell lines with the balanced translocation were successfully transformed from peripheral white blood cells. IHH and cerebellar ataxia often occur together and they are seen in Gordon Holms syndrome and Boucher-Neuhauser syndrome. We hypothesize that one of the breakpoints of this translocation case is likely to harbor a gene responsible for this phenotype. A positional cloning technique was applied to clone each of the breakpoints. FISH mapping for a breakpoint at 12q13 in this patient has led to the isolation of a BAC RP11-4N23, which crosses this breakpoint. Currently FISH with fosmid clones overlapping this clone is underway to refine the breakpoint region. These chromosome translocations afford the potential to define additional genes involved in IHH/Kallmann syndrome.

Validation of Applied Biosystems 3730 genetic analyzer for STR-based relationship testing. *J. Cummings[1], J. Kibler[2], M. Roche[2], M. Marfori[2], T.D. Kupferschmid[2], D.D. Einum[1]* 1) Sorenson Genomics, Salt Lake City, UT; 2) Sorenson Forensics, Salt Lake City, UT.

Background: The Applied Biosystems (ABI) 3130 and 3700 genetic analyzers are capillary electrophoresis-based instruments utilized in the relationship testing community for fragment analysis. However, the 3130 has limited high-throughput capabilities and the 3700 often involves unpredictable capillary failures. With the release of the next-generation 3730 platform, high throughput processing is achievable while maintaining low failure rates. This study's objective was to validate the Identifiler multiplex (ABI) on the 3730 for relationship testing applications in a high throughput laboratory. **Methods**: Genomic DNA used in this validation were isolated from buccal swabs using Qiagens QIAamp Swab BioRobot Kit. The samples were then normalized using a modified PicoGreen quantitation assay and amplified using the Identifiler PCR kit on GeneAmp 9700 thermocyclers. Amplified products were processed on a 3730 48-capillary array and the resulting genotypic data was analyzed with GeneMapper. Data quality parameters examined in this study included crosstalk, concordance, precision, sensitivity and stutter. **Results**: Crosstalk was assessed with zebra and checkerboard plate configurations whereby signal was examined in blank wells and was detected only when input DNA was increased to 6.5ng. Data concordance was examined by analyzing controls and ladders with published genotypes as well as examining samples from NIST. No instances of non-concordance were observed. Run-to-run and capillary-to-capillary precision was evaluated by examining migration of a series of allelic ladders. For all alleles, the detected size ranges were less than 1.0 base pair. Sensitivity studies involved input DNA quantities of 6.5ng, 3.25ng, 1.62ng, 0.81ng, 0.4ng, 0.2ng and 0.1ng. With addition of less than 0.4ng, stochastic effects became prominent. Stutter percentages all fell within thresholds recommended by the manufacturer. **Conclusion**: This study demonstrates that the 3730 yields reliable and consistent results within the context of high-throughput fragment analysis for relationship testing laboratories.

A mild neurological phenotype of mucolipidosis type IV in a patient with an altered C-terminus of mucolipin-1.

E. Goldin[1], A.M. Cooney[2], C.R. Kaneski[2], Y. Blech-Hermony[1], S. Stahl[2], R. Schiffmann[2] 1) Medical Genetics Branch, NHGRI, NIH, Bethesda, MD; 2) Developmental and Metabolic Neurology Branch, NINDS, NIH, Bethesda, MD.

Mucolipidosis IV (MLIV) is caused by mutations in mucolipin-1 (MCOLN1), a gene encoding a cation channel of the TRP family. Most Ashkenazi Jewish patients have one of two severe mutations that result in a null phenotype, presenting with eye abnormalities that lead to progressive blindness and severe psychomotor retardation. Patients also suffer achlorohydria, causing extremely elevated levels of blood gastrin. Lysosomal inclusions are found in most cells, and fibroblasts are autofluorescent. MRI shows partial agenesis in the corpus callosum and a degenerative process in the cerebellum. A variety of mutations have been described in other patients, causing intermediate forms of the disease that range from the most severe phenotype to mild developmental abnormalities and slowing of the retinal degeneration. The patient described here presented with only a mild loss of vision and a very mild motor deficit, and otherwise lives a normal life appropriate for his age. In contrast, his fibroblasts demonstrate autofluorescence similar to all other MLIV patients and his blood gastrin is elevated. DNA sequencing identified two frame-shift mutations in MCOLN1, but only one of them is expressed. This mutation alters the C-terminus of the protein. Electrophysiology of a construct of the mutant protein was tested in liposomes and minor abnormalities in the protein function were detected. The lack of brain abnormalities in this patient implies that a minor deficiency of mucolipi-1 does not necessarily impact brain development. This case contributes significantly to the literature because it broadens the spectrum of clinical heterogeneity encountered in ML-IV, and underscores the important role of the ophthalmologist in making this diagnosis.

The effect of gestational age, transfusions, and dietary supplementation with medium chain triglyceride on ms/ms profiles of presumptive positive patients for medium chain acyl coa dehydrogenase deficiency. *C. Dvorak[1, 2], T. Narumanchi[1,2], A. Cunningham[1], K. Weissbecker[1], M. Jenkins[1], J. Smith[1], D. Werling-Baye[3], C. Myers[3], J. Thoene[1, 2], H. Andersson[1, 2]* 1) Human Genetics Program, Tulane Sch Medicine, New Orleans, LA; 2) Dept of Pediatrics, Tulane Sch Medicine, New Orleans, LA; 3) Louisiana DHH - Office Of Public Health - Genetic Diseases Program.

Newborn screening for medium chain acyl CoA dehydrogenase deficiency (MCADD) is based on elevations of medium chain fatty acids in the blood spot, but numerous factors in the newborn period may cause elevations of medium chain fatty acids which are unrelated to inherited disease. We present the final results of a study on the effect of gestational age, packed red blood cell transfusions, and dietary supplementation with Medium Chain Triglyceride (MCT) oil on the MS/MS profile of patients who were presumptive positives for Medium Chain Acyl CoA Dehydrogenase deficiency [MCADD]. Data was collected from September 2005 until Januray, 2007 for a total of 55 presumpitve positive MCADD patients (51 screened in Iowa, 4 screened by Pediatrix). Because Louisianas NBS lab was damaged by Hurricane Katrina, newborn screening is being performed in Iowa, with final diagnosis being done following confirmatory testing by clinicians in LA. The single greatest predictor of a false positive for MCADD was gestational age. No patients under 32 weeks gestation proved to truly have MCADD. Also, these patients were more likely to reccieve PRBCs, and MCT-containing nutritional supplementation. Based on our findings, we recommend that for preemies < 32 weeks, blood for NBS be obtained prior to the start of TPN or transfusion, as this may reduce the number of presumptive positives. If this is not possible, an acylcarntine profile, along with free and total carnitine, and urine organics should be obtained, once the child is on PO feeds that do not contain MCT oil.

17q duplication: a rare chromosomal abnormality associated with brachyrhizomelia. *D.F. Garcia[1], C.M. Lourenço[1], A.C. Laus[2], S.A. Santos[2], L. Martelli[1,2]* 1) Medical Genetics Division, School of Medicine of Ribeirao Preto, University of Sao Paulo, Brazil; 2) Department of Genetics, School of Medicine of Ribeirao Preto, University of Sao Paulo, Brazil.

Abnormalities of chromosome 17 are relatively rare , apart from those found in hematologic malignancies such as the isochromosome 17q. Duplication 17q has been associated with a clinically recognizable syndrome, characterized by psychomotor retardation, short stature, microcephaly, narrow palpebral fissures, flat nasal bridge, long philtrum, cleft palate, large mouth, thin upper lip, low-set and malformed ears, brachyrhizomelia and hyperlaxity of limb joints. In addition, cardiac and cerebral anomalies are described. We report a female with 17q duplication and severe rhizomelic shortening of the limbs and brachydactyly. The patient is a 18 month-old female, the first child of healthy, young and non-consanguineous parents. She was born at term and by cesarean delivery. Her birth weight was 1900g, length 64.5cm and OFC41.5cm (all bellow 3rd percentile). She had a patent ductus arteriosus surgically corrected soon after birth. She developed seizures with one month-old and had delayed milestones. Physical exam showed microcephaly, curly hair with alopecia areas, midface hypoplasia, bulging eyes with convergent strabismus, short neck, short nose with depressed nasal bridge, low-set and posteriorly rotated ears, umbilical hernia, bilateral clinodactyly of 5th fingers, brachydactyly and rhizomelic limb shortness. Her x-rays showed no metaphyseal anomaly or calcifications. Abdominal and cranial ultrasonography were normal.Blood karyotype showed duplication of the distal region of 17q in all metaphases. Parental karyotypes were normal. Until now, few liveborn cases of partial trisomy for the distal region of 17q were reported. Cases of 17q duplication show marked variability in clinical expression, possibly related to the extent of the duplicated segment. A study of more patients is needed to refine the phenotypic mapping of chromosome 17 and to correlate different clinical syndromes with the extent of the 17q duplication.

Major locus for Centrotemporal Sharp Waves in Rolandic Epilepsy families maps to chromosome 11p. *L.J. Strug[1], T. Clarke[2], B. Bali[2], P.L. Murphy[2], D.A. Greenberg[1], D.K. Pal[2]* 1) Dept Biostatistics, Columbia Univ, New York, NY; 2) Dept Epidemiology, Columbia University, New York, NY.

Introduction: Centrotemporal sharp waves (CTS) are the EEG hallmark of rolandic epilepsy (RE). CTS are also found in many other neurodevelopmental disorders including autism. RE and its characteristic EEG trait is presumed to be genetic. Although not yet established, the inheritance of RE appears complex while the inheritance of CTS appears autosomal dominant. We conducted a linkage study of CTS in RE families to determine a region of the genome that contributes to the etiology of CTS in RE families. **Methods:** We ascertained 40 families for linkage through a single RE proband. By definition, all RE probands have the CTS trait. Their siblings (age 4 to 16 years) underwent sleep-deprived EEG to determine their CTS status. Observations from individuals without an EEG, or those remaining awake without showing CTS were treated as unknown in the linkage analysis. We used GENEHUNTER and a modified version of LIPED to perform multipoint and two-point linkage analysis, respectively. We analyzed our families assuming dominant (gene frequency = 0.006) and recessive (gene frequency = 0.1) modes of inheritance, maximizing over penetrance. **Results:** We observed a maximum multipoint lod score of 4.30 at marker D11S914 on chromosome 11, assuming a dominant mode of inheritance, no heterogeneity, and 50% penetrance. The maximum two-point lod score at D11S914 was 3.1. **Conclusions:** A locus at chromosome 11p12-p13, inherited dominantly with incomplete penetrance, plays a major role in determining the presence of CTS in RE families. This locus overlaps that recently reported in a genomewide screen for autism (Szatmari et al, 2007). We will conduct fine mapping studies to localize the gene responsible for the strong linkage signal.

A genotype-phenotype correlation of small supernumerary marker chromosomes (sSMC) in human. *T. Liehr[1], K. Mrasek[1], N. Kosyakova[1,2], J. Vermeesch[3], S.W. Cheung[4], A. Weise[1]* 1) Institute of Human Genetics and Anthropology, Friedrich Schiller University, Jena; Germany; 2) Research Centre for Medical Genetics, Russian Academy of Medical Sciences Moscow, Russia; 3) Center for Human Genetics, University Hospital Leuven, Herestraat 49, Leuven, Belgium; 4) Baylor College of Medicine, Houston, Texas, USA.

Small supernumerary marker chromosomes (sSMC) are present in 0.044% of newborn and 0.075% of prenatal cases. In infertile or mentally retarded 0.125% or 0.288% are sSMC-carriers, respectively (Liehr & Weise 2007, Int J Mol Med 19:719-31). Overall, in about 30% of sSMC carriers an abnormal phenotype is observed. However, individual clinical outcome of sSMC presence is difficult to predict. Phenotypic consequences can appear due to differences in euchromatic DNA-content, uniparental disomy of the sSMCs homologous chromosomes, and/or different degrees of mosaicism. We did own studies on ~400 cases with sSMC using (sub)centromer-specific probe-sets and/or array-CGH. Moreover, we performed a review of the literature and thus, we suggested a first chromosome specific genotype/phenotype correlation for sSMC (Liehr et al., 2006 Cytogenet Genome Res 112:23-34) based on ~1650 cases. At present (04/2007) the sSMC-homepage (http://www.med.uni-jena.de/fish/sSMC/00START.htm) comprises ~2400 cases with sSMC. Thus, we are now able to present upgraded data on centromere-near chromosomal imbalances and their clinical consequences. Interestingly, clinically normal cases are reported, which have - due to sSMC presence - partial trisomies of several MB in size. The possible mechanisms involved have to be determined in future studies. In summary, ~50 year after first description of an sSMC, molecular cytogenetics provides now approaches for the comprehensive characterization of these marker chromosomes. This will lead to an improved genetic counseling of cases especially with de novo sSMC and it will be possible to define clear syndromes within the clinically and genetically group of patients with sSMC. Supported by the DFG (436 WER 17/5/05, 436 RUS 17/22/06, WE 3617/2-1, LI820/11-1), Boehringer Ingelheim Fonds, Ev. Studienwerk Villigst.

Gene Regulation Studies of the Friedreich Ataxia Locus Using Genomic Reporter Assays. *N. Puspasari[1,2], P.A. Ioannou[1,2], M.B. Delatycki[1,2], J.P. Sarsero[1]* 1) Bruce Lefroy Centre for Genetic Health Reserach, Murdoch Childrens Research Institute, Royal Childrens Hospital, Parkville, Victoria, Australia; 2) Department of Paediatrics, The University of Melbourne, Royal Childrens Hospital, Parkville, Victoria, Australia.

Friedreich ataxia (FA) is a progressive cardio and neurodegenerative disease caused by a trinucleotide repeat expansion in the first intron of the *FXN* gene, resulting in the insufficiency of frataxin protein production but not its complete loss. As the coding sequence of the *FXN* gene is unaltered, targeted upregulation of gene expression may restore cellular frataxin to therapeutic levels in patients. Unravelling the mechanisms that regulate *FXN* gene expression would therefore lead to a rational approach for the pharmacological restoration of frataxin levels and the therapy of FA. However, no information is currently available about the position of any long-range, *cis*-acting regulatory sequences that regulate human *FXN* gene expression. We have established a system for the bioinformatic identification and experimental verification of regulatory mechanisms that direct the expression of the *FXN* gene. Utilisation of data from the sequence assemblies of the human and other mammalian genomes for cross-species comparative genomics analysis has identified a number of conserved, non-coding regions surrounding the *FXN* gene. To investigate the role of these regions identified in human gene, we have developed a dual-reporter BAC vector that contains an *FXN-EGFP* genomic reporter consisting of the fusion of the EGFP gene to the entire normal genomic human *FXN* locus on a BAC clone. The construct also contains an independently expressed gene encoding DsRed-Express fluorescent protein as an internal control. The roles of the conserved, non-coding sequences is being evaluated by their deletion or modification in the context of the *FXN-EGFP* genomic reporter, The EGFP/DsRed-Express ratio will provide a sensitive and specific assay for detecting the effects of deletions of regulatory regions of the gene while simultaneously allowing for correction of differing transfection efficiencies.

Identification of a point mutation associated with SMA by direct sequencing of genomic DNA. *K. Segers, V. Mathias, S. Gaillez, V. Bours* Dept Human Genetics, CHU Sart Tilman, Liege, Belgium.

Spinal muscular atrophy (SMA) is an autosomal recessive disease characterised by degeneration of motor neurones of the anterior horn of the spinal cord. Spinal muscular atrophy is linked to locus 5q13 in more than 95% of patients. This region, containing the SMN1 gene (Survival Motor Neurone) associated with SMA, is inverted and duplicated. SMN2 is a highly homologous gene located in the centromeric duplicated region. Homozygous deletion of SMN1, located in the telomeric position, accounts for the disease in 98% of patients and has been reported in infantile, intermediate and adult onset disease. Some small intragenic SMN1 mutations have also been described. Sequencing of the SMN1 gene at the genomic level is complicated by the presence of the homologous SMN2 gene. Search for point mutation is usually performed from cloned cDNA of the SMN1 gene. Here we report the identification of a point mutation, p.Y272C, by direct sequencing of the SMN genes at the genomic level in DNA stored from a deceased baby affected by Werdnig Hoffmann syndrome. This analysis permit to confirm the clinical diagnostic and to identify SMA carrier in the family. This result shows the relevance of performing sequencing at genomic level for SMA diagnostic.

Hax1 gene mutation in an Iranian family affected to Kostmann disease and result of PND in the 5th pregnancy.

G. Vakili[1], Y. Shafeghati[1], H. Abolghasemi[2], M. Horwitz[3] 1) Genetics Research Center, University of Social Welfare sciences and Rehabilita, Tehran, Iran; 2) Baghyatallah Hosp.and Medical Science University, Tehran, Iran; 3) Medical Genetic Div., Dept.Medicine, University of Washington, Seattle, USA.

Severe congenital neutropenia (SCN) or Kostmann syndrome is a rare type of neutropenia. It is inherited by autosomal recessive pattern. Consanguineous marriage mostly is a predisposing factor. Patients suffer from severe and recurrent bacterial infections (pneumonia, otitis media, abcesses, and.....). This disease was reported by Kostmann in a large consanguineous family from Northern part of the Sweden (1956). In this report we will present an Iranian family, with two affected children and two abortion. Parents are second cousins. Both of the sibs showed neutropenia from early infancy. They have had recurrent severe bacterial infections. The older one was a boy, who showed Myelodysplastic (MDS) changes after the age of 15 and died from AML when he was 16-year-old. The younger one is a 14-year-old girl just with the similar symptoms. The response of both of them was favorable to G-CSF. Mutation analysis of the ELA2 gene by direct DNA sequencing of PCR-amplified genomic DNA did not identify any abnormalities. In searching of mutations in other candidate genes, a homozygous mutation found in HAX1 gene in the proband, and each of the parents was heterozygous carrier for the mutation. The mutation was W44X, same as described by Klein and Welte in their Nature Genetics paper. After mutation detection in the family, the mother became pregnant. But the fetus was homozygote for the mutation.The family decided to terminate the pregnancy.

Biological Process of Aging: A Study on antioxidant enzymes, DNA damage, Smoking and Body mass index.

P.K.R. THAVANATI[1], K.R.R. KANALA[2], A. ESCOTO DE DIOS[3], J.M. CANTU GARZA[1] 1) Instituto de Genetica, Departamento de Biologia Molecular y Genomica, Centro Universitario de Ciencias de la Salud, Universidad de Guadalajara, 950 Sierra Mojada, Col.Independencia, Guadalajara. Jal. 44340, Mexico; 2) Department of Anthropology, School of Biological & Earth Sciences, Sri Venkateswara University, Tirupati-517 502. Andhra Pradesh. India; 3) Genetica, Centro de Investigacion Biomedica de Occidente, Instituto Mexicano del Seguro Social, 900 Sierra Mojada, Col. Independencia, Guadalajara. Jal. 44340, Mexico.

Oxidative damage to DNA is shown to be extensive and could be a major cause of physiological changes associated with aging and degenerative diseases such as cancer, cardiovascular diseases, immune-system decline, diabetes mellitus etc.,. Antioxidants are believed to decrease the attacks on DNA by free radicals and thus, protect against mutations that cause disease status. It has also postulated that, variation in the life-style measures act as stimulants of free radical generation, DNA damage and reduced antioxigenic potential. Understanding how such damage contributes to age-related changes requires attention to explain how these different mechanisms relate and potentially interact with each other. The present study involves the findings on endogenous antioxidant enzyme levels and DNA damage which are critically examined in order to evaluate whether oxidants do contribute to the initiation and / or propagation of ageing for which 220 healthy male volunteer samples from the defined electoral area (suburbs of Tirupati, Andhra Pradesh, India) aged 20-80 years were studied for the evaluation of lymphocyte antioxidant enzymes i.e., glutathione S-transferase, superoxide dismutase, catalase and DNA damage in relation to smoking and BMI. A two fold increase of lymphocyte free radical generation and DNA damage in older than in younger age groups is observed. And, an increased free radical generation and reduced antioxidant potential form a link between cigarette smoking and oxidative stress represented by antioxidant imbalance. Body mass index had a positive relation with oxidative stress but, antioxidant levels didnt vary with.

Associated malformations in patients with abdominal wall defects. *C. Stoll, Y. Alembik, B. Dott, M.P. Roth*
Genetique Medicale, Faculté de Médecine, Strasbourg, France.

Gastroschisis and omphalocele (exomphalos) are the most common types of congenital abdominal wall defects(AWD).The reported types of associated malformations in AWD vary between different studies,as well as the percentage of associated malformations. The purpose of this investigation was to assess,in a geographically defined population, the prevalences at birth of associated malformations in patients with AWD which were ascertained between 1979 and 2003 in 334,262 consecutive births.Of the 86 patients with omphalocele (total prevalence 2.57 per 10,000),64 had associated malformations which were further classified into groups with chromosomal abnormalities(25 cases),non chromosomal recognized syndromes including Goltz, Beckwith-Wiedeman, Marshall-Smith,Meckel-Gruber,Oto-palato-digital type II, pentalogy of Cantrell, CHARGE, and fetal valproate; sequences,including body stalk anomaly, exstrophy of bladder,and OEIS; and patients with non syndromic multiple congenital anomalies(MCA)(26 cases).Malformations of the musculo-skeletal system,the urogenital system,the cardiovascular system,and the central nervous system were the most common other congenital anomalies occurring in patients with MCA. For gastroschisis,the total prevalence was 1.85 per 10,000.However,there was a significant increase over the study period in the total prevalence.The maternal age-specific prevalence was highest in the 15-19 year age group.Of the 62 patients with gastroschisis,12 had associated malformations including one chromosomal abnormality, 2 limb-body wall complex, one skeletal dysplasia, one amyoplasia congenita, and 7 non syndromic MCA. Prenatal detection identified all the cases with AWD after 1999. In conclusion the overall prevalence of associated malformations, which was close to three in four patients in omphalocele and to one in five patients in gastroschisis, emphasizes the need for a thorough investigation of patients with AWD. A routine screening for other malformations need to be considered in patients with AWD. Genetic counseling seems warranted in most of these complicated cases.

Associated malformations in patients with anorectal malformations. *M.P. Roth, B. Dott, Y. Alembik, C. Stoll*
Genetique Medicale, Faculté de Médecine, Strasbourg, France.

Patients with congenital anorectal malformations (ARM) often have other associated congenital defects. The reported incidence and the types of associated malformations vary between different studies. The purpose of this investigation was to assess the prevalences at birth of associated malformations in patients of a geographically defined population with ARM which were collected between 1979 and 2003 in 334,262 consecutive births. Of the 174 patients with ARM during the study period, 49.4% had associated malformations.Patients with associated malformations were further classified into groups with non syndromic multiple congenital anomalies; chromosomal abnormalities; non chromosomal syndromes including Townes-Brocks, Walker-Warburg, Ivemark,Fetal alcohol,Klippel Feil,Pallister-Hall,Facio-auriculo-vertebral spectrum, deletion 22q11.2;sequences,including OEIS,Pierre Robin and sirenomelia;and associations including VATER and MURCS. Malformations of the urogenital system (81.1%) and of the skeletal system (45.5%)were the most common other congenital anomalies occurring with ARM in multiply malformed patients without recognized entities, fol¬lowed by malformations of the cardiovascular system,the digestive system,and the central nervous system. Weight, length, and head circumference of children with ARM and multiple associated malformations were lower than in controls, as was the weight of the placenta. Prenatal detection by fetal ultrasonographic examination was rarely made in isolated ARM. However, even in multiple associated malformations, prenatal detection by fetal ultrasonographic examination had a low sensitivity, 36%.In conclusion the overall prevalence of malformations, which was close to one in two infants, emphasizes the need for a thorough investigation of patients with ARM. A routine screening for other malformations may be considered in patients with ARM, and genetic counseling seems warranted in most of these complicated cases.

The importance of updating the family cancer history: Longitudinal risk assessments of 2508 breast cancer survivors. *L. Madlensky, WHEL Study Group* Moores UCSD Cancer Center, UC San Diego, San Diego, CA.

BACKGROUND: Eligibility for cancer syndrome genetic testing is largely based on family history criteria. Over time, pedigrees change as family members are diagnosed with new cancers. We sought to quantify the change in the proportion of breast cancer patients eligible for BRCA testing over a period of time.
METHOD: Data were obtained from the WHEL study, a randomized trial of diet in breast cancer survivors. Detailed cancer family histories were taken at baseline and again at study exit (mean 7.5 yrs later, range 5-11 yrs). We classified women as eligible if they had at least a 10% risk of a BRCA1/2 mutation according to the Myriad prevalence tables. At study exit, we also asked women to self-report whether they ever heard of BRCA testing, and if they had ever had testing.
RESULTS: A total of 2508 women provided both baseline and exit data. At baseline, 206 (8.2%) were classified as eligible for BRCA testing. At study exit, an additional 150 women (6%) were eligible. Of those eligible at baseline, 39 (18.9%) experienced new breast cancer diagnoses (age 50) or ovarian cancers in their families vs. 309 women (13.4%) who were not initially eligible at baseline (p=0.028). At study exit, 15% of those eligible had never heard of BRCA1/2 testing while 25% of those not eligible had not heard of testing (p0.001). Of those who had heard of testing, 24% of those eligible vs. 7% of those not eligible reported undergoing testing (p0.001).
CONCLUSIONS: Our data represent the largest report to date of changes in cancer family history over time. As these data were not obtained from high-risk genetics clinics, the results are relatively applicable to a community sample. However, our clinical trial sample was predominantly White and highly educated limiting broad generalization. The number of breast cancer survivors with high risk family histories nearly doubled over a relatively short period of time, underscoring the importance of updating the cancer family history in clinical practice.

52,608 gene-based SNPs association study to identify genes related to myocardial infarction. *K. Ozaki[1], H. Sato[2], A. Iida[1], H. Mizuno[2], A. Takahashi[1], T. Nakamura[1], H. Lwin[1], S. Ikegawa[1], M. Hori[2], Y. Nakamura[1], T. Tanaka[1]* 1) SNP research center, RIKEN, Tokyo, Japan; 2) 2) Department of Internal Medicine and Therapeutics, Osaka University Graduate School of Medicine, Osaka, Japan.

To clarify genetic backgrounds in the pathogenesis of myocardial infarction (MI), we have performed large scale case-control association study in a Japanese population using 52,608 haplotype-based single-nucleotide polymorphism (SNP) markers. We have identified two susceptible loci on chromosome 22q12.1 and 3p21.2-p21.1. Following linkage disequilibrium (LD) mapping and haplotype analyses revealed that six SNPs of novel gene on chromosome 22q12.1, all of which were in complete LD, and a SNP in the inter-alpha (globulin) inhibitor 3 gene (*ITIH3*) on chromosome 3p21.2-p21.1 showed markedly significant association with MI (^{2}=25.27, *P*=0.0000005 for one SNP in the novel gene, ^{2}=24.88, *P*=0.00000061 for a synonymous SNP in exon 2 of *ITIH3*; comparison of allele frequency, approximately 3,400 affected individuals versus 3,800 controls). Within first locus, we isolated a complete cDNA of a novel gene, designated *MIAT* (myocardial infarction associated transcript). *MIAT* has five exons and in vitro translation assay showed that *MIAT* did not encode any translational product, indicating that this is likely to be a functional RNA. In vitro functional analyses for SNPs in *MIAT* and *ITIH3* revealed that the minor variant of one SNP in exon 5 of *MIAT* and the major variant of the SNP in *ITIH3* increased transcriptional level to each of the gene. Moreover, unidentified nuclear protein(s) bound more intensely to risk allele than non-risk allele in the case of *MIAT*, and two different proteins bound to each of the allele for the SNP in *ITIH3*. Our findings suggest that *MIAT* and *ITIH3* SNPs are novel genetic risk factors of MI.

Identification of functional SNPs in TIM3 promoter region. *J. Zhang, J. He, A. Sandford, P. Paré* Respiratory Medicine Division, St. Paul's Hospital iCAPTURE Center, Vancouver, B.C., Canada.

Background: T-cell immunoglobulin mucin-3 (TIM3) is a TH1-specific type 1 membrane protein that regulates TH1 proliferation and the development of tolerance. TIM3 protein and its genetic variants have been suggested to play a role in regulating allergic diseases. One association study reported that 3 single nucleotide polymorphisms (SNPs) in TIM3 were significantly related to atopy and eczema using white and Hispanic family samples. Similar results were obtained using Korean samples. Objective: The aim of this study is to determine the promoter region of TIM3 and the influence of genetic variation in that region on transcriptional regulation of TIM3. Methods: We performed 5' rapid amplification of cDNA ends (RACE) and reverse transcription-polymerase chain reaction (RT-PCR). We screened for polymorphisms in the promoter region. Deletion analysis was used to localize the promoter region of TIM3. Results: We found that there are two promoter regions in TIM3. One is from -214 bp to +58 bp and another is from -1.6 kb to -914 bp relative to the transcription start site. None of the SNPs or the haplotype affected the transcriptional activity. Conclusion: Our findings indicate that SNPs and haplotypes in TIM3 promoter region do not have a functional effect but it is possible that other SNPs in the gene could account for the association with asthma.

A dysmorphic newborn with partial monosomy of 7q36-->qter and partial trisomy of p24-->pter. *M. SOYLEMEZ, G. TOKSOY, C. SAYAR, A. GIRAY, T. YARDIMCI, B. TURKOVER* DEPARTMENT OF GENETICS, ZEYNEP KAMIL WOMAN AND CHILDREN HOSPITAL, ISTANBUL, Turkey.

We report on a 3 month-old male presenting with intrauterin growth retardation, facial dysmorphic features such as "premature craniosynostosis, microphthalmia, blepharophimosis, narrow forehead, bitemporal narrowing, large ears", mental retardation, cardiac defects, microcephaly and hypotonia. Cytogenetic studies revealed an apparent robertsonian translocation between chromosome 15 and 22. Additional material on chromosome 7q was identified and determined to be from chromosome 3p by analysis with fluorescence in situ hybridization (FISH). The karyotype is 45,XY,der(15;22)(q10;q10),add(7)(q36).ish t(3;7)(p24;q36) de novo. His father and mother had a normal karyotype. The robertsonian translocation seen in all metaphases between 15 and 22 chromosomes was not expected to explain dysmorphic features. It was concluded that the phenotypic features were due to partial monosomy of 7q36-->qter and partial trisomy of 3p24-->pter.

Recruitment Approaches for a Cancer Registry-Based Study of BRCA1/2 Mutations among Young African American Breast Cancer Patients. *S.T. Vadaparampil[1,2], J. Weber[2], J.A. Betts[2], T. Pal[1,2]* 1) Dept. of Interdisciplinary Oncology, University of South Florida College of Medicine, Tampa, FL; 2) Div. of Cancer Prevention and Control, H. Lee Moffitt Cancer Center and Research Institute, Tampa, FL.

The prevalence and penetrance of BRCA1/2 mutations in the African American (AA) community is largely unknown. This lack of knowledge is perpetuated by low rates of participation by AA women in clinical and research BRCA1/2 genetic counseling and testing. This abstract describes approaches, materials, and procedures developed to promote participation in a population-based study of BRCA1/2 mutations among young AA women with early onset breast cancer recruited through the Florida Cancer Data System (FCDS). Study recruitment involves 2 mailed contacts followed by a phone call from the study team. A multi-step approach to optimize recruitment at each of these contact points was implemented using: (1) a Community Advisory Panel (CAP) to develop and refine the study recruitment brochure, phone script, questionnaire, and procedures; (2) pilot testing of materials with the target audience; and (3) review of pilot testing results with the CAP. Based on this process, the study brochure was modified to include personal vignettes and photos of AA women, the terms Women of Color and Black Women, and the legacy that BRCA1/2 testing may leave for the family and AA community as a whole. The recruitment phone script was modified to highlight information about the relationship of BRCA1/2 genes and early onset breast cancer in AA women. The study questionnaire now includes lay explanations of medical terms that were difficult for participants to understand and preparatory suggestions to shorten interview time. Finally, study procedures now include the option of telephone-based genetic counseling and an in-home blood collection process to minimize participant time and travel burdens. By utilizing these methods, the study team hopes to increase participation among young AA breast cancer patients. The lessons learned from the current study can be applied to other genetics studies recruiting individuals from a variety of cultural and ethnic backgrounds.

Genomic Heritage of Axillary Lymph Node Metastases in Breast Cancer Patients. *H.L. Patney[1], T.E. Becker[1,3], B. Deyarmin[1], R.M. Jordan[1], J.A. Hooke[3], R.E. Ellsworth[1,2], C.D. Shriver[3], D.L. Ellsworth[1]* 1) Clinical Breast Care Project, Windber Research Inst, Windber, PA; 2) Henry M. Jackson Foundation for the Advancement of Military Medicine, Rockville, MD; 3) Clinical Breast Care Project, Walter Reed Army Medical Center, Washington, DC.

Metastatic breast cancer is an aggressive disease associated with recurrence and decreased survival. To better understand how genomic alterations in metastases may affect outcome in patients with metastatic disease, we used allelic imbalance to determine the molecular heritage of primary breast tumors and corresponding metastases to the axillary lymph nodes. Paraffin-embedded samples from primary breast tumors and matched metastases (n=146) were collected from 26 patients with node-positive breast cancer involving multiple axillary nodes. Hierarchical clustering was used to assess overall differences in patterns of allelic imbalance and phylogenetic analysis inferred the molecular heritage of axillary lymph node metastases. Genetically divergent lineages of metastatic tumors were present in the axillary lymph nodes, suggesting that multiple molecular mechanisms may govern the process of metastasis in individual patients. Progenitor cells for some metastases appeared to acquire metastatic potential early in the disease process and progressed with few genomic alterations, while other metastases may have developed later and harbored many chromosomal alterations present in the primary tumor. Genomic heterogeneity among axillary lymph node metastases may be associated with response to adjuvant therapy, recurrence, and survival, and thus may be important to improving clinical management of breast cancer patients.

Augmented androgen production in Polycystic Ovary Syndrome: Genetic assessment in an Indian cohort. *A. Maitra, M.K. Pusalkar, J.S. Gokral, C. Saravanan, P.K. Meherji* Molecular Endocrinology, National Inst. For Research in Reproductive Health, Mumbai, Maharashtra, India.

Polycystic ovary Syndrome (PCOS) is a common cause of infertility in females, affecting about 5-10% of women worldwide. The syndrome is known to have a complex multigenetic basis. However genetic variations underlying it have still not been defined. Available evidence through in vitro cultures as well as global gene expression profiling of theca cells from PCOS ovaries suggests involvement of promoters of two genes in androgen pathway viz. CYP11A1 and CYP17 in augmentation of androgen production as seen in the syndrome. Present study aims at identifying genetic variants in these promoters vis a vis their association with raised androgen levels. A pentanucleotide repeat (tttta) polymorphism in CYP11A1 and a T>C polymorphism in CYP17 were screened. A cohort of 97 consecutively identified Indian women with PCOS were studied along with 45 age and BMI matched controls. Diagnosis of PCOS was based on the consensus definition specified in Rotterdam Conference (2003-2004). Androgen profile included Testosterone, Androstenedione, DHEAS and 17- Hydroxyprogesterone. Promoters for CYP11A1 and CYP17 were screened by PCR-sequencing from genomic DNA. Testosterone and Androstenedione levels were significantly increased in the PCOS subjects compared to controls ($p<0.05$). The increase was associated with T>C polymorphism in the CYP17 promoter. The polymorphic allele was also significantly higher in frequency in the PCOS group compared to controls. CYP 11A1 and CYP17 were both found to be polymorphic in about 50% of the PCOS cases, which was significant compared to controls. Their association with raised androgens was also seen. The study for the first time reports allelic frequencies of the CYP11A1 and CYP17 promoter variants in an Indian cohort. Association of these variants with PCOS and raised androgens is also highlighted from this screening of a limited, but defined group of women.

Screening for sickle cell disease on dried blood: the application of a new ELISA-test on African newborns. *L. Mutesa[1], F. Boemer[1], L. Ngendahayo[2], S. Rurisa[3], E.K. Rusingiza[4], N. Cwinya-Ay[4], D. Mazina[5], P.C. Kariyo[6], R. Schoos[1], V. Bours[1]* 1) Center for Human Genetics, Univ Liege, Belgium, Liege, Belgium; 2) Department of Pathology, National University of Rwanda, Butare, Rwanda; 3) Department of Obstetrics and Gynecology, National University of Rwanda, Kigali, Rwanda; 4) Department of Pediatrics, National University of Rwanda, Butare, Rwanda; 5) Department of Public Health, University of Liege, Liege, Belgium; 6) Department of Pediatrics, University of Burundi, Bujumbura, Burundi.

Objectives: To evaluate the feasibility of a systematic neonatal screening for sickle cell disease in the region of Great Lakes in Central Africa using a new approach with limited costs. Setting: Sickle cell disease is a major public health problem in Africa. Methods: Between July 2004 and July 2006, 1825 newborn dried blood samples were collected onto filter papers in four maternity units from Burundi, Rwanda, and the East of the Democratic Republic of Congo. We tested the presence of hemoglobin C and S in the eluted blood by an enzyme-linked immunosorbent assay (ELISA) test using a monoclonal antibody. All ELISA positive samples (Multiple of median above 1.5) were confirmed by a simple molecular test (PCR-restriction). The statistica software version 7.1 was used to create graphics and to fix level of MoM cut-off, whereas the chi-square of Pearson was used to compare the genotype incidences between countries. Results: Among the 1825 newborn samples screened by ELISA-test, 97 (5.32 %) were positive. Sixty (3.28 %) of these samples were heterozygous for Hb S, 4 (0,22 %) for Hb C, whereas 2 (0,11 %) newborns were Hb SS homozygotes. Conclusions: The lower cost and the high specificity of ELISA-test are appropriate for developing countries, and such a systematic screening for sickle cell anemia is therefore feasible.

Sperm aneuploidy frequencies analyzed before and after chemotherapy in testicular cancer and Hodgkins lymphoma patients. *H.G. Tempest[1], E. Ko[1], P. Chan[2], B. Robaire[2], A. Rademaker[3], R.H. Martin[1]* 1) Department of Medical Genetics, University of Calgary, Calgary, Alberta, Canada; 2) Department of Pharmacology and Therapeutics, McGill University, Montreal, Quebec, Canada; 3) Department of Preventative Medicine, Northwestern University, Chicago, Illinois, USA.

In this study, multi-color fluorescent in-situ hybridization (FISH) was utilized to detect sperm aneuploidy for chromosomes 13, 21, X and Y in individuals before and after chemotherapy for testicular cancer (n=12) and Hodgkins lymphoma (n=11). Aneuploidy was assessed before, 6 months and 1-2 years after the initiation of treatment and compared to age matched controls (n=19). Slides were coded and analyzed blindly with a minimum of 5,000 sperm cells scored per patient, per chromosome at each time point where sperm was available (635,396 sperm scored). At 6 months, testicular cancer and Hodgkins lymphoma patients showed significant increases in XY disomy and nullisomy 13 frequencies, and significantly higher frequencies of sex chromosome disomy and nullisomy 21 were found in testicular cancer patients. Aneuploidy frequencies, for the most part, declined to pre-treatment levels at 12 months. However, there were elevated aneuploidy frequencies for some chromosomes up to 24 months after the intiation of treatment. When Hodgkin's lymphoma and testicular cancer patients were compared to each other and with controls, cancer specific differences were identified. Hodgkins lymphoma patients, in particular, exhibited a significant increase in aneuploidy frequencies for all chromosomes at all time points compared to controls and testicular cancer patients. Because of elevated aneuploidy frequencies prior to and up to 24 months from the start of chemotherapy, and to facilitate informed decisions regarding their future reproductive choices, patients should receive genetic counseling about the potentially increased risk of an aneuploid conceptus from sperm cryopreserved prior to chemotherapy, and for conceptions up to two years from the initiation of treatment.

A generalized combinatorial approach for detecting gene by gene and gene by environment interactions. *X.-Y. Lou[1], G.-B. Chen[1], L. Yan[2], J.Z. Ma[3], J. Zhu[2], R.C. Elston[4], M.D. Li[1]* 1) Dept Psychiatry & Neurobehavioral Sciences, Univ Virginia, Charlottesville, VA; 2) Institute of Bioinformatics, Zhejiang University, Hangzhou, P. R. China; 3) Dept Public Health Sciences, Univ Virginia, Charlottesville, VA; 4) Department of Epidemiology and Dept Biostatistics, Case Western Reserve University, Cleveland, OH.

The widespread multifactor interactions pose a significant challenge to identifying genetic determinants involved in complex diseases. The traditional methods are typically underpowered because of the problem referred to as the curse of dimensionality. Currently available combinatorial approaches, such as the multifactor dimensionality reduction method (MDR), the combinatorial partitioning method (CPM), and the restricted partition method (RPM), are promising tools and have a straightforward correspondence to the concept of the phenotype landscape that unifies biological, statistical genetic and evolutionary theories. However, they do have limitations, such as not allowing for covariates, which restrict their practical use. In this study, we develop a generalized MDR (GMDR) by using a class of more efficient and comprehensive statistics (e.g., the score statistic) that permits adjustment for discrete and quantitative covariates and is applicable to both dichotomous and continuous phenotypes in various population-based study designs. Benefiting from eliminating the background noise due to risk-conferring covariates, the new method has the increased prediction ability and statistical power compared with the existing combinatorial approaches in the literature. Computer simulations support our theoretical expectation and indicate that the GMDR method has superior performance in its ability to identify epistatic loci. In summary, GMDR can serve the purpose of identifying contributors to population variation better than do the other existing methods. The project is supported by NIH grant DA-12844.

Interactively and jointly contribution of CHRNA4, CHRNB2, BDNF and NTRK2 to tobacco dependence. *M.D. Li[1], X.-Y. Lou[1], G. Chen[1], J.Z. Ma[1], R.C. Elston[2]* 1) Department of Psychiatry and Neurobehavioral Sciences, University of Virginia, Charlottesville, VA; 2) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH.

Extensive epidemiological data indicate that vulnerabilities to nicotine dependence (ND) are influenced by genes, environmental factors, and their interaction. Our recent studies support a genetic association of the nicotinic receptor alpha 4 subunit (CHRNA4), brain-derived neurotrophic factor (BDNF), and neurotrophic tyrosine kinase receptor 2 (NTRK2) with ND. Although the interacting effects of BDNF with NTRK2 and CHRNA4 with CHRNB2 have been established experimentally using in vitro and animal models, no human genetic study is reported demonstrating that BDNF interacts with NTRK2 or CHRNA4 with CHRNB2 affecting smoking behavior. To determine if the four genes are affecting ND, we genotyped 6 SNPs for CHRNA4 and BDNF, 9 SNPs for NTRK2, and 4 SNPs for CHRNB2 in a case-control sample containing 275 unrelated smokers with a FTND score of 4.0 or more and 348 unrelated nonsmokers. By using a newly developed algorithm by this group, called generalized multifactor dimensionality reduction (GMDR) method, we found highly significant gene interaction effects on ND for the gene pairs of CHRNA4 and CHRNB2, CHRNA4 and NTRK2, CHRNB2 and NTRK2, and BDNF and NTRK2. Furthermore, we found a significant interaction of CHRNA4 and BDNF on ND. No significant interaction was detected for the genes CHRNB2 and BDNF. Together, this study provides evidence on the presence of interaction among the four genes in affecting ND. Although CHRNB2 alone was not associated with ND in several previously reported association studies on ND, we found it affects ND through interaction with CHRNA4 and NTRK2.

Comparison of spectrum of deletions within the CCM genes between Italian and American populations. *C.L. Liquori[1], S. Penco[2], T.P. Leedom[1], F. Squitieri[2], D.A. Marchuk[1], F. Gianfrancesco[3]* 1) Dept Molecular Gen & Microbiol, Duke Univ, Durham, NC; 2) Neurogenetics Unit IRCCS Neuromed, Pozzilli (IS), Italy; 3) Institute of Food Science, National Research Council, Avellino, Italy.

Cerebral cavernous malformations (CCMs) are vascular abnormalities of the brain that can cause a variety of neurological disabilities, including stroke and seizures. Familial forms of CCM are inherited in an autosomal dominant fashion and three CCM genes have been identified. We recently determined that large genomic deletions in the CCM2 gene represent 15% of mutations in a large CCM cohort from the U.S. A 77.6 kb deletion spanning CCM2 exons 2-10 displays an identical recombination event in 10 CCM families/probands, and haplotype analysis suggests that this common deletion derives from a founder mutation within our cohort. In the current study, we examined an Italian CCM cohort consisting of 24 CCM1, 2, 3 mutation-negative proband/families. The common CCM2 deletion spanning exons 2-10 is not present in this population. Further analysis of the Italian cohort by multiplex ligation-dependent probe analysis (MLPA) identified a total of 10 deletions - five in the CCM1 gene, four in the CCM2 gene, and one in the CCM3 gene. A duplication within the CCM2 gene was also identified. We conclude that there appear to be elements within all three of the CCM genes that predispose them to large deletion/duplication events. However, the common deletion spanning *CCM2* exons 2-10 appears to be specific to the U.S. population.

Training Students to be the Teachers: Using Peer Led Team Learning to Instruct Undergraduate Students as Science Museum Docents. *T.C. Rosser[1], R.E. Pyatt[2], K.R. Powell[3]* 1) Dept Human Genetics, Emory Univ Sch Medicine, Atlanta, GA; 2) Dept of Pathology, Ohio State University, Columbus, OH; 3) Center for Behavioral Neuroscience, Georgia State University, Atlanta, GA.

From June 2004 through January of 2005, the Fernbank Museum of Natural History in Atlanta hosted the traveling exhibit The Genomic Revolution described as the most comprehensive presentation on the complex subject of genomics at that time. The museum is typically self-guided but because of the complexity of the topic and a functional lab within the exhibit, it was decided to staff The Genomic Revolution with a team of paid undergraduate docents. A docent (derived from the latin word docere meaning to teach) serves as a bridge between the museum and the attendees, acting as the face and voice of the collection. Our challenge was to create a training program covering genetic principles along with the communication and leadership techniques needed for their interpretation in a museum setting. While the course content was organized around the physical arrangement of the exhibit, the basic structure was modeled on Peer Led Team Learning (PLTL). The PLTL system uses small group sessions to allow students to workshop challenging questions as a unit outside of direct instructor intervention. Each group has a student leader who demonstrates knowledge of the material, has shown outstanding leadership, and possesses good communication skills. Instruction began with a general review of concepts presented in a lecture format. All further training consisted of a short introduction for each section by an instructor followed by a PLTL workshop on that subject. Evaluation of the training program was conducted through student self assessment after two weeks working on the exhibit floor. Students reported a gain of knowledge in most of the areas covered such as Genetically Modified Organisms or Cloning and a majority felt the PLTL discussions on these subjects were very helpful in their training as a docent. PLTL successfully served as a framework in which to instruct students in the scientific content and promote the synthesis of that information which are both necessary as a museum docent. .

Multiplexed genotyping using a novel digitally inscribed bead-based system. *J. Yeakley[1], E. Chao[2], J. Velasquez[2], M. Lopez[2], T. McDaniel[1], I. Lewis[1], H. Chen[1], S. Oeser[1], R. Smith[1], M. Graige[1], S. Barnard[1], J. Sirkis[1], J. Moon[1], S. Lipkin[2]* 1) Research & Development, Illumina, Inc., San Diego, CA; 2) Dept. of Medicine, University of California Irvine, Irvine, CA.

Genotyping of clinical samples has been limited to low levels of multiplexing, ranging from one to a few dozen single nucleotide polymorphisms (SNPs) per sample. By increasing multiplexing levels, a clinical lab can increase information content per sample, decreasing costs and sample material requirements. We have adapted the GoldenGate Assay for simultaneously genotyping 96 to 1536 SNPs to the BeadXpress System, a new high-throughput platform that utilizes microbeads with unique, digitally inscribed holographic codes. Genotyping on this platform ranges from 96 to 384 multiplexing, using the same GoldenGate Assay that has proven highly robust for millions of genotypes. In preliminary tests, we have observed greater than 99% call rates, and greater than 99.5% rates for reproducibility and heritability. In a test of 96 SNP genotypes chosen for a study of colorectal cancer, a point mutation in the MSH2 gene, previously implicated in predisposition to several cancers, was correctly genotyped when compared to qPCR analysis of the same samples. Together with genotyping data from reference samples, the GoldenGate Assay on the BeadXpress System has yielded highly reproducible and accurate genotypes, suggesting that this approach will prove useful for rapid refinement of SNPs for development of clinical genotyping tests.

Single cell microRNA and mRNA profiling reveals global gene expression changes during mouse ES differentiation. *R. Tan[1], L. Bahreinifar[1], D. Ridzon[1], K. Guegler[1], W. Strauss[2], C. Chen[1]* 1) Applied Biosystems, Foster City, CA; 2) Department of Molecular, Cellular, & Developmental Biology, University of Colorado, Boulder, CO 80309.

We describe a new method for simultaneously quantifying mouse microRNA (miRNA) and target messenger RNA (mRNA) genes from each of 70 single cells. The method is based on multiplex RT, multiplex preamplification, and singleplex real-time TaqMan PCR assays. Single cell expression signature could classify individual ES, embryoid body (EB), and somatic cells. Significant inter-cell variations of both miRNA and mRNA expression were observed within or between ES cell lines, indicating the heterogeneity of ES cells. Highest variability was observed among EB cells, demonstrating that EB cells undergo differentiation at different stages. Interestingly, expression of ES marker gene OCT4 and signaling gene Tdgf1 was absent in 3T3 and splenocyte cells, highly expressed in ES cells, and significantly reduced in EB cells. Furthermore, there is no correlation in expression levels between miRNAs and their predicted target mRNAs, supporting translational repression model. Our results gain new insight of both miRNA and mRNA expression patterns at a single cell level.

Suggestive evidence for linkage of 5-Year Change in Bone Mineral Density to Chromosome 6q: The San Antonio Family Osteoporosis Study. *J.R. Shaffer[1], C.M. Kammerer[1], J.M. Bruder[2], S. Cole[3], T.D. Dyer[3], L. Almasy[3], J.W. MacCluer[3], J. Blangero[3], R.L. Bauer[2], B.D. Mitchell[4]* 1) University of Pittsburgh, Pittsburgh, PA; 2) University of Texas Health Science Center at San Antonio, San Antonio, TX; 3) Southwest Foundation for Biomedical Research, San Antonio, TX; 4) University of Maryland, Baltimore, MD.

Rapid bone loss in later life, particularly in those who have achieved low peak bone mineral density (BMD) in their earlier years, is a major contributor to osteoporosis and bone fracture. While cross-sectional studies have identified putative quantitative trait loci (QTLs) influencing variation in BMD, such studies cannot adequately distinguish loci affecting loss of BMD with age from those affecting the acquisition of peak bone mass occurring in young adulthood. To this end, we measured areal BMD (g/cm^2) of the hip by dual-energy x-ray absorptiometry at two time points and calculated 5-year annualized BMD change in 243 Mexican Americans (ages 45-65, 35% men) from 34 extended kinships (138 sibling pairs, 112 first-cousin pairs, and 86 other relative pairs). We then performed genome-wide linkage analysis of BMD change using a 10 cM density scan. We adjusted for the following covariates: sex, baseline BMD, baseline weight, menopausal status, and interim change in weight. The additive residual heritability for hip BMD change was 0.53 ($p = 0.006$). We observed suggestive evidence for linkage to chromosome 6q for hip BMD change (multipoint LOD = 2.5, cM = 103) near marker D6S1056. This locus was not implicated in our previously reported genome-wide linkage screen for cross-sectional BMD from this sample, and has not been reported in previous studies of BMD in other populations. This region may harbor one or more genes affecting the rate of BMD loss with age. Identifying the genes and pathways involved may provide important targets for therapeutic intervention to prevent age-related bone loss.

Investigation of mismatch repair protein expression in ovarian tumors. *J. Wey[1], D. Boulware[1], N. Valkov[2], S. Livingston[2], S. Nicosia[2], J-H. Lee[1], R. Sutphen[1], J. Schildkraut[3], S. Narod[4], T. Sellers[1], T. Pal[1]* 1) Moffitt Cancer Center, Tampa, FL; 2) Univ of S FL, Tampa, FL; 3) Duke, NC; 4) Univ of Toronto, Canada.

Background: The frequency of mismatch repair (MMR) deficiency in epithelial ovarian cancer (EOC) has ranged from 2-17%. Limited data exist regarding representative sampling from paraffin-embedded EOC tissue blocks utilized for construction of tissue microarrays (TMA) in preparation for immunohistochemistry(IHC). Methods: EOC tumor blocks from 59 cases were investigated by IHC for expression of hMLH1, hMSH2, and hMSH6. TMAs were created using three replicate 1 mm cores sampled from the center of a donor tissue block. Loss of expression of at least one protein was observed in an unexpectedly high number of cases, prompting creation of full sections of the donor blocks, which revealed lack of expression in the central portion, but positive expression in the periphery. Follow-up analyses for cases initially lacking expression were performed by obtaining cores from the periphery of up to 5 additional donor tissue blocks (triplicate cores per block). A linear mixed model for each protein was used to investigate differences between results from the initial donor block and follow-up blocks. Results: Loss of expression of at least one protein was revealed for 17 of the 59 (29%) cases. Follow-up analyses of the 17 cases that initially showed loss of protein expression revealed loss of expression in only 6 cases (10%). For each protein, statistically significant differences ($p<0.05$) were detected between the initial donor block and the majority of the follow-up blocks. Conclusions: When performing IHC analyses for loss of MMR protein expression in ovarian carcinomas, it is important to preferentially sample from the periphery of tumor blocks where exposure to tissue fixatives is optimal. This may reduce the likelihood of tissue fixation as the cause of the lack of protein expression.

International Variation in Rates of Uptake of Preventive Options in BRCA1 and BRCA2 Mutation Carriers. *K. Metcalfe[1,2], D. Birenbaum-Carmeli[3], J. Lubinski[4], J. Gronwald[4], H. Lynch[5], P. Moller[6], P. Ghadirian[7], W. Foulkes[8], E. Friedman[9], C. Kim-Sing[10], P. Ainsworth[11], B. Rosen[12], S. Domchek[13], T. Wagner[14], N. Tung[15], S. Manoukian[16], F. Couch[17], P. Sun[2], S. Narod[2]* 1) Faculty of Nursing, Univ Toronto, Toronto,Canada; 2) Women's College Research Institute, Toronto,Canada; 3) University of Haifa, Israel; 4) Pomeranian Medical University, Szczecin,Poland; 5) Creighton University School of Medicine, Omaha,USA; 6) Rikshospitalet-Radiumhospitalet Medical Centre, Oslo,Norway; 7) Centre Hospitalier de lUniversitaire Montréal,Canada; 8) McGill University, Montréal,Canada; 9) Tel-Aviv University, Israel; 10) British Columbia Cancer Agency Vancouver,Canada; 11) London Health Sciences Centre, London,Canada; 12) Princess Margaret Hospital, Toronto,Canada; 13) University of Pennsylvania, USA; 14) Medical University of Vienna and Private Trust for Breast Health, Austria; 15) Beth Israel Deaconess Medical Centre, Boston,USA; 16) Medical Genetics Service, Istituto Nazionale Tumori, Milan, Italy; 17) Mayo Clinic, Rochester, MN.

Objective: We report on preventive practices in women with mutations from 8 countries and examine differences in uptake by country. Methods: Women with a BRCA1/2 mutation were contacted and asked about cancer preventive practices. Results: 2365 women with a BRCA1 or BRCA2 mutation from 8 countries were included. The questionnaire was completed a mean of 4.0 years (range 1.5-10.3 years) after testing. 1390 women (59%) had a bilateral prophylactic oophorectomy. Of the 1198 women without breast cancer, 228 (19%) had had a prophylactic bilateral mastectomy. Among those who did not have a prophylactic mastectomy, only 49 women (5%) took tamoxifen for breast cancer prevention. Approximately half of the women at risk for breast cancer had taken no preventive option, and relied solely on screening. There were significant differences in the uptake of the preventive options by country. Conclusion: A minority of women with a BRCA1 or BRCA2 mutation opt for prophylactic mastectomy or take tamoxifen for the prevention of hereditary breast cancer. Approximately one-half of women at risk for breast cancer rely on screening alone.

Overlap between *WTX* and *WT1* mutations in Wilms tumors. *E.C. Ruteshouser, N. Alam, S.M. Robinson, V. Huff*
Department of Cancer Genetics, The University of Texas M. D. Anderson Cancer Center, Houston, TX.

Wilms tumor is genetically heterogeneous, and until recently only one Wilms tumor gene was known, *WT1* at 11p13. However, *WT1* is altered in only ~20% of Wilms tumors. A second Wilms tumor gene, *CTNNB1* encoding -catenin, is altered in ~15% of Wilms tumors, but *CTNNB1* mutations are rarely observed in the absence of *WT1* mutations. Recently a new Wilms tumor gene, *WTX* at Xq11.1, was reported (Rivera et al., *Science* 2007;315:642-5). This study identified mutations in *WTX* in 30% of a group of 51 Wilms tumors and reported no overlap between tumors with mutations in *WTX* and *WT1*.

To assess the frequency of *WTX* mutations and their relationship to *WT1* mutations in a second, larger panel of Wilms tumors (*n*=124), we conducted a complete mutational analysis of *WTX* that included sequencing of the entire coding region as well as quantitative PCR to identify deletions of the *WTX* gene. Twenty-six (21%) tumors carried a total of 27 *WTX* mutations; 7 of these were point mutations (5.6%) and 20 were deletions (16.1%). Surprisingly, given the results of the previous study, we observed an equal frequency of *WTX* mutations in tumors with *WT1* mutations (22.2%) and tumors with no *WT1* mutation (20.3%). However, *WTX* mutations were rare in tumors carrying known protein-stabilizing mutations of *CTNNB1*. *WTX* has been shown to negatively regulate WNT/-catenin signaling (Major et al., *Science* 2007;316:1043-6), and our data are consistent with this observation and suggest that *WTX* and *CTNNB1* mutations may be functionally redundant.

We assessed expression of *WTX* through real-time quantitative RT-PCR analysis and observed an apparently random distribution of *WTX* deletions between the active and inactive X chromosomes in Wilms tumors from females, with the deletions in 5/9 tumors occurring on the inactive X. Taking these data into account, we have found *WTX* mutations on the active X chromosome in 21 of 124, or 16.9%, of Wilms tumors overall. Our findings suggest that the process of Wilms tumorigenesis requires inactivation of more than one cellular pathway, one involving *WT1* and the other involving *CTNNB1* and *WTX*.

Predicting Gene Coverage: How many SNPs are enough? *A. Mukherjee[1], K. Roeder[2], B. Devlin[3]* 1) Univ Pittsburgh, Pittsburgh, PA; 2) Carnegie Mellon Univ, Pittsburgh, PA; 3) Univ Pittsburgh School of Medicine, Pittsburgh, PA.

In a candidate gene study the strategy is to measure a set of single nucleotide polymorphisms (SNPs) in the vicinity of each gene of interest and test for association. The effectiveness of these studies depends on how well the tag SNPs represent the genetic variation within the candidate genes. An effective set of tag SNPs will reveal association between the phenotype and one or more SNPs even when a causal polymorphism located in the proximity is not measured. Ideally one would choose the tag SNPs based on a complete catalog of genetic variants in the region; however, such a listing is often not available, and the best available resource is HapMap. Although the coverage of HapMap is good on average, it varies by region. The goal of this inquiry is to build a model using available covariates to determine whether or not the coverage of a particular gene is good. If the gene appears to be poorly tagged, additional work could be performed to obtain more SNPs in the region to evaluate the effectiveness of tag SNPs as proxies for potential causal alleles, we estimated how well they predicted unmeasured SNP genotypes in the proximity. To conduct this experiment we relied on the SeattleSNP database, which includes fully sequenced regions of the genome. The two databases have 173 genes with at least one SNP in common. Mean R^2 for each of these genes was calculated by regressing each non-tag SNP on the tag SNPs to determine the R^2. A classification and regression tree (CART) model was developed in which mean R^2 per gene was predicted by the number of tag SNPs, density of tag SNPs, and total SNP density. Including both common and rare SNPs, the average prediction using our CART model was high (55.8%). Even for genes with only 1-2 tag SNPs the mean prediction was good (55.1%). As expected, for genes with low linkage disequilibrium between SNPs, few tag SNPs and high total SNP density, prediction was lower. With our CART model we can estimate the SNP coverage of other genes for which we do not possess a complete listing of SNPs. As an illustration, we estimated tag SNP coverage of the genes from one of our candidate gene association studies.

Large Germline Deletions of the Fumarate Hydratase Gene in Patients with HLRCC. *A.B. Santani[1], C. Vocke[2], L. Middleton[2], W.M. Linehan[2], C.A. Stolle[1]* 1) Dept of Pathology and Lab Medicine, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Urologic Oncology Branch, National Cancer Institute, Bethesda.

Hereditary leiomyomatosis and renal cell cancer (HLRCC) is characterized by cutaneous leiomyomata, uterine leiomyomata and renal cell carcinoma and is associated with mutations in the fumarate hydratase (FH) gene. Using DNA sequence analysis missense, nonsense, splice site and frame shift mutations may be identified in 85-90% of patients with HLRCC, while the molecular cause is unknown in the remaining 10-15%. Failure to identify mutations in all patients might be due to the inability of the current PCR-based assays to detect disease causing mutations such as large duplications and deletions. Previous reports have identified whole gene deletions in three families with HLRCC. To determine whether gene deletions could be responsible for HLRCC in some of our patients, we developed a relative quantitative (RQ) PCR assay to test probands and family members in whom HLRCC was strongly suspected but who tested negative for a point mutation in the FH gene. RQ-PCR primer/probe sets were designed for 8 exons of the FH gene and the albumin gene (internal control). The copy number of each exon was determined using the ddCt method. A complete deletion of the FH gene was identified in 17 individuals from one large family. In addition, complete FH gene deletions were identified in probands from two other unrelated families. Among our mutation positive probands, complete deletions account for about 5% of disease causing mutations. The identification of deletions by RQ-PCR, therefore, increases the detection rate for FH gene mutations to about 90-95%. Use of genetic testing for early identification of HLRCC in patients and at risk family members improves diagnostic certainty and reduces costly screening procedures for at-risk members who have not inherited a disease-causing mutation. Early recognition of clinical manifestations may also allow timely intervention and improved outcome. The RQ-PCR assay is a simple, high resolution technique for rapid detection of exon dosage, and diagnostic testing for HLRCC should include quantitative analysis of the FH gene in addition to sequence analysis.

Duplication of 16q22.3qter/13.6 Mb DNA characterized by G-banding, FISH, SKY and array CGH. *J. Xu[1], B. Hamilton[1], V.M. Siu[2]* 1) Cytogenetics; 2) Medical Genetics, London Health Sciences Centre and University of Western Ontario, Canada.

A 6-year-old girl presented with developmental delay, mild dysmorphism and extreme anxiety. G-banding showed additional material of unknown origin attached to a distal 3q. Telomere FISH and SKY identified the addition as being a translocation of 16q22.3qter onto 3q. The patients karyotype is 46,XX,der(3)t(3;16)(q29;q22.3).ish der(3)(wcp16+,3qter+,16qter+). The mother had a normal female karyotype and the father was not available for study. Genomic DNA was extracted from 11-month old fixed cell pellet leftover from the original cytogenetic investigations. Array CGH analysis using CytoChip (BlueGnome) at 870 kb resolution with 3550 BACs showed duplication of 14 clones covering 13.6 Mb (genomic position: 74852437.50-88532307.50) in the 16q. In addition, the array identified deletion of 2 clones of 71.6 kb (genomic position: 2638138-2719693) at 6p22.1. The presence of 3qter probe in the der(3) and the results of CGH analysis indicate that there is very little deletion of distal 3q material, making this a pure dup(16)(q22.3qter). Six cases of dup 16q22qter have been reported in literature; all had another chromosomal rearrangement. This is probably the first case of pure dup 16q22.3qter. Similar findings to a dup 16q case with der(Y)t(Y;16)(q12;q22) (Clin Dysmorphol 2005,14:177-81) include developmental delay, speech delay and dysmorphism. More case reports are needed to establish a phenotype of dup 16q22.3qter. This study further demonstrates that CGH array can assist in the molecular definition (size and genomic position) of cytogenetic rearrangements and detect submicroscopic aberrations. As well, our data suggest that fixed cytogenetics cell pellets (up to 11 months in our lab) may be used for array CGH analysis.

A population-based WGAS identifies novel genes associated with androgenic alopecia, while confirming association with androgen receptor. *X. Yuan[1], D.W. Waterworth[1], K.S. Song[1], V. Mayor[2], M. Firmann[2], G. Waeber[2], P. Vollenweider[2], V. Mooser[1]* 1) GlaxoSmithKline R&D, King of Prussia PA, RTP, NC and London UK; 2) CHUV University Hospital Lausanne Switzerland.

BACKGROUND: Androgenic alopecia (AGA, or male pattern baldness) is a major unmet medical need and shows some association with premature cardiovascular diseases (CVD). AGA has a genetic component, and the androgen receptor (AR) has been associated with this condition. No genome-wide linkage or association scan has been reported so far for AGA. Here, we performed a nested case-control study within the Affymetrix 500K genotyped Lausanne population-based study to identify novel genes associated with AGA, as assessed using the Hamilton classification, in men aged 35-75. METHODS: A total of 591 cases with AGA (aged 35 to 65 years with Type V-VIIIA) were compared to 561 discordant controls without AGA (aged 45-55 years with Type I/IA, or aged 55-75 years with Type I - IIA). In the primary analysis, single point analysis was performed using logistic regression and the Armitage trend test. RESULTS: A robust association was identified between 2 SNPs within the AR gene and AGA (OR = 1.4, CI = 1.1-1.8, $p = 0.01$; and OR = 1.6, CI = 1.3-1.9, $p < 0.0001$). Similarly, we found some degree of association between AGA and other candidate-genes for AGA, such as SRD5A2, CYP19 and keratins. In addition, we identified 411 SNPs within 87 genes with P-values < 10E-4, 49 of which are expressed in hair follicle. Further analyses including biological data mining and statistical analysis are being performed to examine closely the genes of interest, and a replication dataset is being sought for in an attempt to verify these results and thereby identify novel potential drug targets for AGA.

Haplotypic Variants in DRD2, ANKK1, TTC12 and NCAM1 co-Regulate the Comorbidity of Alcohol and Drug Dependences. *B.Z. Yang[1,4], H.R. Kranzler[5], H. Zhao[2], J.R. Gruen[3], X. Luo[1,4], J. Gelernter[1,4]* 1) Psychiatry; 2) EPH; 3) Pediatrics, Yale Univ Sch Med, New Haven, CT; 4) VA CT Healthcare Center, West Haven, CT; 5) Univ CT Health Center, Farmington, CT.

DRD2 is a functional candidate gene for substance use disorders (SUDs), including alcohol dependence (AD) and drug dependence (DD). Many studies of the association of *DRD2* with SUDs have been conducted, but the results have been inconsistent. The odds ratio of comorbid DD with AD, adjusted for demographic characteristics, is as high as 18.7 (Compton et al 2007). This comorbidity apparently generates heterogeneity of SUD phenotypes that could confound the mapping of genes. We hypothesized that prior inconsistent results were influenced by the heterogeneity of the SUDs and the presence of multiple risk variants for SUDs mapped in a small region close to *DRD2* (Gelernter et al, 2006). We conducted two separate association studies of comorbid AD and DD in 1220 European-American subjects using family-based and case-control designs and 43 single nucleotide polymorphisms (SNPs) mapped to the gene cluster of *NCAM1*, *TTC12*, *ANKK1* and *DRD2*. We used a generalized linear model and haplotype score tests for the case-control sample, and the family-based association test for the family sample. The result of haplotype associations centered on *TTC12* exon 3 both in the case-control and family samples (optimal individual haplotype simulated $p(p_{\text{oihs}}) = 0.000015$). Another associated haplotype extended from *ANKK1* exon 8 to *DRD2^C957T* in both designs ($p_{\text{oihs}} = 0.0028$). *NCAM1* exon 12 markers showed global significance in both case-control and family samples, but were significant for a specific haplotype association ($p_{\text{oihs}} = 0.0029$) only for the family sample. Population stratification was excluded as a possible cause of false positive association. LD contrast tests between cases and controls support selection at *TTC12* exon 3 and *ANKK1* exon 2. We conclude that variants in exon 3 of *TTC12*, exon 12/intron 13 of *NCAM1*, and the two 3 ends of *ANKK1* and *DRD2* co-regulate risk for the comorbidity of alcohol and drug dependence. Compton WM et al Arch Gen Psychiatry V64, 2007. Gelernter et al Hum Mol Genet. 2006 V15, 2006.

Whole genome 500K SNP microarray delineates duplication/deletion of 8p in a child with MR/MCA. *S. Newton*[1], *M. Ito*[1,2], *X.L. Huang*[1], *J.M. Milunsky*[1,2,3] 1) Center for Human Genetics, BUSM, Boston, MA; 2) Department of Pediatrics, BUSM, Boston, MA; 3) Department of Genetics and Genomics, BUSM, Boston, MA.

Whole genome microarray is a useful method for detecting cryptic unbalanced chromosomal abnormalities. This technique has proven valuable in evaluation of patients with mental retardation, developmental delay, autism, and/or congenital malformations. We report a 9 year old Brazilian male who was evaluated due to mental retardation, agenesis of corpus callosum, dysmorphic features, scoliosis, absent language, and limited mobility. Hypotonia and delay at 4 months of age prompted an MRI revealing corpus callosum agenesis. He has no reported history of cardiac problems or seizures. He demonstrates bruxism and midline hand-wringing. An upper GI series revealed congential malrotation. He has scoliosis (25^{o}). OFC is in the 50-75th centile, weight and height are <3rd centile. Multiple dysmorphic features include: long eyelashes, arched eyebrows, elongated face, bulbous nasal tip, anteverted nares, and smooth, prominent philtrum. He has a high arched palate, micrognathia, and widely spaced teeth. He has tapered digits and fifth finger clinodactyly. High resolution chromosome analysis in addition to whole chromosome 8 painting revealed an apparent interstitial inverted duplication in the 8p21.3-23.1 region. 500K SNP microarray analysis was performed to further delineate the duplication. Analysis revealed a 31.2 Mb duplication at 8p22-11.21. In addition, a 6.8 Mb deletion at 8p23.3-23.1 was revealed that was confirmed by FISH. Parental studies have been requested. Inv dup/del 8p has been well documented in the literature with a clinical picture consisting of agenesis of the corpus callosum, hypotonia, M/R, dysmorphic features, orthopedic abnormalities, and heart defects. Given our patients clinical findings and the reported literature on inv dup/del 8p, this finding likely explains his phenotype. SNP microarray analysis proved helpful in this case, revealing a 6.8 Mb cryptic deletion not detected by high resolution chromosome analysis, and clarifying the size of the duplication. This additional information may potentially lead to more optimal anticipatory guidance in the future.

Identification of mosaic partial trisomy 12p (Pallister-Killian Syndrome) by FISH analysis. *C.W. Yu[1], O.B. Evans[2], H. Huang[1], C. Thompson[1], O.A. Abdul-Rahman[1]* 1) Dept Preventive Medicine; 2) Dept Pediatrics, Univ of Mississippi Med Ctr, Jackson, MS.

Pallister-Killian Syndrome (PKS) was first reported in 1977 with mosaicism in fibroblasts for an extra chromosome composed of 12p. PKS was characterized by profound psychomotor retardation, inability to sit or speak, seizures, and joint contractures. We report a case of partial duplication of 12p in an infant with unusual chromosome rearrangements identified from blood lymphocytes. A Caucasian female infant was born at 39 weeks gestation to a 22 year-old primigravida mother and 22 year-old father. The mother experienced tonsillitis during the pregnancy, but was otherwise uncomplicated. The infant could not sit or crawl at nine months and was hospitalized for seizures at ten months. On physical examination at 11 months, the infant had a head circumference 45.3 cm, height of 74.6 cm, and weight of 12.6 kg. The dysmorphic features included a board forehead with high anterior hairline, hypertelorism, flat nasal bridge, short upturned nose, down turned corners of the mouth, short fingers, single transverse crease in the right hand, and hypotonia. Chromosomes from PHA stimulated blood cultures were analyzed. Five of the eighty G-banded metaphases examined had extra material on the terminal short arm of chromosome 12. G-banding suggested that it might be a translocation from chromosome 21 or a duplication of 12p. Both parental chromosomes were normal. Tissue chromosome study was not available. FISH studies were done using locus specific probes for loci TEL (12p13.1) and AML1 (21q22), telomere probes for 12pter and 12qter, and whole chromosome panting probes for 12. FISH and cytogenetic studies suggest that the derivative 12 possibly has double interstitial duplications from 12p12.2 to 12p13.31, which might have resulted from repeated DNA replications within a crossing-over loop in a somatic cell. The infant has mosaic tetrasomy of segment 12p12.2 to 12p13.31 (three on the derivative chromosome 12 and one on the normal chromosome 12) and has clinical features of PKS, further demonstrating the critical genomic regions and the phenotypic expressions.

Association between a polymorphism in PDE10A and bone mineral density. *L.S. Wood[1], A.B. Seymour[1], E.H. Pickering[2], D.S. Lee[2], P. Banerjee[3]* 1) Pharmacogenomics/Translational and Molecular Medicine, Pfizer, Groton, CT; 2) Statistics, Pfizer, Groton, CT; 3) Translational and Molecular Medicine, Pfizer, New York, NY.

Osteoporosis is a complex disorder that involves a decrease in bone mineral density (BMD). A number of candidate genes have been implicated in osteoporosis but to identify other targets for therapeutic modulation of the disease we investigated 219 SNPs from 31 candidate genes to determine if any were genetically associated with BMD. The SNPs were initially examined in 368 healthy post-menopausal Caucasian women. The model for the initial analysis of the data (adjusted for age, years post-menopause and BMI) was run on all the markers and the results were sorted by the interaction p-value (marker with BMI). A total of 63 SNPs showed association with BMD (q-value = 0.5) and were then tested in a second population that contained 688 healthy post-menopausal women and 863 osteopenic women. One SNP, rs4709081, in the gene PDE10A, showed consistent association in both data sets. The expected positive correlation between BMD and BMI for subjects with the CC rs4709081 genotype (15% of the population studied) does not hold. One possible implication is that the CC individuals could be more susceptible to fractures as their BMI increases. The SNP rs4709081 is located in the first intron of PDE10A and is of unknown function, most likely serving as a surrogate for the causal variant.

A powerful approach via forest to identifying gene and gene-gene interactions revealing a resistant haplotype associated with age-related macular degeneration. *H.Z. Zhang, X. Chen, C.T. Liu, M.Z. Zhang* Dept Epidemiology/Public Hlth, Yale Univ Sch Medicine, New Haven, CT.

Multiple genes and interactions among genes and among genes and environmental factors are believed to underlie most complex diseases. However, such interactions are difficult to identify. While there have been recent successes in identifying genetic variants for complex diseases, it remains to be difficult to identify gene-gene and gene-environment interactions. To overcome this difficulty, we propose a forest-based approach and a concept of variable importance. Analyses of both real data and simulated data based on published genetic models demonstrate the effectiveness of our approach. For example, our analysis of published data set on age-related macular degeneration (AMD) not only confirmed a known genetic variant (p-value <0.005) for AMD, but also revealed an un-reported haplotype surrounding single nucleotide polymorphism (SNP) rs10272438 on chromosome 7 that was significantly associated with AMD (p-value = 0.045). These significance levels are obtained after the consideration for a large number of SNPs. Thus, the importance of this work is two-fold: a powerful and flexible method to identify high-risk haplotypes and their interactions, and the revelation of a potentially resistant region for AMD.

Evc and Lbn are co-expressed in structures affected by Ellis van Creveld Syndrome. *K. Lipscomb Sund[1,2], D.W. Benson[1,2]* 1) Molecular & Developmental Biology, Genetic Counseling, University of Cincinnati, Cincinnati, OH; 2) Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

Atrioventricular septal defects (AVSDs), limb dwarfism, and polydactyly are features of recessively-inherited Ellis van Creveld (EvC) syndrome. Linkage mapping and positional cloning led to identification of associated human mutations in two previously unknown non-homologous genes, EVC (31%) or EVC2/LBN (38%), which are encoded head-to-head on chromosome 4. Mutation analysis in a small cohort of patients with EvC syndrome confirmed loss-of-function mutations and led us to explore the role of Evc and Lbn in cardiac and limb morphogenesis. Evc and Lbn riboprobes created for in-situ hybridization ascertained endogenous expression patterns in murine hearts at 9.5-12.5 dpc, when atrioventricular (AV) septation occurs. Peptide specific antibodies generated for immunohistochemistry confirmed expression patterns and identified cellular compartmentalization of the proteins. Evc and Lbn co-localization was evident in murine NIH3T3 and ATDC5 cell lines. In the mouse long bone growth plate, there was co-expression in the pre-hypertrophic and hypertrophic zones. In the developing heart, Mf-20 and Pecam co-staining revealed Evc is expressed in endocardial, mesocardial and mesenchymal cells while Lbn is predominantly found in myocardium and mesenchyme. We identified overlap of Evc and Lbn protein in cardiac structures affected by EvC syndrome, including the atrial septum, AV junction, and AV valves. The presence of Evc and Lbn in key structures during cardiogenesis indicates their importance in contributing to vavuloseptal morphogenesis. Bone expression patterns and cellular localization provide insight into protein function because co-localization of Evc and Lbn in the pre-hypertrophic zone is followed by nuclear translocation of Evc in the hypertrophic zone. Based on human mutations predicated to result in a complete loss of protein function, a bidirectional genomic organization expected to lead to coordinate expression, and evidence of mRNA and protein co-localization in structures exhibiting EvC pathology, we believe that co-expression of Evc and Lbn is necessary for proper function.

The ATP-binding cassette transporter 2 (TAP2) gene is strongly associated with Systemic Lupus Erythematosus (SLE). *P.S. Ramos[1], L. Bera[1], P.M. Gaffney[2], K.L. Moser[2]* 1) Dept Medicine, Univ Minnesota, Minneapolis, MN; 2) Oklahoma Medical Research Foundation, Oklahoma City, OK.

SLE is a systemic autoimmune disease characterized by antibody production against nuclear antigens. The interferon (IFN) pathway is clearly implicated in disease pathogenesis, as shown by the overexpression of IFN-inducible genes observed in SLE and other autoimmune diseases. We are currently analyzing the interferon regulatory factor 2 (IRF2) gene for its possible contribution to disease susceptibility. Given the potential role of multiple IFN pathway genes in disease predisposition, we chose single nucleotide polymorphisms (SNPs) from several genes known to interact with IRF2 and tested them for association with SLE in our collection of 453 Caucasian families. We used the standard Transmission Disequilibrium Test (TDT) on ATP-binding cassette transporter 1 (TAP1) (mean r2=0.87), TAP2 (mean r2=0.71), tapasin (or TAP binding protein, TAPBP) (mean r2=0.26), tumor protein p53 (TP53) (mean r2=0.53), IRF2 binding protein 1 (IRF2BP1) (mean r2=1.0) and IRF2BP2 (mean r2=0.75). Several SNPs in TAP2 showed evidence for association, the strongest effect being found with a SNP that localizes in the 3UTR and mRNA of the gene (P = 1.33x10-6). This is the largest cohort studied to date that implicates TAP2 in SLE predisposition. Additional analyses are currently underway to replicate this finding and determine if this effect is independent of the MHC. No evidence of association was found for the other genes screened in this study. Further analyses are warranted to pinpoint the exact mechanism by which this variant might affect TAP2 function and consequent antigen presentation, thus contributing to SLE predisposition.

DNA methylation profiles in diffuse large B-cell lymphoma and their relationship to gene expression status. *X. Wang[1], T.C. Greiner[2], B.L. Pike[1], D.D. Weisenburger[2], Y. Hsu[1], G. Renaud[3], T.G. Wolfsberg[3], M. Kim[1], D.J. Weisenberger[1], K.D. Siegmund[1], W. Ye[1], S. Groshen[1], R. Mehrian-Shai[1], W.C. Chan[2], P.W. Laird[1], J.G. Hacia[1]* 1) Biochemistry & Molecular Biology, University of Southern California, los angeles, CA; 2) University of Nebraska Medical Center, Omaha, NE; 3) National Institutes of Health, Bethesda, Maryland.

While gene expression, genomic copy number, and mutational analyses have provided key insights into the genetic basis for the extensive pathologic and biologic heterogeneity in diffuse large B-cell lymphoma (DLBCL), considerably less is known about its epigenetic underpinnings. Here, we evaluated the DNA methylation levels of over 500 unique gene-associated CpG islands in fourteen DLBCL tumors using McrBC-based CpG island microarray, MethyLight, and bisulfite sequencing analyses. Although we observed variation in DNA methylation across all DLBCL, we identified twelve CpG islands (*AR*, *CDKN1C*, *DLC1*, *DRD2*, *GATA4*, *GDNF*, *GRIN2B*, *MTHFR*, *MYOD1*, *NEUROD1*, *ONECUT2*, and *TFAP2A*) showing significant methylation in greater than 85% of the tumors surveyed. Interestingly, we found that the methylation levels of CpG islands proximal to *FLJ21062* and *ONECUT2* differed between activated B-cell-like (ABC-DLBCL) and germinal center B-cell-like (GCB-DLBCL) subtypes, which have distinct clinical outcomes. In addition, we compared the methylation and expression status of sixty-seven genes located within 500-bp of our methylation assays. Our observations are more consistent with the potential involvement of DNA methylation in the maintenance relative to the initiation of gene silencing. Nevertheless, the proportional reductions in *BNIP3*, *MGMT*, *RBP1*, *GATA4*, *IGSF4*, *CRABP1* and *FLJ21062* expression with increasing methylation suggests that epigenetic processes could be causally involved in the initial stages of gene silencing. Overall, the genes highlighted in our analyses warrant further investigation into their roles in the development and progression of DLBCL and potential as clinical biomarkers.

Presence of Yq microdeletions in men with Cryptorchidism. *Z. Arora[1], R. Kumar[2], R.K. Sharma[4], R. Kumar[3], R. Dada[1]* 1) 2ND YEAR, AIIMS, New Delhi, Delhi, India; 2) anatomy,AIIMS,New Delhi,India; 3) UROLGY,AIIMS,New Delhi,India; 4) Army R and R Hospital.

The incidence of cryptorchidism in full-term infants is approximately 3%, whereas it is 33% in males born prematurely.However, spontaneous testicular descent may occur in the newborn, and by 1 yr of age. In recent years, a growing body of evidence has demonstrated the existence of a genetic basis for primary testiculopathies related to microdeletions in the euchromatic region of the Y chromosome long arm (Yq11), where an azoospermia factor (AZF) has been suggested to exist. Analysis of the microdeletions resulted in the identification of three loci in Yq11 involved in the control of spermatogenesis, corresponding to three nonoverlapping regions: AZFa, AZFb, AZFc. The AZFa locus is located on proximal Yq11 (Yq11.21), while AZFb and AZFc are located on distal Yq11 (Yq11.23). The aim of this study was to study Yq microdeletion in those cases with Cryptorchidism which do not show any improvement in semen parameters post surgery. A total of 21 normal patients with confirmed Cryptorchidism and 20 fertile cases (controls) were included in the study. Cytogenetic analysis was done in all the cases and controls to rule out any chromosomal abnormality.PCR for the microdeletion analysis was done in each case using the primers for AZF region on peripheral blood. The sequence tagged site primers tested in each case were sY86 (AZFa); sY127 (AZFb); sY254 (AZFc). The PCR products were analyzed on a 1.8% agarose gel. PCR amplifications found to be negative were repeated at least three times to confirm the deletion of a given marker. All the 21 cases band of appropriate size was observed in cases for AZFa (320bp) and out of the 21 patients 19 cases had a AZFc(350bp) loci intact. In 20 out of the 21 patients a band of appropriate size was also observed for AZFb locus (274bp).1 case showed a microdeletion in the AZFb region.2 case showed AZFc deletion. None of the controls had any of such deletions.All the bilateral cryptorchoid cases were azoospermic with FSH levels.

Clinical and demographic characteristics of 122 patients with Type 3 Gaucher disease. *A. Tylki-Szymanska[1], A. Vellodi[2], A. El-Beshlawy[3], J.A. Cole[4], E. Kolodny[5]* 1) Child Mem Health Inst, Warsaw, Poland; 2) Great Ormond St. Hosp Child, London, UK; 3) Ped Hosp Cairo Univ, Cairo, Egypt; 4) Genzyme Corp, Cambridge, MA, USA; 5) NYU Sch Med, NY, USA.

Purpose: To describe the demographic and clinical characteristics of patients with type 3 Gaucher disease (GD3). **Methods:** Data from all patients diagnosed with GD3 enrolled in the Neurological Outcomes Sub-Registry of the ICGG Gaucher Registry as of March 2007. Demographics, clinical characteristics of Gaucher diagnosis, and neurological manifestations at first assessment were analyzed. Patients were on ERT for varying times as of the first assessment. **Results:** We identified 122 patients enrolled in the Sub-Registry. Neurological symptoms were first noted before 2y in 54%; 2-18y in 44%. Forty-three percent showed abnormal symptoms of ability to look to the extreme up or down, abnormal slow object tracking (40%), or convergent squint (35%). Wide based gait was noted in 22%, assistance with walking or non-ambulatory in 14%. Frequency (mean age of onset) for muscle weakness was 24% (2.7y); extrapyramidal features, 19% (4.9y); spasticity, 15% (6.9y); tremor when reaching, 21% (9.7y); tremor at rest, 14% (11.2y). Seizures were reported in 16 patients (14%); 2 patients reported myoclonic seizures. The clinical characteristics as of Gaucher disease at diagnosis were: anemia in (61%); thrombocytopenia (120 $x10^3/mm^3$) in 52% of non-splenectomized patients; moderate splenomegaly (5 to 15 MN) in 6% and severe splenomegaly (15 MN) in 94% of patients; moderate hepatomegaly (1.25 to 2.5 MN) in 65% and severe hepatomegaly (2.5 MN) in 32% of patients; growth retardation (56%); and bone pain (11%). Forty-five percent reported Caucasian ethnicity and 36% reported Arab ethnicity. Most common genotypes reported were L444P/L444P (72%), L444P/D409H (9%), D409H/D409H (7%), and L444P/Rare allele (5%); full sequencing was not performed in all patients. **Conclusion:** GD3 affects patients of different ethnicities; most common genotype is L444P/L444P. Neurological symptoms typically begin before 2y (54%) and appear in nearly all patients before 18y (98%).

AN UNUSUAL CHROMOSOMAL CHANGE IN A PATIENT WITH MULTIPLE MYELOMA. *H.O. Shah[1,2], N. Chen[1], Y. Zhong[1], R. Nagwekar[1], H. Yu[1], J. Lin[1,2]* 1) Department of Pathology, Nassau University Medical Center, East Meadow, NY; 2) Health Science Center, State University of New York, Stony Brook, NY.

Multiple myeloma (MM), a mature B-cell lymphoproliforative neoplasm, is characterized by clonal proliferation of malignant plasma cells in the bone marrow with monoclonal gammopathy and clinically manifested by bone destruction, anemia, immunosuppression and renal failure. The etiology of MM is largely unknown and the role of genetic abnormalities is still uncertain. The primary chromosomal translocations in MM involving 14q32 (*IgH* locus) include t(11;14)(q13;q32), t(4;14)(p16.3;q32.3), t(6;14)(p25;q32) and t(14;16)(q32.3;q23), of which, t(11;14)(q13;q32), being most common, results in up-regulation of cyclin D1. Other translocations (secondary) or abnormalities including t(8;14)(q24;q32), 1q21 aberrations, 13q14 and 17p13 deletions have been associated with disease progression, poor prognosis and response to chemotherapy. Clinically, t(4;14), t(14;16) and 17p13 deletion are associated with poor prognosis, while 13q14 deletion is linked with intermediate prognosis, and all others correlate with good prognosis. We present here a 50 year-old Hispanic male with initial presentation of acute kidney failure. CT abdomen/pelvis revealed a hypodense mass causing collapse and destruction of L4 vertebra and other multiple lytic bone lesions. Kidney biopsy showed kappa-light chain cast nephropathy. Bone marrow aspirate and biopsy revealed that diffuse infiltrate of plasma cells with diffusely positive for CD138 and kappa-light chain. Flow cytometry confirmed plasma cell neoplasm with kappa-light chain restriction. Chromosomal study on bone marrow aspirate observed a *de novo* Robertsonian translocation with the karyotype: 45,XY,der(13;14)(q10;q10). Finding of chromosomal abnormality with a balanced rearrangement in this case is unusual in MM patients. This chromosomal structural change may affect the *IgH* locus and related oncogenes on chromosomes 13 and 14, which may trigger the development of MM and render a poor prognosis in this patient. Routine cytogenetic study in newly diagnosed MM patients may provide clinically useful information for predicting prognosis and therapeutic response.

The genetic evaluation of macroglossia. *Y. Zarate, R. Hopkin* Div Hum Genetics, Cincinnati Chlds Hosp Med Ctr, Cincinnati, OH.

Macroglossia is a relatively common reason for genetic evaluation.Several etiologies have been defined with POSSUM listing over 70 conditions that can cause it.Little research has been published on the evaluation or management of patients with this anomaly.

We performed a retrospective chart review of patients who were initially evaluated for macroglossia alone or in combination with other findings.To date records on 36 patients have been reviewed. At the time of evaluation average age was 92 days, gestational age at birth was 36 +/- 4.8 weeks and birth weight of 3100 grams +/- 1186. Some relevant historical findings were positive family history in first degree relative for macroglossia, twin gestation and gestational diabetes. Atleast 3 studies were recommended in 15/36 patients (41.7%).Abdominal and renal ultrasound was the most frequent in 24/35 patients (68.5%). Other studies included chromosomal analysis, alpha feto protein (AFP)levels, urine mucopolysaccharidosis (MPS) screen, Beckwith Wiedemann (BWS)molecular testing and thyroid function tests. Abnormalities in BWS molecular were seen in 2/7 (28.5%). A single abnormal chromosome result was found (1/16: 6.2%). Abnormal ultrasounds and AFP were common in BWS but not in other patients.

BWS was the most frequent diagnosis seen in 22/36 patients (61.1%). Macrosomia was not universal in BWS but twinning was an important predictor of BWS. An expanded search that included macroglossia as a physical exam finding at any point independently of the reason for the initial evaluation, revealed 36 additional patients. Several other conditions were identified in small numbers including 9q34 deletion syndrome, transient neonatal diabetes, neurofibromatosis type I, Cardio Facio Cutaneous syndrome, Klippel-Trenaunay Weber syndrome among others.

These findings indicate that while BWS is the most frequent diagnosis associated with macroglossia there are a number of other less common conditions that may present with this finding.The diagnostic approach to this population will vary depending on the associated findings.

New MeCP2-target neuronal genes potentially associated with Rett syndrome. *C. Yang[1], M. Soutome[1], K. Endoh[1], S. Yokoi[2], I. Imoto[2], T. Taira[3], J. Inazawa[2], T. Kubota[1]* 1) Epigenetic Medicine, Univ Yamanashi, Yamanashi, Japan; 2) Mol Cytonetics, MRI, Tokyo Medical Dental Univ, Tokyo, Japan; 3) Mol Cell Biol, Univ Yamanashi, Yamanashi, Japan.

Rett syndrome (RTT) is an X-linked dominant disease caused by *MEPC2* mutations. MeCP2 protein is exclusively expressed in neurons in the brain and bound to the methylated promoters of genes to regulate their expression, indicating that pathogenesis of RTT is deregulation of the target genes in neurons. Although several targets have been reported, identification of MeCP2 targets remains important issue for better understanding of RTT. To identify new targets, we first searched "triple-positive" BAC clones which contain MeCP2 binding, DNA methylated and histone H3K9 dimethylated sites using ChIP-on-chip technology. Within the regions of the 22 BAC identified, we found five neuronal genes. Of these, we found that four genes had the MeCP2-binding sequence motif (CpG-A/T runs) in their upstream regions. Out of these four genes examined, we confirmed MeCP2-binding and promoter methylation in three genes (which encode two neural cell-cell interaction molecules and one transport associate molecule in neuronal dendrites) in SH-SY5Y neuronal cultured cells by ChIP analyses and bisulfite-sequencing, respectively. These preliminary data suggest that the three neuronal genes may be new MeCP2 targets and potentially contribute to symptoms in RTT, such as autism and epilepsy.

Population structure in European American populations - Impact on the design and analysis of Genome-Wide Association Studies (GWAS). *K. Yu[1], Z.M. Wang[2], Q.Z. Li[1], S. Wacholder[1], R. Hoover[1], D. Hunter[3], S. Chanock[1,4], G. Thomas[1], CGEMS project team* 1) DCEG, NCI, Rockville, MD; 2) SAIC-Frederick, Frederick, MD; 3) Department of Epidemiology, Harvard School of Public Health, Boston, MA; 4) Pediatric Oncology BRanch, NCI, Bethesda, MD.

Population stratification can lead to bias in estimates of disease association in GWAS due to the existence of population sub-structure differences in cases and controls. The several study designs and correction methods proposed to overcome these difficulties have seldom been evaluated on large datasets to date. The genome-wide scans performed as part of the Cancer Genetic Markers of Susceptibility (CGEMS) has identified the genotypes of over 500,000 SNPs for approximately 4,400 individuals participating in two prospective studies. All are self-described as of European origin. The two studies were conducted independently with different centers of recruitment. The participants from NHS in the study of breast cancer are females working in the medical area; the PLCO participants in the study of prostate cancer are males who volunteered for a trial of cancer screening. Despite these differences, the structure of the populations recruited in PLCO and NHS appears similar, demonstrating two major and one minor significant axis of genomic variation when a set of 6,000 uncorrelated SNPs is used in a principal component analysis. The application of the STRUCTURE program on the combined genotypes of CGEMS and HapMap reveals a small number of individuals whose ancestral origin is shared between Europe Africa or Asia. However, such intercontinental admixture may not account for all the population structure observed in the CGEMS data. By combining cases and controls within and among studies we are exploring potential inflation in false positive rate and loss in statistical power that will result from the use of groups of cases and controls that are recruited independently. Population stratification may cause an inflated false positive rate. There is at least a theoretical possibility that markers appear to be associated with disease only because they are associated with the phenotype of being a nurse or being a trial volunteer.

Circulating TGF-beta as a prognostic and therapeutic biomarker in Marfan syndrome. *P. Matt, J. Habashi, T. Holm, E. Klein, M. Gamradt, D. Huso, J. Van Eyk, H. Dietz* Inst of Genetic Medicine and Div of Cardiology, Johns Hopkins Univ Sch of Med, Baltimore, MD.

Aortic root dilatation is the main cause of mortality in Marfan syndrome (MFS), a disorder caused by mutations in the gene encoding fibrillin-1 and consequent dysregulation of TGF-beta signaling. Recent evidence suggests that losartan, an AT1 antagonist that blunts TGF-beta activation, may be a productive treatment for MFS. Currently there are no surrogate markers for the therapeutic effect of losartan that can be used to develop and individualize therapeutic regimens. Optimal doses of losartan for this indication may differ from those currently used to treat hypertension. Serum samples from a MFS mouse model (*Fbn1* C1039G/+) and wild-type littermates treated with losartan or placebo were collected at 10 weeks, 6 months and 10 months of age. Total TGF-beta1 serum concentrations were measured by ELISA. Echo measurements of the aortic root were obtained at 10 months of age. TGF-beta serum levels were higher in C1039G/+ mice compared to wild-type mice (p=0.01; 80.0 ng/ml (n=5) vs. 58.3 ng/ml (n=4) at 10 weeks, 117.4 ng/ml (n=11) vs. 87.0 ng/ml (n=6) at 6 months, 137.5 ng/ml (n=3) vs. 103.0 ng/ml (n=2) at 10 months, respectively). Losartan-treated C1039G/+ mice had lower mean TGF-beta serum levels compared to C1039G/+ mice treated with placebo (p=0.007; 92.9 ng/ml (n=5) vs. 117.4 ng/ml (n=11) at 6 months, 101.2 ng/ml (n=13) vs. 137.5 ng/ml (n=3) at 10 months, respectively). Mean TGF-beta levels in losartan-treated C1039G/+ mice and wild-type mice were indistinguishable (p=0.3; 92.9 ng/ml (n=5) vs. 87.0 ng/ml (n=6) at 6 months, 101.2 ng/ml (n=13) vs. 103.0 ng/ml (n=2) at 10 months, respectively). Echo analyses revealed smaller mean aortic root diameters in 10 month old wild-type and losartan-treated C1039G/+ mice compared to age-matched C1039G/+ mice treated with placebo (p=0.001; 1.94 mm (n=2) and 2.06 mm (n=13) vs. 2.4 mm (n=3), respectively). Correlation was observed between TGF-beta1 levels and aortic root diameter in untreated C1039G/+ mice (R^2=0.6). Circulating TGF-beta1 is a promising biomarker for prognostication and monitoring the therapeutic response to losartan in MFS.

Three-year-old girl with Juvenile Huntington Disease. *S. Sakazume[1,3], H. Ohashi[1], S. Yoshinari[2], T. Ishii[4]* 1) Division of Clinical genetics, Saitama childrens medical center, Saitama, Saitama, Japan; 2) Division of Neurology, Saitama childrens medical center, Japan; 3) Division of Clinical genetics, Gunma childrens medical center, Shibukawa, Gunma, Japan; 4) Division of Clinical genetics, Chiba university, Chiba, Japan.

Huntington disease is neuron degenerative disease showing involuntary movement and change in character, commonly-noted in the scene of genetic counseling in adult. The causative mutation is 5 CAG repeat expansions of HD gene, also paternal anticipations are observed in some cases. Here we describes relatively rare early childhood onset HD. The patient is a girl born with term uneventful delivery. During infancy, her motor and mental development was normal. On her third year of life, she could walk stably and run, and speak meaningful words and many short sentences. Also her growth was normal. At the age of 2 years and 11 months, her care giver noticed ataxic gait and difficulty in speech. At the age of 3 years and 6months, she could not speak any meaningful words. Around the same time, convulsive seizure started frequently and it was diagnosed as epilepsy by EEG. The convulsion was controlled by Carbamazepine. Brain MRI showed no abnormal findings at the time. Her CAG repeat of HD gene was remarkably expanded until 160 repeat. Her mother was also diagnosed as a patient of HD just after her delivery. The mothers CAG expansion was about 60 repeat. In this family, patients were identified at least in four generations. This patient is a one of the youngest patient ever diagnosed and maternal CAG expansion is characteristic in this case.

Significant association of human CR1 polymorphisms and cerebral malaria. *P. Teeranaipong[1], J. Ohashi[1], R. Kimura[1], J. Patarapotikul[2], P. Nuchnoi[2], H. Hananantachai[2], I. Naka[1], C. Putaporntip[3], S. Jongwutiwes[3], S. Looareesuwan[2], K. Tokunaga[1]* 1) Department of Human Genetics, Graduate School of Medicine, University of Tokyo, Tokyo, Japan; 2) Faculty of Tropical Medicine, Mahidol University, Bangkok, Thailand; 3) Department of Parasitology, Faculty of Medicine, Chulalongkorn University, Bangkok, Thailand.

Complement receptor type 1 (CR1 or CD35) is immune-regulatory membrane glycoprotein found on various cell types including erythrocytes and granulocytes. In human malarial infection, CR1 has been shown to be a ligand for rosette formation and the higher expression of CR1 on the erythrocyte in patients with cerebral malaria than in those with mild malaria has been reported in several populations, suggesting an important role of CR1 in the pathophysiology of cerebral malaria. Therefore, we investigated the possible association of *CR1* polymorphisms with cerebral malaria in a Thai population. A total of 473 malaria patients infected with *Plasmodium falciparum* were classified according to WHO criteria into 3 groups: 202 mild malaria, 165 non-cerebral severe malaria and 108 cerebral malaria patients. Seven nonsynonymous coding SNPs, one SNP in intron 27, so called HindIII SNP, four promoter SNPs and five 3UTR SNPs were analyzed. Of these, a SNP in the *CR1* promoter region (PSNP02C>T) was strongly associated with protection against cerebral malaria (P-value = 0.0009). The frequency of the derived allele (T) was increased in mild malaria patients than in cerebral malaria patients. The PSNP02 was located in the putative transcription binding site of Brn-2, a member of POU domain transcription factor. Thus, PSNP02 may influence the expression level of CR1 and confer the protection against cerebral malaria. Interestingly, the frequency of the derived allele (T) of PSNP02 showed high frequency (97.8%) in the present population as well as in HapMap East Asian populations. This might reflect some strong selective forces that have acted on this promoter SNP during human evolution.

Localization Of The *Cis*-enhancer Element For Mouse *Col10a1* Expression In Hypertrophic Chondrocytes *In Vivo*. *Q. Zheng[1, 6], B. Keller[1, 4], G. Zhou[3], D. Napierala[2], Y. Chen[2], B. Zabel[4], A. Parker[5], B. Lee[1, 2]* 1) Molec & Human Genetics, Baylor College Med, Houston, TX; 2) Howard Hughes Medical Inst., Baylor College Med, Houston, TX; 3) Dept. of Orthopedics, Case Western Reserve University, Cleveland, OH; 4) Center of Pediatrics and Adolescence Medicine, University Hospital of Freiburg, D-79106, Germany; 5) Respiratory and Inflammation Res. Area, Astrazeneca, Cheshire U.K; 6) Dept. of Anatomy and Cell Biology, Rush University Medical Center, Chicago, IL.

We and others had previously shown that 4kb or 4.6kb *Col10a1* promoter containing Runx2 or AP-1 (Activator Protein-1) elements contribute to its hypertrophic chondrocyte-specific expression *in vivo* (Zheng et al., 2003; Gebhard et al., 2004). These data suggest that the *Col10a1* distal promoter (-4.4 to -3.8 kb) harbors a critical enhancer that mediates its tissue specificity. To further localize the tissue-specific enhancer element, we have generated series of transgenic reporter mice containing 600, 300 or 150 base pairs of DNA derived from this region upstream of the *Col10a1* basal promoter driving *LacZ* gene. We identify a 150bp *Col10a1* promoter element (-4.3 to -4.15 kb) that is sufficient to direct its tissue-specific expression *in vivo*. *In silico* analysis of this region identified several putative transcription factor binding sites including two potential AP-1 sites within 5- and 3- ends, respectively. Interestingly, transgenic mice using reporter constructs deleted for these two putative AP-1 elements still showed tissue-specific reporter activity. Electrophoretic mobility shift assays using oligonucleotide probes derived from this region and MCT cell nuclear extracts identified DNA/protein complexes that were enriched from cells stimulated to hypertrophy. Moreover, these elements mediated increased reporter activity on transfection into MCT cells. These data identify a minimal cis enhancer required for tissue specific *Col10a1* expression *in vivo* and putative DNA/protein complexes that may contribute to the regulation of chondrocyte hypertrophy.

Hereditary Deafness in Iran. *H. Najmabadi[1], C. Nishimura[2], K. Kahrizi[1], N.C. Meyer[2], N. Bazazzadegan[1], J.L. Sorensen[2], M. Mohseni[1], Y. Riazalhosseini[1], M. Malekpour[1], G. Assadi tehrani[1], A. Daneshi[3], M. Farhadi[3], P. Imani[1], A. Anousheh[1], A. Nazeri[1], S. Abedini[1], N. Nikzat[1], S. Arzhangi[1], R.J.H. Smith[2]* 1) Genetic Research Ctr, Univ Social Welfare/Rehab, Tehran, Tehran, Iran; 2) Molecular Otolaryngology Research Laboratories, Department of Otolaryngology, University of Iowa, Iowa, IA, United States; 3) Research Center of Ear, Nose, Throat, and Head and Neck Surgery, Iran university of Medical sciences, Tehran, Iran.

Genetic testing for deafness in Iran is well established. The population is extremely heterogeneous, which means that ethnic-specific data are required. We have generated much of these data by screening over 2000 families segregating autosomal recessive non-syndromic deafness (ARNSD). All patients were screened for mutations in GJB2 and GJB6 (DFNB1), and if no mutations were identified, haplotypes were reconstructed by typing three short tandem repeat polymorphisms flanking 20 known ARNSD loci. In a subset of families, genome-wide linkage analysis was completed. For approximately 30% of families, we have been able to establish a genetic cause for deafness. Over half have mutations in GJB2, and after GJB2, mutations in SLC26A4 and TECTA are most commonly detected. We have also found mutations in MYOVIIA, TMPRS53, MYO15A, VLGR1, USH1C and TMC1. In addition, we have described a new syndrome, a contiguous gene deletion syndrome that involves both deafness and infertility in males. The data from the Iranian population attest to its diversity and contribute to the current body of knowledge regarding the deafness of genetics. Key Words: Hereditary hearing loss, Iran, Linkage,.

Mutation Spectrom of Pendred Syndrome in Iranian Population. *M. Mohseni[1], K. Kahrizi[1], F. Azizi[2], C. Nishimura[3], N. Bazazzadegan[1], A. Dehghani[1], M. Sayfati[1], M. Taghdiri[1], P. Jamali[1], A. Daneshi[4], R.J.H. Smith[3], H. Najmabadi[1]* 1) Genetics Research Center, University of Social Welfare and Rehabilitation Sciences, Tehran, Iran; 2) Endocrine Research Center , Taleghani hospital, Tehran, Iran; 3) Molecular Otolaryngology Research Laboratories, Department of Otolaryngology Head and Neck Surgery, University of Iowa, Iowa, IA, United States; 4) Research Center of Ear, Nose, Throat, and Head and Neck Surgery, Tehran, Iran.

Mutations in the SLC26A4 gene in DFNB4 locus is responsible for syndromic (Pendred syndrome) and non-syndromic hereditary hearing loss(HHL). In many populations mutations in this gene have been reported as a second cause of HHL. The objective of this study was to investigate the prevalence of SLC26A4 mutations in our HHL consanguineous families. After completing clinical evaluation the signed consent form was taken from each family. We included 80 families with two or more affected individuals, who have been referred to Genetics Research Center (GRC). All families had previously been tested negative for the DFNB1 locus were candidate for homozygosity mapping using STRs for DFNB4 locus. Families localized to this region were subjected to complete DNA sequencing. Eleven out of eighty families were mapped to DFNB4. Sequence analysis of eleven linked families revealed eight mutations (T420I, 1197delT, G334Y, R409H, T721M, R79X, S448L, L445W) . The T420I , G334V and R79X were novel mutations, we couldn't find any mutation in four linked families. We didn't detect any non syndromic individual with mutation in our study. We have been able to identify mutation in SLC26A4 gene only in 7 out of 80 families (8.75%). we detected in 11 families some degrees of diffuse or nodular goiter, three out of 11 families showed thyroid function impairment and in five of 11 families positive prechlorate discharge test. All of affected had normal temporal bone scan. This investigation, demonstrated that the SLC26A4 gene mutation is the most prevalent syndromic hereditary hearing loss in Iran. This result is in accordance with reports from other countries. Key words: DFNB4, SLC26A4 gene, hereditary hearing loss, Pendred, PDS.

Case-only analysis ignoring control genotypes is efficient for detecting gene-gene interactions in case-control studies. *C. Li*[1]*, M. Li*[2] 1) Ctr Human Genetics Research, Vanderbilt Univ, Nashville, TN; 2) Dept of Biostatistics and Epidemiology, Univ of Pennsylvania, Philadelphia, PA.

Complex diseases often result from the interplay of multiple genetic and environmental factors. When we suspect two genes interact to modify disease risk, we may want to test for their interaction. Screening for interaction has also been proposed for genome-wide studies. However, the commonly used approaches often suffer from low power. In case-control studies, the most commonly used approach for gene-gene interaction analysis is logistic regression, in which we compare two joint genotype distributions, one for cases and one for controls, to determine if their genotype distributions are significantly different. When the subjects are sampled from a homogeneous population and the two loci of interest are unlinked or linked but are in linkage equilibrium, the control genotypes may provide little additional information over the prior knowledge of independence between the loci in the population, but contribute additional variation that has to be taken into account, lowering the power to detect interaction. To reduce such variation, we propose case-only analysis, in which the control genotypes are ignored, as an efficient and powerful alternative test of gene-gene interaction even when control genotypes are available. The appropriateness of the case-only analysis relies on the definition of no-interaction, which is scale dependent. Using analytical arguments and simulations, we show that (1) under the multiplicative definition of no interaction, i.e., additivity on the log-risk scale, the case-only approach is more appropriate and more powerful than logistic regression and the latter has inflated type I error, and (2) under the additive definition of no interaction, i.e., additivity on the penetrance scale, both approaches may have inflated type I error rates, but the case-only approach can control the type I error rate better than logistic regression when the relative risks are near one (e.g. RR=1.5). Our results indicate that case-only analysis is a powerful alternative to logistic regression for detecting gene-gene interactions, even when the control genotypes are available.

Analysis of Fibroblast growth factor 15 cis-elements reveals two conserved enhancers which are closely related to cardiac outflow tract development. *H. Saitsu*[1, 2], *K. Shiota*[2, 3], *M. Ishibashi*[2] 1) Department of Human Genetics, Graduate School of Medicine, Yokohama City University; 2) Department of Anatomy and Developmental Biology, Graduate School of Medicine, Kyoto University; 3) Congenital Anomaly Research Center, Graduate School of Medicine, Kyoto University.

Fibroblast growth factor 15 (Fgf15) is expressed in the developing mouse central nervous system and pharyngeal arches. Fgf15 mutant mice showed defects of the cardiac outflow tract probably because of aberrant behavior of the cardiac neural crest cells. In this study, we examined cis-elements of the Fgf15 gene by transient transgenic analysis using lacZ as a reporter. We identified two enhancers: one directed lacZ expression in the hindbrain/spinal cord and the other in the posterior midbrain (pmb), rhombomere1 (r1) and pharyngeal epithelia. Interestingly, human genomic regions which are highly homologous to these two mouse enhancers showed almost the same enhancer activities as those of mice in transgenic mouse embryos, indicating that the two enhancers are conserved between humans and mice. We also showed that the mouse and human pmb/r1 enhancer can regulate lacZ expression in chick embryos in almost the same way as in mouse embryos. We found that the lacZ expression domain with this enhancer was expanded by ectopic Fgf8b expression, suggesting that this enhancer is regulated by Fgf8 signaling. Moreover, over-expression of Fgf15 resulted in up-regulation of Fgf8 expression in the isthmus/r1. These findings suggest that a reciprocal positive regulation exists between Fgf15 and Fgf8 in the isthmus/r1. Together with cardiac outflow tract defects in Fgf15 mutants, the conservation of enhancers in the hindbrain/spinal cord and pharyngeal epithelia suggests that human FGF19 (ortholog of Fgf15) is involved in early development and the distribution of cardiac neural crest cells and is one of the candidate genes for congenital heart defects.

Atlantoaxial dislocation is associated with MTHFR (C677T) polymorphism. *M. Pradhan[1], S. Agarwal[1], S. Behari[2]*
1) Dept Of Medical Genetics, SGPGIMS, Lucknow, UP, India; 2) Dept of Neurosurgery, SGPGIMS, Lucknow, UP, India.

Atlantoaxial dislocation (AAD) has a high incidence in the Indian subcontinent. Depending upon the type of defect this can be either reducible or irreducible type. AAD has been detected as early as 5 yrs of age and its presence since birth cannot be ruled out. Hence, this congenital defect which is more common in this part of the world; may be due to nutritional deficiency during intrauterine life in genetically predisposed individuals. We looked into the MTHFR gene polymorphism (C677T and A1298C) in 75 patients and 60 matched controls. CT genotype frequency of MTHFR 677CT polymorphism in AAD (OR 3.00, 95 % CI 1.28-7.14; p =0.005) as well as in the irreducible subgroup (OR 2.81, 95 % CI, 1.17-6.86; p =0.01) was significantly higher than controls. The frequency of T alleles was also higher (25.3%) in AAD compared to the control group [15%] (OR 1.92, 95% CI 0.97-3.37; p = 0.053). There was no association of A1298C polymorphism in MTHFR gene in any of the group. Hence, it can be predicted that C677T polymorphism in MTHFR gene plays an important role in causation of AAD. Widespread use of periconceptional folic acid has resulted in reduced occurrence of this disease in those part but still seen in areas where it is not being practiced.

Mutation screening of FLT-1 in preeclampsia. *S.M. Zeng[1], J. Yankowitz[1], D. Merrill[2], J. Murray[3]* 1) Department of OB/GYN, Univ of Iowa, Iowa City, IA; 2) Department of OB/GYN, Wake Forest School of Medicine; 3) Department of Pediatrics, Univ of Iowa, Iowa City, IA.

Preeclampsia (PE) is a complex pregnancy-specific disorder, characterized by hypertension and proteinuria in the second or third trimester of pregnancy. PE is a leading cause of maternal and neonatal mortality and morbidity worldwide. The etiology of PE remains unclear, but genetic susceptibility is widely accepted as an etiological factor. A number of candidate genes have been reported. FLT-1 (fms-like tyrosine kinase 1 also known as vascular endothelial growth factor receptor 1 (VEGFR-1)) has been considered a good candidate gene from evidences from molecular biology, clinical and animal models. This gene is composed of 30 exons coding a transmembrane receptor protein. We previously found that 2 SNPs (single nucleotide polymorphisms) in the non-coding region of FLT-1 (intron 17 and upstream) are linked to PE risk. The current study will describe mutations of the coding area of FLT-1 in patients with PE. Diagnosis of PE is according to standard criteria. Each exon and its flanking regions (20-50 base pairs) were amplified, and sequence analysis performed with POLYPHRED and CONSED programs. We sequenced all 30 exons and flanking regions of FLT-1 in 92 Caucasian patients with PE and predicted an effect of mutation on FLT-1 protein structure with PolyPhen program. Sequencing analysis demonstrated 9 mutations in the coding region of FLT-1, including 1 nonsense, 4 missense and 4 silent mutations. One nonsense mutation is caused by alteration of tyrosine codon into stop codon due to C to A transversion at third nucleotide at codon 1213. The 4 missense mutations were I623V in exon 13, K828R in exon 17, E1002A in exon 21 and S1247G in exon 29. Polyphen showed that the alteration of amino acid in all 4 missense mutations had a benign effect on the protein structure of FLT-1. The 4 silent mutations were P365P in exon 8, T568T in exon 13, A897A in exon 19 and P1068P in exon 24. In the flanking regions we found 6 SNPs 3 to exons 3, 14, 19, 23, 28 and 30, and one T insertion 5 to exon 17. Analysis showed that all 4 missense mutations, 1 silent mutation, and one mutation in a flanking region are at sites with high conservation. The association of these mutations and PE risk may warrant further study.

Evaluation of N-myc amplification status in 14 neuroblastoma tumours by FISH. *M.J. Marafie[1], R. Mittal[2], S. Abulhasan[1], Z. Mohammed[1], A. Al Adwani[1]* 1) Cancer Genetics, Kuwait Medical Genetics Center, Maternity Hospital, Kuwait; 2) Kuwait Cancer Control Center, Kuwait.

Neuroblastoma is the most frequent malignant solid tumour of early childhood with two thirds of the cases presenting in children younger than 5 years. It arises from embryonal neural crest, including adrenal medulla, paravertebral sympathetic ganglia, and sympathetic paraganglia. Neuroblastoma tumours show a wide clinical and biological heterogeneity, from spontaneous regression forms to cancers with a rapid and fatal progression. Several parameters are used to predict the biological behaviour of an individual tumour more precisely, such as N-Myc oncogene amplification (10 copies), DNA ploidy, deletion or allelic loss of the short arm of chromosome 1, the expression of nerve growth factor receptor encoded by NTRK1 gene, and telomerase activity. These Tumour-derived biomarkers are suggested to have the key role in determining the aggressiveness and progression of the tumours. However, N-myc oncogene amplification is considered the most important factor to evaluate survival and therapeutic choices in these patients, more intensive than usual chemotherapeutic regimens are used for patients with aggressive tumours. We investigated the N-myc amplification status of neuroblastoma tumours derived from 14 patients, using fluorescence in situ hybridization. Eight samples showed N-myc amplification, all came from patients with high risk stage 4 neuroblastoma. Those who received special chemotherapeutic regimen, responded well to treatment and are up to now with good prognosis. FISH is a sensitive technique that facilitates characterization of neuroblastoma tumours and aids in improving the clinical management of particular patients.

New congenic strains reveal complex interaction of Cd36-deficiency with genomic background in determination of metabolic syndrome features. *O. Seda[1,2,3], M. Morysova[1], L. Sedova[1,3], L. Kazdova[2], F. Liska[1], J. Tremblay[3], D. Krenova[1], P. Hamet[3], V. Kren[1]* 1) First Faculty of Medicine, Charles University in Prague; 2) Institute for Clinical and Experimental Medicine, Prague, Czech Republic; 3) Research Centre CHUM, Montreal, Quebec, Canada.

Deficiency of fatty acid translocase Cd36 has been shown to play major role in pathogenesis of metabolic syndrome in spontaneously hypertensive rat (SHR). We have derived 2 new congenic strains PD.SHR4 using marker-assisted approach for introgression of chromosome (chr.) 4 region of SHR origin including defective Cd36gene into genetic background of PD rat strain, highly inbred model of metabolic syndrome. We have subjected standard diet-fed adult males of PD and PD.SHR4 strains (n=8/strain) to metabolic, morphometric and transcriptomic (Affymetrix Rat 1.0 ST Exon array) profiling. The differential segment of SHR origin spans ca 20Mb between markers D4Rat139 and D4Rat125in PD.SHR4a congenic strain and ca 39Mb of telomeric chr.4 segment in PD.SHR4b. We observed significantly improved glucose tolerance and lower fasting insulin in both PD.SHR4 strains compared to PD. On the other hand, PD.SHR4a strain showed highest concentrations of LDL cholesterol compared both to PD and PD.SHRb. Both congenic strains had smaller LDL particle sizes and lower HDL cholesterol than PD. The expression profile revealed 18 transcripts with >1.5fold difference in expression after FDR correction (0.1), e.g. prostaglandin D2 synthase (2.2 fold in PD vs. PD.SHR4a). None of the differentially expressed transcripts resides in the introgressed chr.4 segment.
The transfer of chr.4 region of SHR origin, previously ascertained as a quantitative trait locus for dyslipidemia and insulin resistance, into PD genetic background resulted in paradoxical amelioration of insulin resistance and deterioration of lipid metabolism. Our results suggest that apart from mutant Cd36 allele, other genomic features present in the SHR-derived segment play a role in pathogenesis of metabolic syndrome. Their eventual phenotypic outcome is then a function of complex interactions with particular environment and genomic background, upon which they operate.

A new mouse model for Proliferative Diabetic Retinopathy. *J.T. Tosi, J.M. Kasanuki, K.M. Janisch, S.H. Tsang*
Bernard & Shirlee Brown Glaucoma Laboratory, Edward S. Harkness Eye Institute, and Dept. of Pathology, Columbia Univ. College of Physicians & Surgeons, New York, NY.

PURPOSE: Patients with proliferative diabetic retinopathy suffer a high incidence of ocular complications leading to diminished vision and activities of daily living. Chronic hypoxia induces vascular endothelial growth factor (VEGF) expression, causes damage to blood vessels in the eye and results in widespread leakiness and focal areas of closure of the vessels. We hypothesize that diabetic retinopathy phenotypes can be simulated in the mouse by upregulation of hypoxia inducible factor (HIF) signaling, which is known to directly regulate VEGF expression. METHODS: Using a transgenic mouse system, HIF-1a was expressed in the retina, using a bipolar cell-specific driver. Dynamic fluorescein angiographies were performed after single FA dye injections (20 mg) into tail veins of mice. A scanning laser ophthalmoscope was used for video angiography. Quantitative immunoblots were performed to assess levels of HIF-1a expression. RESULTS: We observed angiographic evidence of wide-spread microaneurysms, capillary closure, vitreous hemorrhage and neovasularization of the optic discs, due to sustained expression of HIF-1 and VEGF. Mice also developed iris neovascularization and cataracts, similar to patients with proliferative diabetic retinopathy. CONCLUSIONS: Retinopathy phenotypes result from overexpression of HIF-1a and VEGF. This is the first appropriate animal model that can be used for the development of novel therapies for proliferative diabetic retinopathy. Treatments that interrupt the HIF-1a response may prevent proliferative retinopathy. Dissection of the HIF-1a induced pathways will be relevant to the treatment of diabetic vascular diseases in which hypoxia or ischemia plays an important pathophysiologic role.

Molecular Basis of Short Stature in Trichorhinophalangeal Syndrome. *D. Napierala[1], K. Sam[1], R. Morello[1], Q. Zheng[1], T. Bertin[1], T. Sibai[1], R. Shivdasani[3], B. Lee[1,2]* 1) Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX; 2) Howard Hughes Medical Institute; 3) Dana-Farber Cancer Institute and Harvard Medical School, Boston, MA.

Mutations in the human *TRPS1* gene cause a dominantly inherited craniofacial and skeletal dysplasia trichorhinophalangeal syndrome (TRPS). Patients with TRPS have short stature, hip abnormalities, cone-shaped epiphyses, and premature closure of growth plates reflecting defects in endochondral ossification. The *TRPS1* gene encodes for the transcription factor TRPS1 that has been demonstrated to repress transcription *in vitro*. To elucidate the role of Trps1 in endochondral bone formation, we analyzed *Trps1* mutant mice deleted for the GATA DNA-binding domain (TrpsGT mice). Histological analyses of long bones demonstrated delayed onset of chondrocyte hypertrophy in TrpsGT mice in comparison to WT littermates. Morphometric analyses of the growth plate and RNA in situ hybridizations demonstrated that zones of proliferating, prehypertrophic and hypertrophic chondrocytes are elongated in TrpsGT mice in comparison to WT littermates. Interestingly, the mineralization of perichondrium was more advanced in TrpsGT mice than in WT littermates. Since both mineralization and chondrocyte maturation are regulated by the Runx2 transcription factor, and because the expression of Runx2 and its target genes in chondrocytes is increased in TrpsGT mice, we tested whether Trps1 could repress *Runx2* gene expression and/or Runx2 protein function. Our in vitro studies demonstrated that Trps1 directly interacts with Runx2; moreover Trps1 strongly represses the Runx2-mediated transactivation of the target reporter construct. Taken together, abnormalities in the growth plate in the TrpsGT mice and *in vitro* functional studies strongly suggest that one of the roles of Trps1 during endochondral ossification is spatial and temporal repression of Runx2. Dysregulation of this function underlies the growth plate alterations in TRPS1 loss of function.

Multiple candidate gene analysis identifies *CALB1(calbindin1)* as a susceptibility gene for sporadic Parkinsons disease. *I. Mizuta[1,2], W. Satake[1], T. Tsunoda[3], M. Watanabe[4], A. Takeda[5], K. Hasegawa[6], M. Yamamoto[7], N. Hattori[8], M. Murata[9], T. Toda[1,2]* 1) Div Clinical Genetics, Osaka Univ Grad Sch Med, Suita, Osaka, Japan; 2) CREST, JST, Saitama; 3) SNP Res Center, RIKEN, Yokohama; 4) Dept Neurol, Univ Tsukuba, Tsukuba; 5) Div Neurol, Dept Neuroscience, Tohoku Univ Grad Sch Med, Sendai; 6) Dept Neurol, Sagamihara National Hosp, Sagamihara; 7) Dept Neurol, Kagawa Prefectural Central Hosp, Takamatsu; 8) Dept Neurol, Juntendo Univ Sch Med, Tokyo; 9) Dept Neurol, Musashi Hosp, NCNP, Tokyo, Japan.

Parkinsons disease (PD) is the second most common neurodegenerative disorder characterized by the loss of dopaminergic neurons in the substantia nigra of the midbrain. Our recent case-control association study of 268 SNPs in 121 candidate genes identified -*synuclein (SNCA)* as a definite susceptibility gene for sporadic Parkinsons disease (PD) ($P=1.7x10^{-11}$). To find other susceptibility genes, additional 34 SNPs of 17 genes were included in the screen. Of 302 SNPs in total, excluding SNPs in *SNCA*, those in *NDUFV2, FGF2, CALB1 and B2M* showed significant association ($P < 0.01$, 882 cases and 938 control subjects). Association analysis of these SNPs was replicated in another sample panel (521 cases and 1003 control subjects). Only the SNP *rs1805874* in *calbindin1 (CALB1)* showed significance again ($P=7.1x10^{-5}$, recessive model). Next, statistical combinational effect of *CALB1* and *SNCA* was analyzed. In homozygotes of PD-associated allele of *SNCA*, *rs1805874* revealed no significance, however, in the others, *rs1805874* showed significant association with PD ($P=8.7x10^{-5}$, ^{2} statistics). Logistic regression analysis showed the significant additional effect of the two SNPs (combined $P=8.9x10^{-17}$), however, showed little significant interaction ($P=0.05$). CALB1 is a calcium-binding protein that is widely expressed in neurons. It is known that there is a relative sparing of the CALB1-positive dopaminergic neurons in PD brains compared with CALB1-negative ones. Taken together, our genetic analysis suggests that *CALB1* is associated with PD independently of *SNCA*.

***PPARG* Gene Variants Are Associated with Diabetes Risk in the Womens Health Initiative - Observational Study.** *T. Niu[1,2], Y.-H. Hsu[3,4], Y. Song[1], L. Tinker[5], J. Hsia[6], S. Liu[4,7]* 1) Div of Prev Med, Dept of Med, BWH, Harvard Med School, Boston, MA; 2) Pgm Mol & Genet Epi, Dept of Epidemiology, HSPH, Boston, MA 02115; 3) Mol and Integ Physiol Sci Pgm, HSPH, Boston, MA 02115; 4) Pgm on Genomics & Nutr, Dept of Epidemiology, UCLA SPH, Los Angeles, CA 90095; 5) FHCRC, Seattle, WA 98109; 6) Dept of Med, George Washington Univ, Washington, DC 20037; 7) Dept of Med, UCLA David Geffen School of Med, Los Angeles, CA 90095.

The association of the *PPARG* gene with risk of diabetes mellitus (DM) was studied in the Womens Health Initiative (WHI) Observational Study (OS) using a two-stage approach. First, we genotyped 105 *PPARG* single nucleotide polymorphisms (SNPs) in a developing panel (N_d = 244) where we identified 24 haplotype-tagging SNPs (htSNPs). Second, we genotyped the 24 htSNPs in 1543 DM cases during a median follow-up period of 5.9 years and 2132 controls matched by age, ethnicity, clinical center, time of blood draw, and length of follow-up. In single-SNP analyses, compared with the *Pro12* allele, *Ala12* allele was associated with a significantly lower risk of DM [odds ratio (OR) = 0.53, 95% confidence interval (CI): 0.32-0.86, P = 0.0112]. Under the dominant genetic model, compared with the *Pro12*/*Pro12* genotype, *Ala12* carrier genotypes were associated with a significantly reduced DM risk (OR = 0.56, 95% CI: 0.35-0.89, P = 0.0137); in the meta-analysis of 21118 cases and 28142 controls (k = 54 studies), the summary OR of the *Ala12* carrier genotypes was 0.81 (95% CI: 0.74-0.87, $P = 1.45\times10^{-7}$) for the random effects model, given significant evidence of heterogeneity (I^2 = 43%, P = 0.0005). The sliding window (window width=3) haplotype-based analysis identified that haplotypes formed by *Pro12Ala-rs1373640-rs2972162* were significantly associated with the risk of DM (LRT ^{2} = 15.308, df = 5, P = 0.009). Our study with the most comprehensive assessment of the *PPARG* gene in the prospective WHI-OS strongly supports a significant relationship between the *PPARG Pro12Ala* polymorphism and DM risk.

An i(21) case caused by paternal low level mosaicism. *H. Numabe[1], H. Uchio[2], H. Doi[2], S. Adachi[2], T. Yorifuji[2], T. Nakahata[2], K. Tomiwa[1], S. Kosugi[1]* 1) Department of Clinical Genetics, Kyoto University Hospital, Kyoto, Kyoto, Japan; 2) Department of Pediatrics, Kyoto University Hospital, Kyoto, Kyoto, Japan.

Case: The case is a 7-day-old boy with Down syndrome who is the first child by ICSI (intracytoplasmic sperm injection). He was transferred to our hospital because of heart murmur. At his birth the mother was 33 and the father was 31 years old. Labor and delivery were uneventful. The gestational age was 37 weeks and 1 day and the birth weight 2,764g. A cardiac echogram demonstrated ASD (atrial septal defect), VSD (ventricular septal defect), and PDA (patent ductus arteriosus). His karyotype was 46,XY,i(21)(q10). To reveal the origin of i(21), we performed the chromosome analyses of his parents who have normal phenotypes. The mothers karyotype was 46,XX,inv(9)(p12q13) which is known as a normal variant. The fathers karyotype was 45,X,dic(Y;21)(p11.3;p11.2) in total count of 20 cells, and 45,X,dic(Y;21)(p11.3;p11.2)[48]/46,XY,r(21)(p13q22.3)[2] in 50 cells. To reveal low level mosaicism of i(21), we examined 100 cells employing the FISH technique. As the final result, the fathers karyotype was ish dic(Y;21)(SRY+,D21S259/D21S341/D21S342+,Tel 21q+),21(D21S259/D21S341/D21S342x1, Tel 21qx1)[91]/Yp11.3(SRYx1),21(D21S259/D21S341/D21S342x1,Tel 21qx1),r(21)(D21S259/D21S341/D21S342+,Tel21q+)[8]/Yp11.3(SRYx1),21(D21S259/D21S341/D21S342x1, Tel 21qx1),?i(21)(Tel 21q++, D21S259/D21S341/D21S342++)[1]. The father has a low level mosaicism of i(21) in blood cells, and may have a similar or higher level mosaicism in gonad.

Extension of the clinical spectrum of Danon disease. *R.H. Lekanne Deprez[1], A.J. van der Kooi[2], I.M. van Langen[1], E. Aronica[3], P.A. van Doorn[6], J.H.J. Wokke[7], E. Brusse[6], C.T. Langerhorst[4], P. Bergin[8], L.R.C. Dekker[5], M. Visser[2]* 1) Clinical Genetics, University of Amsterdam, Academic Medical Centre, Amsterdam, Netherlands; 2) Neurology, University of Amsterdam, Academic Medical Centre, Amsterdam, Netherlands; 3) Pathology, University of Amsterdam, Academic Medical Centre, Amsterdam, Netherlands; 4) Opthalmology, University of Amsterdam, Academic Medical Centre, Amsterdam, Netherlands; 5) Cardiology, University of Amsterdam, Academic Medical Centre, Amsterdam, Netherlands; 6) Neurology, University Medical Centre Dijkzigt, Rotterdam, Netherlands; 7) Neurology, University Medical Centre Utrecht, Utrecht, Netherlands; 8) Neurology, Auckland Hospital, New Zealand.

Danons disease is known as an X-linked dominant disorder characterized by severe cardiomyopathy, mental retardation and mild myopathy in males, and cardiomyopathy in female carriers. All but one reported mutations are truncating and located in the exons shared by the three splice variants. In affected males all mutations lead to (almost) complete absence of LAMP-2 staining of muscle tissue. A family is presented with a variant of Danon's disease caused by a novel mutation in the LAMP2 gene. Three affected brothers and a maternal nephew showed normal intelligence, progressive myopathy, mild cardiac abnormalities, and retinopathy. Serum CK activity was slightly elevated, muscle biopsy showed autophagic vacuoles. LAMP-2 staining was apparently normal. One female carrier suddenly died at the age of 28 from a hitherto unrecognized cardiomyopathy. LAMP2 gene analysis revealed a new missense mutation (c.1150G>C) in splice variant B, leading to an amino-acid change (p.Gly384Arg).

A 5-year old Argininemia patient diagnosed by Newborn Screen achieved normal growth and development. *S. Yano[1], K. Moseley[1], R. Schein[1], Y. Watanabe[2]* 1) Pediatrics/Genetics Div, 1G24, Women's & Children's Hp, USC, Los Angeles, CA; 2) Department of Pediatrics and Child Health, Kurume University, Kurume, Japan.

Introduction: Argininemia is a rare disorder due to Arginase 1 deficiency. Approximately 20 patients have been reported and only a few reports describing long-term clinical observations are available. Patients are usually asymptomatic in early infancy and are diagnosed late after the onset neurological symptoms. The clinical presentation includes spastic paraplegia, mental retardation, and seizures. With the initiation of newborn screen by MS-MS, arginine levels are measured and noted to be elevated, allowing for diagnosis shortly after birth. It is not well known if early intervention can prevent the neurological insults. Case Report: The patient is an almost 5-y-old Hispanic male born at term by NSVD (BW 7lb 13oz). Newborn screening showed a blood arginine of 327mM (ref: 0-140) at 30 hours of age, a repeat serum arginine at 2 months of age was 768mM (ref: 12-133). Arginase I was undetected on enzyme assay. Initiation of diet management with protein restriction as well as treatment with sodium benzoate, carnitine, and vitamin supplementation started at 3 months of age. He had mild speech delay that resolved by age 2 1/2. The patient's serum arginine level has remained between the range of 2-4 times the normal levels. He has mild liver dysfunction with elevated transaminases and prolonged PT and PTT. Currently the patient has normal physical findings without evidence of spasticity. He underwent a complete developmental assessment at age 4 10/12, which showed normal development. Discussion: Argininemia is a rare urea cycle defect. Long term prognosis of patients with arginninemia has not been well known, particularly for patients who are diagnosed prior to occurrence of neurological symptoms. The presented case with history of initiation of treatment from 3 months of age, showed normal growth and development over the past 5 years. This case illustrates that newborn detection of argininemia is possible and early treatment may enable patients to avoid or at least postpone the onset of neurological involvement.

In-vivo genetic screen for functionally active nuclear import inhibitors. *J. Rosenbluh, A. Loyter* Biological Chemistry, The Hebrew University of Jerusalem,Israel Jerusalem, Israel.

Trafficking of proteins into the cell nucleus is an energy dependent process which involves binding of nuclear localization signals (NLS) within the protein to cellular receptors (kariopherins). Upon binding the kapiopherin-protein complex is transported through the nuclear pore complex. Interestingly, the NLS signal has been found to be of diverse sequence namely, proteins contain many different sequences with no apparent consensus sequence. Many pathogenic proteins such as viral or oncogeneic proteins function in the cell nucleus and thus contain a functional NLS. Inhibiting nuclear translocation of pathogenic proteins may serve as a novel mechanism for therapy. We have designed a yeast screening system which enables to detect in-vivo functionally active nuclear import inhibitors. This assay is based on the use of a LexA DNA binding domain, Gal4 activation domain fusion protein which does not contain an NLS. Only when a protein with a functionally active NLS is added the fusion protein can be imported to the nucleus and activate LexA regulated genes. Using this system in a yeast strain which contains a LexA-Ura3 regulated gene allows activation of the Ura3 gene only if the construct is translocated to the nucleus. Supplementing the media with the Ura3 toxin 5-FOA results in survival only of yeast cells that the fusion protein is not imported to the nucleus. To summarize in the above described method only if a nuclear import inhibitor exists the yeast cell can grow on media containing 5-FOA. A random peptide library embedded in a scaffold protein was used to screen for nuclear import inhibitors of the viral HIV-1 Tat protein. The Tat protein is an essential HIV protein required for viral transcription. Five peptides were found that inhibit to various extends Tat nuclear import, when tested these peptides were able to inhibit Tat also in different assays. Thus these peptides are a potential lead compound for development of anti-HIV drugs.

Combined linkage peak fine-mapping strategy identifies locus for muscle strength on chromosome 12. *A. Windelinckx[1], G. De Mars[1], W. Huygens[1], M. Peeters[1], J. Aerssens[2], R. Vlietinck[3], G. Beunen[1], M. Thomis[1]* 1) Dept of Biomedical Kinesiology, K.U.Leuven, Belgium; 2) Dept of Translational Medical Research, Tibotec, Belgium; 3) Dept of Human Genetics, K.U.Leuven, Belgium.

Given the increasing use of genomewide linkage scans for complex traits, fine-mapping of the resulting linkage peaks becomes an important challenge. Fine-mapping techniques mostly focus on refining linkage peaks by genotyping additional markers. However, often no selection regarding e.g. location or functionality is done on the markers, resulting in a less than ideal approach for follow-up association analyses using the same marker data. In an alternative strategy, (association) analyses are restricted to polymorphisms within positional candidate genes. The latter approach does not allow for additional linkage analyses and is only appropriate when focus is on a limited number of candidate genes. To overcome the disadvantages of both strategies, we propose a combined strategy by covering the whole linkage region with additional markers, selected based on their location in or near positional candidate genes. Selection of candidate genes is based on a gene prioritisation procedure based on similarity to genes known to influence the trait of interest using a bioinformatics approach (ENDEAVOUR). TagSNPs and coding SNPs within the candidate genes are determined using CEPH genotypes within Haploview and SNP selection is based on functionality, initial priority ranking of the gene, minor allele frequency and budgetary and genotyping platform technological criteria. Analyses are performed using linkage and association analyses and combined family-based association analysis. Application of this strategy on a previously determined linkage peak (90cM) for isometric and dynamic knee muscle strength on chromosome 12 resulted in the identification of a new locus for muscle strength. Linkage analyses on selected strength measurements resulted in maximal LOD-scores ranging from 0.30 to 2.05 and follow-up family-based association analyses identified a marker locus with p-values for association between 0.000044 and 0.43. This SNP is located in a gene that presumably has a role in the myostatin signaling pathway.

Multiple ADH genes are associated with head and neck cancers in three large independent studies. *P. Brennan, M. Hashibe, V. Gaborieau, J. McKay On behalf of the Central Europe, ARCAGE and the Latin America head and neck cancer study.* Genetic Epidemiology Group, International Agency for Research on Cancer, Lyon, France.

The alcohol dehydrogenase (ADH) pathway comprises 7 distinct ADH genes and is a key candidate gene pathway for cancers of the head and neck. In order to elucidate the potential role of this pathway for head and neck cancers we have genotyped 15 candidate SNPs in the 7 ADH genes in a large case-control study comprising 811 head and neck cancer cases and 2598 controls from 5 countries of Central Europe (Russia, Poland, Romania, Czech Republic and Slovakia). When comparing the common homozygous genotype to possession of one or two variant alleles, two of the 15 SNPs provided a strongly significant protective effect against head and neck cancer; ADH2 R48H (rs1229984), OR=0.49, 95% CI (0.35-0.69), p0.0001) and ADH7 A92G (rs1573496); OR =0.57, 95%CI (0.45-0.72), p0.0001. We subsequently genotyped these two SNPs in a second study of head and neck cancer comprising 1323 cases and 1352 controls from 7 European countries. A similar effect was observed for ADH2 R48H (OR=0.59, 95% CI 0.44-0.78, p=0.0002), and a weaker effect was observed for ADH7 A92G (OR=0.79, 95% CI (0.63-0.97), p=0.03). Finally, in a third study of head and neck cancer from 3 Latin American countries (Brazil, Argentina and Cuba), including 1711 cases and 1285 controls and we identified similar effects for both ADH2 R48H (OR=0.61, 95%CI (0.46-0.82, p=0.0008) and ADH7 A92G (OR=0.70, 95% CI (0.55-0.90), p=0.0056). When results were pool across all 3 studies the effect of ADH2 was significant at p10-11 and for ADH7 at p10-7, after adjusting country, age, sex, tobacco and alcohol. These results would appear to confirm that variants in both ADH2 and ADH7 are associated with head and neck cancer. Linkage disequilibrium between these two variants was minimal and neither had an important effect on alcohol consumption. This would suggest that functional effects of these two variants, or other variants that are closely associated with them, independently alter the risk of head and neck cancer.

The leukemia associated gene *RUNX1T1* (*MTG8/ETO*) is involved in brain and heart development. *L.A. Larsen[1], L. Zhang[1], G. Barbi[2], K. Møllgård[3], E. Bendsen[4], R. Møller[1], R. Ullmann[5], Z. Tümer[1], N. Tommerup[1]* 1) Wilhelm Johannsen Centre for Functional Genome Research, Department of Cellular and Molecular Medicine, University of Copenhagen, Copenhagen, Denmark; 2) Department of Human Genetics, University of Ulm, Ulm, Germany; 3) Department of Cellular and Molecular Medicine, University of Copenhagen, Copenhagen, Denmark; 4) Department of Obstetrics and Gynaecology, University Hospital of Odense, Odense, Denmark; 5) Max-Planck-Institute for Molecular Genetics, Berlin, Germany.

The chromosome breakpoints of the t(8;21) translocation associated with acute myeloid leukemia disrupt the *RUNX1* (*AML1*) gene and the *RUNX1T1* (*MTG8/ETO*) gene and generate a fusion protein. Involvement of RUNX1 in hematopoitec development is well documented but the normal function of RUNX1T1 is poorly understood. We report a 28 year old male patient with a constitutional balanced t(5;8)(q33;q22) translocation, where the chromosome 8 breakpoint disrupts the *RUNX1T1* gene. The patient has moderate mental retardation with autoaggressive behaviour, congenital heart defect (VSD) and minor craniofacial dysmorphism. Using FISH the chromosome breakpoints were mapped to a 27 Kb region at 8q21.3 (within intron 1 of *RUNX1T1*) and a 102 Kb region at 5q31.3 (no gene in breakpoint region). Immunohistochemistry analysis using human and rat embryonic tissues showed that RUNX1T1 is expressed in several tissues including the central nervous system, eye, heart, pancreas, colon and kidney during embryonic development. In the developing neurons of human embryonic brain RUNX1T1 expression was high in the cortical plate and moderate in the intermediate and subventricular zone, while expression was not observed in the ventricular zone. In the human embryonic heart RUNX1T1 expression was moderate. Real-time quantitative RT-PCR analysis confirmed a high expression of RUNX1T1 in the developing brain and revealed a gradually decreased expression of the gene in the heart during embryonic day 40-65. The phenotype of our patient combined with the expression during embryonic development suggests that RUNX1T1 is involved in the development of human brain and heart.

Are H19 mutations involved in Silver-Russell syndrome? *N. Schoenherr[1], G. Binder[2], E. Korsch[3], H.A. Wollmann[2], T. Eggermann[1]* 1) Institute of Human Genetics, Unversity Hospital RWTH Aachen, Aachen, Germany; 2) Children's Hospital, University of Tübingen, Germany; 3) Children's Hospital, University of Köln, Germany.

(Epi)mutations of 11p15 are associated with the overgrowth disorder Beckwith-Wiedemann syndrome (BWS) and with the primordial growth retardation disease Silver-Russell syndrome (SRS). In 11p15 two imprinting control regions (ICR1 and ICR2) regulate the expression of 14 imprinted genes. While (epi)mutations in the ICR2 are responsible for ~50% of BWS cases, in SRS only one case with a maternal duplication restricted to ICR2 was published. More than 35% of SRS patients show a ICR1 hypomethylation. The ICR1 is paternally methylated and regulates the expression of the oppositely imprinted genes IGF2 and H19. The function of the untranslated RNA H19 is still unknown but the finding that H19 is relative highly conserved among mammals indicates a profound functional relevance. Due to the supposed function of the H19 sequence in the regulation of the imprinted region 11p15 we searched for mutations in this gene in 44 SRS patients. We detected three SRS patients with variants in the transcribed region of H19. In two cases (SR17; SR81) different 3 bp deletions in exon 1 could be identified (g.8616_8618delGGG; g.8818_8820delAGG (AF087017)). Patient SR93 carried a 39 bp duplication affecting exon 2 and intron 2 (g.9867_9906dup39). All three variants were not detected in controls and are localised in evolutionary conserved regions. SR93 additionally showed a ICR1 hypomethylation. We performed splicing as well as expression analyses to figure out the functional consequences of these mutations. Splicing studies revealed a deviation from the normal H19 splicing behaviour in SR81 and SR93. Expression analysis on blood lymphocytes carried out in SR93 did not verify an altered expression pattern of H19. Nevertheless, our results indicate a relevant role of H19 mutations in the aetiology of SRS: functional effects of these variants, e.g. chromatin restructuring of the ICR1 or an altered function of the antisense RNA, are well conceivable and make further investigations of the biological role of H19 necessary.

Identification of HNF1alpha mutations in MODY3 patients. *W. Wuyts[1,2], I. Callebaut[2], L. Rooms[1], L. Vits[2], K. Storm[2]* 1) Dept Medical Genetics, Univ Antwerp, Antwerp, Belgium; 2) Dept Medical Genetics, University Hospital Antwerp, Antwerp, Belgium.

Maturity Onset Diabetes of the Young (MODY) is a monogenic form of diabetes mellitus accounting for approximately 1 to 2% of non-insulin dependent diabetes. MODY is characterised by early onset pancreatic -cell dysfunction and autosomal dominant inheritance. It is a genetic heterogeneous condition with already several causal genes identified. In Europe, MODY type 2, caused by mutations in the glucokinase gene and MODY type 3 caused by mutations in the HNF1alpha transcription factor gene are the most prevalent forms.

We have performed genetic testing for MODY type 3 in 286 probands referred to our center. All probands full filled at least two of the following criteria: early-onset hyperglycaemia (age of onset < 40 years), the absence of beta cell auto-antibodies and a positive familial history for diabetes with at least two successive generations affected.

Molecular screening of the HNF1alpha gene was performed by PCR amplification and sequencing of all coding exons (exon 1-10). In 47 probands (16,4%) a potential pathogenic variant was detected. Fourty-one different mutations were identified while six mutations were detected in more than 1 patient. Approximately 50% of the mutations were missense mutations, 30% truncating mutations and 20% variants (likely) affecting splicing. Although mutations were present in every exon, exon 4 appeared most affected with a mutation in this exon in 20% of the patients.

These results show that mutations in the HNF1alpha gene are a significant cause of MODY in our patient population.

TBX22 missense mutations found in X-linked cleft palate (CPX) patients affect DNA binding, transcriptional repression and sumoylation. *E. Pauws[1], A.M. Andreou[1], M.C. Jones[2], G.E. Moore[1], J.J. Brosens[2], P. Stanier[1]* 1) Institute of Child Health, 30 Guilford Street, London WC1N 1EH, United Kingdom; 2) IRDB, Imperial College London, Du Cane Road, London W12 0NN, United Kingdom.

The T-box transcription factor TBX22 is essential for normal craniofacial development as demonstrated by the finding of nonsense, frame shift, splice site or missense mutations in patients with X-linked cleft palate and ankyloglossia (CPX). To better understand the function of TBX22, here we studied 9 different naturally occurring missense mutations that are phenotypically equivalent to loss-of-function alleles. Since all missense mutations are located in the DNA-binding T-box domain we investigated their effect on DNA binding in an EMSA assay using a TBX22 specific binding site. We find that all mutants exhibit compromised DNA-protein interactions, with the strongest effects seen with missense mutations at or near predicted contact points with the DNA backbone. The transcriptional function of TBX22 was investigated using a luciferase reporter assay which demonstrated that TBX22 functions as a transcriptional repressor. In this assay all missense mutations showed impaired repression activity. We demonstrate that TBX22 is a target for the small ubiquitin like modifier SUMO-1 and that this modification is a requirement for the observed repressor activity. Although the site of SUMO attachment is located at K63, upstream of the T-box domain, we find that all pathogenic CPX missense mutations attenuate SUMO-1 modification. This suggests that the loss of TBX22 function associated with missense mutations may be linked by a general mechanism affecting SUMO conjugation as well as DNA binding. Orofacial clefts are well known for their complex etiology and variable penetrance, involving both genetic and environmental risk factors. The sumoylation process is also subject to and profoundly affected by similar environmental stress. Our data supports recent evidence that suggests that SUMO modification represents a common mechanism involved in the regulation of normal craniofacial development and is involved in the pathogenesis of both Mendelian and idiopathic forms of orofacial clefting.

Association of genetic variations in HTR2A gene with rheumatoid arthritis. *M. Seddighzadeh[1], A. Kling[2], L. Ärlestig[3], L. Alfredsson[4,5], S. Rantapää-Dahlqvist[3], L. Padyukov[1]* 1) Department of Medicine, Karolinska Institutet and Hospital, Stockholm, Sweden; 2) Division of Clinical Pharmacology, University Hospital, Umeå, Sweden; 3) Department of Public Health and Clinical Medicine, Rheumatology, University Hospital, Umeå, Sweden; 4) Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden; 5) Stockholm Center for Public Health, Karolinska University Hospital, Stockholm, Sweden.

Background: There is wide evidence for a negative association between rheumatoid arthritis (RA) and schizophrenia. Furthermore, the serotonin receptor (HTR2A) has been demonstrated to have implications for the pathophysiology of schizophrenia. Therefore we found it relevant to investigate the association between the genetic polymorphisms within HTR2A gene and RA. Methods: The HTR2A gene polymorphisms were analysed in RA patients and controls from two Swedish cohorts using PCR based restriction endonuclease mapping or TaqMan allelic discrimination with more than 4000 individuals included in the current study. Results: At the discovery stage it was demonstrated that there is significant difference in the genotype frequency of rs6313 (T102C polymorphism) between the RA patients and controls (p=0.006). In the validation stage 6 more SNPs and extended number of samples was investigated. In this stage a trend in associations for SNPs rs6313, rs6314 and rs6311 (p=0.0088, 0.0074, 0.0069) was seen, although it was lost after correction for multi-comparison. However, haplotype frequency analysis based on these three SNPs showed significantly low representation of TTT combination in RA patients in comparison with controls (3.5% and 5.5%, p=0.0002 in Chi-square test, empirical p=0.0032 after 10 000 permutations). Conclusion: The present study demonstrates that there are genetic polymorphisms at HTR2A gene which are associated with susceptibility for RA suggesting possible links between the serotonergic system and development of the disease.

Frequency analysis of autosomal dominant Spinocerebellar Ataxia (AD-SCA) in the patients from southern Italy.
E. Mannarino, P. Tarantino, D. Civitelli, I.C. Cirò Candiano, S. Carrideo, F.E. Rocca, F. Annesi, E.V. De Marco, G. Provenzano, V. Greco, G. Annesi Inst Neurological Sci, National Research Council, Cosenza, Italy.

Autosomal dominant spinocerebellar ataxias (AD-SCA) constitute a clinically, genetically and pathologically heterogeneous group of neurodegenerative disorders characterized by degeneration of spinocerebellar pathways with variable involvement of other neural systems. These disorders are caused by variable trinucleotide repeat expansions within SCA1, SCA2, SCA3, SCA6, SCA7, SCA8, SCA12, SCA17 and DRPLA genes. The aim of our study was to estimate the frequency of AD-SCA in patients from Southern Italy. We analyzed 945 subjects affected by progressive ataxia as a cardinal clinical feature, by pyramidal and extrapyramidal signs and by peripheral neuropathy. The known trinucleotide repeat expansions were assessed in the SCA1, SCA2, SCA3 SCA6, SCA7, SCA8, SCA12, SCA17 and DRPLA genes. Genomic DNA was amplified with fluorescent primers spanning the SCA expansions and PCR products were separated onto a capillary sequencer. Genetic analysis showed the presence of pathological repeat expansions in SCA1, SCA2 and SCA17 genes in a portion of the examined patients, and allowed us to identify 33 individuals affected with SCA1 belonging to 18 families; 42 individuals affected with SCA2 belonging to 28 families and 3 individuals affected with SCA17 belonging to 3 families. No cases of SCA3, SCA6, SCA7, SCA8, SCA12 and DPRLA were identified. Compared with the overall Italian distribution, the mutation distribution within the AD-SCA genes in Southern Italy appears to be peculiar. Indeed, the frequency of SCA1 expansion is higher than in Middle and in Northern Italy and, on the contrary, SCA3, SCA6, SCA7, SCA8, SCA12 and DRPLA expansions are absent in our sample. SCA2 expansion is the most frequent, while only a few patients carrying SCA17 expansion were detected. Moreover, our results suggest an involvement of additional loci associated with AD-SCA in the patients in whom genetic analysis excluded the presence of pathological repeat expansions in the herein explored genes.

Variations in *GRHL2* contribute to Age-Related Hearing Impairment (ARHI) in different European populations.

L. Van Laer, E. Van Eyken, E. Fransen, J.R. Huyghe, T. Wienker, I. Pyykkö, C.W.R.J. Cremers, H. Kremer, I. Dhooge, D. Stephens, E. Orzan, M. Pfister, M. Bille, A. Parving, M. Sorri, P. Van de Heyning, G. Van Camp, European ARHI Consortium European ARHI consortium from Antwerp (Belgium), Bonn (Germany), Cardiff (UK), Copenhagen (Denmark), Ghent (Belgium), Nijmegen (the Netherlands), Oulu (Finland), Padova (Italy), Tampere (Finland), Tübingen (Germany).

Age-Related Hearing Impairment (ARHI) is the most prevalent sensory impairment in the elderly. Approximately 50 % of 80-year-olds suffer from a hearing loss of 25 dB or more. ARHI is a complex disease caused by an interaction between environmental and genetic factors. The contribution of various environmental factors has been relatively extensively studied. In contrast, investigations to identify the genetic risk factors have only recently been initiated. So far only 2 putative susceptibility genes have been reported. Here we describe the results of an association study on 2540 ARHI samples derived from 9 centres from 7 different European countries. The degree of hearing loss was expressed with a Z-score. In 70 candidate genes, which were chosen among the monogenic hearing loss genes identified in mice and men in addition to several strong functional candidates, a total of 768 tag SNPs was selected based on Hapmap data. Genotyping was performed by Illumina. After data polishing, statistical analysis on all samples combined resulted in a p-value that survived correction for multiple testing for a *GRHL2* SNP. Other SNPs in this gene were, though less strongly, associated as well. Subsequently, analysis of each population separately was performed, resulting in significant associations in two populations and a trend towards significance in a third population. Moreover, the direction of the association was identical in all nine populations, providing further proof for the validity of this association. Subsequently, fine-mapping of this locus was performed.

Family-based study of ten immunity-related genes and tuberculosis: association with TLR2, TLR9, SLC11A1, and NOS2A. *W.K. Scott[1], W.F. Hulme[1], J.B. Rimmler[2], M.E. Stryjewski[3], E.H. Abbate[4], R. Estevan[4], J.R. Gilbert[1], C.D. Hamilton[2]* 1) University of Miami, Miami, FL; 2) Duke University, Durham, NC; 3) CEMIC, Buenos Aires, Argentina; 4) F.J. Muñiz Hospital, Buenos Aires, Argentina.

Tuberculosis (TB) is a significant cause of premature mortality worldwide. Ten percent of exposed individuals develop pulmonary TB, suggesting that host factors, partly under genetic control, determine development of active TB. We collected samples from 233 African-American and 165 white families with at least one case of pulmonary TB. People older than 14 years with culture-confirmed pulmonary TB and children younger than 14 years with culture- or clinically-confirmed TB were recruited from the North and South Carolina TB control programs and the outpatient clinics of F.J. Muñiz Hospital, Buenos Aires, Argentina. Unaffected siblings, parents, and spouses/partners were enrolled as controls. We examined 167 haplotype-tagging SNPs (tagSNPs) in ten immunity-related genes (TLR2, TLR4, TLR9, SLC11A1, NOS2A, TNFA, INFG, INFGR1, VDR, PARK2) for association with TB. tagSNPs were selected from HapMap Phase II data and captured the common variation (minor allele frequency (MAF) 5 %) in each gene with $r^2$0.8. Other coding SNPs with MAF 1% were genotyped as well. Genotypes were determined using TaqMan assays. Analyses using the association in the presence of linkage (APL) test were conducted stratified by self-reported race to limit confounding. In African-American families, TB was associated with SNPs in TLR2 (rs653939, p=0.04), TLR9 (rs352139, p=0.03; rs187084, p=0.049), SLC11A1 (rs3731865, p=0.03), and NOS2A (rs2255929, p=0.03; rs2314809, p=0.004; rs2779248, p=0.04). Only TLR2 (rs3804100, p=0.04) was associated with TB in white families. None of these SNPs has known functional significance, but may be in linkage disequilibrium with a functionally relevant variant. While associations in TLR2, TLR9 and SLC11A1 have been previously detected in subsets of these families, the findings with intronic SNPs near the 3 end of NOS2A (rs2255929, rs2314809) are novel. These results suggest that innate immunity genes are potential risk factors for development of TB, particularly in individuals of African descent.

Transitioning to self-management (TSM): Experience with Marfan syndrome (MFS). *R.E. Pyeritz[1], B.A. Bernhardt[1], E. Giarelli[2]* 1) Medicine, Univ PA, Philadelphia, PA; 2) Sch of Nursing, Univ PA, Philadelphia, PA.

Self-management requires disease knowledge, adherence to recommendations, and health-promoting behaviors. TSM occurs as parents transfer to the child management responsibility in partnership with providers. This study describes the process of TSM in people with MFS, and offers provider recommendations. A sample of 107 (15 providers, 39 parents and 53 MFS patients, 14-35yrs) were recruited through a genetics clinic and the National Marfan Foundation, and interviewed by phone. MFS patients described TSM as: becoming knowledgeable about MFS, their health history, and the health care delivery system; the gradual acceptance of MFS and adoption of realistic expectations and behaviors to monitor and promote health, and follow provider recommendations. Patients engaged in frequent self-surveillance including awareness of heart beat, attention to body pain and side effects of medications. Five concurrent shifts lead to successful TSM: perception (invisible malady to one perceived), orientation (present to future), ownership (parent to child), reasoning (competitive to cooperative), and sphere (private to public). Providers can facilitate a shift in perception by teaching patients how to listen to their bodies, understand the relevance of symptoms, and when medical attention is required. A shift in orientation is facilitated by discussing future medical needs, reproductive plans, career, and impact of behaviors on future health. A shift in ownership is facilitated by encouraging parents to allow the child greater role in their health care, and the provider modeling respect for the childs opinions and concerns. A shift in reasoning is encouraged when a provider attends to the patients perspective and seeks compromise, thereby transferring control. A shift in sphere is facilitated by encouraging the child to interact with others with MFS, and to discuss MFS with others. Transitioning is more than the transfer to adult care, and involves gradual changes in knowledge, attitudes and behavior that are influenced by parents and providers. TSM is an incremental and life-long series of adaptations to maintain control and hope in the context chronic illness.

In Chediak-Higashi syndrome melanocytes, giant melanosomes do not target to the dendritic tips actin network.
W. Westbroek, A. Helip-Wooley, H. Dorward, W.A. Gahl Medical Genetics Branch, NHGRI/MGB/NIH, Bethesda, MD.

Chediak-Higashi syndrome (CHS) is a rare autosomal recessive disorder caused by mutations in the CHS1 gene. Clinical characteristics include partial oculocutaneous albinism, recurrent infections, a bleeding diathesis, enlarged lysosomes in every cell type, and late-onset progressive neurological impairment. We report a CHS patient with two truncating CHS1 mutations, i.e., a nonsense (p.R514X)) and a frameshift mutation (p.F3298fsX3304). This patient had significant hypomelanosis of the skin, hair and eye. In normal melanocytes, melanosomes undergo microtubule and actin-dependent transport toward the dendritic periphery. Actin-mediated transport is dependent on the Rab27a/Melanophilin/Myosin Va tripartite complex. Rab27a-GTP interacts through its geranylgeranyl lipid tail with the melanosomal membrane, where it acts as a receptor for its effector, Melanophilin, and the Myosin Va motor protein. We investigated whether the melanosomes in CHS were correctly tethered to the actin filaments in the dendritic tips. Bright field microscopy revealed that CHS melanocytes harbor enlarged melanosomes that localized to the cell body and dendrites, but not to the dendritic tips, as observed in normal melanocytes. Confocal microscopy showed that Rab27a did not associate with enlarged melanosomes in cultured CHS melanocytes. Furthermore, Melanophilin and Myosin Va did not co-localize with the enlarged melanosomes; in normal melanocytes, Melanophilin and Myosin Va nearly always co-localized with peripheral melanosomes. Next, we employed a melanosome-specific transcript of Myosin Va fused to GFP for additional studies. In normal melanocytes, Myosin Va-GFP co-localized with Rab27a, Melanophilin, and melanosomes, while in CHS co-localization occurred only with Melanophilin in the dendritic tips. This investigation showed that the Rab27a/Melanophlin/Myosin Va tripartite complex did not form on enlarged CHS melanosomes. Absence of melanosome tethering to the actin in dendritic tips of melanocytes could explain the skin hypomelanosis associated with CHS.

International Registry and Growth Charts for Morquio A: Insights in the natural course of the disease. *A.M. Montano[1], S. Tomatsu[1], G.S. Gottesman[1], M. Smith[2], T. Orii[3]* 1) Dept Pediatrics, St Louis Univ, St Louis, MO, USA; 2) Int Morquio Org, Phoenix, AZ, USA; 3) Dept Pediatrics, Gifu Univ, Gifu, Japan.

Mucopolysaccharidosis IVA (MPS IVA; Morquio A disease) is a lysosomal storage disorder caused by deficiency of N-acetylgalactosamine-6-sulfate sulfatase. A progressive skeletal dysplasia is commonly observed among the MPS IVA patients. The assessment of physical activity and growth of MPS IVA patients is essential for monitoring disease activity, progression and response to treatment. To understand the natural course of this disease and to provoke awareness, we conducted a study in which MPS IVA patients were asked to fill out a questionnaire with inquiries regarding family history, diagnosis, signs and symptoms, height, weight, surgical history, physical activity, and general complaints. In this study, Morquio A growth charts are based on the cross sectional and longitudinal data provided by the questionnaire. 2,695 measurements of height and weight were obtained from 326 patients (172 males, 154 females) from 42 countries enrolled in the Morquio A Registry program. The mean age of patients was 14.9 years for males and 19.1 years for females. Initial symptoms and diagnosis were reported at a mean age of 2.1 and 4.7 years, respectively. 50% of patients underwent surgical operations to improve their quality of life. The most frequent surgical sites include neck (51%), ear (33%), leg (26%) and hip (25%). The birth length for affected males and females was 52.2 4.7 cm and 52.2 4.5 cm, respectively. The mean of birth weight for affected boys was 3.53 0.66 kg and for affected girls was 3.44 0.61 kg, which is similar to values of normal control charts. On the other hand, the final adult height for affected males and females was 122.5 22.5 cm and 116.5 20.5 cm, respectively. The mean weight for men over 18 years old was 43.02 18.02 kg and for women 36.7 14.5 kg. Resulting charts of height and weight centiles for Morquio A patients were compared with those of the Center of Disease Control and Prevention. The results of this study provide a reference for assessment in the medical routine follow-up and in the evaluation of the efficacy of novel therapies.

A new statistical approach for mapping modifier genes taken advantage of family structure. *R. Secolin, C.S. Rocha, I. Lopes-Cendes* Department of Medical Genetics, State University of Campinas, Campinas, São Paulo, Brazil.

The objective of this study was to develop and validate a new statistical strategy for mapping modifier genes using the 500,000 SNP maps (Genome-Wide Human SNP Array 5.0 - Affymetrix). Our strategy takes advantage of family structure and uses the probabilities of IBD sharing alleles in affected concordant relative pairs and the IBD non-sharing alleles in discordant sib pairs. The algorithm was implemented in R environment. In order to test for the power to detect genes of minor effect we use a set of 23 unrelated pedigrees segregating a type of epilepsy, familial mesial temporal lobe epilepsy (FMTLE). Complex segregation analysis and linkage studies have showed that FMTLE is likely to be caused by a major gene segregating in an autosomal dominant pattern; however, the presence of minor effect genes, modifying the main phenotype, was also detected. In fact, clinical variability of the disease among individuals in the same family is observed. Data from our large cohort of FMTLE individuals have demonstrated that 70% of them present **benign** epilepsy (with good seizures control), and 30% have **refractory** epilepsy (resistance to medical treatment). We simulate the scenario in which we genotyped 99 individuals from the 23 FMTLE pedigrees, generating a total of 221 concordant relative pairs and 22 discordant sib pairs. Simulated linkage data for 507,220 SNPs were calculated by LODPAL software from S.A.G.E.. LODPAL result values were converted to *p* values and corrected for multiple tests by the False Discovery Rate (FDR). None of the 507,220 simulated SNPs resulted in *p* values less then $1x10^{-6}$. However, a test SNP simulated as linked to the **benign** epilepsy phenotype resulted in a *p* value = $1x10^{-14}$. These results showed that this new strategy of non-parametric linkage analysis have enough statistical power for mapping FMTLE modifier genes in our sample of FMTLE pedigrees. In addition, we expect truly positive results between $1x10^{-6}$ *p* value $1x10^{-14}$. The SNPs genotyping step is already in progress in our laboratory.

Allelic dropout does not affect findings of genetic association. *R.B. Ramoni[1,2], C. Hayes[3], M.M. Werler[4], S. Hernandez-Diaz[5], K.T. Kelsey[6], P.L. Williams[7], M.F. Ramoni[2,8]* 1) Department of Developmental Biology, Harvard School of Dental Medicine, Boston, MA; 2) Harvard Partners Center for Genetics and Genomics, Harvard Medical School, Boston, MA; 3) Sackler School of Graduate Biomedical Sciences, Tufts University, Boston, MA; 4) Slone Epidemiology Center, Boston University, Boston, MA; 5) Department of Epidemiology, Harvard School of Public Health, Boston, MA; 6) Department of Genetics and Complex Diseases, Harvard School of Public Health, Boston, MA; 7) Department of Biostatistics, Harvard School of Public Health, Boston, MA; 8) Childrens Hospital Informatics Program, Division of Health Sciences and Technology, Harvard Medical School and Massachusetts Institute of Technology, Boston, MA.

Allelic dropout (ADO) is one of the most common genotyping errors. When parental genotypes are not available, ADO is detected by testing for deviation from Hardy-Weinberg equilibrium. If a particular locus is found to significantly deviate from such equilibrium, the entire locus is removed from the analysis. Here we present a mathematical model of the effects of ADO on the identification of genetic associations in case-control studies. We provide an analytical proof that the error always biases the results towards no association and, therefore, that any identified associations will hold in the presence of any degree of ADO. These results suggest the reconsideration of previously discarded data and published negative findings, and they should inform the design of future genetic association studies. The findings are broadly applicable because the standard strategy of assessing the validity of genotypes at a locus by testing for deviation from Hardy-Weinberg equilibrium in the control subjects alone implies the assumption that the phenotype will not affect the ADO. Furthermore, the general formulation of the model allows for extension to account for the unusual circumstances in which this assumption does not hold.

SOX9 micro- and macrodeletions are not uncommon in campomelic dysplasia. *G. Scherer[1], W. Jin[1], M. Wessels[2], R. Hordijk[3], C. van Ravenswaaij[4], E. Obersztyn[5], E. Blair[6], E. McPherson[7], D. Sillence[8]* 1) Inst Hum. Genet., Univ. Freiburg, Germany; 2) Dept. Clin. Genet., Erasmus Univ. Rotterdam, Netherlands; 3) Dept. Clin. Genet., Academic Hospital Groningen, Netherlands; 4) Dept. Hum. Genet., UMC Nijmegen, Netherlands; 5) Dept. Med. Genet., Inst. Mother and Child, Warsaw, Poland; 6) Dept. Clin. Genet., Churchill Hospital, Headington, UK; 7) Marshfield Clinic, Marshfield, WI, USA; 8) Dept. Clin. Genet., New Children's Hospital, Parramatta, Australia.

Campomelic dysplasia (CD), an autosomal dominant skeletal malformation syndrome, results from mutations within *SOX9*, a 5.4 kb gene consisting of three exons, or from translocations interrupting the 1 Mb *cis*-regulatory domain upstream of *SOX9*. Only three cases with complete deletion of *SOX9* have been reported, all several Mb in size, and one case with a 1.5 Mb deletion located 380 kb upstream of *SOX9*. We have screened 60 cases with clinically and radiologically confirmed (15 cases, group 1) or suspected CD (45 cases, group 2) for *SOX9* deletions, using quantitative PCR. In these non-translocation CD cases, no *SOX9* coding region mutation had been detected by sequencing. We found deletions in four cases of group 1. Two are microdeletions that removed exons 1 and 2 (2225 bp deletion) or exon 2 plus part of exon 3 (2177 bp deletion), while two are macrodeletions of 2.2 Mb and 4.4 Mb. Sequencing of breakpoint-spanning PCR products showed 3 bp homologies at the deletion junctions in three of these deletion cases. Short 2-6 bp homologies occur frequently at deletion junctions in the human genome. In group 2, three deletions of approximate sizes of 150 kb, 850 kb and 1.4 Mb all encompassing the *SOX9* gene were detected, but due to sample limitation, their exact endpoints could no be delineated. Scanning the 1 Mb *SOX9* upstream control region with amplicons spaced 100 kb apart in 11 group 1 and 23 group 2 cases did not uncover another upstream deletion case. In conclusion, *SOX9* deletions are more frequent than previously supposed and can efficiently be detected by quantitative PCR, including deletions in the range of a few kb that go undetected by array CGH.

Does cryopreservation lead to an increased DNA-fragmentation Index (DFI) in human spermatozoa? *T. Winkle[1], P. Dietl[1], F. Gagsteiger[1,2], S. Köder[1], J. Eckert[3], M. Susa[3], N. Ditzel[1,2]* 1) ReproGen- Ulm, Ulm, Germany; 2) IVF-Zentrum Ulm, Ulm, Germany; 3) Diagnostik- Zentrum Ulm, Ulm, Germany.

Cryopreservation is often used to store human germ cells, especially spermatozoa. After thawing, these spermatozoa are examined in accordance with WHO-criteria as to concentration, motility and morphology before being used for assisted reproduction techniques (ART). However, sperm chromatin integrity is never examined, in spite of the fact that it has been demonstrated that spermatozoa with a high DNA-fragmentation index (DFI) lead to poorer ART outcome. So we examined whether the act of cryopreservation using liquid nitrogen leads to an increased DFI. On the one hand we stained a part of the native semen sample with Propidiumiodide (PI) according to a slightly modified protocol of the Nicoletti assay (Nicoletti et al. 1994) and analyzed the spermatozoa with a fluorescence activated cell sorter (FACS) to obtain the DFI. On the other hand the remaining part of the sample was frozen and stored in the gas phase of liquid nitrogen (-196C) over night. After thawing the next day, the frozen samples were also stained with PI and measured in the FACS. In this preliminary study we analyzed semen samples of 15 patients so far. Until now we can find a significant correlation between cryopreservation and an increased DFI. According to our results we can say that there is a tendency that cryopreservation increases the DFI in human spermatozoa. Thus new possibilities of reducing the DFI in semen samples should be developed to increase the chances of fertilization for patients especially after cryopreservation of spermatozoa.

Using the optimal ROC curve to design a predictive genetic test. *Q. Lu, R.C. Elston* Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH.

Current extensive genetic research into common complex diseases, especially with the completion of genome-wide association studies, is bringing to light many novel genetic risk loci. These new discoveries, along with previously known genetic risk variants, offer an important opportunity to improve health care. For researchers who are interested in applying these new finding into clinical practice soon, we introduce a powerful tool to help design a new predictive genetic test. By utilizing the information from any previous association study, the method can provide an estimate of its classification accuracy and the required sample size to verify this accuracy. The proposed predictive test is asymptotically more powerful than tests built on any other existing method and can easily be extended to scenarios where loci are linked or interact. We illustrate the approach for the case of Type 2 diabetes. For a general population, we incorporate recently discovered risk factors into the proposed test and find a potentially better predictive genetic test. The area under the ROC curve (AUC) of the proposed test has a higher value (AUC=0.669) than that of the existing test (AUC=0.580). We also investigate a predictive genetic test for subjects at high risk of diabetes. Based on 44 single nucleotide polymorphisms (SNPs), the discriminative ability of this test for high risk individuals could reach an even higher level of accuracy (AUC=0.855).

Genetic Testing in 323 cases of Fatal Pulmonary Thromboembolism in the City of New York Revealed Racial Stratification. *Y. Tang[1], E.T. Bieschke[1], S.J. Jeudy[1], S. Sainte-Marie[1], Y.A. Kim[1], S. Pack[1], B.A. Sampson[2], M. Prinz[1]*
1) Forensic Biology; 2) Forensic Patholgy, Office of Chief Medical Examiner, New York, NY 10016.

Fatal pulmonary thromboembolism (PE) is a common cause of death encountered in the forensic pathology setting and usually presents as a complication of deep venous thrombosis (DVT). The pathogenesis of venous thrombosis is multifactorial and requires interaction between both inherited and acquired risk factors. Heterozygous or homozygous Factor V Leiden (G1691A) or prothrombin (G20210A) mutations, and homozygous MTHFR (C677T) variant have been recognized as common independent genetic risk factors in DVT. In order to investigate the frequency of these genetic risk factors in fatal PE and to understand the genotype and phenotype correlation, we have validated a genetic testing method to detect the three common mutations, using multiplex PCR-SNaPshot technologies, on postmortem tissue and blood samples. Between March 2005 and May 2007, we have tested 323 cases of fatal PE in the Office of Chief Medical Examiner in the City of New York. We found that 48 of the 323 cases were positive for at least one mutation. The genetic testing results were categorized by the demographic data and acquired contributing factors. We found the overall frequency of three mutations in PE cases is highest in Whites (34.15%), followed by Hispanics (28%), very low in Blacks (3%), and zero in Asian cases; in contrast, the number of fatal PE instances in our study is highest in Blacks (54.8%), followed by Whites (25.4%), and Hispanics (15.5%), and very rare in Asians (1.5%). Blacks were also associated with high percentage of idiopathic PE with unknown acquired contributing factors. This study suggests that there are racial disparities in genetic risks contributing to fatal PE. Further research focused on delineating the genetic risks in black populations is warranted. Detailed characterization of the mutation spectrum in fatal PE is vital for providing accurate diagnosis of cause of death and efficient preventative treatment to the high-risk family members.

Identification and application of European substructure ancestry information and markers. *C. Tian[1], R.M. Plenge[2], P.K. Gregersen[3], M.F. Seldin[1]* 1) Rowe Program, UC Davis, Davis, CA; 2) Broad Institute, Cambridge, MA; 3) North Shore-LIJ Res Inst, Manhasset, NY.

European population genetic substructure was examined in >1000 subjects of European descent, each genotyped with >300K SNPs. Both STRUCTURE and principle component (PC) analyses showed the largest division/vector differentiated northern from southern European ancestry. A second vector using PC further separated Italian, Spanish and Greek subjects from those of Ashkenazi Jewish ancestry as well as distinguishing among northern European populations. In separate analyses of northern European subjects other substructure relationships were discerned e.g. Irish subjects were distinguished from those of eastern and northern European descent. [Eigen values (mean +/- SD) for 4 grandparent defined subjects showed: Eastern European, -.096 +/- .013; Swedish, -.054 +/- .017; German, -.040 +/- .016; United Kingdom, .016 +/- .025; Irish, .055 +/- .013] Additional studies defined European substructure ancestry informative markers (ESAIMs). A robust set of 1400 ESAIMs for identifying north/south European ancestry was developed using selected subject subsets. The STRUCTURE results (K = 2) from subjects with 4 grandparental data (not used for ESAIMs selection) showed clear separation of self-identified subjects Ashkenazi Jewish heritage (mean 83% south; median, 87%) from 37 subjects of Western, Northern or Central heritage belonging to the northern group (mean 4% south; median, 3%), and 51 subjects of Greek, Italian, or Spanish origin were intermediate (mean south, 41%; median, 42%). The mean individual 90% Bayesian confidence interval (CI) using these 1400 ESAIMs was 12.7%. Smaller ESAIMs sets showed strong correlations with the 1400 set e.g. 384 ESAIMs, r2 = .970, CI = 17.2%. Additional studies are defining ESAIMs to ascertain and control for other differences in European substructure. The results provide further insight into European population genetic substructure and also demonstrate that ESAIMS can be used for improving type 1 and type 2 error rates in association testing of candidate genes and in replication studies of WGA scans including examples from rheumatoid arthritis studies.

PTEN Sequencing Improves the Diagnostic Yield in a Clinical Sample of Patients Evaluated for Idiopathic Autism Spectrum Disorders. *E. Varga, K. Ratliff-Schaub, M. Pastore, K. McBride, G.E. Herman* Childrens Research Institute and Dept. of Pediatrics, The Ohio State University, Columbus, OH.

We performed a retrospective chart review of 108 unrelated, newly-referred patients with an isolated autism spectrum disorder (ASD) evaluated in Genetics Clinic over a period of 26 months. The referral population consisted of 81 patients who met DSM-IV criteria for autistic disorder, 16 with PDD-NOS and 7 with Asperger syndrome. There were 4 females with Rett syndrome (confirmed by MECP2 sequencing); these subjects were excluded since 3 were referred for developmental delay (no autism) and 1 for suspected Rett syndrome. Of included subjects (n=104), 89 were male and 16 female (ratio 5.6:1) with an age range of 18 m - 16.5 y. Genetic testing was performed at the clinicians' discretion based on tiered testing guidelines developed by geneticists and developmental pediatricians at our institution. First tier testing included a high-resolution karyotype, DNA for fragile X syndrome, plasma amino acid and urine organic acid analysis, homocysteine, lead level and hearing screening. Second-tier testing included chromosomal microarray, MECP2 gene sequencing, DNA methylation for PWS/AS, urine guanidinoacetate profile and purines/pyrimidines ratio, uric acid, and PTEN gene sequencing (if HC95%) as appropriate. The overall diagnostic yield of testing was 11% (12/105). Three subjects had a karyotypic abnormality (47, XYY; mos, 47, XX, +r(8)(p12q11.2)[28]/46,XX[4]; and 46,XY, del 17p11.2(SMS-). One abnormality was detected on chromosomal microarray, a submicroscopic deletion of 3 BAC clones in 1q21 that was also present in the patients asymptomatic mother. One had a high lead level as an infant (documented level of 34 ug/dL; nl <3). None had fragile X syndrome or abnormal metabolic testing. Six patients had heterozygous mutations in the PTEN gene (3 de novo; 2 inherited; 1 parents pending). All patients with PTEN mutations had macrocephaly (98%). The disproportionate number of cases with PTEN mutations represents a referral bias. Nonetheless, these data suggest that PTEN sequencing in ASD patients improves diagnostic yield and is warranted in ASD patients with macrocephaly.

Allele frequency of the COL2A1 3' VNTR in patients with pectus excavatum. *M. Stacey[1], S. Neumann[2], V. Proud[3], A. Fecteau[4], A. Pastor[4], R. Kelly[5], D. Nuss[5]* 1) Ctr Pediatric Research, Eastern Virginia Medical Sch, Norfolk, VA; 2) Department of Psychiatry and Behavioral Sciences, Eastern Virginia Medical School, Norfolk, VA; 3) Dept. Pediatrics, Division Medical Genetics, Children's Hospital of the King's Daughters, Norfolk VA; 4) Dept Surgery, Hospital for Sick Children, Toronto, Canada; 5) Dept Surgery, Children's Hospital of the King's Daughters, Norfolk, VA.

Pectus excavatum (PE) is the most common congenital anomaly of the chest wall causing compromised cardiac and pulmonary function. In a practice with approximately 55% Caucasian and 45% African-American patients, 95% of PE patients are Caucasian, with 45% showing familial tendencies suggesting a genetic etiology. Gene variants are known to be inherited with specific disorders, and thus variants may be at different frequencies in a patient population compared to controls. COL2A1 is expressed in cartilage, is responsible for tissue strength and durability and thus play a role in the etiology of PE. We investigated the 3VNTR of the COL2A1 gene to identify allele frequency variation of this gene in 110 patients with PE, 122 family members and 30 controls. The VNTR was amplified by PCR and the number of repeats verified by sequencing. A significant increase ($p>0.05$) in heterozygosity was observed in patients vs. controls and unaffected family members. The number of tandem repeats within the VNTR in PE families was 7-13, with a peak at 10-11 repeats. These values are surprisingly similar to published results of Asians (8-12 repeats) rather than European Caucasians (13-15). A skewed distribution in the inheritance of the COL2A1 gene was suggested in this preliminary study in patients with pectus excavatum.

Sequence Evaluation of FGF and FGFR Gene Conserved Non-Coding Elements in Nonsyndromic Cleft Lip and Palate Cases. *B.M. Riley, J.C. Murray* Pediatrics, University of Iowa, Iowa City, IA.

Nonsyndromic cleft lip and palate (NS CLP) is a complex birth defect resulting from multiple genetic and environmental factors. We have previously reported the sequencing of the coding region of genes in the fibroblast growth factor (FGF) signaling pathway, in which missense and nonsense mutations contribute to approximately 5-6% NS CLP cases. Mutation searches in human disease should include both coding regions of genes and neighboring non-coding elements to comprehensively examine the functional elements within each FGF or FGFR locus. We report the sequencing of conserved non-coding elements (CNE) in and around 11 of the FGF and FGFR genes, which identified 55 novel variants. Seven of the novel variants are highly conserved among 8 species and 31 variants alter transcription factor binding sites, 8 of which are important for craniofacial development. In addition, 33% of individuals sequenced have a novel CNE variant that was conserved across 6 species or are located in craniofacial transcription factor binding sites. There were combinations of two or more coding and CNE variants in 15 NS CLP cases, suggesting that an accumulation of variants in the FGF signaling pathway may contribute to clefting. In the aggregate, adding CNE variants to the mix of more traditional mutations that can contribute to CLP affords opportunities for improved genetic counseling and understanding of complex gene/gene interactions.

The Syndrome of Megalencephaly, Mega Corpus Callosum and Complete Lack of Motor Development: Case Report. *C.A. Williams, H.J. Stalker, A.I. Dagli* Raymond C. Philips Research and Education Unit,Division of Genetics, Department of Pediatrics, University of Florida, Gainesville.

The syndrome of megalencephaly, mega corpus callosum and complete lack of motor development (OMIM 603387) is an apparently rare condition since only 3 cases have been reported [Gohlich-Ratmann et al., Am J Med Genet, 1998]. Affected infants have severe macrocephaly, muscular hypotonia and profound cognitive deficits. The cause for the MCC syndrome is unknown, no familial cases have yet been reported, and both autosomal recessive and spontaneous dominant genetic mechanisms are possibilities.

We describe an additional case diagnosed at 15 months of age. Prior to the syndrome diagnosis, extensive metabolic and genetic studies, including array-based comparative genomic hybridization, were normal. Neonatal and postnatal MRIs showed generalized, severe enlargement and thickening of the corpus callosum, bilateral megalencephaly, generalized cortical thickening and apparent pachygyria. The corpus callosum thickness, on a midsagittal T1 weighted image, was: genu 1.03 cm, body 0.86 cm and splenium 0.98 cm (normal average values for age 15 months are, 0.75 cm, 0.4 and 0.8 cm respectively [Iai et al., Acta Paediatr, 1994]). The MCC syndrome is thus a congenital macrocephaly condition associated with a distinct MRI phenotype.

.

How is mRNA expression predictive for protein expression? - a correlation study on human circulating monocytes. *Y.Z. Liu[1], P. Xiao[2,4], Y.F. Guo[2,3], S.F. Lei[2], F.Y. Deng[2], X.D. Chen[2], L.M. Li[2], S. Wu[2], Y. Chen[2], H. Jiang[2], L.J. Tian[2], J.Y. Xie[2], X.Z. Zhu[3], S.P. Liang[2], H.W. Deng[1,2,3]* 1) Univ. of MO -Kansas City; 2) Hunan Normal Univ., China; 3) Xian Tiaotong Univ., China; 4) Creighton Univ., Omaha, NE.

A key assumption in studying mRNA expression is that mRNA expression is informative to predict protein expression. However, only limited studies on yeast or human tissues explored how much information the mRNA expression could provide for the corresponding protein expression. To investigate the relationship between mRNA and protein expression levels in vivo in normal human cells, we performed correlation analyses on mRNA-protein expression in freshly isolated human circulating monocytes from thirty unrelated females. The expressed proteins for 71 genes were quantified and identified by two-dimensional electrophoresis coupled with mass spectrometry. The corresponding mRNA expressions were quantified by Affymetrix gene expression array technology. Significant mRNA-protein expression correlation ($r = 0.235$, $P < 0.0001$) was observed for the whole data set including all studied genes and all the samples. The correlations vary in different biological categories of gene ontology. For example, the highest correlation was achieved for genes for extracellular region in terms of Cellular Component ($n = 15$, GO: 0005576, $r = 0.643$, $P < 0.0001$) and the lowest correlation was obtained for genes for regulation ($n = 16$, GO: 0050789, $r = 0.099$, $P = 0.213$) in terms of Biological Process. At the genome level, fifty percent of the samples showed significant positive correlation for the 71 genes and the average mRNA expression value in all the samples was significantly correlated with the average protein expression level ($r = 0.296$, $P < 0.01$). However, at the population level, only five studied genes demonstrated significant positive correlation across all the samples. Our results showed an overall positive correlation between mRNA and protein expression levels. However, the moderate and varied corrleations suggest that mRNA expression may be sometimes useful but certainly far from perfect in predicting protein expression levels.

Power of affected-relative allele-sharing models in a small number of moderate-sized pedigrees. *C. Xing*
McDermott Ctr, Univ Texas SW Medical Ctr, Dallas, TX.

For some complex but less common diseases, doctors can usually only collect through probands a small number of moderate-sized pedigrees with multiple affected members. Linkage screen for allele sharing identical by descent (IBD) among affected relatives is routinely the first step toward identifying the disease-disposing genes. In this study we compared the power of three affected-relative allele-sharing models including the non-parametric linkage (NPL) method, the so-called Kong and Cox linear model, and the exponential model in a small number of moderate-sized pedigrees. The NPL method gives liberal p-values whereas the Kong and Cox linear model provides conservative p-values, which is different from their usual behavior that the former is more conservative while the later is more appropriate in case of incomplete inheritance information. The Kong and Cox exponential model gives proper significance levels. In summary, the exponential model should be advanced in case of a small number of moderate-sized pedigrees with multiple affected members. Moreover, the odd phenomenon of liberal NPL scores but conservative Kong and Cox linear scores at the same region may indicate excess allele sharing IBD among the affected.

A log Bayes factor-based Taxonomy approach for large-scale genetic studies. *K. Song, X. Yuan, X. Lin, A. Angelakopoulou, R.A. Gibson, L. McCarthy, L. Griffiths, D. Waterworth, V. Mooser, C. Bowman* GlaxoSmithKline R&D, King of Prussia PA and London UK.

New methods are needed to identify putative disease-causing variants while dealing with multiple testing issues, gene-gene interactions and population stratification in large-scale genetic studies. A simple visualization method called Taxonomy (v3, http://taxonomy.delrieu.org), which uses empirically-derived log Bayes factor, was recently developed to find genetic variants and to identify heterogeneity for large datasets. Here, we first used various simulations to evaluate the properties of the method and then examined its operating characteristics on a dataset comprising 763 cases with migraine and 769 controls without migraines, genotyped for 5784 SNPs within 1696 genes (described in Drug Discovery Today 2005, 10:177). Whilst there was some overlap between the genes identified using the minimum p-value in single marker analysis and Taxonomy, this new method indicated that 2 genes (out of 98 genes which were associated with migraine with a p value 0.05 in the minimum p-value with permutation) were markers of stratification rather than disease status. Taxonomy also detected some interesting association for 5 putative susceptibility genes that were weakly (i.e. p = 0.14) associated with migraine in the minimum p-value analysis. Altogether, this study indicates that Taxonomy has the potential to separate disease susceptibility SNPs from SNPs associated with diseases due to stratification, and is a novel multivariate method to reduce false positive rates, without multiple testing adjustments.

Natural gene expression variation in Down syndrome modulates the outcome of gene dosage imbalance. *P. Prandini[1], S. Deutsch[1], R. Lyle[1,7], M. Gagnebin[1], C. Delucinge Vivier[2], M. Delorenzi[3,8], C. Gehrig[1], P. Descombes[2], S. Sherman[4], F. Dagna Bricarelli[5], C. Baldo[5], A. Novelli[6], B. Dallapiccola[6,9], S.E. Antonarakis[1]* 1) University of Geneva,CH; 2) NCCR Genomic Platform, University of Geneva,CH; 3) Swiss Institute of Bioinformatics (SIB), Lausanne,CH; 4) Emory University School of Medicine, Atlanta,USA; 5) Genetics Laboratory, Galliera Hospital, Genoa,IT; 6) IRCCS-CSS, San Giovanni Rotondo and CSS-Mendel Institute, Rome,IT; 7) Ullevål University Hospital, Oslo, NO; 8) Swiss Institute of Experimental Cancer Research (ISREC), Epalinges,CH; 9) University of Rome "La Sapienza", Rome, IT.

Down syndrome (DS) is characterized by extensive phenotypic variability with most traits occurring in only a fraction of affected individuals. Substantial gene expression variation is present among normal individuals and this variation has a strong genetic component. Since DS is caused by genomic dosage imbalance, we hypothesize that gene expression variation of human chromosome 21 (HSA21) genes in DS individuals has an impact on the phenotypic variability among affected. We studied gene expression variation in 14 lymphoblastoid (LCLs) and 17 fibroblast cell lines from DS individuals and an equal number of controls. Gene expression was assayed using qRT-PCR on 100 and 106 HSA21, and 23 and 26 non-HSA21 genes in each cell type respectively. Gene expression variation in DS and normal samples was evaluated using the Kolmogorov-Smirnov test. According to the degree of overlap in expression levels, we classified all genes into 3 groups: (A) non-overlapping; (B) partially overlapping; (C) extensively overlapping expression distributions between normal and DS samples. We hypothesize that in each cell type, group A genes are the most dosage sensitive and likely involved in the constant DS traits; those in group B might be involved in variable DS traits, whereas those in group C are not dosage sensitive and less likely to participate in DS pathological phenotypes. This study provides the first extensive data set on HSA21 gene expression variation in DS and underscores its role in modulating the outcome of gene dosage imbalance.

Association of *MET* gene variants with autism susceptibility. *I. Sousa[1], N. Sykes[1], T.G. Clark[1], C. Allan[1], J. Lamb[2], K. Kobayashi[1], A. Pagnamenta[1], A.J. Bailey[3], A.P. Monaco[1], IMGSAC[4]* 1) Wellcome Trust Centre for Human Genetics, Oxford, United Kingdom; 2) CIGMR, The University of Manchester; 3) University Department of Psychiatry, Warneford Hospital, Oxford, UK; 4) http://www.well.ox.ac.uk/~maestrin/iat.html.

Autism is a common severe neurodevelopmental disorder, with evidence from twin and family studies for a complex genetic predisposition. The IMGSAC genome screen for linkage in affected sib-pair families identified a principal susceptibility locus on chromosome 7q (AUTS1) covering approximately 40Mb (with ~ 200 genes), that has subsequently shown evidence of increased sharing in several independent multiplex samples and in two meta-analyses. Taking into account its location under the linkage peak (7q31) and the fact that it has been recently reported to be associated with autism, we carried out a family based study on the *MET* gene, which encodes for a pleiotropic receptor tyrosine kinase. Therefore, using HapMap data (phase II - release 21) to assess the patterns of linkage disequilibrium across the gene, 28 haplotype-tagging SNPs were selected using Tagger from Haploview 3.2 (with r^2 0.8, MAF 0.05). We have genotyped 27 SNPs using the Sequenom and Illumina platforms, on a sample of 1702 individuals from 355 multiplex IMGSAC families, with sample and SNP genotyping success rates of ~99% and 100% respectively. Association analysis performed so far, using both single locus and haplotype approaches, showed significant results with the intron 1 SNP rs38845 (*P0.003*) and with the intronic haplotype rs38845/rs38846 (*P0.001*). In addition, a promoter SNP (rs1858830) previously reported to be associated with autism (its C allele resulting in a decrease in *MET* promoter activity) is being genotyped using an RFLP assay in our families, and association analysis will be performed and presented. Overall, these results provide further evidence that the *MET* gene plays a role in autism susceptibility.

Optimizing the power of association studies by using disease samples from other studies to augment the controls.

J. Zhuang[1], A. Morris[1], K. Zondervan[1], F. Nyberg[2], A. Jawaid[3], B. Barratt[3], L. Cardon[4] 1) Wellcome Trust Centre for Human Genetics, Oxford Univ., UK; 2) Discovery Medicine and Epidemiology, AstraZeneca, Sweden; 3) Research and Development Genetics, AstraZeneca, UK; 4) Fred Hutchinson Cancer Research Center, Seattle, WA, USA.

In the past year, genome-wide association studies have proven to be successful by revealing a number of new disease loci. In doing so they have highlighted the fact that many loci of modest effect remain undetected due to the need for sample sizes involving 1000s-10000s individuals. Large-scale international initiatives such as the Wellcome Trust Case Control Consortium (WTCCC), the Genetic Association Information Network (GAIN), and the database of genetic and phenotypic information (dbGaP), aim to facilitate discovery of modest-effect genes by making genome-wide data publicly available. These resources are designed to improve the detection of disease genes by allowing otherwise disparate disease datasets to be combined at the level of raw data. However, the power to detect allelic association also relies on the size and attributes of the control sample so these same disease samples can, in principle, also dramatically increase power via judicious use as genetically-matched controls for other traits. Using the case-control design, we have developed three strategies for optimally combining external cases to augment control samples and increase power. We present the biological motivation for the problem and the theoretical potential for the public data to contribute striking gains in power. We then use the WTCCC data and a large number of simulations to evaluate the power of the approach and show the retention of nominal significance levels when no real effects are apparent. We demonstrate the practical utility of these procedures in the WTCCC data, in which we show that previously undetected loci can be revealed (and subsequently replicated) which would have otherwise been missed because they were below thresholds of detection.

Familial Glaucoma In Taxiarches, a Small Greek Village. *M.K. Wirtz[1], A.G.P Konstas[2], J.R. Samples[1], A. Dimopoulos[2], K. Kaltsos[2], A. Economou[2], I. Georgiadou[2]* 1) Dept Ophthalmology, CE-Res, Casey Eye Inst/OHSU, Portland, OR; 2) Glaucoma Unit, University Department of Ophthalmology, AHEPA Hospital, Thessaloniki, Greece.

Purpose: To initiate a prospective study of glaucoma in a Greek village reported over 30 years ago to have several large families with primary open angle glaucoma (POAG). Methods: Random individuals from Taxiarches were interviewed in regards to history of glaucoma in their family, examined and blood samples were drawn. Consent was obtained according to the guidelines of the University of Thessaloniki. Examinations included visual acuity, ocular nerve assessment by slit lamp, intraocular pressure and corneal thickness measurement and blood pressure. POAG was defined as characteristic optic nerve cupping, vertical cup to disc ratios > 0.6 or asymmetry > 0.2 between the fellow eyes. Affected individuals were followed up at the University of Thessaloniki to determine if they had exfoliation, a common finding in Greece and for visual field testing. Results: Twenty-two of the 127 participants were diagnosed with glaucoma and 15 were suspects. The 22 affected individuals and 11 of the suspects belonged to 11 pedigrees, the largest of which contained 6 affected individuals. Fourteen individuals, 12 of whom had glaucoma, have subsequently been examined at the University of Thessaloniki. Only 1 had exfoliation glaucoma, 12 had visual field loss consistent with POAG and no exfoliation. Screening of myocilin showed that 11 of the patients with glaucoma had the Thr377Met mutation. The remaining 11 affected individuals had no myocilin mutation. Two patients with POAG were homozygous for the Thr377Met mutation. Conclusions: The village of Taxiarches is a rich resource for studying familial glaucoma with 17% of the random individuals diagnosed with glaucoma. Eleven pedigrees were identified with two or more affected family members. The Thr377Met myocilin mutation is prevalent in the village. Future studies are planned for follow-up of a larger sampling of the village to assess environmental and genetic factors affecting POAG.

Natural History and Molecular Genetics of Pediatric Bilateral Testicular Tumors. *M.T. Collins[6], R. Nandagopal[1], D.P. Merke[1], E.W. Leschek[2], T. Shawker[3], S.K. Libutti[4], J.A. Carney[5], C.A. Stratakis[1]* 1) NICHD, NIH; 2) NIDDK; 3) Dept. of Diagnostic Radiology, Warren Grant Magnuson Clinical Center, NIH; 4) Surgery Branch, Center for Cancer Research, NCI; 5) Dept. of Laboratory Medicine & Pathology, Mayo Clinic College of Medicine; 6) Craniofacial & Skeletal Diseases Branch, NIDCR, NIH.

Testicular tumors are rare in childhood, constituting about one percent of all pediatric solid tumors. Unlike malignant tumors (e.g. seminoma, embryonal carcinoma), most benign testicular tumors (BTTs) are part of identifiable genetic syndromes. We studied the largest series of patients (N=94) with BTTs to date; all were seen over the past 20 years at the National Institutes of Health. Each had one of the following conditions: Carney Complex (N=44), Peutz-Jeghers Syndrome (N=7), Congenital Adrenal Hyperplasia (N=11), McCune Albright Syndrome (N=31), or Familial Male Precocious Puberty (N=1). We analyzed retrospectively all males who presented to the NIH with BTTs from 1985-2006. Information gathered for each patient included age, gender, clinical characteristics, mutational analysis, management, and when present, histological findings and surgical outcomes. In total, 257 males were studied; 94 had testicular involvement, documented by abnormal ultrasound findings. All of these patients had bilateral tumors; none progressed to malignancy. Thirteen underwent an invasive procedure (excisional biopsy/orchiectomy), prompted by testicular enlargement, gynecomastia, or suspicious ultrasound features. None of the tumors had histological signs of malignancy, recurred locally, or metastasized. All of these patients had a mutation in one of the following five genes: *PRKAR1A*, *STK11/LKB1*, *CYP21A2*, *GNAS*, or the LH receptor gene (*LHCGR*). We conclude that childhood BTTs are usually benign and are associated with genetic syndromes that have been molecularly elucidated. In retrospect, few of our patients needed excisional biopsy or orchiectomy. Molecular testing for *PRKAR1A, STK11/LKB1, CYP21A2, GNAS*, or *LHCGR* should be considered in patients with BTTs to confirm the benign nature of the lesion and for clues to the presence of a molecularly-defined syndrome.

Confounding between recombination and selection, and a novel genome-wide method for detecting selection. *P.F. O'Reilly[1], E. Birney[2], D.J. Balding[1]* 1) Epidemiology and Public Health, Imperial College London, London, United Kingdom; 2) European Bioinformatics Institute, Wellcome Trust Genome Campus, Hinxton, Cambridge, United Kingdom.

In recent years there have been major developments of population genetics methods to estimate both rates of recombination and levels of natural selection. However, genomic variants subject to positive selection are likely to have arisen recently, and consequently had less opportunity to be affected by recombination. Thus, the two processes have an intimately-related impact on genetic variation, and inference of either may be vulnerable to confounding by the other. We illustrate here that even modest levels of positive selection can substantially reduce population-based recombination rate estimates in humans. We also show that genome-wide scans to detect loci under recent selection in humans have tended to highlight loci in regions of low recombination, suggesting that confounding with recombination rate may have reduced the power of these studies. Motivated by these findings we introduce a new genome-wide approach for detecting selection, based on the ratio of pedigree-based to population-based estimates of recombination rate. Simulations suggest that this Ped/Pop approach has good power to discriminate between neutral and adaptive evolution. The LRH method (Sabeti et al. 2002), which does allow for the confounding effects of recombination, has good power only for partial selective sweeps. Since selective sweeps are often rapid, the relevant time interval may be short. In contrast, the power of the Ped/Pop method is maintained for many generations after the fixation of an advantageous variant. Unusually for a multi-marker method our approach also shows good power in regions of high recombination. We apply the method to human HapMap and Perlegen data sets, finding confirmation of reported candidates as well as identifying new loci that may have undergone recent intense selection.

***MTHFR/VDR* genes variants interaction, bone mineral density and osteoporosis.** *O.M. Mutchinick, M.A. López, J.J. Morales* Genetica, Inst Natl Ciencias Medicas Nutricion, Mexico, D.F., Mexico. E-mail: osvaldo@servidor.unam.mx.

Osteoporosis (OPS) is the bone mineral disorder most frequently found in adults, particularly in postmenopausal women (PMW), and one of the most frequent causes of morbidity and mortality in women over 50. Reduced bone mineral density (BMD) is the main metabolic feature and major determinant of the disease. Although controversy exists, VDR variants have been associated with low BMD, OPS and bone fractures. In a previous study we showed that the homozygous bb prevalence of the Bsm1 variant of VDR was significantly higher in cases than controls, though not associated to reduced BMD. Recently has been claimed that the common C677T MTHFR variant and low serum folate increase the risk of OPS and bone fractures. The very high prevalence of the T allele and TT genotype in the Mexican population and the reported low capacity to absorb folate by the elderly, prompted us to investigate the interaction effect on BMD of diverse variants of VDR with those of genes involved in folate metabolism.We studied 67 PMW with OPS. Of the VDR we studied the BsmI, FokI, ApaI and TaqI variants and the C677T and A1298C of MTHFR, and the common variants of MTR, MTRR genes. The methodology was based on DNA extraction, PCR amplification and RFLPs analysis with restriction enzymes. The results showed that the only significant gene-gene interaction associated to decreasing BMD were bb/CT and bb/TT combined genotypes of the VDR and MTHFR gene variants, and that the differences were statistically significant. Although the differences of the BMD appears small (bb/CC: 0.69; bb/CT: 0.63, bb/TT: 0.64 and for bb/CT and bb/TT together 0.64), to the knowledge of physicians specialized in OPS, they are significant. P values of the comparisons among the BMD between the different combined genotypes (bb/CC vs bb/CT; bb/CC vs bb/TT and bb/CC vs bb/CT+bb/TT) were 0.02, 0.06 and 0.005 respectively. The above findings suggest that the presence of one 677T allele of MTHFR in the presence of the homozygous bb of BsmI of VDR, insert a considerable harmful effect on the BMD of PMW resulting a risk factor for OPS, interaction to our knowledge not previously described.

Extreme Phenotype Candidate Gene Association Study within Endogenous Opioid System in Major Depressive Disorder. *S. Mee[1], C. Reist[1,2], L. Mee[1,2], R. Moyzis[3], W.E. Bunney[2]* 1) Dept Psychiatry, VA Long Beach , Long Beach, CA; 2) Dept Psychiatry, University of CA Irvine, School of Medicine; 3) Dept Biochemistry, University of CA Irvine, School of Medicine.

Background: Major depression plagues approximately 10% of the worldwide population. Depression is widely understood to be a complex genetic disorder with heritability estimated as high as .50. No genes conclusively predisposing to this complex genetic disorder have been identified. There is substantial evidence of a link between chronic pain and depression, including the observation that affective states directly influence pain intensity, higher rates of depression in chronic pain patients and analgesic properties of some antidepressants. The endogenous opioid system, central to the experience of pain, has also been implicated in the pathophysiology of depression both in animal models and clinically. Recently, investigators have utilized extreme discordant phenotype-based study designs for diseases presumed to be influenced by multiple genetic factors of individually small effect. We are investigating whether genetic variants within POMC, proenkephalin, mu, and delta opioid receptors are associated with major depressive disorder in a case-control design of rigorously defined phenotype. Methods: Subjects were recruited from the outpatient psychiatric population of the VALBHCS medical center and screened with the full SCID-DSM IV, chart review and clinical interview with an experienced psychiatrist. Approximately 5 markers per gene, selected on the basis of population frequency from HapMap published data, were genotyped in subjects and healthy, ethnically matched controls. Polymorphism frequencies and mutation screening were compared and tested for allelic association. Results: Variants within the delta opioid receptor indicate tentative evidence of association with the case group. Ongoing analysis will be completed by 10/2007. Conclusion: Converging Evidence of links between the endogenous opioid system and depression suggests the utility of selecting candidate genes in pain neuropathways for genetic association studies of depression.

FIGLA mutations cause premature ovarian failure in a subset of Chinese women with POF. *H. Zhao[1,2], Z-J. Chen[1], Y. Qin[1,2], S. Wang[1], J.L. Simpson[2], A. Rajkovic[2]* 1) Center for Reproductive Medicine, Shandong Provincial Hospital of Shandong University, Jinan,SD,China; 2) Departments of Obstetrics and Gynecology, Baylor College of Medicine, Houston, TX, USA.

OBJECTIVE: Premature Ovarian Failure (POF) is a common cause of hypergonadotropic ovarian failure and infertility, affecting 1-2% of women. POF is a genetically heterogenous disease, with few known causative genes. We utilized a candidate gene approach to study if FIGLA, a transcriptional regulator preferentially expressed in the ovary, is mutated in Chinese women with POF. MATERIALS AND METHODS: 100 Chinese POF women, as well as 304 control age-matched women, were recruited for this study. The coding regions of FIGLA gene were amplified using polymerase chain reaction (PCR) with 4 pairs of specific primers. Sequencing was performed after PCR amplification on ABI Prism Sequencer 3130XL (Applied Biosystems). To further test whether the missense or deleted (c.16C>A and c.423-425delAAC) alleles affect FIGLAs ability to dimerize with itself or E12, we employed a yeast two-hybrid strategy to study protein-protein interactions. RESULTS: Three novel variants were identified in four POF individuals: c.16C>A (p.A4E), c.20-41del (p.P6fsX77) and c.423-425delAAC (p.140delN). The c.20-41delta causes a frameshift mutation with haploinsufficiency. Functional analyses by the yeast two-hybrid assay demonstrated that p.140delN mutation disrupted FIGLA binding to the E12 HLH domain. The c.20-41 delta and c.423-425delAAC mutations were not present in the 304 control women. CONCLUSION: Our findings show that a subset of Chinese women with sporadic premature ovarian failure harbor mutations in FIGLA. Haploinsufficiency in transcription factors is known to cause many human Mendelian disorders, and c.20-41delta frameshift results essentially in haploinsufficiency by terminating FIGLA open reading frame immediately after the first five amino acids. Moreover, we show that the c.423-425delAAC disrupts FIGLAs interaction with E12. High throughput sequencing of genes involved in the FIGLA pathway will be useful to detect other genes that play critical roles in premature ovarian aging.

Importance of dental anomalies to the diagnosis of Smith-Magenis syndrome: description of two cases. *C.R.L. Silva[1], C.S. Teixeira[1], R.S. Honjo[1], D.R. Bertola[1], L.M.J. Albano[1], A.C.V.K. Santos[2], C. Rosenberg[2], C.A. Kim[1]* 1) Genetics Unit, Instituto da Criança, São Paulo, SP, Brazil; 2) Departamento de Genética e Biologia Evolutiva - USP, São Paulo, SP, Brazil.

Smith-Magenis syndrome (SMS) is a contiguous gene syndrome caused by interstitial microdeletion in 17p11.2. It is characterized by craniofacial dysmorphisms, characteristic behavioral abnormalities and sleep disturbances. Dental anomalies have been rarely reported. Here we describe two sporadic cases of SMS associated with the dental abnormalities. Case 1: male, 18 yo, first child of a non-consanguineous healthy couple, was referred at age 7 due to short stature and delayed neurocognitive development. Physical examination: short stature, peculiar craniofacial features (brachycephaly, broad forehead, upslanting palpebral fissures, thick lips, thick lobes of the ears, long eyelashes), pulmonary stenosis, hypoplastic nipples, cryptorchidism, brachydactyly, and congenital hip dislocation. Karyotype (G banding): 46, XY. Dental findings: caries, missing teeth (left upper and lower second premolars and right lower second premolar) and taurodontism. Case 2: male, 17 yo, second child of a non-consanguineous and healthy couple, presented with speech delay. Clinical findings at 10 yo: short stature, brachycephaly, broad forehead, midfacial hypoplasia, broad nasal bridge, elongated palpebral fissures, cupid's bow upper lip, hoarse voice, brachydactyly, clinodactyly of 5th fingers, persistence of fetal fingerpads, mental retardation, hyperactivity, high limiar to pain and polyembolokoilamania. Odontological examination: taurodontism. After a long clinical follow-up without a definitive diagnosis, just recently array-CGH became available and detected a microdeletion (1,6Mb in case 1 and 3,6Mb in case 2) suggestive of SMS, confirmed by FISH. Both patients did not present sleep disturbances. In the literature, dental anomalies in SMS include especially taurodontism and tooth agenesis. Our report reinforces that these dental findings are important ones, suggesting that they could be another clue in the diagnosis of SMS.

Mutation detection rate and genotype-phenotype correlations in patients with mutations in Ush2A, the gene encoding for Usherin. *E. Tsilou[1], J. Schultz[2], M.R. Meltzer[1], R. Caruso[1], A. Griffith[2], A. Madeo[2], C. Brewer[2], C. Zalewski[2], T. Friedman[2]* 1) National Eye Institute, National Institutes of Health, Bethesda, MD; 2) National Institute on Deafness and Other Communication Disorders, National Institutes of Health, Bethesda, MD.

Usher syndrome type II (USH2) is characterized by moderate to severe high-frequency hearing impairment, intact vestibular responses and progressive visual loss due to retinitis pigmentosa. Four loci are known for USH2, and three genes have been identified. USH2A is the most frequent molecular subtype of Usher syndrome. The purpose of this study was to define the mutation detection rate of USH2A and the clinical characteristics of patients with mutations in this gene. Mutation analysis of USH2A was performed in 19 patients with clinical characteristics of Usher syndrome type II (age range: 11 to 65 years, mean age of 40 years). All patients underwent audiologic, vestibular and ophthalmic evaluation. From the 19 patients, 16 total patients (84%) were found to have mutations in USH2A. 7 patients (37%) had two USH2A mutations identified, while 9 (47%) patients had only one USH2A mutation that we could find. 9 of these mutations were novel. All 16 patients had audiologic and vestibular responses consistent with Usher type II. Two patients were found to have vertical nystagmus. Both patients had normal brain imaging studies. Mean age of perceived night blindness was 18.7 years and mean age of retinitis pigmentosa diagnosis was 23 years. Visual acuity ranged from 20/16 to light perception and mean LogMar visual acuity for patients with measurable visual acuity was 0.39 (Snellen equivalent of 20/50). 10 of 16 patients (62.5%) had cataract in at least one eye. All patients had some degree of visual field constriction and moderately to severely reduced photopic and scotopic responses consistent with retinal degeneration. The degree of visual field constriction was dependent on age. Mutation detection rate and clinical findings in our patients are similar to a previously reported series. Long-term follow-up of USH2A patients are underway to better define the rate of retinitis pigmentosa progression in this group of patients.

Identification of novel mutations and sequence variation in the Zellweger syndrome spectrum of peroxisome biogenesis disorders. *W.Y. Yik[1], S.J. Steinberg[2], P.K. Dranchak[1], A. Moser[2], H. Moser[2], J.G. Hacia[1]* 1) 1Department of Biochemistry and Molecular Biology University of Southern California 2250 Alcazar Street, IGM 240 Los Angeles, CA 90089, USA; 2) 2Peroxisomal Diseases Laboratory Kennedy Krieger Institute Baltimore, MD.

Peroxisome biogenesis disorders (PBD) are a complex group of autosomal recessive diseases that result in neurological, skeletal, hepatic, and renal abnormalities. Approximately 80% of PBD patients are in the Zellweger syndrome spectrum (PBD-ZSS). In turn, 90% of PBD-ZSS patients are caused by mutations in the *PEX1*, *PEX6*, *PEX10*, *PEX12* and *PEX26* genes which are essential for the assembly of functional peroxisomes. Here, we have developed cost-effective sequencing assays to survey the mutational spectrum of these five *PEX* genes in a cohort of 60 PBD-ZSS patients. A total of 54 unique sequence variants were identified, including 18 novel mutations predicted to disrupt protein function.Overall, direct sequencing provides a reasonable approach for the molecular diagnosis for PBD-ZSS patients and for refining our knowledge of PEX gene functional domains.

Dental evaluation of Kabuki syndrome patients. *C.S. Teixeira, C.R.L. Silva, R.S. Honjo, D.R. Bertola, L.M.J. Albano, C.A. Kim* Genetics Unit, Instituto da Criança, São Paulo, SP, Brazil.

Kabuki syndrome (KS) is a multiple congenital anomalies syndrome of unknown cause, first described in 1981 based on Japanese patients. It is characterized by a peculiar facies, postnatal growth deficiency, mild to moderate mental retardation, immunological deficiency, unusual dermatoglyphic patterns with persisting fingerpads, and various skeletal and visceral anomalies. The main features of the facial dysmorphisms are: arched eyebrows, with sparse or dispersed lateral third of the eyebrow, long palpebral fissures with eversion of the lateral portion of the lower eyelid, hypoplastic columella and prominent ears. Oral manifestations are commonly observed in KS (68% of the cases) and may comprise micrognathia, retrognathia, high-arched palate, cleft lip/palate, bifid tongue and uvula, widely spaced teeth, ectopic permanent first molars, delayed tooth eruption pattern, impacted teeth and other dental anomalies such as hypodontia, conical teeth, neonatal teeth, large pulp chamber and absence of incisors teeth. In this study, 10 patients with clinical diagnosis of KS were evaluated by dental examination and panoramic radiographic. Absence of the incisors teeth were found in 7 patients (70%), and lateral incisors were the most common absent teeth. Among these 7 patients, 2 presented dental absences in the both arches (upper and lower), 4 presented absences in only one arches and 1 patient presented associated absence of a superior canine. Because of the absent teeth, the patients had presented widely spaced teeth, and in these cases, orthodontic treatment was indicated. Caries were found in 50% of the patients, but it might be associated with mental retardation and bad hygiene. Although a large number of distinctive dental findings have been described in the literature, in our cohort teeth agenesis is the only and very prevalent feature. This specific abnormality may be helpful in establishing the diagnosis solely based on clinical grounds thus far.

Whole-genome association quality assurance using probe intensity data. *L. Li, K.S. King, L.R. Budde, D.P. Yarnall, C.J. Cox, K.J. Davies, E.H. Lai, M.G. Ehm, M.R. Nelson* Pharmacogenetics, GlaxoSmithKline.

Genetic association studies are increasingly carried out on a genome-wide scale, wherein up to a million single nucleotide polymorphisms (SNPs) may be genotyped and tested. Although the development of technology and calling algorithms have resulted in relatively high average genotyping accuracy, various sources of experimental variability can result in genotyping errors, which may lead to false positive associations. This is particularly true with small sample sizes, such as in many pharmacogenetic studies, in which many of the most significantly associated results may be enriched for genotyping errors. In three recent Affymetrix 500K whole-genome association studies of adverse drug reactions, we followed up the top association results by genotyping the selected SNPs with single base chain extension genotyping assays to confirm the microarray-based genotypes. We found that many of the strongest associations in each of the studies could be explained by genotyping inconsistencies between the two platforms: 9 of 10, 7 of 10, and 12 of 41. Although such confirmatory genotyping can help to eliminate associations due to genotyping errors, it can add a substantial amount of additional cost and time to a project. We present methods that use the microarray probe intensity data to assess the quality of genotypes for top associated markers and apply them to these three Affymetrix 500K-based studies. In most instances, the intensity data patterns identify the SNPs with genotyping errors and can eliminate them from further follow up. In addition to its application to post analysis confirmation, this method can also be applied as a pre-analysis filter to exclude low precision markers.

Identification of men with a genetic predisposition to prostate cncer: targeted screening in BRCA1 and BRCA2 mutation carriers and controls. The IMPACT study: pilot data. *A. Mitra*[1], *E. Bancroft*[2], *R. Eeles*[1,2] 1) Cancer Genetics, Institute of Cancer Research, London, UK; 2) Cancer Genetics, The Royal Marsden Hospital NHS Foundation Trust, London, UK.

Introduction The relative risk of prostate cancer (PC) in BRCA1 and BRCA2 carriers under the age of 65 years may be as high as 1.85 and between 7.33 and 23 fold respectively. IMPACT, the largest international prospective screening study of men with a known genetic predisposition to PC, aims to assess the role of targeted PSA screening and to determine the incidence and pathology of PC in this group. Methods 500 BRCA1 carriers and 350 BRCA2 carriers aged 40-69 will be recruited over 5 years. 850 controls will be recruited from men who are predictive test negative for a known familial mutation. Annual serum PSA, free:total PSA, testosterone and sex hormone binding globulin is taken. Prostate biopsy is offered if PSA is above 3ng/ml. The pilot study is recruiting in 8 UK cancer genetics centres and 2 international centres. Results 70 men (27 BRCA2, 19 BRCA1 and 24 controls) have been recruited to the study so far. Uptake rates have varied between centres but range from 76% to 94%. 4 men have had a PSA above 3ng/ml. A BRCA1 carrier and a control group man have been diagnosed with PC (Gleason score 3+4, stage T2b, PSA 3.8ng/ml and Gleason score 3+3, stage T2b, PSA 4.3ng/ml respectively). A 69 year old BRCA2 mutation carrier, PSA 6.7, has been found to have benign prostatic hypertrophy (BPH). A 69 year old control with a PSA of 7.2ng/ml had BPH only. Conclusions One of the limiting factors of the ERSPC and PLCO studies is the low recruitment rate in the target populations. In European countries that randomise men into a screening and control group, uptake rates are 25-46%. In those countries that randomise only to a screening arm the recruitment rate is 64%. Surveys suggest that as few as 3% of eligible men participate in the PLCO study. It appears that men who are at an increased genetic risk of developing PC are more likely to enter a PC screening study. This has implications for future targeted screening as new increased risk genotypes are identified by genome wide association studies.

Public-Private Partnerships and Genetic Research: Data-Sharing Issues. *D.N. Wholley* Research Administration, Foundation for the NIH, Bethesda, MD.

Public-private partnerships are becoming increasingly important in creating large-scale collaborations and community resource projects for scientific research. These projects allow researchers to tackle opportunities and solve problems in the pre-competitive sphere which a single entity cannot tackle effectively alone, either because of scale, lack of available funding, or because the very nature of the problem requires cooperation amongst academic, government, and industry partners. The resulting requirements to share data and infrastructure, however, carry with it significant responsibilities: protecting the confidentiality and respecting the consent of study participants, ensuring that use of data is not restricted by premature or predatory claims on intellectual property, balancing the needs of principal investigators to publish results versus the imperative to provide broad public access to data, and managing conflicts of interest, antitrust, and confidentiality in dealings with commercial partners. My talk therefore will focus less on specific technical standards for interoperability than on the business and policy infrastructures that enable and sustain them. I will cite several examples from current public-private partnerships managed by the Foundation for the National Institutes of Health (FNIH) such as the Genetic Association Information Network (GAIN) and The Biomarkers Consortium.

Benefit of Whole-Genome 500K SNP Microarray in Clinical Practice. *J.M. Milunsky[1, 2, 3], M. Ito[1, 2], T.A. Maher[1], A. Milunsky[1, 2]* 1) Center for Human Genetics, Boston Univ Sch Medicine, Boston, MA; 2) Dept Pediatrics, Boston Univ Sch Medicine, Boston, MA; 3) Dept Genetics and Genomics, Boston Univ Sch Medicine, Boston, MA.

Chromosomal deletions and duplications are a major cause of developmental disabilities including mental retardation (MR), developmental delay (DD), and autistic spectrum disorder (ASD), as well as multiple congenital anomalies (MCA). Targeted and whole-genome arrays are now clinically available to detect these genomic imbalances. We have utilized the previously validated 500K Affymetrix SNP microarray (two 250K arrays) to clinically evaluate over 100 patients with several different postnatal indications. The first group were those with known or suspected unbalanced chromosomal rearrangements to further refine their deletion/duplication. The second group were those with apparently balanced karyotypes who had abnormal phenotypes. The third group were those with mental retardation/developmental delay/ASD/MCA. Abnormal findings from the first array were confirmed and further refined with the second array and FISH studies. When available, parental samples were obtained to determine if the rearrangement was familial vs. de novo or to assess the significance of a possible variant. Several unexpected findings were revealed including more complex chromosomal imbalance (chromosome 8 deletion in addition to the known duplication), an unsuspected diagnosis (chromosome 7q11.22-7q11.23 duplication), and an unrelated diagnosis (HNPP in a child with a balanced 5/6 translocation and developmental delay). An interstitial deletion was detected in a child with MR/MCA and his normal mother in the paternally imprinted chromosome 1p31.3 region adding further complexity to the interpretation of abnormal findings. Multiple additional chromosomal deletions and duplications (several atypical involving known loci) were found. Further refinement of genomic imbalance by SNP microarrays may eventually optimize anticipatory guidance and also may allow better genotype/phenotype correlations. Whole genome SNP microarrays are a valuable tool to determine genomic imbalance in patients with MR, DD, ASD and/or MCA.

Genetic variants of Clock transcription factor are associated with individual susceptibility to obesity. *S. Sookoian, C. Gemma, T. Fernández Gianotti, A. Burgueño, C.J. Pirola* Department of Molecular Genetics and Biology of Complex Diseases.Instituto de Investigaciones Medicas A Lanari. CONICET. University of Buenos Aires,Argentina.

Altering circadian rhythmicity results in pathophysiological changes resembling metabolic syndrome and fat accumulation. Then we investigated the role of gene variants and derived haplotypes of the CLOCK transcription factor in obesity and related quantitative metabolic traits. Research Design and Methods: 715 lean and 391 overweight/obese unrelated subjects, aged 34.48.6, were included in a population-based cross sectional study. Six tag SNPs showing a minor allele frequency >10 % (rs1554483 C/G; rs11932595 A/G; rs4580704 C/G; rs6843722 A/C; rs6850524 C/G and rs4864548 A/G) encompassing 117 kb of chromosome 4 and representing 115 polymorphic sites (r2 >0.8) were genotyped. Association was tested by PLINK and WHAP software while multiple testing was controlled by permutation test. Results: the genotype frequencies of four tSNPs, rs1554483, rs6843722, rs6850524 and rs4864548, showed significant (empiric p= 0.009950, 0.01492, 0.01492 and 0.009950 respectively) association with overweight/obesity. Haplotype analysis showed that only paired haplotypes including rs1554483 and rs4864548 showed a significant effect on disease status. Combinations of these SNPs (haplotype block CG and GA) are responsible for the gene effect (GA frequencies cases: 0.47% vs. controls: 0.41%, empiric p=0.0102). These findings were replicated in an independent case-control hospital-based study and the combined Mantel-Haenszels fixed effect (MH) was OR 1.82, CI: 1.31-2.54, p=0.00034, for the paired haplotype which included CG and GA for the rs1554483 and rs4864548. Conclusions: our study suggests a putative role of the CLOCK polymorphism and related haplotypes in susceptibility to obesity. Carrying the diploid haplotype of rs1554483G and rs4864548A was associated with 1.8-fold increase for being overweight/obese.

Schizophrenia candidate gene association study in a large European ancestry sample. *A.R. Sanders[1], J. Duan[1], M. Martinez[2], D. He[1], G.J. Burrell[1], N.G. Buccola[3], B.J. Mowry[4], R. Freedman[5], F. Amin[6], D.W. Black[7], J.M. Silverman[8], W.F. Byerley[9], R.R. Crowe[7], C.R. Cloninger[10], D.F. Levinson[11], P.V. Gejman[1]* 1) ENH & Northwestern Univ, Evanston, IL; 2) INSERM, Toulouse, France; 3) LSU Health Sci Ctr, New Orleans, LA; 4) QCSR & Univ Queensland, Brisbane, Australia; 5) Univ Colorado Health Sci Ctr, Denver, CO; 6) Atlanta VA Med Ctr & Emory Univ, Atlanta, GA; 7) Univ Iowa, Iowa City, IA; 8) Mt. Sinai School of Medicine, New York, NY; 9) UCSF, San Francisco, CA; 10) Washington Univ, St. Louis, MO; 11) Stanford Univ, Palo Alto, CA.

Introduction: We now present all data from a study of 14 schizophrenia candidate genes: *RGS4*, *DISC1*, *DTNBP1*, *STX7*, *TAAR6*, *PPP3CC*, *NRG1*, *DRD2*, *HTR2A*, *DAOA*, *AKT1*, *CHRNA7*, *COMT*, and *ARVCF* (data for 336 SNPs in a smaller sample were previously presented). The experimental design included a large sample size, dense gene coverage, and use of AIMs to ensure ancestral similarity of cases and controls. Methods: The European ancestry (EA) sample included 1,870 cases (90% schizophrenia and 10% schizoaffective; 20% familial) and 2,002 controls screened for psychosis. Outliers were excluded based on analysis of 194 AIMs. SNPs (N=789, chosen for tagging, from previous reports, or functionality) were genotyped using SNPlex and Taqman, with 648 passing extensive data cleaning procedures. Results: There were 31 SNPs (27 not previously reported as associated) with nominal p0.05 for single-SNP tests of association (Armitage), of which 3 had nominal p0.01 (two in *STX7*, one in *NRG1*). None were significant after correction for the number of tests. Haplotype analyses did not demonstrate increased significance. For tag SNPs, the q-q plot deviated slightly from the null line, but was under that line, consistent with a lack of evidence for association. Conclusions: We have not found significant evidence for association to these genes in our sample. The fact that these genes are not robustly associated in a large sample bolsters the case for systematic large-scale association studies, including linkage disequilibrium (LD) mapping of candidate regions, genome-wide association (GWA) approaches, and large-scale sequencing.

GENETIC ASSOCIATION OF THE CHRNA3-CHRNB4 GENE CLUSTER WITH BEHAVIORAL DISINHIBITION IN YOUNG ADULTS. *I.R. Schlaepfer[1,2], A.C. Collins[1], R.P. Corley[1], T.J. Crowley[4], J.K. Hewitt[1,3], N. Hoft[1], C.J. Hopfer[4], J. Lessem[1], S.H. Rhee[1,3], M.C. Stallings[1,3], S.E. Young[1], M.A. Ehringer[1,2]* 1) Institute for Behavioral Genetics, University of Colorado, Boulder, CO; 2) Department of Integrative Physiology, University of Colorado, Boulder, CO; 3) Department of Psychology, University of Colorado, Boulder, CO; 4) Division of Substance Dependence, Department of Psychiatry, University of Colorado, Denver, CO.

Behavioral disinhibition is a manifestation of impulsive behavior that is important in the psychopathology of disorders like drug addiction, ADHD and conduct disorder (CD). Previous research from our lab has shown that genomic variations between the CHRNA3 and CHRNB4 genes are associated with the early age of initiation of tobacco and alcohol use, suggesting inherited vulnerability markers for behavioral disinhibition leading to early age of drug experimentation. Here we report our findings with markers in the CHRNA3-B4 region and CD and behavioral disinhibition composite phenotypes in young adults from Colorado. Our behavioral disinhibition variables include CD, ADHD, substance experimentation and novelty-seeking scores from young adults aged 17 to 21 years. Since SNP frequency calculations revealed ethnic-specific allele distributions in Caucasians, African-Americans and Hispanics, we conducted the genetic analysis including ethnicities as covariates in the statistical genetics program WHAP. Two SNPs previously shown to be associated with age of initiation for tobacco use were associated also with lifetime symptoms of CD scores (p 0.03). Additionally, an adjacent synonymous SNP in the Exon 2 of the CHRNA3 gene was found to be associated with CD ($p = 0.01$), behavioral disinhibition ($p = 0.008$) and typical patterns of alcohol ($p = 0.004$) and tobacco use ($p = 0.04$). The patterns of use followed an additive model, where the more risk alleles of the Exon 2 variation significantly predicted the number of times using alcohol and tobacco in both males and females of our sample. In conclusion, our results emphasize the potential relationship between genetic variations in the CHRNA3-B4 region and behaviors that promote early age of experimentation with drugs.

Confirmation of IL12B and IL23R associations with psoriasis. *R.P. Nair[1], M. Weichenthal[3], P.E. Stuart[1], S. Jenisch[3], H.W. Lim[2], A. Ruether[3], S. Schreiber[3], E. Christophers[3], J.J. Voorhees[1], J.T. Elder[1]* 1) Univ Michigan, Ann Arbor, MI; 2) Henry Ford Hospital, Detroit, MI; 3) Univ Kiel, Kiel, Germany.

Psoriasis is a common inflammatory and hyperproliferative skin disease with a multifactorial genetic basis. At least 9 linked loci have been reported, and several have been replicated. Attempting to identify loci that may have been missed by linkage analyses, Cargill et al (AJHG 80:273) performed a genome-wide association analysis using gene-centric markers, identifying two associated genes, IL12B and IL23R. They reported association with the major allele (A-G) of the IL12B haplotype rs3212227 (3' UT) - rs6887695 (60 kb 5). For IL23R, a common allele (C-G) of the haplotype rs7530511 (L310P) - rs11209026 (Q381R) was disease-associated. We examined these four SNPs for association with psoriasis in two groups of North American and German Caucasians: (1) 1,178 psoriasis cases and 2,001 controls and (2) 462 pedigrees of varying sizes. Genotyping of the SNPs was performed by primer extension (SnapShot, ABI). Case-control data were analyzed by the Cochran-Armitage test for linear trend of association and family data were analyzed by the PDT. Results for case-control data were combined across geographic cohorts using the generalized Mantel-Haenszel procedure. Both IL12B markers showed highly significant association with psoriasis in the case-control set (rs3212227 OR=3.05 homoz, 1.96 het, $p=1.0 \times 10^{-9}$; rs6887695 OR=2.34 homoz, 1.56 het, $p=1.7 \times 10^{-11}$) and the family cohort (rs3212227 $p=7.4 \times 10^{-3}$; rs6887695 $p=3.7 \times 10^{-4}$). The IL23R markers tested also showed significant association for the cases and controls (rs7530511 OR=1.33 homoz, 1.06 het, p = 0.014; rs11209026 OR=1.95 homoz, 1.25 het, $p = 7.4 \times 10^{-4}$), but not for the families (rs7530511 p=0.30; rs11209026 p=0.19). The trend in families was in the direction of association for the known risk alleles. Our results confirm associations between IL12B and IL23R and psoriasis in Caucasians. They also provide a likely genetic basis for the strong clinical association between psoriasis and Crohns disease, and help to explain the efficacy of biologicals targeting p40, the product of the IL12B gene, in both disorders.

Johanson-Blizzard Syndrome: Report of a Molecularly Confirmed Mild Case Associated with Unilateral Postaxial Hexadactyly. *A.G. Shealy[1], B. Kaplan[2], C.A. Crowe[1]* 1) Cleveland Clinic Genomic Medicine Institute, Cleveland, OH; 2) Department of Pediatric Gastroenterology, Cleveland Clinic, Cleveland, OH.

Johanson-Blizzard syndrome (JBS) is a rare autosomal recessive condition that causes exocrine pancreatic insufficiency and distinctive hypoplastic nasal alae in all cases. Mental retardation, sensorineural hearing loss, short stature, scalp defects, dental problems and abnormal hair patterns are present in a majority of cases. Rarer features include hypothyroidism, imperforate anus and genitourinary anomalies. An estimated incidence is reported to be 1/250,000. There is an increased risk of death in childhood usually due to severe malabsorption. JBS is caused by mutations in the *UBR1* gene on chromosome 15q.

This 7 year-old female patient was referred to genetics by gastroenterology for evaluation of possible JBS. Pancreatic insufficiency (PI) was diagnosed at 18 months of age secondary to the presence of undigested food in foul-smelling stools. While her birthweight was normal, there was a history of poor weight gain, and prior to diagnosis of PI, her weight and height had dropped to slightly below the 3rd percentile. At diagnosis, she was placed on fat-soluble vitamins and pancreatic enzyme replacement. Her growth parameters improved and she is now in the 10-25th percentiles. She continues to receive pancreatic enzyme replacement but has low normal levels of vitamins, even after parents discontinued supplementation. A 2006 CT revealed complete fatty replacement of the pancreas. Additional features of JBS in this girl with normal intelligence, include hypoplastic nasal alae, small deciduous teeth, an upsweeping frontal hairline, multiple moles and hearing loss. Research testing for mutations in *UBR1* detected two mutations, (IVS1+4G>C and c.1978-1980delGTT), molecularly confirming the diagnosis of JBS. Parental carrier testing is pending. Interestingly, this patient was found to have postaxial hexadactyly of her left hand. Although fifth finger clinodactyly has been reported, to our knowledge no cases of JBS in conjunction with hexadactyly have been published. There was no one else in this non-consanguinous family with similar features.

Cleft lip and palate in a fetus with thanatophoric dysplasia (TD) type 1. *S. Ramanathan[1], D. Lewis[2], R. A. Morotti[3], H. K. Rosenberg[4], L. Mehta[1]* 1) Div. of Medical Genetics, Schneider Children's Hospital at North Shore, Manhasset, NY; 2) Div. of Maternal Fetal Medicine, North Shore Hospital, Manhasset, NY; 3) Dept. of Pathology and; 4) Dept. of Radiology Mt. Sinai Medical Center, New York, NY.

TD is a lethal skeletal dysplasia classified as TD type 1 with micromelia, bowed femurs, with or without cloverleaf skull and TD type 2 with straight femurs and cloverleaf skull. We report on a fetus with TD1 and the unusual finding of unilateral cleft lip and palate (CLP). This was the second pregnancy for a 24 year old woman and her 29 year old partner. Family history was not significant for birth defects. Comprehensive ultrasound done at 20 weeks of pregnancy noted severe micromelia of all the long bones with the femurs and humeri measuring 14w2d, small thoracic circumference and possible cloverleaf skull. Unilateral cleft lip was noted. Following pregnancy termination, post-mortem external examination of the fetus showed narrow thorax, short limbs, relative macrocephaly and unilateral CLP. Post-mortem fetal X-rays confirmed marked shortening and bowing of the long bones with telephone receiver femurs, short ribs and diffuse severe platyspondyly. Cloverleaf skull was not confirmed. Testing on amniocytes for common TD mutations in the *FGFR3* (fibroblast growth factor receptor 3) gene showed the Nt742C>T (R248C) mutation. R248C is the most common TD mutation and is associated with TD1. To our knowledge, this is the first report of cleft lip and palate in a fetus with TD1. The fibroblast growth factors (FGFs) have pleiotropic effects in craniofacial development. Mutations in *FGFR3* have been associated with a range of clinical phenotypes, including achondroplasia, Muenke syndrome and LADD syndrome. Orofacial clefting is not a common finding in any of these syndromes. However, clefting is associated with *FGFR2* mutations (Apert and Beare-Stevenson syndromes) and *FGFR1* mutations (Kallmann syndrome 2). While the clefting in this fetus may be coincidental, this report adds to the evidence that impaired FGF signaling contributes to the etiology of cleft lip and palate.

Gene expression analysis of quadriceps muscle from patients with infantile-onset Pompe disease. *R. Palmer[1], K. Ciociola[1], M. Zhang[2], S. Richards[1], R. Mattaliano[3], R. Pomponio[1]* 1) Clinical Laboratory Science, Genzyme Corp, Framingham, MA; 2) Gene Analysis, Genzyme Corp, Framingham, MA; 3) Therapeutic Protein Development Genzyme Corp, Framingham, MA.

Pompe disease is an autosomal recessive disorder caused by a deficiency of acid alpha glucosidase (GAA), the enzyme required to hydrolyze lysosomal glycogen to glucose. Despite the common underlying deficiency, disease phenotype and response to enzyme replacement therapy (ERT) varies and may be influenced by other genetic and environmental factors. As a means to identify possible genetic modifiers of disease and response, we used Affymetrix HU133 Plus 2.0 Genechips to analyze RNA expression profiles of baseline quadriceps muscle biopsies from patients with infantile-onset Pompe enrolled in a clinical trial for treatment with MYOZYME (alglucosidase alfa). Comparison of chip data between patients based on clinical outcome data yielded a list of differentially expressed genes, a subset of which we have confirmed by qRT-PCR. While many of the observed differences likely reflect stress-related changes due to the overall glycogen load observed in each sample, a smaller subset, including MYH1, MYH4, MYH8, ANKRD1, and ANKRD2, point to subtle differences in muscle fiber composition and response to stretch that may contribute to differences in severity and therapeutic response between patients. Additionally, concordant upregulation of several genes involved in insulin receptor signaling suggest possible alterations in glucose uptake and utilization that could accelerate the ongoing glycogen accumulation in some patients. Taken together, this data provides insight into the transcriptional differences present between patients which may contribute to differences observed in patient severity and outcome to therapeutic intervention.

Twin complex rearrangements of Xq28 caused by distinct break-induced replication in haemophilia A. *C.R. Sheen[1], U.R. Jewell[2], C.M. Morris[2, 3], S.O. Brennan[1], C. Férec[4,5], P.M. George[1], M.P. Smith[6], J.M. Chen[4,5]* 1) Molecular Pathology, Canterbury Health Laboratories, Christchurch, Canterbury, New Zealand; 2) Cancer Genetics Research Group, Christchurch School of Medicine and Health Sciences, University of Otago, Christchurch, New Zealand; 3) Cytogenetics Unit, Canterbury Health Laboratories, Christchurch, New Zealand; 4) Institut National de la Santé et de la Recherche Médicale (INSERM), U613, 29220 Brest, FranceDistrict Health Board, Christchurch, New Zealand; 5) Etablissement Français du Sang-Bretagne, 29220 Brest, France; 6) Haematology Service, Canterbury District Health Board, Christchurch, New Zealand.

Rearrangements of the genome are a well-recognized cause of genetic disease and can form through a variety of mechanisms. We describe a complex rearrangement that causes severe haemophilia A, elucidated using a variety of PCR based methods and confirmed using array-CGH. The rearrangement consists of a 15.5 kb deletion/16 bp insertion that deletes exon 1 and the promoter of the Factor VIII gene, located 0.6 kb from a 28.1 kb deletion/263 kb insertion at Xq28. We propose that the rearrangement was formed by distinct cellular responses to double strand breakage. The latter insertion/deletion can be explained by break-induced replication, while we propose a novel model of break-induced serial replication slippage for the former. This may provide an alternative explanation to oligonucleotide capture for the frequent observation of short inserted sequences at deletion breakpoint junctions. The copy number of several genes is affected by this rearrangement, with deletion of part of the Factor VIII gene (causing haemophilia A) and the FUNDC2 gene, and duplication of the FAM11A, HSFX1, MAGEA9 and MAGEA11 genes. Given that the patient has manifested no detectable phenotype other than haemophilia, it appears the biological effects of the other genes involved are not strictly dosage dependent.

Sample size calculations in matched case-control studies. *X. Liu, R. Chakraborty, M. Rao* Ctr Genome Information, Univ Cincinnati, Cincinnati, OH.

The basic premise is a 1:1 matched case-control study, where each case is matched with a control on a number of variables. The goal is to test the equality of k odds ratios stemming from k+1 distinct matching scenarios. In the literature, conditional likelihood approach is used for calculating sample size for detecting specific departures from the null hypothesis of no association with a given power (See Sinha and Mukherjee 2006). In this paper, we use the full likelihood for calculating sample sizes. Comparisons are made between the two approaches.

Haptoglobin genotyping and cardiovascular risk in subjects with diabetes mellitus. *A. Millson[1], B.D. Horne[2], J.L. Anderson[2], J.F. Carlquist[2], W.L. Roberts[1,3], E. Lyon[1,3]* 1) ARUP Inst for Clin & Exp Path, ARUP Laboratories, Salt Lake City, UT; 2) Intermountain Health Care, Salt Lake City,UT; 3) Pathology Dept, University of Utah, Salt Lake City, UT.

Haptoglobin (Hp) is a serum protein with many functions. The best known is as an anti-oxidant, binding hemoglobin released during red cell hemolysis, thus reducing kidney damage. Hp is composed of 4 polypeptide chains, 2 alpha and 2 beta. The alpha chain has two common alleles, Hp1 and Hp2, the Hp2 allele resulting from a duplication of Hp1. The beta chain is identical in all Hp types. The biochemical properties of the haptoglobin molecule vary depending on which alleles are present (Hp1-1, Hp1-2 or Hp2-2). Haptoglobin genotype has been shown to be an independent risk factor in individuals with diabetes mellitus for coronary artery disease (CAD). We evaluated a series of 3,137 subjects enrolled in the Intermountain Heart Collaborative Study Registry to assess possible association of haptoglobin genotype and CAD. About 70% of the study group had severe CAD and 60% showed abnormal glucose metabolism. 705 out of 3,137 subjects were diabetic. All subjects had >3 years of clinical follow-up. Haptoglobin genotyping was performed on the LightCycler™ using two polymerase chain reactions, one for the Hp1and one for the Hp2 allele, followed by fluorescent monitoring using hybridization probes. One of the study objectives was to assess risk of atherosclerotic complications in the diabetic subjects. Our primary endpoint was angiographic CAD. Our secondary endpoints were death due to myocardial infarction (MI), all-cause death and MI. The genotype frequencies were similar between the diabetics and non-diabetics. We found our primary endpoint of angiographic CAD to be significant, p=0.013 with the p-trend = 0.0003, in only the diabetic subjects with the Hp1-1 genotype. Our findings are similar to the Framingham Offspring cohort study (2004) yet contradict other studies which found diabetics subjects with the Hp2-2 genotype at increased risk for CAD.

Affymetrix Annotation Search, a tool for data mining whith Affymetrix data. *C.S. Rocha, I. Lopes-Cendes* FCM, Unicamp, Campinas, Sao Paulo, Brazil.

Purpose

The Affymetrix Annotation Search is a web tool developed to facilitate for biologists to get annotation data from Affymetrix GeneChip. Starting with a list of identifiers (Probe Set IDs) this tool can search on a database the annotation corresponding to these identifiers. To make easier the data mining, was included links to others databases like: NetAffx, UniGene, Ensembl, SwissProt and OMIM. Was implemented too a filter by chromosome, this filter allows the user to diminish the amount of data to analyze directing his search to a especific chromosome.

Methods

This tool was developed to be web based. A SQL database was created with the Affymetrix annotation data, with the Probe Set ID field as primary key. The web tool was written in perl language using the CGI module for web aplication and the DBI module to database manipulation.

Summary of Results

The database has the annotation of all 54.675 Probe Sets presents in the HG-U133 Plus 2 Affymetrix GeneChip and can be fed with the others Affymetrix chips as requested.

Conclusion

This tool can help biologists that work with Affimetrix GeneChip, because it facilitate the analysis of the big amount of data that a microarray experiment generates, with the filter option, the user could have less but more specific data, with the external links the user have easily a lot of interesting information about his Probe Set.

The tool is freely aviable at: http://lgm.fcm.unicamp.br:9001/cgi-bin/affy/affy_annotation.cgi.

MNGIE disease: Four novel mutations in five Mexican families. *N. Monroy, L. Macías, J. Arteaga, O. Mutchinick*
Genetics, National Institute of Medical Sciences and Nutrition,Salvador Zubirán. Mexico City, Mexico.

Mitochondrial neurogastrointestinal encephalomyopathy (MNGIE) is a rare autosomal recessive disease caused by mutations in the nuclear gene encoding thymidine phosphorylase (TP) that generate diverse alterations of mitochondrial DNA (mtDNA). MNGIE is clinically defined by gastrointestinal dismotility, cachexia, ptosis, opthalmoparesis and peripheral neuropathy. At this point of time, 87 cases have been described as the result of 52 different TP mutations. We describe the clinical and molecular characteristics of 8 affected individuals in five Mexican families. A total of 28 relatives were also included; 18 of which were heterozygous carriers and 10 were wild type homozygous. Clinical data, neuro-physiological, and manometric tests were performed. Genomic DNA (and total RNA, when necessary) was isolated and the complete gene sequenced. mt DNA was also studied. Computational analyzes of the DNA and protein sequences were done. Consanguinity was confirmed in 3 families and suspected in the other two. Families were grouped in two categories: 1) with diarrhea and 2) with vomiting and intestinal pseudo-obstruction. Individuals of group 1 are still alive, while 5/6 patients of group 2 died. Additionally other clinical variations regarding progression of the disease and main symptoms were observed. Sequencing of the TP gene revealed 4 new mutations: L133P, G152R, P300S, IVS5+110_111insAG and one previously described (S471L), all of them in homozygous state. In the fourth family (AG insertion) it is supposed that the mutation generated a new splicing acceptor site, but not mutant transcript was observed. In this case, we propose a mechanism of nonsense-mediated mRNA decay. The mtDNA analysis showed multiple deletions and a 65-96% depletion in all patients. An interesting finding is the interfamilial variability for age onset, progression and gastrointestinal symptoms and the high intrafamilial concordance for the same variables. The last could be explained because the patients share the same mutations.

Specific sequence variations within the 4q35 region are associated with FSHD. *R.J.L.F. Lemmers[1], M. Wohlgemuth[2], K. van der Gaag[1], P. van der Vliet[1], P. de Knijff[1], G.W. Padberg[2], R. R. Frants[1], S.M. van der Maarel[1]*
1) Department of Human Genetics, Leiden University Medical Center, Albinusdreef 2, 2333 ZA, Leiden, The Netherlands; 2) Department of Neurology, University Medical Center Nijmegen, P.O. box 9101, 6500 HB, Nijmegen, The Netherlands.

Autosomal dominant facioscapulohumeral muscular dystrophy (FSHD) is mainly characterized by progressive wasting and weakness of the facial, shoulder and upper-arm muscles. FSHD is caused by contraction of the macrosatellite repeat D4Z4 on chromosome 4q35. The D4Z4 repeat is very polymorphic in length and D4Z4 rearrangements occur almost exclusively via intrachromosomal gene conversions. Several disease mechanisms have been proposed, but none of these models can comprehensively explain FSHD as conditions in addition to repeat contraction need to be met to cause disease. Almost identical D4Z4 repeat arrays have been identified on chromosome 10q26 and on two equally common chromosome 4 variants; 4qA and 4qB. Yet, only repeat contractions of D4Z4 on chromosome 4qA cause FSHD, contractions on the other chromosomes are not pathogenic. We hypothesized that allele-specific sequence differences between 4qA, 4qB and 10q alleles underlie the 4qA specificity of FSHD. Sequence variations between these alleles have been described before, but the extent and significance of these variations proximal, within and distal to D4Z4 have not been studied in detail. We examined additional sequence variations in the FSHD locus including a relatively stable simple sequence length polymorphism (SSLP) proximal to D4Z4, a SNP within D4Z4 and the A/B variation distal to D4Z4. Based on these polymorphisms, we demonstrate that this subtelomeric domain of chromosome 4q can be subdivided into nine distinct haplotypes, of which three carry the distal 4qA variation. Interestingly, we show that repeat contractions in one of these 4qA haplotypes is not associated with FSHD. We also show that each of these haplotypes has its unique sequence signature and propose that specific SNPs in the disease haplotype are essential for the development of FSHD.

Large highly conserved non-coding transcripts are mutational targets in cancer. *D. I. Smith[1], D.S. Perez[1], A.L. Ducharme-Smith[1], J. Pritchett[1], S. Ganapathiraju[1], D.A. Ahlquist[2]* 1) Lab Med & Path/Exper Path, Mayo Clinic, Rochester, MN; 2) Department of Medicine, Mayo Clinic, Rochester, MN.

Whole-genome tiling arrays are a powerful tool to identify novel transcripts across the entire human genome. We utilized these arrays with normal human bronchial epithelial cells (NHBE) comparing the transcriptional expression of untreated cultures to those exposed to either growth under hypoxic conditions or to the cigarette carcinogen NNK. Our initial results demonstrate the existence of numerous non-coding transcripts (NCTs) that are either transcriptionally active and/or stress-responsive across the genome. Of the non-coding sequences identified, the ratio of transcriptionally active regions (TARs) to stress-responsive regions (SRRs) is approximately 5 to 1. We focused on characterizing novel, large (>400 bp), abundantly-expressed, and highly-conserved non-coding (nc) TARs. Using real-time RT-PCR we observed that some of the ncTARs displayed tissue-specific expression while others were more ubiquitously expressed. Many of these large conserved ncTARs were also found to have aberrant expression in different cancers. A subset of the ncTARs examined were also mutated in different cancers. The role of these ncTARs in the normal cell, as well as the role that mutations in these sequences play in cancer development is presently unknown. We have also begun to identify a novel group of large, highly-conserved sequences whose expression is apparently altered by cellular stress. A number of these ncSRRs also have aberrant expression in different cancers and are being similarly examined to determine if they are also targets of mutation in different cancers. Collectively, this analysis has only examined the most abundantly-expressed or most differentially altered transcripts across the human genome, thus, there are potentially thousands of additional large, highly-conserved NCTs across the human genome. Future studies will attempt to determine the mechanistic action of such non-coding sequences in normal cellular function and disease, and how they might interact with protein-coding genes within crucial signaling pathways.

Conditional linkage with the UGT1A1 gene and whole-genome association studies of serum bilirubin. *J-P. Lin[1], J.P. Schwaiger[2], L.A. Cupples[3], C.J. O'Donnell[4], G. Zheng[1], V. Schoenborn[2], S.C. Hunt[5], F. Kronenberg[2]* 1) Office of Biostatistics Research/NHLBI, NIH; 2) Division of Genetic Epidemiology/Innsbruck Medical University, AUSTRIA; 3) Department of Biostatistics, Boston University School of Public Health; 4) Framingham Heart Study/NHLBI/NIH; 5) Department of Internal Medicine, University of Utah.

Many studies have shown an inverse association between serum bilirubin and cardiovascular disease (CVD). Previously, we conducted genome-wide linkage studies and identified a major locus at the 2q telomere affecting bilirubin levels with LOD=3.8 (the highest LOD in the rest of the genome was 1.3). Within this region, there is a candidate gene, UDP-glucuronosyltransferase (UGT1A1). The insertion of a TA in the promoter, allele 7 (wild type: allele 6) designated UGT1A1*28, decreases gene transcription. We conducted association studies in 1780 Framingham Heart Study (FHS) subjects followed for 24 years and found individuals with genotype 7/7 to have significantly higher bilirubin levels and 1/3 the CVD risk, RR=0.30, than those with genotypes 6/6 and 6/7. We carried out a conditional linkage study using the largest 330 families from the FHS to investigate whether the UGT1A1*28 was responsible for the linkage peak of our previous linkage study. Conditional on the UGT1A1*28 association, LODs of the linkage peak dropped from 3.8 to 0.4, suggesting that the UGT1A1 association may fully explain the linkage result. We also carried out an Affymetrix 100K SNP whole-genome association study on bilirubin using GEE and confirmed the top ranked SNPs with SOLAR. The closest SNP, rs1113193, about 15,000 bp away is in linkage disequilibrium with UGT1A1*28. This SNP always ranked within the top 10 SNPs using different analytic methods, different Framingham examinations, and different ranking methods, with p-values ranging from 1.38E-08 to 9.33E-06. Our studies suggested that the UGT1A1 may be the only gene with a large effect controlling serum bilirubin levels. Since the polymorphism may have a substantial impact on the development of CVD, and the 7/7 genotype is found in 10-16% of Caucasians, the gene may be an important target for therapeutic intervention.

A comparison of allele frequencies estimates in 6,174 SNPs genotyped in HapMap and Seattle SNPs. *A.D. Skol*[1], *M.L. Feolo*[2] 1) Sec Genetic Med, Univ Chicago, Chicago, IL; 2) NCBI, National Library of Medicine, NIH, Bethesda, MD.

We examined the accuracy between probe-based genotyping conducted by The HapMap (HM) project, and genotypes derived by sequencing conducted by SeattleSNPs (SS). SS genotypes were obtained by targeted sequencing of genic regions in 23 CEPH Utah individuals. HapMap genotype data came from probe-based genotyping of the 60 CEPH Utah founders. A subset of subjects was genotyped in both groups on 5,128 SNPs, allowing us to test for genotyping inconsistencies. 1,828 SNPs were genotyped in 17 subjects by both HM and SS. Of the 6,174 SNPs, 2,932 were polymorphic in 1 sample. We identified 103 SNPs (1.7%) for which 1 individuals genotype was called differently by HM and SS. Of these, 68 have a single discrepant subject, 19 have two discrepant subjects, and 16 have 3 discrepancies. Of the 38,458 opportunities to detect discrepancies, we found only 258 discrepant genotypes (0.7%). We tested for allele frequency differences between the SS and HM samples using a standard Chi-squared test of independence. The distribution of p-values, which we expect to be uniformly distributed between 0 and 1, shows an excess of significant results at the .0001 and .001 levels. We also discovered that of the 103 SNP with 1 discrepant genotype, 24 are monomorphic in HM, but have at least one heterozygous SS individual. The converse occurs only 5 times. When there is no genotype discrepancies this imbalance is not observed. We determine empirically if heterozygotes are being overcalled by sequencing or undercalled by conventional genotyping by examining the linkage disequilibrium pattern between the SNP in question and those in the surrounding region. In summary, we find that data quality of both sequence data from SS and genotype data from HM is of very high quality. A small proportion of SNPs may appear monomorphic when using conventional genotyping methods when a SNP is present in the primer sequence or due to limitations of the genotype calling algorithm. As more genes are resequenced such SNPs can be identified, allowing either the redesign of primers or substitution of a SNP in linkage disequilibrium with the problem SNP.

Fragile X mental retardation protein deficiency leads to spontaneous mGluR5-dependent internalization of AMPA receptors. *M. Nakamoto[1], V. Nalavadi[2], M.P. Epstein[1], U. Narayanan[1], G.J. Bassell[2], S.T. Warren[1, 3, 4]* 1) Dept of Human Genetics; 2) Dept of Cell Biology; 3) Dept of Biochemistry; 4) Dept of Pediatrics, Emory Univ. School of Medicine, Atlanta, GA.

Fragile X syndrome (FXS), a common inherited form of mental retardation, is due to the functional absence of the fragile X mental retardation protein (FMRP), an RNA-binding protein that regulates the translation of specific mRNAs at synapses. Altered synaptic plasticity has been described in a mouse FXS model. However, the mechanism by which the loss of FMRP alters synaptic function, and subsequently causes the mental impairment, is unknown. Here, in cultured hippocampal neurons, we used siRNAs against *Fmr1* to demonstrate that a reduction of FMRP in dendrites leads to an increase in internalization of the -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptor (AMPAR) subunit, GluR1, in dendrites. This abnormal AMPAR trafficking was observed spontaneously at basal level, without synaptic stimulation by exogenous agonist and was rescued by MPEP, an mGluR5-specific inverse agonist. Since AMPAR internalization is dependent upon local protein synthesis following mGluR5 stimulation, FMRP, a negative regulator of translation, may be viewed as counter balancing signal, wherein the absence of FMRP leads to an apparent excess of mGluR5 signaling in dendrites. Because AMPAR trafficking is a driving process for synaptic plasticity underlying learning and memory, our data suggest that hypersensitive AMPAR internalization in response to excess mGluR signaling may represent the principal cellular defect in FXS, which may be corrected using mGluR antagonists.

Mice Carrying Novel Mutations in *Frem1* Have Phenotype Similar to that Seen in Fraser Syndrome. *O. Shchelochkov[1], D.A. Scott[1], X. Lin[1], M. Justice[1], D.W. Stockton[2], B. Lee[3]* 1) Dept of Mol and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Wayne State University School of Medicine, Detroit, MI; 3) Howard Hughes Medical Institute.

Fraser syndrome is a complex developmental malformation syndrome with autosomal recessive inheritance. In humans it is characterized by cryptophthalmos, limb and genital anomalies, and internal organ abnormalities, which may include renal agenesis, and gastrointestinal malformations. Blebbed mouse mutants are considered the murine model of Fraser syndrome with mutations described in *Fras1*, *Grip1*, *Frem1* and *Frem2* genes. Here we describe two mouse strains generated by ENU mutagenesis, EYE2 and CRF11. Phenotypic analysis of these non-complementing strains revealed a spectrum of eye defects ranging from unilateral microphthalmia to bilateral cryptophthalmos, renal defects and hemorrhagic blisters *in utero* similar to previously described 'bleb' strains. Linkage analysis was used to define the location of the mutations in these mice within a ~3 Mb interval on mouse chromosome 4 that contained the *Frem1* gene. Sequencing of *Frem1* in these stains revealed a missense mutation in EYE2 in exon 8 (c.1687A>T, 563I>F) and a nonsense mutation in CRF11 in exon 13 (c.2477T>A, 826L>X). Additional phenotypic findings not previously identified in *Frem1* mice included lung segmentation defects, a propensity to the development of rectal prolapse and, in one EYE2 mouse, a retrosternal diaphragmatic hernia. Similar defects have been reported in a small portion of patients with Fraser syndrome. In summary, we have described two novel *Frem1* mutations in mouse strains, which share both common and rare phenotypic findings with patients with Fraser syndrome. These mutations include the first missense mutation to be described with this phenotype. Although to date no *FREM1* mutations have been identified in human cases of Fraser syndrome, this gene remains an attractive candidate gene for this syndrome.

Fragile X Related Protein 2 (FXR2P) interacts with non-POU domain containing, octamer binding protein (NonO). *S.S. Pataskar, D.L. Nelson* Department of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX. USA.

Fragile X syndrome is a common form of mental retardation caused by the absence of the FMR1 protein, FMRP (Fragile X Mental Retardation Protein).Two paralogs of FMRP have been identified, FXR1P and FXR2 (Fragile X Related Protein). All three proteins share highly conserved RNA binding domains, high sequence similarity and show overlap in their tissue distribution. FXR2P shows high expression in brain and testes similar to FMR1P. NonO (also called p54nrb)is an unusual nucleic acid binding protein expressed ubiquitously. It not only binds both DNA and RNA but also interacts with other nucleic acid binding proteins. NonO enhances association of many DNA binding proteins to their targets. NonO interacts with the Parkinson's disease associated DJ-1 protein. NonO is also involved in splicing of mRNAs. NonO modulates the transcriptional activity of Androgen Receptor. NonO has also been shown to be associated with circadian clock protein, PERIOD 1 and modulates activity of PER proteins antagonistically. FXR2P has also been shown to modulate clock activity, and *Fxr2* knockout mice showed irregularities in their circadian cycles.We investigated interaction between NonO and FXR2P. Our results indicate that endogenous FXR2P coimmunoprecipitates endogenous NonO in cell lysates prepared from mouse tissues and cell lines. Both FXR2P and NonO are RNA binding proteins and play a role in regulating clock proteins. Direct interaction between FXR2P and NonO suggests a potential mechanism for clock abnormalities in *Fxr2* knockout mice and adds to our understanding of the various functions carried out by members of the Fragile X gene family.

Interstitial 6q25 deletion accompanied by an unexpected *STS* (Xp22.31) microdeletion. *F.M. Mikhail, E.J. Lose, K. Goodin, A.J. Carroll* Dept. of Genetics, Univ. of Alabama at Birmingham, Birmingham, AL.

At least 60 cases with deletions of the long (q) arm of chromosome 6 have been reported to date. To correlate phenotype with genotype; 6q deletions have been classified into three groups: group A with del(6)(q11q16), group B with del(6)(q15q25), and group C with del(6)(q25qter). Interstitial deletions in the distal region of 6q are relatively rare, and have been shown to cluster in band 6q25. Here we report an 11.5-year-old boy with an interstitial distal 6q deletion who was seen in our clinic because of history of mental retardation, developmental delay, and dysmorphic features. He displayed some overlapping features of group B and C 6q deletions. These included IUGR, mental retardation, developmental delay, autism, no speech, eye anomalies in the form of exophthalmos, ear anomalies in the form of small low set ears with a preauricular pit on the left ear, hand anomalies in the form of bilateral single transverse palmar creases with short fingers, and foot anomalies in the form of short widely spaced toes with narrow nails. HRB chromosome analysis revealed an interstitial deletion on 6q [del(6)(q25.2q25.3)]. Using the 32k BAC tiling path array CGH chip, we were able to precisely map the breakpoints of the deletion, which was estimated to be ~6.3 Mb in size. Unexpectedly however, array CGH analysis also demonstrated that the patient carries an ~1.5 Mb *STS* gene microdeletion on the short (p) arm of chromosome X, which was confirmed by FISH analysis using the *STS* probe. Nullisomy of the *STS* gene is consistent with the clinical diagnosis of X-linked ichthyosis. Clinically, the boy had bilateral congenital cataracts and his skin was scaly and dry. The patients final karyotype was 46,XY,del(6)(q25.2q25.3).ish del(X)(p22.31p22.31)(*STS*-). In conclusion, our patient represents a perfect example for the clinical usefulness of whole genome array CGH analysis, which was able not only to map the breakpoints of the distal 6q deletion but also revealed the *STS* microdeletion. Parental chromosome and FISH analyses are underway. Detailed description of our patients clinical features and comparison with previously reported distal 6q deletions will be presented.

Molecular analysis of the CYP1B1 gene in congenital glaucoma Brazilian patients. *M.B. Melo[1,3], M.D. Paolera[2], C. Caixeta-Umbelino[2], N. Kasahara[2], M.N. Rocha[3], F. Richeti[3], C.A. Longui[3], G.V. Almeida[2], R. Cohen[2], C. Mandia Jr.[2], V.P. Costa[4], J.P. Vasconcellos[4]* 1) CBMEG, University of Campinas, Campinas, São Paulo, Brazil; 2) Department of Ophthalmology, Santa Casa de São Paulo, São Paulo, Brazil; 3) Laboratory of Molecular Medicine, Santa Casa de São Paulo, São Paulo, Brazil; 4) Department of Ophthalmology, University of Campinas, São Paulo, Brazil.

Purpose. Primary congenital glaucoma (PCG) is a severe form of glaucoma, which has its onset from neonatal period to three years of age and when hereditary is transmitted as an autosomal recessive trait with variable penetrance. Three loci have been described, but only one gene was identified, CYP1B1, located in the GLC3A locus, on chromosome 2p21. The aim of this study was to screen PCG Brazilian patients and their parents for mutations in the CYP1B1 gene. Methods. Thirty three PCG patients from 30 different families were evaluated through direct sequencing of the CYP1B1 gene coding regions and intron/exon boundaries. Results. Mutations were detected in 9 of 30 unrelated patients, a prevalence of 30%. Ten different mutations were observed, three of which, to our knowledge, are being reported for the first time. A deletion at exon 2, 4635delT, that leads to a stop codon at aminoacid 277 was observed in two unrelated patients. In three brothers (two twins), two other new alterations were described in heterozygosity, 4523delC in exon 2, leading to a stop codon at aminoacid 243 and a T to A point mutation in exon 3, at position 7970, changing a leucine for a glutamin (L378Q). Four patients were compound heterozygous, 2 were homozygous and in three only one mutation was detected. The previously reported polymorphisms 3793T to C, R48G, A119S, L432V, D449D and N453S were also identified in our patients. Conclusions. This work reports a 30% prevalence of CYP1B1 mutations in PCG Brazilian patients, describing three new different alterations related to the disease. Taken together, the two studies involving Brazilian patients reflect the genetic heterogeneity of the disease in this population and open possibilities to further analysis in other candidate loci.

Down Syndrome: Genomic analyses link genes for GI malformation and leukemia. *T. Tirosh-Wagner[1], J.O. Korbel[2], A.E. Urban[2], X-N. Chen[1], M. Snyder[2], J.R. Korenberg[1]* 1) Medical Genetics, Cedars-Sinai, Los Angeles, CA; 2) Yale University, New Haven, CT.

Down syndrome (DS) is a major cause of mental retardation (MR), gut disease and increased risk for leukemia. The question remains as to which of the 352 genes or clusters contribute most to cognitive or disease risks in persons with DS. Usually caused by trisomy 21, rare individuals with duplication of small regions provide opportunities to identify genes whose increased copy number are sufficient to cause DS features. We present multi-disciplinary data of 14 partial trisomy 21 people, combined with their molecular breakpoints and focus hypotheses linking genes to DS. Molecular analyses of following resolutions; 1) 100kb-3Mb by high resolution FISH with 350 BACs (13 subjects) and Southern blot dosage (13 sub) and 2) 50bp-300bp by high density isothermal oligomer microarrays employing 355,083 oligomers/chip, tiled at ~1/100bp unique genomic sequence, from 21p (10Mb) to 21qter (12 sub). Results: Cases: 1) MR, duplication (dup): pter-27.5Mb, 42.3-44.7Mb, 45.9Mb-qter; 2) MR, dup: pter-30.2Mb; 3) Low Normal function, dup: pter-33.0Mb & 46.7Mb-qter; 4) MR, 4 copies: pter-30.6Mb; 5) MR, Duodenal stenosis, dup: 24.8-41.5Mb; 6) MR, dup: 28.9-41.4Mb; 7) MR, dup: 34.1-46.6Mb; 8) MR, AMKL, dup: 17.9-31.4Mb, 36.1-42.9Mb; 1 copy: 42.9Mb-qter; 9) Transient leukemoid reaction (TLR), dup: 16.5-41.3Mb; 4 copies: 41.3Mb-qter; 10) MR, dup: 19.2Mb-qter; 11) MR, duodenal stenosis, dup:19.5Mb-qter; 12) MR, Hirschsprungs Disease, dup: 33.5-46.2Mb; 13) MR, Hirschsprungs Disease, dup: 28.8-46.9Mb; 14): imperforate anus,TRL. dup:30.4Mb-qter; Conclusions: The candidate region (CR) for leukemia and TLR (3/14 cases) includes maximum limits 30.4-42.9 Mb, minimum 36.1-42.9. Genes include CLDN17 - TSGA2(max); exclude TPTE-GRIK (max) and TIAM (min). The CR for duodenal stenosis and imperforate anus (3/14) includes the region from 30.4-41.5Mb, genes SOD1 to BACE2; for Hirschsprung's Disease (2/14) includes the region from 33.5-46.2Mb, genes IFNAR1 to COL18A. These results focus animal and cellular models targeting treatment of DS and identify dosage sensitive steps for disease in the normal population.

Novel *CHMP4B* mutations underlie autosomal dominant cataracts linked to chromosome 20q. *A. Shiels[1], T.M. Bennett[1], H.L.S. Knopf[1], K. Yamada[2], K-i. Yoshiura[3], N. Niikawa[3], S. Shim[4], P.I. Hanson[4]* 1) Ophthalmology/Visual Sci, Washington Univ Sch Medicine, St Louis, MO; 2) Ophthalmology/Visual Sci, Nagasaki Univ Grad Sch Biomedical Sciences, Nagasaki, Japan; 3) Human Genetics, Nagasaki Univ Grad Sch Biomedical Sciences, Nagasaki, Japan; 4) Cell Biology/Physiology, Washington Univ Sch Medicine, St. Louis, MO.

Cataracts are a clinically and genetically heterogeneous disorder of the ocular lens, and a leading cause of visual impairment. Here we report linkage of autosomal dominant progressive childhood posterior sub-capsular cataracts segregating in a 6-generation Caucasian-American family to STR markers D20S847 (Z = 5.50, = 0.0) and D20S195 (Z = 3.65, = 0.0) on 20q. Haplotyping with SNP markers refined the cataract locus to the physical interval rs2057262-[3.8 Mb]-rs1291139. Sequencing of positional-candidate genes detected a heterozygous A>T transversion in exon-3 of the gene for charged multi-vesicular body protein-4B (*CHMP4B*) that co-segregated with affected status. Similarly, we detected a heterozygous G>A transition in exon-3 of *CHMP4B* co-segregating with autosomal dominant posterior polar cataracts in a Japanese family. Neither coding change was present in 192 controls or the SNP database. The A>T transversion was predicted to result in the missense substitution of valine (V) for a phylogenetically conserved aspartic acid residue (D), whereas, the G>A transition resulted in the substitution of lysine (K) for a conserved glutamic acid residue (E). Transfection studies of cultured cells revealed that a truncated form of the recombinant D>V-mutant protein had a different sub-cellular distribution than wild type and an increased capacity to inhibit release of virus-like particles from the cell surface, consistent with deleterious gain-of-function effects. Our data provide the first evidence that *CHMP4B*, which encodes a key component of the endosome sorting complex required for transport-III (ESCRT-III) system of mammalian cells, plays a vital role in the maintenance of lens transparency.

A genetic instrumental variables analysis of the effects of maternal smoking on oral cleft risks. *G.L. Wehby, A. Marcinow, X. Quin, M.A. Mansilla, J.C. Murray* Pediatrics, University of Iowa, Iowa City, IA.

Background: The effects of maternal smoking on oral cleft (OC) risks have been estimated without accounting for maternal self-selection into smoking based on her expectations of pregnancy risks. Since risk expectations are typically unobserved, self-selection cannot be addressed by classical analyses which would result in biased estimates. Objectives: This study aimed at estimating the effects of maternal smoking prior to or during the first trimester of pregnancy on OC risks accounting for self-selection using an instrumental variables (IV) model with smoking genetic variants as instruments. Methods: 15 SNPs in DBH, DDC, CCK, GABAB2, CHRNA4 and TPH genes previously shown to be related to smoking were typed in 212 OC cases and 170 controls from Iowa. The IV model ex-post randomizes the sample into groups that are comparable on unobservable self-selection characteristics and provides unbiased estimates under the assumptions that the instruments are significant predictors of smoking and that they are only related to OC through smoking. The IV model was fit using Two-Stage Least Squares regression adjusting for maternal education, alcohol and multivitamin use. Instruments were based on SNP variants and haplotype probabilities. Results: Five SNP variants in DBH, DDC, GABAB2 and CHRNA4 significantly increased smoking probability (RRs=2.0-3.0) in a multivariate regression (satisfying IV assumption 1). Smoking had no effect on OC under a classical model (RR=1.2, insignificant), but increased OC risks under the IV model (RR= 1.5-3.9 using various instrument combinations; larger RRs significant at $p<0.05$). The hypothesis that the genetic instruments were unrelated to OC except through smoking could not be rejected (IV assumption 2 satisfied). Conclusions: Results suggest that the contribution of smoking to OC risks has been underestimated perhaps by up to three times due to women at higher OC risks being less likely to smoke. The study has important counseling implications and provides a novel approach to study smoking-gene interactions and the effects of other behavioral and health factors with genetic components on perinatal outcomes.

Identification of major QTLs and positional candidate genes for gene by smoking interactions in hypertension and blood pressure traits. *M.E. Montasser, L.C. Shimmin, M.S. Leduc, C.L. Hanis, E. Boerwinkle, J.E. Hixson* Human Genetics Center, School of Public Health, University of Texas at Houston.

Hypertension (HT) is mediated by the interaction of many genetic and environmental factors. Previous genome-wide linkage scans have localized numerous loci that show linkage to HT or blood pressure (BP), but results have proven difficult to replicate in part due to gene by environment interactions. Here we investigate the influences of gene by smoking (GxS) interaction on HT and BP in 4,764 sibships from the GENOA study (African Americans, Mexican Americans, European Americans). We used variance component methods for genome-wide linkage analysis of systolic BP (SBP), diastolic BP (DBP), and HT status separately for smokers, nonsmokers, and in the combined group for each race. We localized major QTLs for SBP only in nonsmokers on chromosome 15q26 (LOD=3.4), and only in smokers on chromosome 7q21 (LOD=1.4). The 15q26 and 7q21 QTLs show strong evidence for GxS interactions (p = 0.0004 and 0.009, respectively). We also found QTLs for SBP which do not show evidence for GxS interactions including chromosomes 17q24 (LOD=4.2), 20q12 (LOD = 3.5), and 6p22.2 (LOD=2.1). To follow-up linkage results, we have genotyped GENOA sibships for 167 SNPs on 25 positional candidate genes located in the linked regions on chromosomes 15q26 and 17q24. Using FBAT, we identified significant associations with SBP (only in smokers) in two genes in the 15q26 region including a nonsynonymous SNP in the gene for alanyl aminopeptidase (ANPEP), and an intronic SNP in the insulin-like growth factor 1 receptor (IGF1R) gene. We also found associations with DBP (only in nonsmokers) for an intronic SNP in the gene for neuronal nicotinic acetylcholine receptor alpha 5 subunit (CHRNA5) that previously has been associated with nicotine dependence. For the chromosome 17q24 region, we found significant associations with BP traits for two genes including cAMP-dependent protein kinase type I-alpha regulatory subunit (PRKAR1A) and apolipoprotein H (APOH). These results demonstrate the importance of considering gene by environment interactions in dissecting the genetic components of complex traits.

8q24 deletion identified by a-CGH without the Langer-Giedion phenotype. *M. Mulatinho[1,2], J. Llerena Jr.[1,3], N. Rao[2]* 1) UFRJ, RJ, Brazil; 2) UCLA, CA; 3) FIOCRUZ, RJ, Brazil.

We describe a case of a girl with large and malpositioned central incisors, partial cutaneous syndactyly in hands (interdigital webs), small hands and feet, centripetal obesity, preterm, small stature, retarded intra-uterine growth, severe myopia, genu valgum and developmental delay. A 450 G-band karyotype was 46,XX,t(5;6)(q35.1; p22.2) de novo. Since this translocation was de novo, it was suggested that a submicroscopic/molecular loss of DNA could be causing the phenotypic abnormality. Array-CGH (a-CGH) with 6kb resolution (Nimblegen) was performed with the intention of uncovering the genes disrupted in the translocation. There was no loss of DNA material at the translocation breakpoints on chromosomes 5 and 6. However, a 12.3 Mb deletion at 8q24.12-q24.22 was observed. A retrospective HR G-band analysis (550 bands) showed a suspicious 8q deletion. This region of 8q24 region is associated to Langer-Giedion Syndrome (LGS) or Trichorhinophalangeal Syndrome, Type II (TRPS). Its a contiguous gene syndrome, in which affected individuals present with multiple dysmorphic facial features and exostoses due to loss of function of TRPS1 and EXT1 genes. Mental retardation is not necessarily associated with LGS, an important feature for genetic counseling. In our case, a-CGH showed that the EXT1 and TRPS1 genes were present, which is consistent with an absence of the expected LGS phenotype. On the other hand, the genes MYC associated with hematopoietic tumor activity, and KCNQ3, linked to benign familial neonatal convulsions/epilepsy (BFNC2) were deleted. The proband has not exhibited any features of malignancy yet, and did not present with any neonatal seizures or epilepsy in childhood. To our knowledge, this is the second such case to have a balanced translocation in addition to a deletion in the region 8q24. Bowen et al (1985) described a small deletion on chromosome 8 in addition to an apparently balanced translocation (2;9)(q21;q13) (PubMed ID: 3879433). In our study, a-CGH helped to delineate a detailed karyotype for proper clinical diagnosis and genotype-phenotype correlation. Detailed results and the reported LGS variants will be presented.

The relationship between meiotic recombination in human spermatocytes and aneuploidy in sperm. *R. Martin[1], F. Sun[1], M. Oliver-Bonet[1], E. Ko[1], A. Rademaker[2], P. Turek[3]* 1) Department of Medical Genetics, University of Calgary, Calgary, AB; 2) Department of Preventive Medicine, Northwest University Medical School, Chicago, IL; 3) Departments of Urology and of Obstetrics, Gynecology, and Reproductive Sciences, University of California San Francisco, San Francisco, CA.

In humans, abnormalities in the number or position of crossovers have been associated with nondisjunction in both males and females. We previously determined, by single sperm PCR, that a decreased frequency of recombination between the X and Y chromosomes is associated with nondisjunction and the production of aneuploid human 24,XY sperm. The aim of this study was to determine if there is an association between the frequency of recombination observed in human pachytene spermatocytes and the frequency of aneuploidy in sperm from the same men. Six patients who were undergoing vasectomy reversals donated a small sample of testicular tissue for meiotic analysis. Six to twelve months after the vasectomy reversals, a second sperm sample was obtained from each patient to test for aneuploidy frequencies using fluorescence in situ hybridization (FISH) analysis. The meiotic analysis of pachytene spermatocytes was performed using new immunocytogenetic techniques which allow the visualization of the synaptonemal complex (SCP1, SCP3), the centromere (CREST), and the sites of recombination (MLH1, a DNA mismatch repair protein that marks the location of recombination). A minimum of 100 pachytene spermatocytes were analyzed for each male. Individual meiotic bivalents were identified with centromere-specific multicolour FISH and the number of MLH1 signals recorded for individual chromosomes. The frequency of sperm aneuploidy was analyzed for chromosomes 1,9,13,21,X and Y. A Pearson correlation coefficient was used to determine the relationship between the frequency of meiotic recombination for an individual chromosome (eg 21) with the frequency of sperm aneuploidy for that chromosome. No correlation was observed for any of the chromosomes. This first direct test of an association between recombination and sperm aneuploidy for autosomes suggests that there is no direct association, at least for normal men.

Social support, communal coping and psychological status in sisters in Hereditary Breast and Ovarian Cancer (HBOC) families. *J.A. Peters[1], L. Koehly[2], L. Hoskins[1], N. Kuhn[2], A. Letocha[2], R. Kenen[3], J. Loud[1], M.H. Greene[1]* 1) Clinical Genetics Branch, DCEG, NCI/NIH/DHHS, Rockville, MD; 2) SBRB/NHGRI/NIH/DHHS, Bethesda, MD; 3) The College of New Jersey, Ewing, NJ.

Adult sisters in HBOC families often undergo genetic counseling and testing together but the social context of their long-term adjustment to genetic information is rarely a focus of research. We conducted a quantitative, descriptive, cross-sectional study of 65 sisters from 31 HBOC families within a larger Breast Imaging Study (NCI-01-C-009) for high risk women. The aims were to consider how the size of the sisters social networks and which communal coping measures related to psychological distress. We performed social network analyses using data from the Brief Symptom Inventory-18 to determine anxiety, somatization and depression and the Colored Eco Genetic Relationship Map (CEGRM) to identify family and non-family members of participants social support networks. Intra-family correlation coefficients suggest that these sisters share perceptions of breast cancer risk and worry, but not ovarian cancer risk and worry. Additionally, sisters indicated shared levels of anxiety and somatization, but not depressive symptoms. Communal coping indices of shared support resources were related to anxiety and somatization, with larger numbers of shared emotional supports associated with lower levels of anxiety and lower levels of somatization. Having more shared informants regarding cancer risk was positively associated with somatization. Having a large emotional support network was negatively associated with anxiety. Participants with lower depression scores had more persons playing multiple support roles and fewer individuals providing tangible assistance. In summary, we found that quantity, function, and communal aspects of social exchanges are differentially correlated with self-reported anxiety, somatization and depression. Understanding the specific ways in which quality, quantity and types of supportive relationships impact sisters well-being will allow us to develop appropriate management strategies to help cancer-prone families better adjust to their cancer risk.

A Comparison of Principle Component Analysis and Factor Analysis Strategies for Uncovering Pleiotropic Factors. *X. Wang[1], C.M. Kammerer[1], S.J. Anderson[2], J. Lu[3], E. Feingold[1]* 1) Dept Human Genetics, Univ Pittsburgh, Pittsburgh, PA, 15261, USA; 2) Dept Biostatistics, Univ Pittsburgh, Pittsburgh, PA, 15261, USA; 3) Epidemiology Data Center, Graduate School of Public Health, Univ Pittsburgh, Pittsburgh, PA, 15261, USA.

Principal component analysis (PCA) and factor analysis (FA) are often used to uncover common factors (both genetic and environmental) that contribute to complex disease phenotypes, but little formal evaluation of the performance of these two methods has appeared in the literature. We conducted a comparison analysis using simulated data from nuclear families. We first simulated 7 underlying (unobserved) genetic and environmentally determined traits. Then we derived two sets of 50 complex (observed) traits using algebraic combinations of the underlying components. We next performed PCA and FA on these complex traits. We studied three aspects of the performance of the methods: 1) the ability to detect the underlying genetic/environmental components; 2) whether the methods worked better when applied to raw traits or to residuals (that is, after regressing out potentially significant environmental covariates); and 3) whether heritabilities of composite PCA and FA phenotypes were higher than those of the original complex traits and/or underlying components. Our results indicate that both multivariate analysis methods behave similarly in most cases, although FA is better able to detect predominant signals from an underlying trait. Using residuals in the PCA or FA analyses greatly increases the probability that PCs or factors detect common genetic components instead of common environmental factors, except if there is statistical interaction between genetic and environmental factors. Finally, although there is no predictable relationship between heritabilities obtained from composite phenotypes versus original complex traits, our results indicate that composite trait heritability generally reflects the genetic characteristics of the detectable underlying components.

Phosphatidylinositol pathway defects in arthrogryposis: autosomal recessive lethal congenital contractural syndrome caused by mutations in *PIP5K1C* and in *ERBB3*. *G. Narkis[1], O. Ofir[1], E. Manor[2], D. Landau[2], M. Volokita[1], K. Elbedour[2], O.S. Birk[1,2]* 1) Dept Development Genetics, Ben-Gurion University, Beer-Sheva, Israel; 2) The Genetics Institute, Soroka Medical Center, Beer-Sheva, Israel.

Lethal congenital contractural syndrome type 2 (LCCS2) is a neonatally lethal form of Arthrogryposis prevalent in Israeli Bedouins. The phenotype is characterized by multiple joint contractures, anterior horn atrophy in the spinal cord, and a markedly distended urinary bladder, suggesting a spinal cord neuropathic etiology. We previously mapped this syndrome to 4.6 Mb (harboring 150 genes) on chromosome 12q13. We now describe a third LCCS phenotype (LCCS3) - similar to LCCS2 yet without neurogenic bladder. Using 10K SNP arrays followed by fine mapping with microsatallite markers, we localized the LCCS3 gene to 3.4 Mb (harboring 120 genes) on chromosome 19p13. Of these genes, 30 candidates were sequenced, identifying a single homozygous mutation in *PIP5K1C*. *PIP5K1C* encodes phosphatidylinositol-4-phosphate 5-kinase, type I, gamma (PIPKI), an enzyme that phophorylates phosphatidylinositol 4-phosphate (PI4P) to generate phosphatidylinositol-4,5-bisphosphate (PIP_2). The mutation causes substitution of aspartic acid to asparagine at amino acid 253 (D253N), abrogating the kinase activity of PIPKI. Based on this finding, we sequenced genes in the LCCS2 locus that encode proteins in pathways interacting with the phosphatidylinositol pathway. We demonstrate that LCCS2 is caused by aberrant splicing of *ERBB3* (Her3), leading to a predicted truncated protein. ERBB3 is known to modulate phosphatidylinositol-3-kinase (PI3K), an enzyme that phosphorylates PIP_2 to produce phosphatidylinositol-3,4,5-triphosphate (PIP_3). ERBB3, an activator of the PI3K/Akt pathway - regulating cell survival and vesicle trafficking - is essential for the generation of precursors of Schwann cells that normally accompany peripheral axons of motor neurons. We suggest that defects in the phosphatidylinositol pathway affecting PIP_2, a molecule active in endocytosis of synaptic vesicle proteins, culminate in lethal congenital arthrogryposis.

Real-time multiplex allele-specific PCR for 35delG genotyping based on SYBR Green I fluorescence. *E.L. Sartorato[1], C.A. Oliveira[1], J.Jr. Pedrazzoli[2], M.L. Ribeiro[2]* 1) Lab de Genetica Molecular Humana/CBMEG, Universidade Estadual de Campinas, Campinas, SP, Brasil; 2) UNIFAG,Universidade Sao Francisco, USF, Braganca Paulista, SP, Brasil.

In developed countries approximately 1 in 1000 children is born with a hearing loss severe enough to require special education services, and about 60% of the cases of isolated deafness have a genetic origin. Although doctors know about more than 100 genes for hearing at the moment, only a few are routinely tested for. The main genetic test being offered at present is a test to screen the gene for the connexin 26 protein. Mutations in the connexin 26 (GJB2) gene are the most commonly known cause of nonsyndromic recessive deafness (NSRD). One specific mutation, a deletion of G, in a sequence of six Gs (35delG), accounting for approximately two thirds of GJB2 alleles from persons with NSRD. The prevalence of heterozygous 35delG carriers among hearing population is high (2-4%) in several countries where this mutation analysis was performed. Thus, the aim of the present study was to develop a single-step and single-tube method for 35delG genotyping by real-time multiplex allele-specific PCR and melting curve analysis. The preliminary results obtained from 10 samples showed a high accuracy compared to those obtained with a conventional allele-specific PCR. Although this method requires expensive equipment, it is inexpensive in terms of consumables. It is also very rapid, reliable and suitable for large-scale screening. This method also would be useful when combined to other diagnostic methods for early diagnosis, and associate to multi-disciplinary services to set the main objective of rehabilitation.

Cowden Syndrome Patients with PTEN Promoter Mutations Demonstrate Abnormal Protein Translation. *R.E. Teresi[1], K.M. Zbuk[1], M.G. Pezzolesi[1], J. Bubenik[2], D.M. Driscoll[2], K.A. Waite[1,3], C. Eng[1,3,4,5]* 1) Genomic Medicine Inst; 2) Dept of Cell Biology; 3) Taussig Cancer Center, Cleveland Clinic; 4) Dept of Genetics; 5) CASE Comprehensive Cancer Center, Case Western Reserve University School of Medicine, Cleveland, OH.

Cowden Syndrome (CS) is an inherited disorder characterized by hamartomas and increased risk of breast cancer, thyroid abnormalities, uterine leiomyoma, and macrocephaly. Germline mutations within PTEN (phosphatase and tensin homolog deleted on chromosome ten) account for 85% of all CS patients, where 10% are promoter mutations associated with an increase frequency of breast cancer. We studied the downstream effect of PTEN promoter variants (-861G/T, -853C/G, -834C/T, -798G/C, and -764G/A) that do not lie within known cis-acting regulatory elements from 5 unrelated CS patients. Paradoxically, protein binding to the PTEN promoter (-893 to -755) does not appear to be altered in the 5 variants, when compared to wildtype (WT). However, reporter assays indicated that 3 of the PTEN promoter variants (-861G/T, -853C/G, and -764G/A) demonstrated ~50% decrease in luciferase activity. Analysis of PTEN mRNA revealed no transcript alterations, thereby suggesting an inhibition of protein translation. MFOLDs mRNA secondary structure predictions suggest RNA structural modifications in 3/5 variants (-861G/T, -853C/G, and -764G/A) when compared to WT PTEN promoter. Additionally, PTEN protein levels were ascertained in available samples and a decrease was observed in variants that cause the largest mRNA secondary structure alterations. These data indicate that PTEN promoter variants can alter normal mRNA secondary structures and resulted in an inhibition of protein translation. Our results stress the importance of looking for PTEN promoter variants in patients that have CS features yet do not have a detectable mutation within its open reading frame, the latter of which is part of clinical routine. Additionally, nucleotide changes within the promoter region do not affect the PTEN protein sequence, therefore, a therapeutic tool that can regulate its transcription and/or translation could be highly effective in this subset of patients.

Co-occurrence of 4p16.3 deletions with both paternal and maternal duplications of 11p15: modification of the Wolf-Hirschhorn syndrome phenotype by genetic alterations predicted to result in either Beckwith-Wiedemann or Russell-Silver syndrome. *S.T. South[1,2], H. Whitby[1], T. Maxwell[1], E. Aston[1], A.R. Brothman[1,2], J.C. Carey[1]* 1) Division of Medical Genetics, Department of Pediatrics, University of Utah, Salt Lake City, UT 84132-2117; 2) ARUP Laboratories 500 Chipeta Way Salt Lake City, UT 84108-1221.

Paternal duplications of chromosome region 11p15 can result in Beckwith-Weidemann syndrome (BWS), whereas maternal duplications of the same region on 11p15 can result in Russell-Silver syndrome (RSS). These two syndromes have numerous opposing phenotypes with BWS characterized by fetal gigantism, macrosomia, asymmetry due to hemihyperplasia, and increased risk for embryonal tumors; whereas, RSS is characterized by prenatal and postnatal growth retardation with a relatively normal head circumference and asymmetry due to hemihypotrophy. The differences in the phenotype are proposed to be due to altered dosage of imprinted genes that control growth within this region of 11p15. Wolf-Hirschhorn syndrome (WHS) is due to deletions of a region in 4p16.3 and is characterized by prenatal and postnatal growth delay, microcephaly, mental retardation/developmental delay, characteristic facial features and seizures. There is no known parent-of-origin effect for deletions of the WHS critical region and no genes are known to be imprinted in this region. We present 3 individuals with apparently identical unbalanced translocations resulting in a derivative chromosome 4 with both a deletion of 4p16.3 and a duplication of 11p15. Two of these individuals are family members with one inheriting the derivative 4 from her balanced mother and the other inheriting the derivative 4 from his balanced father. The third individual is unrelated and inherited his derivative 4 from his balanced father. While the findings of these individuals included some features of WHS and RSS or BWS, the phenotypes as an aggregate are distinct from these syndromes. The genomic and phenotypic characterization of these three individuals will be presented and will demonstrate how unbalanced translocations can result in the modification of chromosome duplication and deletion syndromes.

Significant association between *TIM1* promoter polymorphisms and protection against cerebral malaria in Thailand. *P. Nuchnoi[1], J. Ohashi[2], R. Kimura[2], H. Hanantachai[1], I. Naka[2], S. Krudsood[1], S. Looareesuwan[1], K. Tokunaga[2], J. Patarapotikul[1]* 1) Faculty of Tropical Medicine, Mahidol University,Bangkok, Thailand; 2) Department of Human Genetics, Graduate School of Medicine, University of Tokyo, Tokyo, Japan.

The sequential activation of T helper type 1 (Th1) then Th2 cells is essential for regulating pro-inflammatory Th1 cytokines such as IFN- and TNF, which have been implicated in the development of cerebral malaria. The T cell immunoglobulin and mucin domain (TIM) family of proteins are cell surface proteins involved in regulating Th1 and Th2 immune responses. In this study, variation screening was performed for TIM1, TIM3, and TIMD4 genes, and the possible association between the detected polymorphisms and the severity of malaria was then examined in 478 adult Thai patients infected with Plasmodium falciparum malaria. The TIM1 promoter haplotype comprising three derived alleles (-1637A at rs7702919, -1549C at rs41297577 and -1454A at rs41297579), which were in complete linkage disequilibrium in the study population, was significantly associated with protection against cerebral malaria (P = 0.0009, chi-squared test; odds ratio = 0.41; 95% confidence interval = 0.24-0.71). Allele-specific transcription quantification analysis revealed that the level of mRNA transcribed from TIM1 was higher for the protective promoter haplotype than for the other promoter haplotype (P = 0.004, Mann-Whitney U-test). Engagement with TIM1 in combination with T cell receptor stimulation induces Th2 cytokine production. Thus, the present results suggest that the higher TIM1 expression associated with the protective TIM1 promoter haplotype confers protection against cerebral malaria. High TIM1 expression may induce production of Th2 cytokines, which inhibit production of Th1 cytokines.

Heritability of susceptibility to ionizing radiation induced apoptosis of human lymphocyte subpopulations. *A. Schmitz[1], J. Bayer[1,3], N. Dechamps[1,3], L. Goldin[2], G. Thomas[2,3]* 1) Institut de Radiobiologie Cellulaire et Moléculaire, DSV/CEA , Fontenay aux roses, France; 2) Division of Cancer Epidemiology and Genetics, NCI/NIH Bethesda MD; 3) Fondation Jean Dausset-CEPH, Paris, France.

Association between major changes in chromosomal radiosensitivity and increased susceptibility to cancer has been demonstrated for several rare cancer prone monogenic conditions, It has also been suggested that chromosomal radiosensitivity may be an inherited trait in families of breast cancer patients. In mice, the Prkdc-gene was identified as a candidate for a gene controlling in vivo thymocyte sensitivity to radiation induced apoptosis, as well as for a gene controlling radiation lymphomagenesis. These observations support the possibility that subtle inter-individual variation in radiosensitivity in humans may contribute to cancer susceptibility in the general population and that this trait may in part be genetically determined. To evaluate heritability of intrinsic radiosensitivity, induction of apoptosis in lymphocyte subpopulations was determined by flow cytometry immunophenotyping on samples from 334 related individuals belonging to 38 large kindred-families. Intra-familial correlations and heritability were computed on 199 father-mother-offspring trios. Marked differential susceptibility to ionizing radiation induced apoptosis of naïve and memory T lymphocytes was demonstrated, and although age and sex were significant covariates, their effects only accounted for a minor part of the inter-individual variation. Parent-offspring and sib-sib correlations were significant for radiosensitivity of B cells, T4, T8, and of effector memory (EM) T4- and T8 subpopulations. In the T4-EM subpopulation, the phenotype showed correlations most consistent with dominant or additive genetic effects and segregation analysis in the pedigrees was consistent with the contribution of a bi-allelic dominant locus. Thus, heritability was demonstrated for the susceptibility to ionizing radiation induced apoptosis of lymphocyte populations and segregation of the T4-EM radiosensitivity phenotype was consistent with a Mendelian transmission model involving one major gene.

A study on the chromosome abnormalities in women with premature ovarian failure. *F. Pouresmaeili[1], M. Fallahian[2], F. Azizi[3], E. Azargashb[4], N. Arian[5], S. Karimi[6], A. Shirafkan[2]* 1) Shaheed Beheshti University of Medical Sciences, Faulty of medicine, Genetics & Biochemistry Dept., Evin square, Chamran highway, Tehran 19395-4719, Iran & Fertility-Infertility Health Research Center of Taleghani Hospital, 3rd floor, Evin square, Chamran; 2) Taleghani Hospital, Gynecology & Obstetrics Dept., Evin square, Chamran highway, Tehran, Iran; 3) Taleghani Hospital, Endocrinology Research center, Evin square, Chamran high way, Tehran 19395-4763, Iran; 4) Shaheed Beheshti University of Medical Sciences, Faulty of medicine, Social Medicine Dept., Evin square, Chamran highway, Tehran 19395-4719, Iran; 5) Shaheed Beheshti University of Medical Sciences, Faulty of medicine, Genetics & Biochemistry Dept., Evin square, Chamran highway, Tehran 19395-4719, Iran; 6) Shaheed Beheshti University of Medical Sciences, Faulty of medicine, Genetics & Biochemistry Dept., Evin square, Chamran highway, Tehran 19395-4719, Iran.

Failure of germ cell development is associated with complete ovarian failure,while their decreased number more likely is associated with partial ovarian failure,which takes the form of secondary amenorrhea.Both are highly heterogeneous conditions whose aetiology in most cases is still unknown but they may be considered different manifestations of the same underlying pathogenetic and etiologic processes.A genetic basis has long been suggested even if the frequency and types of chromosome aberrations and gene mutations have still to be determined.We performed a systematic genetic study on 32 women affected by secondary amenorrhea. The inclusion criteria were menopause before the age of 40yrs and FSH levels>40IU/l.The overall percentage of chromosome anomalies was 18.7%with identifable abnormal X chromosome, which were 1 XX/XXX ;2 XX/XO; 1 XX/XY musaics and 2 pure autosomal anomalies,XO.We suggest chromosome study to be performed for all patients with POF. The obtained information will be usefull for patient management, genetic counselling, and future family planning.

Molecular analysis of Krabbe disease in populations from Belgium and Italy: evidence for a founder mutation in late onset Krabbe disease in the Catania (Sicily, Italy) region. *W. Lissens[1], A. Arena[2], S. Seneca[1], M. Rafi[3], G. Sorge[2], L. De Meirleir[1, 4], I. Liebaers[1], D. Wenger[3], A. Fiumara[2]* 1) Dept of Medical Genetics, Univ Hosp VUB, Brussels, Belgium; 2) Dept of Pediatrics, University of Catania, Catania, Italy; 3) Dept of Neurology, Jefferson Medical College, Philadelphia, USA; 4) Pediatric Neurology, Universitair Ziekenhuis Brussel, Brussels, Belgium.

Krabbe disease is an autosomal recessive disorder caused by the deficiency of the lysosomal enzyme galactocerebrosidase. In this study, molecular defects in the GALC gene were investigated in 7 Belgian patients with the classical infantile form of the disease and 8 families with the late onset form from Sicily, Italy. Three of the Belgian patients were homozygous for a common 30kb deletion (IVS10del30kb), two were compound heterozygotes for this mutation and a novel and a previously described missense mutation. Two other unrelated Belgian patients were homozygous for the p.Tyr551Ser mutation. Five unrelated late onset patients from Sicily came from the same region north to the town of Catania. In this region, the proportion of patients with late onset Krabbe disease is high (72%), although these patients represent only 10% of all patients with Krabbe disease in other populations. Three of these patients were homozygous for a novel p.Gly41Ser mutation, the other two were compound heterozygotes for this mutation and previously described frameshift and missense mutations. The p.Gly41Ser mutation was not present in the 3 other late onset patients from other regions of Sicily, in whom known and 4 novel mutations were identified. Expression studies showed that the p.Gly41Ser mutation, that is on a polymorphic p.Thr546 allele which is known to reduce the enzyme activity by 70% relative to p.Ile 546, results in almost complete loss of enzyme activity; the mutation is also on a unique haplotype as studied by intragenic and extragenic dinucleotide polymorphisms. All these results indicate a founder effect in the patients with Krabbe disease from the Catania region. Possibly this mutation occurred in a single ancestor from that region, but was not further spread.

Interaction between familial history of obesity and dietary fat intakes on obesity-related phenotypes. *AM. Paradis[1,2,5], G. Godin[3], L. Pérusse[1,4], MC. Vohl[1,2,5]* 1) Lipid Research Center, Québec, Canada; 2) Institute of Nutraceuticals and Functional Foods, Québec, Canada; 3) Faculty of nursing, Laval University, Québec, Canada; 4) Department of Social and Preventive Medicine, Laval University, Québec, Canada; 5) Department of Food Science and Nutrition, Laval University, Québec, Canada.

Obesity is under the influence of genetic and nutritional factors. The aim of this study was to evaluate whether familial history of obesity (FHO) interacts with dietary fat intake (DFI) to modulate indices of obesity. We recruited 664 participants aged between 18 to 55 years. A positive FHO (FHO+) was defined as having at least one obese first-degree relative and a negative FHO (FHO-) as no obese first-degree relative. Dietary intakes were collected from a food-frequency questionnaire. Body mass index (BMI), weight and waist girth were recorded using standard procedures. Fat mass and fat free mass were assessed by electrical bioimpedance. Individuals with FHO+ and FHO- had similar dietary intakes (energy, fat, protein, carbohydrate, cholesterol, and fibre). After adjustment for age and sex, individuals with FHO+ had higher BMI, weight, waist girth, fat mass and fat free mass ($p<0.001$) than individuals with FHO-. To test for the interaction between FHO and DFI, subjects were stratified on the basis of FHO and further on the basis of the percentage of energy derived from fat. The median value (33% of energy from fat) was used as a cutoff point. The effects of FHO, DFI and the interaction (FHO*DFI) were computed using the general linear model, controlling for age and sex as covariates. Significant interaction effects (FHO* DFI) were observed for BMI, weight, waist girth and fat mass (p interaction = 0.05, 0.04, 0.04, 0.02, respectively). Among individuals with FHO+, indices of obesity increased with increasing amount of DFI whereas these associations were not observed in individuals with FHO-. These results suggest a stronger relationship between DFI and obesity-related phenotypes in subjects with FHO+.

Increased risk of osteopenic fractures in elderly patients with Gaucher disease. *N. Weinreb, L. Costantini* Univ Research Foundation, Coral Springs, FL.

Bone disease is a common cause of morbidity in Gaucher disease (GD). 60% of adult patients (pts) have decreased bone mineral density (BMD). However, in elderly pts, statistically normal BMD may not indicate functionally normal bone strength. Here we report serial dual energy x-ray absorptiometry (DXA) scores and fracture (Fx) occurrence for 29 GD pts age 57-88 (9M, 20F) treated with enzyme replacement therapy (ERT) with imiglucerase, often in conjunction with bisphosphonates. **Results:** Lumbar (L) spine Z-scores were mostly normal during 9.2 4.9 y on ERT: median -0.50; mean (SD) -0.05 (0.41); centiles 10-90: -1.811.21. Nonetheless, new Fx occurred in 13 (44.8%) pts in the hip (6), spine (4), or other location (11), or at multiple sites (7). Fx occurred in 5/8 (62.5%) pts with splenectomy v 8/21 (38.1%) pts without and in 7/20 (35%) N370S homozygotes v 6/9 (67%) with other genotypes. 10y Fx probability: 42% (CI 17-55). L spine T-scores were < -1 for 18/29 pts, indicating persistent osteopenia/osteoporosis in 62%, and < -2.68 in 25%. New Fx occurred in 8/15 (53.0%) pts with T-scores the median of -1.60 v 5/14 (35.7%) with T-scores > -1.60. Pts with low T scores were predominantly women (13/15F v 7/14M) and had higher use of bisphosphonates (86.7% v. 35.7%). Fx were not restricted to pts with the lowest T-scores. Findings were similar for femoral neck T-scores. **Conclusions:** Normal DXA Z-scores in elderly GD pts do not indicate low Fx risk. Low T-scores, as seen in our pts, do confer an important Fx risk. The 42% 10y Fx probability in our elderly GD pts is higher than expected for comparably aged individuals without GD. Because other risk factors such as Fx history, nutritional status, and concurrent illness were similar in our pts regardless of Fx status, cumulative pathophysiology from long-standing, untreated GD may independently increase Fx risk. Treatment with ERT may allow pts to achieve normal Z-scores. However, starting ERT late in life, even in conjunction with bisphosphonates, may not reverse established osteopenia/osteoporosis sufficiently to avoid future Fx. Therefore, detection of bone loss in young pts and early therapeutic intervention to achieve and maintain normal BMD is an important component of GD management.

Large genomic *FBN1* deletions detected by MLPA and SNP arrays provide evidence for true haploinsufficiency in Marfan syndrome. *G. Matyas[1], S. Alonso[1], A. Patrignani[2], M. Marti[2], E. Arnold[3], I. Magyar[1], C. Henggeler[1], T. Carrel[4], B. Steinmann[3], W. Berger[1]* 1) Medical Molecular Genetics, Institute of Medical Genetics, University of Zurich, Schwerzenbach, Switzerland; 2) Functional Genomics Center Zurich, ETH and University of Zurich, Zurich, Switzerland; 3) Division of Metabolism and Molecular Pediatrics, University Childrens Hospital, Zurich, Switzerland; 4) Clinic for Cardiovascular Surgery, University Hospital, Berne, Switzerland.

Purpose: Mutations in the *FBN1* gene cause Marfan syndrome (MFS), an autosomal dominant connective tissue disorder, which displays variable manifestations in the cardiovascular, ocular, and skeletal systems. Current molecular genetic testing of *FBN1*, although powerful, may miss mutations in the promoter region or in other noncoding sequences as well as partial or complete gene deletions and duplications. Methods: We successively applied multiplex ligation-dependent probe amplification (MLPA) and the Affymetrix Human Mapping 500K Array Set, which contains probes for ~500,000 single-nucleotide polymorphisms (SNPs) across the genome, to analyze copy number variation in genomic DNA samples of 101 unrelated patients with MFS or related phenotypes in whom standard molecular testing detected no mutation. Results: We identified *FBN1* deletions in two patients with MFS. Our high-resolution approach narrowed down the deletion breakpoints. Subsequent sequencing of the breakpoint junctions revealed the deletion sizes of 27 and 303 kb, respectively. Surprisingly, both deletions affect the putative regulatory and promoter region of the *FBN1* gene, strongly indicating that they abolish transcription of the deleted allele. This expectation of complete loss of function of one allele, i.e. true haploinsufficiency, was confirmed by transcript analyses.

Conclusions: Our findings emphasize the importance of screening for large genomic rearrangements in comprehensive genetic testing of *FBN1* and extend the molecular etiology of MFS by providing hitherto unreported evidence that true haploinsufficiency is sufficient to cause MFS.

Case Report: a Novel Mutation in VDR Gene in an Iranian family with two affected children with Vitamin D Resistant Rickets and Alopecia totalis. *N. Momenin[1], Y. Shafeghati[1], S.T. Esfahani[2], W. Wuyts[3]* 1) Genetics Research Center, University of Welfare Sciences & Rehabilitation, Tehran, Iran; 2) Children`s Hospital Medical Center,Tehran Medical University,Tehran,Iran; 3) Medical Genetics Center,University of Antwerp,Antwerp,BelgiumÄ.

Background- Hereditary vitamin D resistant rickets type II (HVDRR II) is a rare autosomal recessive disorder, most often caused by mutations in the VitD receptor gene. It is usually presented with rachitic changes not responsive to VitD treatment. Circulating levels of 1,25(OH)2 VitD3 is elevated, thus differentiating it from Vit D dependent rickets type I. Alopecia of the scalp or whole of the body is seen in some families with VitD dependent rickets type II. This is usually associated with a more sever phenotype. Materials and Methods- In this report, we present our findings on a family exhibited the typical clinical features of alopecia totalis, renal tubular acidosis, mild generalized aminoaciduria, refractory rickets in two siblings. The proband is now an 18-month-old boy. He is the 3rd offspring of a healthy couple. At the end of the first month of his life alopecia occurred and progressed to total loss of his scalp hair, along with refractory rickets. The family have had 2 older children, the oldest was a boy and had had similar disease and died at the age of 2 years and 8 months. Results- Alkaline phosphatase was high, PTH was high. Other routine biochemical tests were WNL, but 1+ glycine detected in his urine. Skin biopsy performed and the result was alopecia areata. Mutation analysis for VDR gene by direct sequencing analysis of all coding exons showed a Homozygous c.122G>A(p.Cys41Tyr) variant in exon 2 as a novel point mutation that several arguments point to a pathogenic effect. Conclusion- The older child of the family was a boy which had similar disease and died because of its complications at the age of 32 month. The 2nd child is a healthy 5-year-old girl. Parents are relatives. We should be aware of this very rare disease, whenever we see a patient who is suffering from refractory rickets with alopecia.

Haplotype associations with quantitative traits in the presence of complex multilocus and heterogeneous effects.

K. Shibata[1], L. Diatchenko[2], D.V. Zaykin[1] 1) National Institute of Environmental Health Sciences, National Institutes of Health; 2) Center for Neurosensory Disorders, University of North Carolina at Chapel Hill.

We extend earlier work on characterization of haplotype associations with quantitative traits by incorporating haplotype-specific variance parameters into the likelihood for un-phased data. The inference proceeds within the likelihood framework that involves simultaneous estimation of haplotypic effects and their frequencies. The addition of the haplotypic variance was found to improve power of detecting associations under complex models including those where only a subset of functional polymorphisms has been scored, as well as heterogeneity models where multiple mutations are linked to the haplotypes under study via linkage disequilibrium. We describe the association tests and estimation procedures for specifically haplotypic effects, as well as the inference based on entire un-phased diplotypes. An overall association test including all of the haplotypes at once is derived as well. The method was successful in finding a strong association of adrenergic receptor beta-2 (ADRB2) haplotypes with blood pressure.

Dichloroacetate Induces Apoptosis via Metabolic Targeting in Endometrial Cancer Cells which Exhibit Aerobic Glycolysis. *J.Y.Y. Wong[1], M. Debidda[2], I. De Vivo[1,3]* 1) Medicine, Channing Laboratory, Brigham and Women's Hospital, Boston, MA; 2) The Jerome Lipper Multiple Myeloma Center, Department of Medical Oncology, Dana-Farber Cancer Institute, Harvard Medical School, Boston Massachusetts; 3) Harvard School of Public Health, Boston Massachusetts.

Aerobic glycolysis due hyper-polarization of the mitochondrial membrane is a unique hallmark of numerous cancers. It is characterized by reliance on glycolysis for ATP production despite a readily available oxygen source. This may confer apoptotic resistance in cancer cells since the electron transport system is required for reactive oxygen species and Cytochrome C release for mitochondrial-mediated activation of Caspases. A landmark study showed that treatment of several cancer cell types with Dichloroacetate (DCA) inhibited mitochondrial pyruvate dehydrogenase kinase (PDK), and inhibitor of pyruvate dehydrogenase (PDH), which shifted metabolism from glycolysis to glucose oxidation. This was accompanied by a decrease in mitochondrial membrane potential (MMP) and promoted apoptosis in cancer but not normal cells (Bonnet et al. 2007). The objective of our study is to assess the efficacy of DCA to induce apoptosis specifically in endometrial cancer cells. Seven endometrial cancer cell lines were treated with DCA and analyzed for apoptosis using flow cytometry. Five endometrial cancer cell lines responded to treatment while 2 did not respond. Those which responded to DCA treatment showed a 2 to 5-fold increase in early and late apoptotic cells, a decrease in intracellular calcium levels, a decrease in MMP, and decreased Survivin expression. Endometrial cancer cells which did not respond to DCA showed no difference in the percentage of apoptotic cells, an increase in Survivin expression and no significant decrease in MMP with treatment. The transcript abundance of PDH was found to be greater in a non-responding cell line compared to a responding cell line which may indicate that those unaffected by treatment may be utilizing glucose oxidation. Our results suggest that DCA is a promising cancer therapeutic agent and is effective in those endometrial cancer cell-types which exhibit reliance on anaerobic respiration.

Gene-Gene Interaction between FGF20 and MAOB in Parkinson Disease. *E. Martin[1,2], X. Gao[1,2], W. Scott[1,2], G. Wang[2], G. Mayhew[1,2], J. Vance[2]* 1) Center for Genetic Epidemiology and Statistical Genetics, Univ Miami, Miami, FL; 2) Miami Institute for Human Genomics, Univ Miami, Miami, FL.

The fibroblast growth factor 20 (FGF20) and monoamine oxidase B (MAOB) genes are reported to be associated with PD risk, and both are involved in the dopamine bio-pathway. We investigated the joint effect between polymorphisms in FGF20 and MAOB genes, to see if there was evidence of statistical interaction with risk of PD. All subjects analyzed were white, and families with known parkin mutations were removed. A total of 736 families were used in the final analysis. Statistical analysis was performed by Conditional Logistic Regression (CLR) using sibships as strata. Because MAOB is located on chromosome X and the prevalence of PD differs by sex, we stratified the data set on sex and analyzed males and females separately. Significant two-locus gene-gene interactions were found in white females using CLR between the polymorphism rs1721100 of FGF20 and the polymorphism rs1799836 of MAOB, and between the polymorphism rs1721082 of FGF20 and rs1799836. The risk alleles for each single SNP identified from CLR, rs1721100 C, rs1721082 T and rs1799836 A, are consistent with previous reports. Using indicator variables for the SNP genotypes, rs1721100 G/C with rs1799836 A/A showed significant interaction (P = 0.021), compared with the reference group rs1721100 G/G with rs1799836 G/G. rs1721082 T/A with rs1799836 A/A also showed significant interaction (P = 0.019), compared with rs1721082 A/A with rs1799836 G/G. Using an allele-dose model for the risk alleles, rs1721100 and rs1799836 showed significant interaction (P = 0.019), rs1721082 and rs1799836 also showed significant interaction (P = 0.030) with PD risk. Variants in FGF20 and MAOB have non-independent effects on PD risk in females of our family-based data set. This suggests a statistical interaction between alleles in these genes.

Nonhuman basepaired insertiones in cDNA of fibroblast cells. *Z.V. Vassileva (Nickl)* Zwetelina Vassileva, Biology, Dragan Tzankov Str. 8, St. Kliment Ochridksi University Sofia, Zwetelina Vassileva(Nickl).

Nonhuman base-paired insertions in cDNA of fibroblast cells. Despite of the research activities in the last years there are still many uncertain open questions about the expression regulation during the mRNA processing of some human genes. Analysis of some genes shows irregularities and variations in those sequence structure and composition between the different developmental stages and pathological changes in different tissues. By now some of those irregularities are connected to some known functional mechanisms of microRNAs. Similar activities may occur also in NBIs contained genes. Analysis of some human gene sequences consisting of NBIs would be an advice for analysis of certain connections to other genes families. This would be also a helpful hint for analysis of genes development. One of the above mentioned sequences was amplified in fibroblast cells of human adult smooth vascular tissue. Analyses of all transcripts are made primarily by the use of NCBI Genbank resources.

Multiple genetic determinants of plasma lipid levels in Caribbean Hispanics. *Y.C. Liao[1], H.F. Lin[2], T. Rundek[3], R. Cheng[4], E. Hsi[1], R.L. Sacco[5], S.H.H. Juo[1,2,3]* 1) Graduate Institute of Medical Genetics, Kaohsiung Medical University, Kaohsiung, Taiwan; 2) Department of Neurology, Kaohsiung Medical University, Kaohsiung, Taiwan; 3) Department of Neurology, Columbia University, New York, USA; 4) The Gertrude H. Sergievsky Center, Columbia University, New York, USA; 5) Department of Neurology, Miller School of Medicine, University of Miami, FL, USA.

Objective

To identify candidate genes in relation to plasma lipid levels in Caribbean Hispanics.

Methods and Results

A total of 114 single nucleotide polymorphisms (SNPs) at 17 lipid-related genes were genotyped in 477 Caribbean Hispanics from the Northern Manhattan Study (NOMAS). Analyses for each SNP and haplotype were performed to evaluate the associations with four lipid traits: high- and low-density lipoprotein cholesterol (HDL-C, LDL-C), triglyceride (TG) and total cholesterol (TC). We identified 19 SNPs at 10 genes that were significantly related to lipids ($p<0.01$), including nine involved in the reverse cholesterol transport pathway, and one involved in bile acid synthesis. The significant genes, in conjunction, explained 10.5%, 8.7%, 8.6% and 8.6% of variation in HDL-C, LDL-C, TG and TC levels, respectively. Three genes, namely the apolipoprotein A5, apolipoprotein B and cytochrome p450 polypeptide 7A1 genes, accounted for the largest proportion of variation in HDL-C/TG, TC and LDL-C respectively; while other single genes explained less than 2% of lipid variation.

Conclusions

The present study identified 10 candidate genes that influenced plasma lipid levels in Caribbean Hispanics. Although the genetic effect of individual genes is modest, the cumulative effects of multiple genes lead to a substantially better prediction of inter-individual variations in lipid levels.

Role of ubiquitin-proteasome dysfunction in Lafora disease. *S. Mittal, S. Ganesh* Biological Sciences & Bioengineering, Indian Institute of Technology, Kanpur, UP, India.

Laforas progressive myoclonus epilepsy (called Lafora disease: LD) results primarily from the formation of Lafora body inclusions and neuronal cell death. LD is invariably a fatal disorder as none of the current treatments halt or retard Lafora body formation and neurodegeneration. The main obstacle in developing therapies for LD is the limited understanding of the key molecular events that provoke Lafora body formation and neurodegeneration. The discovery of NHLRC1 gene, encoding an ubiquitin ligase called malin, has led to the hypothesis that dysfunction of the ubiquitin-proteasome pathway (UPP) is pivotal to LD pathogenesis. In order to understand the role of UPP in LD, we have established a cell-based model to define the substrates for, and their cellular functions of malin, to understand the protective role of malin in neuronal cell-death induced by various stresses, and finally, the question as to how defects in malin lead to the formation of Lafora bodies. We would also like to uncover the synergistic function of laforin, a protein phosphatase coded by a second gene involved in LD, using this cellular model. We show here that malin and laforin co-localize in endoplasmic reticulum and form centrosomal aggresomes when cells were treated with proteasomal inhibitors. Laforin and malin form aggresome when expressed together or otherwise, suggesting that the two proteins are recruited to the centrosome independent of each other. Thus, centrosomal accumulation of malin, possibly with the help of laforin, may enhance the ubiquitination of its substrates and facilitate their efficient degradation by proteasome. It is indeed the case, as the cellular level and toxicity of misfolded substrates of malin diminish when they are co-expressed with malin or laforin. Our results further suggest that, in addition to the UPP, the malin-mediated clearance of misfolded proteins is likely to involve autophagy. Taken together our results suggest that defects in malin or laforin may thus lead to increased levels of misfolded and/or target proteins, which may eventually affect the physiological processes of the neuron leading to the LD phenotype.

Study of Genetic Susceptibility to Myocardial Infarction in a Genetic Isolated NF Population. *Y.G. Xie[1,2,3], J.X. Ciu[1], E. Randell[1], J. Renouf[4], G. Sun[2], C. Butt[1], F.Y. Han[1]* 1) Dept Laboratory Medicine, Memorial Univ, St John's, NL, Canada; 2) Dept Genetics, Memorial Univ, St John's, NL, Canada; 3) Dept Pediatrics, Memorial Univ, St John's, NL, Canada; 4) Laboratory Medicine Program, Eastern Health, NL, Canada.

Myocardial infarction (MI) is a complex disease that results from a life-long interplay between genetic and environmental factors. Being a multifactorial disorder, the genetic components of MI may be combined effects of a number of genes with each playing only a small role. Case-control association analysis is a commonly used study design in the field of complex trait genetics. However, the genetic associations with MI in most studies are not consistently reproducible due to inadequate sample size, population heterogeneity, confounding gene-gene and gene-environment interactions, and the complex dependency of the associations. Case control studies using a genetically isolated population are of advantage due to a relatively homogenous genetic background. Furthermore, large sample sizes help to identify weak genetic risk factors which may be the main factors imparting genetic susceptibility in MI. Recent advances in high-throughput genomic technology make it possible to study multiple gene polymorphisms in large populations. Taking advantage of the genetic isolated Newfoundland population, we carried out a large case-control study that involved genotyping 18 gene variants from 11 selected candidate genes in 1,000 patients with MI and 1000 healthy controls. Genotyping of SNPs was conducted using Taq Man SNP genotyping technology on real-time PCR. Our results showed an association between MI and two gene variants THB4 1186C* (OR=1.58, P=0.023) and MTHFR 1298C (OR=1.369, P<0.001). Potential gene-gene interactions were also evident which will be further validated by using a larger sample number. *date has been published.

Information Measure-Based Statistics and Relative Risk and Odds Ratio-Based Statistics for Detection of Gene-Gene and Gene-Environment Interactions. *L. Luo, M. Xiong* Human Genetics Center, Univ of Texas, 1200 Herman Pressler, Houston, TX 77030.

Over the last three decades, epidemiologists have debated intensely about how to define and measure gene-gene and gene-environment interaction in epidemiologic studies. Whether or not gene-gene or gene-environment interaction is present depends on how effects on risk are measured. Two traditional models (additive model and multiplicative model) have been used to measure effects on risk. Recently, some authors propose to use the concept of linkage disequilibrium (LD) to measure gene-gene interaction and gene-environment interaction. In this report, we propose to use mutual information to measure the gene-gene and gene-environment interaction. Then, the principle questions concerning how to define and test interactions in complex diseases are raised. In this report, we address two fundamental issues in study of interactions. First issue is that we investigate the range of interaction which each definition of interaction can cover. Second issue is the power of each statistic for detection of interaction. To unify our study, we develop four new statistics based on two traditional models for cohort study, and case-control study. We compare the power of six test statistics by large-scale simulation study. To further evaluate their power for detection of interactions, the six statistics have been applied to four published datasets. This study provides extremely valuable information for how to define and test interactions in complex diseases and open a new way for association studies of complex diseases.

Dynamic Systems Approach to Complex Diseases. *M. Xiong[1], JD. Reveille[2]* 1) Dept Biostatistics, Univ Texas Health Science, Houston, TX; 2) Div of Rheumatology, Univer Texas Medical School, Houston, TX.

In the past century, most biologists have used locus-by-locus approach to uncover the causes of the diseases. Even if they study gene-gene interaction and gene-environment interaction, they only investigate pair-wise interactions from cross sectional studies. In other words, they only investigate interactions in the steady state of biological systems, ignoring dynamic interaction between the genes and between the gene and environment in the time varying biological systems. However, most phenotypic variations, including those involved in complex diseases and differences in drug response, are generated by integrated actions of multiple genetic and environmental factors, through dynamic, epigenetic, and regulatory mechanisms. It is systems dynamics that determine the health status of humans. To discover the true mechanisms of the complex diseases and get into deep understanding of the development of the diseases, we propose a new paradigm based on dynamic systems theory for studying mechanisms of complex diseases. A biological system that consists of phenotypes, genotypes and environments organized into complex networks are taken as a dynamic system. The complex diseases are assumed to arise from dysfunction of dynamic systems. State-space equations will be used to model biological systems. The complex phenotypes will be taken as observed variables. The environments, drugs and some genotypic information will be taken as input variables. The state variables that determine the states of biological systems are hidden. The partial parameters in the state-space models can be functions of SNPs. The extend Kalman filter will be used to estimate the parameters in the model. Statistical methods will be developed to test difference in stability between the normal individuals and unhealthy individuals. Modern control theory will be used to design interventions to improve human health. As a proof of principle, the proposed dynamic approach will be applied to autoimmune diseases. Our preliminary results show that dynamic systems approach to complex disease will open a new way to study mechanisms of the complex diseases.

Mutation analysis of the pyruvate dehydrogenase E1 gene in 70 Japanese patients with pyruvate dehydrogenase complex deficiency. *E. Naito[1,2], K. Shinahara[1], Y. Kotani[1]* 1) Pediatrics, Inst Health Biosci, Univ of Tokushima, Tokushima, Japan; 2) Pediatrics, Tokushima Red Cross Hinomine Medical and Rehabilitation Center, Tokushima, Japan.

Defects in the pyruvate dehydrogenase (PDH) complex, an important cause of neurologic dysfunction and primary lactic acidosis, affect nearly equal numbers of men and women. Symptoms vary considerably between patients with PDH complex deficiencies, although the great majority of PDH complex deficiencies result from mutations in the X-linked pyruvate dehydrogenase (E1) -subunit gene (PDHA1). Among 70 Japanese patients with PDH complex deficiency (36 female and 34 male) from 63 unrelated families, we identified missense/nonsense mutations of PDHA1 in 49 patients and insertion/deletion mutations in 21 patients. Six families including four with a missense mutation and two with an insertion mutation had two or more affected siblings. In four of these families, all affected individuals were male, while in two families with an N164S mutation in exon 5 both brothers and sisters were affected. Thirty-three different missense/nonsense were found in nine exons, but not exons 1 and 2; three different nonsense mutations were found. Most missense/nonsense mutations occurred in exons 3, 5, 8, and 10, while three mutations at codons N164S, R263G, and R302C accounted for one-third of patients with missense/nonsense mutations (15 of 49); R263G mutations were present in 5 male patients, while R302C mutations were found in 6 female patients. However, 12 different insertion/deletion mutations were found in exons 5, 9, 10, and 11; S388fs mutations in exon 11 were found in 8 male patients. Although total numbers of men and women affected were nearly the same, the distribution of missense/nonsense and insertion/deletion mutations differed between women and men. This difference probably reflects an effect of mutation severity as well as differential X-inactivation in women.

A 46,XX,del(20)(q11.23q13.11) with normal adenosine deaminase (ADA) activity. *T. Sonoda, M. Tomimori, S. Iwashiro, N. Ikewaki, S. Iwamoto* Occup Therapy, Sch Hlth Scu, Kyushu Univ Health & Welfare, Nobeoka, Japan.

We present a patient with 46,XX,del(20)(q11.23q13.11). The proband, a female infant, was born after 41-weeks gestation. The birth weight was 3,082 g, length 51.0 cm and head circumference 34.2 cm. Physical findings included: deep-set eyes, anteverted nostrils, a portwine stain on the forehead, low-set ears, bilateral high axial triradius, right hip dislocation, and general muscular hypotonia. There was no history of recurrent infection. Development quotient (DQ) at 7 months after birth was about 60. The patients G-banded karyotype analyzed on cultured lymphocytes revealed she had an interstitial deletion of 20q (q11.23q13.11). The level of the patients adenosine deaminase (ADA), for which the gene locus is mapped on 20q13.11 was 14.6 IU/L (normal range: 6.8-18.2).

Structural abnormalities of chromosome 20 are rare. A few cases have been reported with ring 20, a few with complete or partial trisomy (mostly of the short arm), and a very few with partial deletion of the short or the long arm. Deletion of the long arm in particular is extremely rare. To our knowledge, only 2 cases have been reported. We present an additional case with interstitial deletion of 20q. We also discuss clinical features and the gene locus of adenosine deaminase (ADA), which is mapped on 20q.

Klinefelter's Syndrome with a chromosomal aberration of 47 XXY. *I. Yoshiuchi*[1,2] 1) Medicine, Yoshiuchi Medical Diabetes Institute, Japan; 2) Medicine, Saiseikai Kanagawa Prefecture Hospital, Kanagawa, Japan.

Diabetes mellitus is a complex disease characterized by insulin resistance and a failure of the pancreatic beta-cell. Klinefelters syndrome is the most common sex chromosomal aberration of human male infertility. The incidence of diabetes mellitus in Klinefelters syndrome is generally high. Most cases of diabetes mellitus in this syndrome show insulin resistance state. A 30-year-old man with diabetes has a chromosomal aberration of 47 XXY and abnormal sex hormonal findings, and was diagnosed as Klinefelters syndrome. His insulin secretion was well preserved in an oral glucose tolerance test and the data of urinary C-peptide, but he required 120 units of insulin per day. He showed severe insulin resistance, severe hyperlipidemia and mild obesity. We also examined the relationship between inflammation markers and glucose metabolism in him. We observed that inflammatory states could contribute to the glucose metabolism and insulin resistance in a case of Klinefelters syndrome with 47 XXY.

Vascular endothelial growth factor gene polymorphisms in thyroid cancer. *M.Y. Lu, P.J. Hsiao, F.Y. Chiang, S.J. Shin, Y.D. Tai, S.H. Juo* Kaohsiung Medical University, Kaohsiung, Taiwan.

Objective: Vascular endothelial growth factor (VEGF) is a potent stimulator for angiogenesis. It has been implicated in growth and metastasis of thyroid cancer. Three functional single nucleotide polymorphisms (SNPs) of VEGF (-2578C/A, -634G/C and +936C/T) are known to be related with VEGF expression. Methods: We conducted a case-control study to evaluate the genetic effects of these three functional SNPs on the development of thyroid cancer and lymph node metastasis. A total of 332 cases and 261 controls were recruited for this study. The genotypes were determined by the TaqMan 5 nuclease assay. Hardy-Weinberg equilibrium (HWE) was tested for each SNP, and genetic effects were evaluated by the x2- test and multiple logistic regression. Results: All three SNPs were in HWE. The A allele of -2578C/A (i.e. SNP rs699947) significantly increased a risk for thyroid cancer (adjusted OR =1.36, 95% C.I = 1.02~1.81, P=0.039). Haplotype analysis yielded a less significant result (an empirical p value of 0.07). There was a tendency of increasing the frequency of the risk allele from controls, patients without lymph node metastasis to patients with lymph node metastasis (P trend = 0.019). The genetic effect was only in men (adjusted OR=1.97, 95% C.I = 1.16 ~ 3.37, P =0.013) but not in women (adjusted OR=1.15, 95% C.I = 0.81~1.62, P =0.437). The other two SNPs did not show significant results. Conclusion: The A allele of the SNP rs699947 increased the risk of thyroid cancer development and regional lymph node metastasis in men.

Genetic Determinants of Patent Ductus Arteriosus in Term Infants. *P.M. Patel, P.A. Romitti, J.M. Dagle, J.C. Murray* Pediatrics, University of Iowa Hospitals and Clinics, Iowa City, IA.

Background: Patent ductus arteriosus (PDA) is the second most common form of congenital heart disease. Recent work on the molecular basis of other forms of congenital heart disease has suggested that a significant fraction of them are inherited in mendelian or near-mendelian fashion with a large contribution from de novo mutations. Objective: Our goal is to identify genetic variations that are present in specific candidate genes associated with PDA in term infants as either common variants contributing to complex causes or rare variants with a strong individual effect. Methods: Our candidate gene selection was based on published reports of genes known to cause syndromic forms of PDA, and on expression studies of genes identified for their role in pathways that normally regulate PDA closure. The genes analyzed include those associated with syndromes with the highest prevalence of PDA and those involved in pathways regulating the closure of PDA. Using DNA samples from 161 term infants from the Iowa site of National Birth Defect Prevention Study (148 triads, 13 diads, total 470 persons), we performed association studies using an initial starting panel of 55 single nucleotide polymorphisms to determine allelic variation in 13 genes representing the syndromic PDAs and 4 genes representing the pathway genes. The candidate genes were evaluated for allelic variation using TaqMan assays and the data was analyzed using family-based transmission disequilibrium test analysis. Results: Statistical analysis revealed that 3 SNPs (TGFBR1rs10760671, TGFBR2rs934328, PTGISrs493694) achieved borderline statistical significance with the conservative Bonferroni correction (P value = 0.001), demonstrating that allelic variation in these genes may play a role in term PDA. Conclusions: These findings suggest a strong association between a variation in the TGFBR and PTGIS genes and the occurrence of PDA in term infants. Additional analysis with other families and polymorphic markers, as well as evaluation of potential candidate genes by sequence analysis, could confirm the identification of one or more genes playing a role in ductal closure.

Dynamic Interaction between Gene and Environment. *X. Zhou[1], H. Xiong[3], F. Alert[1], M. Xiong[2]* 1) Dept Internal Medicine, Univ Texas, Houston, Houston, TX; 2) Human Genetics, Univ Texs, School of Public Health, Houston, TX; 3) Department of Computer Science, Texas A&M Univ, Collage Station, TX.

The traditional interaction between the gene and environment is usually defined and measured in terms of joint action of the genotype and environment in causing variations of phenotypes or diseases which are in the steady states. However, the traditional concept of interaction between the gene and environment is insufficient for getting deep understanding gene-environment interaction. We not only need to study static gene-environment interaction, but also dynamic gene-environment interaction. As a proof of principle, we propose to study dynamic interaction between the gene and environment. In this report, we develop dynamic model of the biological systems perturbed by environment, which describe how the gene and environment jointly affect the dynamical changes of the phenotypes and dynamic properties of the biological systems.. We investigate the input and output stability of the biological systems perturbed by the environment. We propose the statistics based on information theory to measure and test dynamic interactions between the gene and environment. The proposed methods for investigation of dynamic interaction between the gene and environment has been applied to gene expression time course data of the systems sclerosis. In this real dataset, we study Two types of interactions between the gene expression and environment. One type of interaction is the joint contribution of the genotype of either targeted gene or other genes and environment to the change rates of the expression of the targeted genes. Another type of interaction is the contribution of the environment alone to the rate changes of the expressions of the targeted gene. Our preliminary results reveal the pattern of dynamic interaction between the gene and environment and detect the interactions between the gene and environment which are difficult to detect by the traditional methods (including longitudinal data analysis) for detection of the gene-environment interaction.

Enzyme Replacement Therapy in 18 Older, Severely Affected Patients with Pompe Disease. *D.L. Marsden[1], A. van der Ploeg[2]* 1) Genzyme, Cambridge, MA; 2) Erasmus Medical Center, Rotterdam, NL.

Background: Pompe disease, due to a deficiency in lysosomal acid-glucosidase (GAA), results in progressive skeletal muscle weakness and respiratory insufficiency leading to substantially decreased quality of life and often early death. Clinical trials in infants showed that enzyme replacement therapy (ERT) was safe and effective. There are currently limited outcomes data in older patients. We reviewed physician reported outcomes of severely affected juvenile and adult patients treated with recombinant human GAA. **Methods**: Physician reports of outcomes for 18 juvenile and adult patients with severe Pompe disease enrolled in an extension phase of an early clinical trial (3) or a compassionate use program (15) were reviewed. Mean age at ERT initiation was 30.8 14.3 years (N=18); treatment duration ranged from 8 to 75.6 months. At baseline, all patients were wheelchair bound. 17 patients required respiratory assistance by invasive (N=9), non-invasive (N=7), combined invasive/non-invasive (N=1) ventilation. They received a starting dose of 10 mg/kg weekly or 20 mg/kg bi-weekly ERT infusions. **Results**: Most patients showed signs and symptoms of advanced stage Pompe disease prior to ERT. 10 patients demonstrated improvements in respiratory function. Motor function improved for 13 of 18 and stabilized in the remaining 5; no declines in muscle strength or tone were noted. 15 of 16 patients reported positive improvements in quality of life since commencing ERT. Treatment was well-tolerated, with only one report of a mild transient infusion-associated reaction during the first infusions. **Conclusions**: ERT for juvenile and adult patients with severe Pompe disease is associated with gains in respiratory and motor function. Intervention earlier in the disease course was associated with greater improvement. Overall, patients were satisfied with their treatment and reported positive improvements in their quality of life regardless of the magnitude of clinical gains or baseline disease involvement. For rare diseases, all forms of clinical information, including physician reported outcomes, can provide meaningful outcomes data for clinical decision making.

A gene locus for nephrotic syndrome on chromosome 13q21. *C.N. Vlangos[1], S. Heeringa[1], B. Hinkes[1], R. Gbadegesin[1], J. Liu[1], G. Nurnberg[3], P. Nurnberg[3], F. Hildebrandt[1,2]* 1) Dept. of Pediatrics, University of Michigan, Ann Arbor, MI; 2) Dept. of Human Genetics, University of Michigan, Ann Arbor, MI; 3) Gene Mapping Centre, Max Delbrück-Centrum, Berlin, Germany.

Nephrotic syndrome (NS) is defined by proteinuria, edema, hypoalbuminemia, and hyperlipidemia. Genetic causes of NS include recessive mutations in the nephrin (*NPHS1*), podocin (*NPHS2*), *PLCE1* (*NPHS3*), and *LAMB2* genes. Dominant mutations causing NS have been reported in the *CD2AP*, *ACTN4*, *TRPC6*, and *WT1* genes. In order to identify novel genes causing autosomal recessive NS we performed a total genome search for linkage to a novel NS locus using 50k SNP Affymetrix DNA microarrays. DNA from 8 consanguineous multiplex families and 55 consanguineous simplex families was analyzed. In 5 families we detected the presence of only one or two distinct peaks of homozygosity per family, which did not overlap between families. This excludes a shared locus between these families and, therefore, these families were excluded *a posteriori* from linkage calculations. When the 3 consanguineous multiplex families with 3 (F325) and 2 (F1085, F341) affected children were calculated together for linkage analysis, a significant maximum parametric LOD score (LODmax=3.3) was obtained (NPLmax=10.7), thereby identifying a new gene locus (SRN4) for NS on chromosome 13q21.2-q21.32. Haplotype mapping was performed by aligning SNP haplotypes from the 3 multiplex and 55 consanguineous simplex cases at the SRN4 locus. This alignment identified 4 simplex cases with overlapping homozygosity at the SRN4 locus. The SRN4 locus is delimited by family F325 within a 7.7 Mb critical genetic interval by heterozygous markers rs1486946 and rs10492594. This 7.7 Mb critical interval contains only 5 candidate genes: *DIAPH3* (diaphanous homolog 3), *TDRD3* (tudor domain-containing protein 3), *PCDH20* (protocadherin-20), AK127969 (unannotated), and *PCDH9* (protocadherin-9). Direct DNA sequencing of the five candidate genes revealed no disease causing mutations. Further analysis of putative genes in the region is currently being performed to identify a novel genetic cause of nephrotic syndrome at the SRN4 locus.

The Geneticist-Educator Network of Alliances (GENA) Project: An NSF-sponsored Math and Science Partnership Grant to ASHG. *K. Shaw[1], K. Van Horne[1], D. Marsland[2], H. Milne[2], T. Horn[3]* 1) ASHG, Bethesda, MD; 2) National Science Resources Center, Washington, DC; 3) National Association of Biology Teachers, Reston, VA.

The Geneticist-Educator Network of Alliances (GENA) Project will provide the partnering scientific societies involved with tools to instruct, facilitate and measure the meaningful engagement of science, technology, engineering and mathematics (STEM) faculty members in secondary science education. The GENA Project is exploring ways that an ASHG-sponsored secondary science education outreach effort can play a positive role in the career development of both junior (pre-tenure) and senior (post-tenure) level genetics faculty. Exemplary inquiry-based educational materials in genetics will be utilized to design methods to facilitate meaningful interactions between scientists and their local education community. Development of a network of geneticist-educator alliances will be used to design teaching strategies relating to standards and misconceptions in genetics that can to decrease time required for scientists to prepare for outreach, thus maximizing the effective and meaningful interaction between the geneticists and students. To date, 13 geneticist-educator alliances have been selected and trained as part of this program. Over the next two years the GENA project will recruit another 80 geneticists to participate and assist in the development of this model program that will become an integral part of the strategic development plan for the education efforts of both ASHG and GSA, thus making K-12 education outreach a truly systemic aspect of society activities.

Essay Contest Reveals Misconceptions of High School Students in Genetics Content. *K. Van Horne, K. Shaw*
American Society of Human Genetics, Bethesda, MD.

Multiple national educational organizations have called upon scientists to become involved in K-12 education reform. Whether involvement consists of sporadic interaction with students or more sustained partnerships with teachers, the engagement of scientists can take many forms. In this case, scientists from the American Society of Human Genetics, the Genetics Society of America and the National Association of Genetic Counselors have partnered together to organize an essay contest for seventh through twelfth graders as part of the activities surrounding National DNA Day. In addition to promoting genetics education in our middle and high schools and awarding students and teachers who excel in the life sciences, this contest has achieved a secondary goal of identifying student misconceptions in genetics, which may assist K-16 educators actively trying to identify potential barriers to student learning in their own classroom. Through analysis of the critical writings of almost 2,500 essays we have identified a variety of topics where there are large gaps in student understanding, including the broad categories of patterns of inheritance and genetic engineering. We have integrated this data into the Geneticist-Educator Network of Alliances (GENA) Project in order to develop learning cycles that address these specific misconceptions and potentially provide opportunities for successful interventions that will rectify student misconceptions in these areas. This work serves as a resource for others who are considering the use of an essay contest as a teaching or evaluation tool for students in their own discipline as well as a model for others to become engaged in science education reform.

Oligosaccharyltransferase subunits mutations in non-syndromic mental retardation. *F. Molinari[1], S. Romano[1], F. Foulquier[2], W. Morelle[3], P. de Lonlay[1], P.S. Tarpey[4], J. Teague[4], S. Edkins[4], P.A. Futreal[4], M.R. Stratton[4], M. Partington[5], G. Turner[5], G. Matthijs[2], J. Gecz[6], A. Munnich[1], L. Colleaux[1]* 1) INSERM U781, Hopital Necker, Paris, France; 2) Laboratory for Molecular Diagnostics, University of Leuven, Belgium; 3) UMR CNRS/USTL 8576, Université des Sciences et Technologies, Lille, France; 4) Cancer Genome Project, Wellcome Trust Sanger Institute, Hinxton UK; 5) The Gold Service, Hunter Genetics, University of Newcastle, Australia; 6) Department of Genetic Medicine, Women's and Children's Hospital, Adelaide, Australia.

Mental Retardation (MR), defined as an intelligence quotient below 70, is the most frequent handicap among children and young adults. While a large proportion of X-linked MR genes have been identified, only three genes of autosomal recessive non-syndromic MR (AR-NSMR) have been described so far. Here, we report on a new gene involved in an AR-NSMR in two sibs born to first cousin French family. Autozygosity mapping led to the identification of a unique candidate region of 8 Mb on 8p23.1-p22. This interval encompasses the gene TUSC3/OST3 encoding one subunit of the oligosaccharyltransferase (OST) complex which catalyses the transfer of an oligosaccharide chain on nascent proteins, the key step of N-Glycosylation. Sequencing the OST3 gene identified one base-pair insertion in exon 6, c.787_788insC resulting in a premature stop codon, p.N263fsX300, and lead to mRNA decay. Remarkably, screening of an X-linked homologue gene, the OST6 gene, in patients with X-Linked NSMR also identified a missense mutation (c.932T>G, p.V311G) in two boys born from an Australian family. Recent studies of fucosylation and polysialic acid modification of neuronal cell adhesion glycoproteins have shown the critical role of glycosylation in synaptic plasticity (in particular their glycan structures). However, our data provide the first demonstration that a defect in N-Glycosylation can result in NSMR. Altogether, our results demonstrate that fine regulation of OST activity is essential for normal cognitive function development, providing therefore new insights into the understanding of the pathophysiological bases of MR.

High resolution genome-wide copy number analysis by copy number inferring tool (CNIT) and its usage in data from DNA pooling. *C.H. Lin[1], M.C. Huang[2], L.H. Li[3], J.Y. Wu[3], Y.T. Chen[3], C.S.J. Fann[1,3]* 1) Institute of Genome Sciences, Yang-Ming University, Taipei, Taiwan; 2) Institute of Statistical Science, Academia Sinica, Taipei, Taiwan; 3) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan.

Recently copy number variation (CNV) has been found as one of the important genomic structure variants in human population, and some of them are related to specific traits and diseases. Single nucleotide polymorphism (SNP) microarrays provide high resolution tool to analyze human genomes. Although many programs were designed to analyze data from Affymetrix SNP microarrays, they all have high false-positive rates in CN analysis. Copy number analysis tool (CNAT) 4.0 was a newly-developed program with large improvement in CN estimation, but small amplifications and deletions were lost when using genomic smoothing procedure. In this report, we propose Copy Number Inferring Tool (CNIT) algorithm for 100K and 500K SNP microarrays to investigate CNVs at the 29.6 and 7 kb resolution, respectively. CNIT estimated SNP allelic and total CN with reliable p-value. In addition, hidden Markov model (HMM) method was applied to predict CN-changed regions by considering contiguous SNPs. Based on the CN analysis of twenty-three unrelated Taiwanese and thirty HapMap CEPH trios, CNIT showed higher accuracy and power than other programs. The false-positive and false-negative rates of CNIT were 0.001 and 0.0016, respectively. CNIT showed better sensitivity in detection of small amplifications and deletions. Furthermore, DNA pooling of ten normal unrelated individuals was applied to 100K SNP microarray and analyzed by CNIT. Three common CNVs were successfully identified and validated by qPCR experiments. CNIT has high power to detect CN-changed SNPs and DNA segments without smoothing, and is applicable in CNV finding, disease gene mapping and pharmacogenetic studies. SNP microarray coupled with CNIT provided a high resolution tool to investigate subtle chromosomal structures in disease or trait studies of interest. In addition, DNA pooling was performed to identify common CNVRs, suggesting that DNA pooling is a feasible way in CNV studies.

Molecular cytogenetic characterization of a unique and complex de novo 8p rearrangement. *G. Velagaleti[1], S.L. Cooke[2], J.K. Northup[3], N.L. Champaigne[1], W. Zinser[1], P.A.W. Edwards[2], L.H. Lockhart[1]* 1) Dept Pediatrics, Univ Texas Medical Branch, Galveston, TX; 2) Dept Pathology, Cambridge University, Cambridge, UK; 3) Dept Pathology, Univ Texas Medical Branch, Galveston, TX.

Human chromosome 8p is prone to recurrent rearrangements with inv dup del(8p) being most common. Each of these recurrent rearrangements is associated with different clinical manifestations. Some of these recurrent rearrangements at 8p occur as a consequence of an 8p submicroscopic paracentric inversion between the olfactory (OR) gene clusters in one of the parents. Recent reports have shown that some of the rearrangements are unique and complex and are mediated by other repetitive elements within 8p. Here, we report a complex 8p rearrangement with seizures as the major presenting feature. Extensive fluorescence in situ and microarray analyses with tiling path 8p array showed that the rearrangement consists of a terminal deletion of 6.3 Mb from pter to 8p23.1; followed by a single copy segment of 5.3 Mb spanning the 8p23.1 and a duplication of 12 Mb extending from 8p23.1-8p21 region. FISH analyses with BAC clones showed that the rearrangement is unique in that the 8p duplication is a direct tandem duplication and, unlike the more common inv dup del(8p), is not derived from parental submicroscopic inversion. Also unlike the inv dup del(8p), the phenotype in our case is milder with no central nervous system malformations or cardiac defects. Similar to the common inv dup del(8p) our rearrangement also appears to be mediated by the OR repeat clusters at 8p23.1. We propose a mechanism similar to the one proposed to explain the PLP1 duplications in Pelizaues-Marzbacher disease. As per our model, the OR repeats behave similar to the LCRs and cause inherent instability leading to a double strand break (DSB) in the proximity of these OR repeats. This is followed by a strand invasion and copying of the sister chromatid and completion of the event by non homologous end joining (NHEJ) repair. A second DSB in trans near another OR repeat followed by transposition to another site of the duplicated segment and repair by NHEJ leading to interrupted direct duplication with terminal deletion.

FTO gene variants predispose to obesity through a metabolically neutral increase in body weight -The Lausanne CoLaus Study. *V. Mooser[1], C.K. Knouff[1], K.S. Song[1], X. Yuan[1], N. Guex[1], H.A. Stirnadel[1], F. Paccaud[2], A. Pecoud[2], D. Hayoz[2], T.M. Danoff[1], D.K. Burns[1], E.H. Lai[1], L.T. Middleton[1], P. Vollenweider[2], A.D. Roses[1], D.W. Waterworth[1], G. Waeber[2]* 1) GlaxoSmithKline R&D, King of Prussia PA, RTP, NC and London UK; 2) CHUV University Hospital Lausanne Switzerland.

BACKGROUND : FTO gene variants have recently been associated with obesity and with diabetes. One mechanism linking obesity to diabetes is insulin resistance, which clinically is often associated with hyperinsulinemia, dyslipidemia, low-grade inflammation, liver and kidney dysfunction and hypertension. Here we investigated the association between FTO gene variants and these conditions, collectively referred to as the metabolic syndrome, in a Caucasian population.

METHODS : We analyzed 60 FTO gene variants in 5641 extensively phenotyped participants (ages 35 to 75 years) of the Lausanne, Switzerland CoLaus population-based study genotyped using the Affymetrix 500 K SNP chip.

RESULTS : In line with recent reports, several variants within the FTO gene were associated with an increase in body mass index, waist circumference and body fat content. Unexpectedly, however, none of these FTO risk alleles for obesity was associated with fasting blood/plasma levels of leptin, adiponectin, glucose, insulin, lipids, C-reactive protein, liver function tests, nor with blood pressure levels, glomerular filtration rate or microalbuminuria. FTO risk alleles for obesity were associated with an increase in both fat and fat-free mass and, for a given body mass index, with a slightly better metabolic profile among obese individuals.

CONCLUSIONS : FTO gene variants predispose to obesity, but not to the metabolic syndrome, by promoting a metabolically neutral increase in fat and fat-free mass. In absence of association between FTO risk alleles and the intermediate phenotypes linking obesity to diabetes, these findings suggest that the associations of FTO variants with obesity and diabetes are due to two distinct mechanisms.

Variation in the miRNA-433 binding site of FGF20 confers risk for Parkinson disease by over-expression of -synuclein. *G. Wang[1], J. van der Walt[2], G. Mayhew[1], Y. Li[2], S. Züchner[1], W.K. Scott[1], E. Martin[1], J.M. Vance[1]* 1) Institute for Human Genomics, University of Miami , Miami, Fl; 2) Center for Human Genetics, Duke University Medical Center, Durham, NC 27710.

Parkinson disease (PD) is a common neurodegenerative disorder caused by environmental and genetic factors. We have previously shown linkage of PD to chromosome 8p. Subsequently, fibroblast growth factor 20 (FGF20) at 8p21.3-22 was identified as a risk factor in several association studies. To identify the risk-conferring polymorphism in FGF20 we performed genetic and functional analysis of single nucleotide polymorphisms within the gene. In a sample of 729 nuclear families with 1089 affected and 1165 unaffected individuals, the strongest evidence of association came from rs12720208 in the 3 UTR of FGF20. We show in several functional assays that the risk allele for rs12720208 disrupts a binding site for microRNA-433, increasing translation of FGF20 in vitro and in vivo. In a cell-based system and in PD brains, this increase in translation of FGF20 is correlated with increased -synuclein expression, which has previously been shown to cause PD through both over-expression and point mutations. We suggest a novel mechanism of action for PD risk in which the modulation of the susceptibility genes translation by common variations interfere with the regulation mechanisms of microRNA. We propose this is likely to be a common mechanism of genetic modulation of individual susceptibility to complex disease.

Genome-wide association data highlight a series of independent disease signals in regions implicating cyclin-dependent kinase pathways. *N.J. Timpson[1, 3], E. Zeggini[1], M.N. Weedon[2], C.M. Lingdren[1], T.M. Frayling[2], K.S. Elliott[1], H. Lango[2], J.R.B. Perry[2], N.W. Rayner[1], R.M. Freathy[2], J.C. Barrett[1], C.J. Groves[1], A.D. Morris[1], A.T. Hattersley[2], M.I. McCarthy[1]* 1) University of Oxford,UK; 2) Peninsula Medical School, Exeter,UK; 3) MRC CAiTE Centre,UK.

The Wellcome Trust Case Control Consortium recently completed a GWA scan in 1924 UK T2D cases and 2938 controls. Given these data, single-point (SP) result follow-up in additional UK case/control samples and available WTCCC results in other disorders, we aimed to perform SNP-specific, haplotypic and conditional analyses within the WTCCC data-set to dissect the nature of observed association signals and to compare this across T2D and other diseases. A region of chr9 containing genes implicated in the regulation of CDK (cyclin-dependent kinase) has emerged as a confirmed T2D associate in separate follow-up and GW analyses (combined WTCCC/UK/FUSION/DGI OR 1.20 (1.15-1.25) p=2.2x10-15). Further analysis of the genomic structure of this region and comparison to coronary artery disease (CAD) has revealed evidence for (i) two independent signals punctuated by a recombination hotspot, with that upstream of this revealing a second and independent signal for T2D, (ii) strongest association being from haplotypic and conditional analyses indicating the effects of a variant as yet untyped upstream of this feature and (iii) that evidence for association of this region with CAD reveals a third independent association signal. Taking variation matched across all studies, analyses from WTCCC and an independent GWA study gives strong evidence for association between the region of T2D signal upstream of this hotspot and CAD (combined WTCCC/DeCode WGA OR 1.27 (1.22, 1.35). At this SNP there is no evidence for a T2D effect, but this appears to be an independent disease signal (WTCCC CAD signal OR 1.25 (1.19, 1.31) versus 0.97 (0.89 1.05) for T2D). As well as implicating this region in the aetiology of CAD and T2D, analyses suggest that the CAD, upstream T2D signal and downstream T2D signal found are independent. This highlights the importance and complexity of disease risk architecture for this previously unassessed region of the genome.

Natural course of MELAS -Japanese cohort compaired with literature study-. *S. Yatsuga, Y. Akita, J. Nishioka, K. Katayama, T. Matsuishi, Y. Koga, MELAS Study Group* Pediatrics and Child Health, Kurume University School of Medicine, Kurume, Fukuoka, Japan.

Objective MELAS, a maternally inherited multi-system disorders, is the most common mitochondrial disorders. However the natural course and epidemiology has not been discovered. The specific aim of the present study is to estimate the incidence, natural course, and severity of the disease seen in MELAS based on the nationwide survey in Japan, and compared them with the literature. Methods In Japanese cohort study, we analyzed the questionnaires. In literature study, we searched the date base from all publications identified via Medline search using MELAS as a keyword. We categorized the MELAS patients into two subtypes. The patients who firstly recognized any signs of psychomotor developmental delay before the age of 18 year-old defined as juvenile type of MELAS. The patients who firstly recognized any abnormality after the age of 18 year-old defined as adult type MELAS. Result In Japan, MELAS showed 32% of total mitochondrial disorder. In Japanese cohort study, the age of onset, and the death was 9, and 32.2, and 15 and 40 years old in juvenile and adult type. In the literature, the age of onset was 8.3, and 31, the age of death was 18.9 and 41.5 in juvenile and adult type. Among symptoms recognized at the diagnosis of MELAS, the short stature and developmental delay was significantly highly recognized in juvenile than those seen in the adult type. On the other hand, deafness and diabetes mellitus were more significantly recognized in adult than those seen in the juvenile type. Using Japanese mitochondrial disorders rating scale, some juvenile type showed rapidly increase their exacerbation within 5 to 9 years after the onset of disease. However adult type showed slowly increase their exacerbation during all the course of the disease. Using Kaplan-Meier survival analysis, juvenile type has 3.2 times more chance of death than those seen in adult type. Conclusion In Japanese cohort study, MELAS was divided into two subtypes, juvenile and adult type, and was the progressive and currently untreatable inherited disorder.

Mitochondrial dysfunction caused by germline mutations in succinate dehydrogenase subunit genes in Cowden and Cowden-like syndromes. *K. Zbuk[1,2], A. Patocs[1,2], G. Lobo[1,2], T. Sadler[1,2], J. Stein[1,2,3], K. Waite[1,2,3], C. Eng[1,2,3]*
1) Genomic Medicine Institute; 2) Lerner Research Institute; 3) Taussig Cancer Center, Cleveland Clinic, Cleveland, OH.

The majority of patients with Cowden syndrome (CS) harbor germline mutations of the tumor suppressor *PTEN* . However, approximately 15% remain *PTEN* mutation negative, despite increasingly comprehensive analysis including deletion/rearrangment analysis and *PTEN* promoter mutation analysis. Additionally, a large number of patients are assessed for cancer risk who exhibit some features of CS, but who do not meet diagnostic criteria for CS. Referred to as CS-like, >90% of these patients do not have a detectable *PTEN* mutation. It is evident that patients with CS/CS-like phenotypes share certain clinical features with syndromes associated with germline mutations of genes encoding succinate dehydrogenase (SDH) and fumarate hydratase (FH), both part of the mitochondrial respiratory chain. This observation leads to the hypothesis that mitochondria dysfunction could be involved in the pathogenesis of CS. We screened lymphoblastoid cell lines from 128 *PTEN* mutation negative patients with CS or CS-like phenotypes, using manganese superoxide dismutase (MnSOD) protein expression levels as a marker of mitochondrial respiratory dysfunction. 32 patients had increased MnSOD expression levels. These patients were screened for germline *SDHB*, *SDHC* and *SDHD* mutations, and 4 (12.5%) patients were found to have a mutation, none of which were seen in 350 population based controls. Similar to what is commonly observed in patients with germline *PTEN* mutations, lymphoblastoid cell lines from these patients demonstrated activation of the anti-apoptotic pathways protein kinase B (Akt pathway) and mitogen activated protein kinase (MAPK). Finally, we demonstrate an alteration of mitochondrial function, but not *SDH* mutations in 3 of 8 (37.5 %) patients with CS and *PTEN* mutations. These findings suggest that CS syndrome is associated with mitochondrial dysfunction, and that this dysfunction can occur by different molecular mechanisms.

Prevalence and effects of gene-gene and gene-nutrient interactions on serum folate and serum total homocysteine concentrations in the United States: findings from the Third National Health and Nutrition Examination Survey DNA Bank. *Q.H. Yang[1], L.D. Botto[2], M. Gallagher[1], J.M. Friedman[3], C.L. Sanders[1], D. Koontz[1], S. Nikolova[1], J.D. Erickson[1], K. Steinberg[1]* 1) Centers for Disease Control and Prevention (CDC), Atlanta, GA; 2) University of Utah, Salt Lake City, Utah, USA; 3) University of British Columbia, Vancouver, Canada.

Abnormalities in the metabolism of folate and homocysteine are associated with conditions that contribute significantly to morbidity and mortality in the United States. Polymorphisms of genes that code for folate-metabolizing enzymes and differences in folate intake are known to affect blood concentrations of folate and homocysteine, but the effects and interactions of these factors have not been studied on a population-wide basis. DNA specimens from 7,159 people who participated in the National Health and Nutrition Examination Survey (NHANES III) during 1991-1994 were genotyped for polymorphisms of genes coding for folate pathway enzymes MTHFR (677CT and 1298AC), MTRR (66AG), and CBS (844Ins68). The influence of these genetic variants on serum folate and serum total homocysteine concentrations was determined with consideration of sex, age and dietary folate intake in three racial groups. In all of the race/ethnicity groups examined, the serum folate and homocysteine concentrations were significantly related to the MTHFR 677CT genotype but not to the other polymorphisms. People with the MTHFR 677 TT genotype had on average a 20.8% (95% CI 13.8%-27.2%) lower serum folate and 23.8% (95% CI 18.1%-29.7%) higher homocysteine concentration than people with the CC genotype. A moderate daily folic acid intake (mean 150 g/d, 95% CI 138-162) significantly reduced the difference in mean homocysteine concentration between people with MTHFR 677 CC and TT genotypes. The MTHFR 677CT polymorphism was associated with significant differences in serum folate and serum total homocysteine concentrations in the United States population prior to the introduction of folic acid fortification. The effect of MTHFR 677CT on serum total homocysteine concentration appears to be reduced by moderate daily folic acid intake.

Homozygosity mapping of autosomal recessive primary microcephaly (MCPH) in 15 consanguineous families and identification of a new (MCPH7) locus. *A.. Parsian[1], M. Cleves[1], A.J. Parsian[1], M. Watts[1], S.M. Elsayed[2], E. Elsobky[2], A. Jankhah[3]* 1) Dept Pediatrics, Univ Arkansas Medical Sci, Little Rock, AR; 2) Medical Genetic Center, Cairo, Egypt; 3) Shiraz Medical Genetic Counseling Center, Shiraz, Iran.

Autosomal recessive primary microcephaly (MCPH) is a neurodevelopmental disorder characterized by global reduction in brain size affecting mostly the cerebral cortex. The individuals with MCPH suffer from mental retardation of variable degrees. MCPH is a heterogeneous disorder and at least six known genetic loci (MCPH1-6) have been found in humans. Among all, MCPH5, caused by the mutations in ASPM that encodes the human homologue of fly abnormal spindle gene (asp), is the most common. We screened 15 consanguineous families with microsatellite markers in the MCPH1-6 regions. Homozygosity mapping of the affected individuals from these families and linkage analysis identified the linkage of two families to MCPH2 and three to MCPH3. The remaining 10 families were not linked to any of the MCPH1-6 regions. We mapped the MCPH3 locus to a 1.55 cM region of chromosome 9q34 in three separate MCPH3 affected families. We sequenced the open reading frame of the CDK5RAP2 gene using genomic DNA from affecteds in our MCPH3 linked families and did not detect any mutation. Further fine mapping of the 9q34 region identified a new locus (MCPH7) near the marker D9S1881. The best candidate gene in this region is Nek6 that is required for mitotic progression of human cells. Our linkage results also strongly suggest the existence of additional MCPH locus elsewhere in the genome.

Novel GJB2 mutations are associated with autosomal recessive non syndromic hearing loss. *E. Farrokhi[1], M. Hashemzadeh Chaleshtori[1], M. Shahrani[1], M. Dolati[2], L. Hoghoogi Rad[2], H. Pour-jafari[3], D. Farhud[4], A. Crosby[5], K. Ghatreh samani[1], M. Mansouri[1], D. Modaresi-nia[1], M. Jafari[1]* 1) Cellular and Molecular Research Center, Shahrekord University of Medical Sciences, Shahrekord, Iran; 2) Department of Genetics,School of Medical Sciences,Qom University of Medical sciences,Qom,Iran; 3) Department of Genetics,School of Medicine, Hamadan University of Medicil Sciences, Hamadan, Iran; 4) Department of Genetics,School of Public Health,Tehran University of Medical Sciences, Tehran, Iran; 5) Medical Genetics,St Georges Hospital Medical School, University of London, London, United Kingdom.

Mutations of GJB2 gene encoding connexion 26 are the most common cause of hearing loss in many populatioins. We have provided evidence on the pathogenicity of our previously reported GJB2 allelic variants. We described the possibility of pathogenicity for the GJB2 allelic variants including 363delC, 327delGGinsA, H16R and G200R which have been co segregated with autosomal recessive and sporadic non syndromic hearing loss in different families and are not found in control subjects. We also found G130V and K102Q in heterozygous state in two deaf individuals. G130V results in an exchange a residue highly conserved among all the connexins but was found with a rate of 1% in control subjects and K102Q results in an exchange a residue not conserved among all the connexins and not identified in 100 control subjects. We conclude that, 363delC, 327delGGinsA, H16R and G200R may be pathogenic. However, the pathogenicity and inheritance of K102Q and G130V can not be assessed clearly and remains to be identified.

High carrier frequency of the GJB2 mutation (35delG) in the north of Iran. *M. Shahrani[1], M. Hashemzadeh Chaleshtori[1], E. Farrokhi[1], M. Dolati[2], L. Hoghooghi rad[2], H. Pour jafari[3], K. Ghatreh Samani[4], A. Crosby[5]* 1) Cellular and Molecular Research Center, Shahrekord University of Medical Sciences, Shahrekord, Iran; 2) Department of Genetics,School of Medical Sciences,Qom University of Medical sciences,Qom,Iran; 3) Department of Genetics,School of Medicine, Hamadan University of Medicil Sciences, Hamadan, Iran; 4) Department of Clinical Chemistry, Tabriz University of Medical Sciences, Tabriz, Iran; 5) Medical Genetics Unit, St Georges Hospital Medical School, University of London, London, United Kingdom.

Objective: Mutations in the GJB2 gene are a major cause of autosomal recessive and sporadic nonsyndromic hearing loss in many populations. A single mutation of this gene (35delG) accounts for approximately 70% of mutations in white populations with a carrier frequency of 2%-4% in Europe. This study describes the screening of 35delG mutation in 550 unaffected unrelated subjects from 4 provinces of Iran and aims to determine the rate of 35delG carrier frequency in those regions. Methods: Genomic DNA was extracted from 0.5ml peripheral blood following the standard phenol chloroform procedure. The one base pair deletion (35delG) was analysed using a nested PCR procedure; 35delG mutation carriers were subsequently confirmed by sequence analysis. Results: Altogether the 35delG carrier frequency was found to be 1.8% in the populations studied. Of the 4 populations studied, we found a high carrier frequency of 2.8% in Gilan province in the north of Iran. This high rate of carrier frequency is of great importance in genetic counselling and medical care to control deafness in this region of Iran.

Management of hypersensitivity reactions in mucopolysaccharidosis type II (Hunter disease). *E. Miebach, G. Schulze Frenking, M. Beck* Klinikum der Joh Gutenberg University Mainz, Mainz, Germany.

MPS II is an X-linked multisystemic metabolic disorder, caused by the deficiency of the lysosomal enzyme iduronate-sulfatase. Enzyme replacement therapy with Elaprase is now available for affected patients. In our institution, 21 Hunter patients are under treatment with this enzyme preparation. In 8 of these patients an anaphylactoid reaction was observed, mainly in children with neurological involvement. The symptoms occurred between the 5th and 6th infusion. Most of the patients developed flush, urticaria and coughing during the infusion. Drug reactions can be caused by an IgE mediated anaphylaxis or by no-IgE mediated anaphylactoid response. Both reactions are clinically indistinguishable. In general, reaction time varies from 5 minutes to 4 hours after exposure. 1%-20% of patients may experience biphasic anaphylaxis with a recurrence of symptoms after a period of recovery. In our patients, the drug reactions have been treated according a regimen that was adapted from the Guidelines of "Joint task force on practice parameters for adults" (J Allergy Clin Immunol, 2005. 115(3 Suppl 2): S483): 1. Stopping the inciting antigen until recovering. 2. Monitoring of cardiopulmonary status (vital signs), classifying the severity. 3. Pharmacologic therapy (antihistamins, corticosteroids) in all cases. 4. Intravenous volume (saline solution) application in case of hypotension. 5. Oxygen, inhalation with bronchodilators if needed. 6. Further observation, at least for 8 hours in case of moderate or severe reaction. 7. Adapted infusion rate for the following week(s). Using this regimen, no severe reaction with need of resuscitation occurred in our patients receiving enzyme replacement therapy. For further evaluation determination of antibodies is needed.

Polymorphisms in The One-Carbon Metabolism Pathway Genes, Are Associated With Increased Risk For Trisomy 21. *O. Reish[1,2], Y. David[1], E. Manor[3], M. Frydman[2,4], D. Chapman Shimshoni[1]* 1) Medical Genetics Institute, Assaf Harofeh Medical Center, Zerifin,Israel Israel; 2) Sackler School of Medicine,Tel Aviv University, Tel Aviv; 3) The Genetic Institute, Soroka Medical Center and Ben Gurion University, Beer Sheba; 4) The Danek Gertner Genetics Institute, Sheba, Medical Center, Tel Hashomer.

Aim: To evaluate the effect of polymorphisms in the One Carbon Metabolism (OCM) pathway genes, on maternal risk for trisomy 21. The contribution of folic acid was also evaluated. Materials and Methods: Samples included 44 trisomy 21-mothers and 133 controls. All subjects were Jewish, 14 trisomy 21-mothers and 82 control mothers were of Ashkenazi descent. Polymorphisms were analyzed following restriction digest of specific PCR amplicons. Results: Increased risk for trisomy 21 was associated with the Methylene tetrahydrofolate Reductase (MTHFR) 1298C allele (X2 5.6, p=0.009) and MTHFR 1298CC genotype (OR 17.8 95%, CI 2.65-119) among the Ashkenazim. Furthermore, the distribution of genotypic pairs of MTHFR A1298C and C677T alleles (X2 5.153, p=0.001) and pairs of MTHFR A1298C and Methionine synthase reductase (MTRR) A66G alleles (X2 4.68, p=0.09) showed a positive correlation with trisomy 21 pregnancies. In contrast, Methionine Synthase (MS) A2576G polymorphism did not show any association with the risk for trisomy 21 among the Ashkenazi women. In non-Ashkenazi women, the four polymorphisms in the OCM pathway did not show any significant association with the risk for Trisomy 21. Folic acid supplementation significantly reduced the risk for trisomy 21 (OR 4.66 95%, CI 2.24-9.8). Conclusion: This study presents for the first time evidence that MTHFR A1298C polymorphism is a risk factor for Trisomy 21 in Ashkenazi women. The risk for trisomy 21 increases when additional OCM pathway polymorphisms are present in the same individual. Small sample size, non homogeneity in the study group, different genetic background or environmental factors, are possible explanations. Folic acid supplementation reduced the risk for Trisomy 21, probably through replenishment of enzyme activity in the OCM pathway.

The history of Amerindian mtDNA lineages in the Caribbean. *J.C. Martinez-Cruzado[1], A. Feliciano-Vélez[1], E. González-Bonilla[1], P. Valencia-Rivera[1], E. Gómez-Sánchez[1], V. Reyes-Ortiz[1], M. Rivera-Vega[1], A. Álvarez-Serrano[2], A. Román-Colón[1], J.S. Ramírez-Lugo[1]* 1) Department of Biology, University of Puerto Rico at Mayagüez, Mayagüez, PR; 2) Museo Arqueológico Regional Altos de Chavón, La Romana, Dominican Republic.

Christopher Columbus described a people of Arawak culture predominating both in Puerto Rico and Hispaniola, plus other more geographically constrained peoples in the latter island. We aim to learn about the pre-Columbian migrations to the Caribbean that gave rise to these populations through control region sequencing of Amerindian mtDNAs and partial restriction typing of the coding region. Median network analysis of the data obtained from a subset of 122 Amerindian mtDNAs selected from a sample set representative of the Puerto Rico population suggests the presence of 19 maternal lineages, 10 of which account for 89% of all Amerindian mtDNAs on the island. The most frequent lineage, C-I, accounts for 21% and displays a star-like phylogeny, suggesting a demographic expansion soon after its arrival, the time of which is estimated at 2500 YBP. In addition, only and all members of this lineage display a rare 7013 *Rsa*I site loss found only in the Amazon, birthplace of the Arawak culture. Its estimated time of arrival is consistent with that of the South American Saladoids, regarded as the first agricultural society of the Caribbean. Four other lineages, accounting for 36% of all Amerindian mtDNAs, show higher diversity, non-star-like phylogenies, and may stem from Archaic cultures. They all show particular signature polymorphisms not found elsewhere in the continent or the Dominican Republic. Thus, barring *in situ* evolution, different continental origins may be proposed for the peoples who first populated Hispaniola and Puerto Rico. In the Dominican Republic, lineage C-I accounts for only 1.9% of all Amerindian mtDNAs. Hence, female-mediated gene flow between the two islands seems to have been restricted. Haplogroup A accounts for 65% of all Amerindian mtDNAs in the Dominican Republic. A median network constructed from control region sequences of 32 haplogroup A mtDNAs suggests geographic partition within this country.

The ancestry of Y-chromosomes in Puerto Rico. *K. Ocasio-González, A. Díaz-Lameiro, K. Martínez-Vargas, M. López-Muñoz, J.C. Nazario-Borges, J.C. Martínez-Cruzado* Department of Biology, University of Puerto Rico at Mayagüez, Mayagüez, PR.

Most Latin American populations show asymmetric ancestry, with European ancestry predominating in the paternal lineages and Amerindian or African ancestry in the maternal lineages. In consistency with this pattern, the female ancestry of Puerto Ricans has recently been shown to be predominantly Amerindian, followed by African and West Eurasian ancestries in that order. In a progressing program of research, we have identified the haplogroup of 202 Puerto Rican Y-chromosomes through biallelic marker typing and estimated that 151 (74.8%) are of West Eurasian origin, 48 (23.8%) Sub-Saharan African, and 3 (1.5%) Amerindian. In addition, 17 Y-STR loci of 35 samples have been typed, producing 32 haplotypes, the haplogroup of 18 of which have been identified through biallelic markers. The Y-STR data was used to construct a median-joining network that produced five clusters of 18, 4, 3, 3, and 3 haplotypes each. One haplotype of haplogroup still unknown remained separated from all five clusters. Y-STR-haplogroup matching analysis strongly suggested that all Y-chromosomes belonging to each Y-STR cluster shared the same continental origin. For example, all 11 haplotypes for which the haplogroup was known in the 18-haplotype cluster belonged to West Eurasian haplogroup R1b. In that way, two clusters totaling 21 haplotypes, were identified as West Eurasian in origin, and two clusters totaling 7 haplotypes as Sub-Saharan African. The haplogroups of none of the three haplotypes of the remaining cluster have yet been identified. A search in the Y-chromosome haplotype reference database produced results consistent with the deduced origin of the clusters, and suggested that the origin of the remaining cluster is Asian or Native American. It did not suggest an origin for the isolated haplotype. We conclude that, as in other Latin American populations, the continental origin frequency of Y-chromosomes in Puerto Rico is inverted relative to that of mtDNA. We further conclude that Y-STR haplotypes are excellent predictors of haplogroup identity.

Genetic correlation between autistic trait and general intelligence in a proband- based twin sample. *T. Nishiyama[1,2], H. Taniai[3], T. Miyachi[4], K. Ozaki[5], S. Sumi[6]* 1) Dept of Biological Information, Nagoya City Univ, Nagoya, Japan; 2) Master of Public Health Program by Biostatistics, National Institute of Public Health, Wako, Japan; 3) Nagoya Child Welfare Center, Nagoya, Japan; 4) Osaka-Hamamatsu Joint Research Center for Child Mental Development, Hamamatsu, Japan; 5) Japan Science and Technology Agency, Tokyo, Japan; 6) Nagoya Western Rehabilitation Center for Children with Disabilities, Nagoya, Japan.

Background: Mental retardation are the most associated conditions in autistic spectrum disorders (ASDs), although the relation between MR and ASDs remain unresolved. The purpose of this study is to examine genetic and environmental sources of covariation between an autistic trait and intelligence quotient (IQ) in a twin sample.**Methods:**Subjects in the present study ware a cohort of twins born between 1993 and 2001 who were ascertained through at least one proband having an ASD in the catchment area (Sumi 2006). The Childhood Autism Rating Scale (CARS; Schopler 1980) was used to assess a severity of autistic traits among ASDs as a unitary dimension.45 twin pairs with demonstrated diagnostic reliability were subjected to a sex-limited bivariate Cholesky models, incorporating sex differences of each causal influence and correction for ascertainment bias of an autistic trait, by using the Mx software (Neale and Cardon, 1992). **Results:**The model fitting showed significant a genetic correlation between an autistic trait and IQ and the additive genetic contributions to both traits was entirely shared in common. Althogh a significant non-shared environmental correlations between both traits was also found, there was evidence of trait-specific, shared environmental, and non-shared environmental contributions to IQ and trait-specific, non-shared environmental contributions in an autistic trait. The estimated genetic correlations between both traits were -0.96 /-0.95 for boys/ girls, respectively. **Conclusions:**There is substantial overlap between the genetic factors that influence both an autistic trait and IQ to the same extent in both sexes. These findings reinforce the validity of the autistic uni-dimensional view including cognitive abilities.

Can environmental contamination affect mtDNA pedigree mutation rate? *K. López-Álvarez, N. Pérez-Nazario, C. Torres-Vargas, E. Guzmán-Morales, L. Rivera del Toro, V. Figueroa-Tañón, J. Concepción-Acevedo, T. Toro-Ramos, G. González-Guardiola, D. Morales-Hernández, J.C. Martínez-Cruzado* Dept. of Biology, University of Puerto Rico at Mayagüez, Mayagüez, PR.

Cancer rate in Vieques, an island municipality of Puerto Rico, is far higher than in the big island of Puerto Rico. Environmental contamination with mutagenic substances that may increase the DNA mutation rate is a reasonable but unproven hypothesis explaining this observation. We propose that if the underlying mutation rate in Vieques is higher than in Puerto Rico, this effect may be observable in the mtDNA control region in the form of a higher frequency of heteroplasmies as manifested by peak heights in chromatograms. We collected mouthwash samples from 42 maternal families each in Vieques and Puerto Rico, totaling 569 samples and the same number of generational transmissions. As phylogenetic evidence suggests that mutability at some mtDNA sites can vary with haplogroup identity, the same haplogroups were collected at each island except that one haplogroup T mtDNA in Vieques was substituted for a haplogroup J in Puerto Rico. We have sequenced the control region of 140 and 101 samples from Puerto Rico and Vieques, covering 135 and 95 transmissions, respectively. We have found one hereditary heteroplasmy involving a nucleotide substitution for each population. One involved a pyrimidine transition and the other a purine transition at the haplogroup L2-defining position 16390 in a haplogroup U5 background. Preliminarily, the findings do not support a significant mutation rate difference between the islands nor relative to populations studied previously by other investigators. Assuming 20 years per generation, the pedigree divergence rate for the entire control region is estimated at 0.78 mutations/site/Myr (95% CI: 0-1.85).

Genome-wide association study of human narcolepsy using 500,000 SNPs. *T. Miyagawa[1], M. Kawashima[2], N. Nishida[1], J. Ohashi[1], R. Kimura[1,3], A. Fujimoto[1], M. Honda[4], Y. Honda[5], K. Tokunaga[1]* 1) Department of Human Genetics, Graduate School of Medicine, University of Tokyo, Tokyo, Japan; 2) Department of Sleep Disorder Research, Graduate School of Medicine, University of Tokyo, Tokyo, Japan; 3) Department of Forensic Medicine, Faculty of Medicine, Tokai University, Kanagawa, Japan; 4) Tokyo Institute of Psychiatry, Tokyo, Japan; 5) Sleep Disorder Clinic of Seiwa Hospital, Tokyo, Japan.

Human narcolepsy is a sleep disorder that is associated with multiple genetic and environmental factors. Narcolepsy affects 0.02-0.06% of the general population in the United State and Europe whereas 0.16-0.18% in Japan. A genetic factor strongly associated with the disorder has been found in the human leukocyte antigen (HLA) region: the HLA DRB1*1501-DQB1*0602 haplotype. However, it is suggested that narcolepsy susceptibility gene(s) other than HLA also exist because HLA DRB1*1501-DQB1*0602 haplotype carriers are about 12% in the Japanese general population, and the HLA alone cannot statistically explain all the genetic contribution. Therefore, to identify unknown narcolepsy susceptibility gene(s), we performed a genome-wide association study instead of a candidate gene approach. We genotyped approximately 500,000 SNPs in 222 narcoleptic patients and 389 healthy controls (Affymetrix GeneChip Human Mapping 500K Array Set) and performed case-control association analyses. The subjects investigated in this study were all Japanese living in the Tokyo area. Approximately 250,000 SNPs with call rate 95%, HWE P 0.1% and MAF 5% were selected after data cleaning. Significant level (= about 7×10^{-5}) was calculated using false positive report probability (FPRP). About 30 candidate SNPs were selected by referring to the above significant level and genetic information. A replication study is in process now.

A whole-genome association study of global gene expression. *L. Liang[3], A.L. Dixon[1,2], M.F. Moffatt[1], W. Chen[3], S. Heath[4], K.C.C. Wong[1], J. Taylor[2], I. Gut[4], M. Farrall[2], G.M. Lathrop[4], G.R. Abecasis[3], W.O.C. Cookson[1]* 1) National Heart and Lung Institute, Imperial College London, SW3 6LY, England; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, OX3 7BN, England; 3) Center for Statistical Genetics, Dept. of Biostatistics, SPH II, Ann Arbor, MI 48109-2029, USA; 4) Centre National de Genotypage, 91057 Evry Cedex, France.

Variation in gene transcription is important in mediating disease susceptibility, and global identification of genetic variants that regulate transcript abundance will be helpful in mapping human disease genes. We systematically mapped the effects of polymorphism on global gene expression by genome-wide association (GWA). We genotyped 408,298 SNPs to identify expression quantitative trait loci (eQTLs) from measurements of 54,675 transcripts representing 20599 known genes in EBV-transformed lymphoblastoid cell lines (EBVL) in 400 children from nuclear families recruited through a proband with asthma. We found that 15,084 transcripts (28%) representing 6660 genes had heritabilities (H2) > 0.3, exemplifying the wide extent of human genetic variability. We executed whole genome association scans for each of these heritable gene-expression traits and found individual peak association LOD scores between 3.68 and 59.1. We were able to identify significant SNP associations for 81% of traits with an overall H2 > 0.8 with our marker panel, suggesting good coverage of the eQTL genome. The most highly heritable traits were strikingly enriched with gene ontology descriptors for response to unfolded protein (chaperonins and heat shock proteins), regulation of progression through cell cycle, RNA processing, DNA repair, immune responses, and apoptosis. SNPs that regulate expression of these genes are candidates to modify degenerative diseases, malignancy, infection and inflammation. We provide several examples of how our genome-wide eQTL database can be used in the context of disease gene mapping, and we have developed web-based tools to aid others to apply our findings to loci associated with complex diseases.

Mosaic neurofibromatosis type 1 (NF1) in Finland. *J. Ruohonen[1], S. Peltonen[2], J. Peltonen[3], M. Poyhonen[1,4]* 1) Department of Medical Genetics, University of Helsinki, Helsinki, Finland; 2) Department of Dermatology, University of Turku, Turku, Finland; 3) Institute of Biomedicine, Department of Anatomy, University of Turku, Turku, Finland; 4) Department of Clinical Genetics, Helsinki University Central Hospital, Helsinki, Finland.

Background Neurofibromatoses are hereditary diseases that belong to the group of phakomatoses. Neurofibromatosis type 1 (NF1) has distinctive cutaneus features and NF type 2 has mainly intracranial lesions. In the segmental or mosaic type (formerly known as NF5) the disease features of NF1 are distributed regionally on the body. It is caused by a gonosomal mosaicism of the NF1-gene. There is no previous data on mosaic NF1 in Finland. **Methods** Patients disease features were collected from hospital files. A large literature search was made and the cases were compared with the Finnish patients. We used several different criteria found in the literature to classify the patients. The objective was to study the incidence of mosaic NF1 in Finland and the disease features in Finnish patients. **Results** Classification of patients unequivocally according to existing criteria for mosaic NF1 proved difficult. The incidence of mosaic NF1 in Finland (0,0005%) was lower than that found in other countries (0,0014%-0,002%), but in areas where the material was the most comprehensive (Turku and Oulu university hospital districts) the incidences (0,0013% and 0,0011% respectively) were very similar to the other studies. The most common disease feature was the neurofibroma, which was found in 81% of the Finnish patients and in 76% of the cases in the literature. The frequence of café-au-lait-spots was respectively 39% and 35% and that of freckles 26% and 38%. Lisch nodules, mainly unilateral, presented in 15% of the Finnish patients and in 8% of the literature cases. **Conclusions** There is a need for more unified criteria for classifying mosaic NF1. The incidence and disease features of mosaic NF1 in Finland are similar to those found in other countries and in the literature. This material can base further molecular genetic studies on mosaic neurofibromatosis type 1.

Further studies on Lebers hereditary optic neuropathy (LHON) in Russia/Siberia. *N. Volodko, E. Starikovskaya, P. Naidenko, N. Eltsov, R. Sukernik* Laboratory of Human Molecular Genetics, Institute of Cytology and Genetics, Russian Academy of Sciences, Siberian Branch, Novosibirsk, Russia.

LHON (MIM535000) is a form of maternally transmitted visual failure associated with mtDNA mutations affecting genes that contribute polypeptides to the ND (NADH dehydrogenase) subunits of the mitochondrial respiratory complex I. To further clarify the role of the basal polymorphisms of mtDNA Eurasian phylogeny in the expression of pathogenic mtDNA mutations, previously identified in 13 Slavic and 3 aboriginal LHON families from Southwestern Siberia (Volodko et. al. 2006), we filled the gaps existing in the complete sequencing the mtDNAs from the probands of either family. Similar strategy was applied to 7 new LHON families of Slavic-European origin revealed recently, resulting in comprehensive haplotype analysis of 23 LHON families. The phylogeny encompassing complete mtDNAs with three classical LHON mutations (G1178A/ND4, T14484C/ND6 and G3460A/ND1) and two rare (T10663C/ND4L, G3635A/ND1) shows a varying degree of association between haplogroup background and phenotypic expression of these mutations. For example, of 13 pedigrees with G11778A, 9 (70%) were associated with different sublineages of the TJ haplogroup (T2, J2b, J1c), and 4 four (30%) were found to be scattered within the pre-HV cluster. The G3460A mutation detected in 4 families, of whom 3 belonged to native Siberians, were found in association with different derivatives of haplogroup M (C3, D4 and D5a), whereas one of German ancestry with haplogroup R (H*). Contrary to our previous persuasions, the roles of haplogroup J specific or associated variants in the expression of the T14484C remains unclear; of four LHON families with T14484C, only one exhibited association with TJ cluster, while two were distributed among the branches of HV, and one belonged to eastern Eurasian M9.

MicroRNAs: Negative Regulators of PTEN and Modifiers of Cowden Syndrome. *M.G. Pezzolesi[1,2], K.A. Waite[1,2,3], C. Eng[1,2,3]* 1) Genomic Medicine Inst,; 2) Lerner Research Inst,; 3) Tausig Cancer Center, Cleveland Clinic Foundation, Cleveland, OH.

Germline mutations in PTEN are associated with a number of clinically distinct heritable cancer syndromes, including both Cowden syndrome (CS) and Bannayan-Riley-Ruvalcaba syndrome (BRRS). While the majority of patients with CS (85%) and BRRS (60%) harbor PTEN mutations, for a subset of patients without identifiable mutations, the etiology of their disease remains unknown. Furthermore, among patients with PTEN mutations, an imprecise genotype-phenotype correlation exists, suggesting that additional genetic factors may act as phenotypic modifiers. MicroRNAs (miRs), represent one such class of potential modifier. In order to investigate their role in regulating PTEN in CS/BRRS, we chose to assess the expression of miR-21, a miR previously shown to target PTEN, in lymphoblastoid cell lines obtained from 30 CS/CS-like patients without detectable PTEN mutations and 20 healthy controls. In total, 4/30 patients had increased mir-21 expression and all 4 with over-expressed miR-21 were classic CS patients ($P = 0.038$). We subsequently searched for further putative miRs that are computationally predicted to target and regulate PTEN. To determine real functionality, we found that miR-519e negatively regulates luciferase expression through its interaction with PTENs 3UTR while, conversely, miR-26a, miR-20a, and miR22 do not. Additionally, we show that this inhibitory effect is disrupted upon deletion of miR-519es putative seed site, while its over-expression in MCF-7 cells reduces endogenous PTEN expression. Transfection with an antisense miR-519e inhibitor restored PTEN expression to its basal level. Taken together, these data provide compelling evidence of miR-519es involvement in the regulation of PTEN. Our results suggest that miR-21 and miR-519e act as modifiers of PTEN expression and that modulation of mir-21, and possibly miR-519e, may contribute to CS in patients lacking PTEN mutations. Furthermore, these data suggest that miRs may play a role in modulating phenotype and penetrance in patients with CS/BRRS, even those with identical PTEN mutations.

Measures of population structure. *H. Xu, V. George* Department of Biostatistics, Medical College of Georgia, Augusta, GA.

Large-scale genome-wide association studies are promising for unraveling the genetic basis of complex diseases. Population structure is a potential problem, the effects of which on genetic association studies are controversial. The first step to systematically quantify the effects of population structure is to choose an appropriate measure of population structure for human data. The commonly used measure is *Wrights Fst*, which measures the genetic variance between subpopulations as a fraction of the total genetic variance. For a set of subpopulations it is generally assumed to be one value of *Fst*, even though it could be different for distinct loci. Recently, a new *c parameter* was proposed for SNP data, which was assumed to be subpopulation-specific and common for all loci. In this study, we performed extensive coalescent-based simulations of samples with varying levels of population structure to investigate the properties and relationships of both measures. It is found that the two measures generally agree well when the subpopulations have similar levels of differentiation, but may differ otherwise. Based on the comparison results, we propose an *adjusted c parameter* based on the effective population size of each subpopulation. It has the advantage of easy interpretation as one measure of population structure and yet can also assess population differentiation.

Preferential petterns of association of cleft lip with or without cleft palate with others major congenital malformations. *J.J. Morales[1], L. Luna[1], A.R. Villa[2], O.M. Mutchinick[1]* 1) Depto of Genetics, INCMNSZ; 2) Clinical Epidemiology, INCMNSZ, Mexico City.

Approximately 25% of newborns with CL(P) are multiple malformed (MM). The aims of the present study is to determine preferential patterns of association (PPA) of CL(P) with other MCM and to propose a method for the identification of such patters in any type of MM individuals. Data was obtained from the database of the Mexican program of Registry and Epidemiologic Surveillance of Congenital Malformations (RYVEMCE), a case-control hospital-based study. We analyzed 154 cases with CL(P) selected from a total of 588 non-syndromic MM newborns. We observe a total of 1640 MCM corresponding for 31 differences diagnosis. To identify possible preferential associations of CL(P) with other MCM we decide to include only those cases observed at least twice. The analysis was based on the estimation of the respective observed to expected (O/E ratio) method. The expected value was the result of the product of the frequencies observed for CL(P) and each of the MCM included. For this pairwise approach, were obtained the prevalence of CL(P) and each one of the MCM using as denominator the total number of MCM (1640). An O/E value higher than 1and statistically significant according to Poisson test ($P<0.05$) was considered a preferential association. To avoid spurious associations due to the clustering among all defects we use multiple regression logistic (MLR) analysis. Those cases that showed to be preferentially associated were included in a subsequent analysis to further delineate specific patterns creating a correlation matrix . Our result show that CL(P) was significantly associated with 8 different MCM: anencephaly (AN) (15), encephalocele (EC) (7), hydrocephaly (HC) (), microphthalmia (MP) (), severe nose anomalies (SNA) (), microtia (M) (), polydactyly (P) (), and hypospadias (HP) () ($P<0.05$ - $P<0.001$). Among those 3 were specific dyads CL(P)+ AN, CL(P) + P and CL(P) + HP, 2 were triads CL(P)+ M + MP and CL(P) + EC + MP and CL(P) + HC + SNA + MP. This is the first report using the methodology here in described that importantly avoids many spurious associations that are not real PPA.

Saposin B deficiency in mice leads to multiple glycosphingolipids accumulation and slowly developing neurological deficit. *Y. Sun[1], H. Ran[1], M. Zamzow[1], B. Quinn[1], M.T. Williams[2], C.V. Vorhees[2], D.P. Witte[3], H. Cheng[4], X. Han[4], G.A. Grabowski[1]* 1) Div Human Genetics, Cincinnati Children's Hosp, Cincinnati, OH; 2) Div Neurology, Cincinnati Children's Hosp, Cincinnati, OH; 3) Div Pediatric Pathology, Cincinnati Children's Hosp, Cincinnati, OH; 4) Dept Medicine, Washington University School of Medicine, St. Louis, MO.

Saposin B is one of four saposins derived from prosaposin. Saposin B functions as an activator for multiple lysosomal enzymes in the glycosphingolipids (GSL) degradation pathway. Patients with a saposin B mutation present a metachromatic leukodystrophy-like disease. To gain insight into the physiological function of saposin B, saposin B null mice (B-/-) were generated by knock in of a cysteine mutation in exon 7 of the prosaposin locus. No saposin B protein was detected in B-/- mice while saposin A, C and D were expressed at the normal levels. The saposin B-/- mice developed a neurological phenotype at approximately one year old as demonstrated by a significant increase in latency and foot slips on the narrow bridges test. Slight tremor of the head also was visible at 15 month. Sulfatide levels were increased in both brain and kidney, whereas ceramide levels were unchanged. The sulfatide was detected in urine of B-/- mice. Sulfatide storage cells stained by alcian blue were present in brain, spinal cord and kidney. Myelin basic protein levels were not altered in B-/- brain, which suggested that accumulation of sulfatide did not affect myelination. Lactosylceramide (LacCer), globotriaosylceramide (TriCer) and gangliosides were accumulated in B-/- mice at about a year of age, indicating saposin B participated in degradation of LacCer, TriCer and gangliosides in vivo. Activated microglial cells stained with CD68 and activated astrocytes labeled by GFAP demonstrated the proinflammatory response in B-/- mice. These findings indicate that saposin B plays an important role in vivo in degradation of multiple GSLs in lysosomes. Collectively, saposin B deficient mice are a useful model for understanding the contributions of saposins to the GSL metabolism and homeostasis.

Frequency and function of an Asian specific novel CETP variant. *J.M. Reynolds[1], D.L. Lloyd[1], S.P. Williams[2], L.S. Wood[1], J.T. Thompson[1]* 1) Pharmacogenomics, Pfizer, Inc., Groton, CT; 2) DNA Sequencing, Pfizer, Inc., Groton, CT.

Cholesteryl ester transfer protein (CETP) plays an important role in modulating lipid levels and promoting reverse cholesterol transport. Genetic variation in CETP has been clearly associated with HDL cholesterol levels but its association with cardiovascular disease and related phenotypes has been more controversial. Some of this lack of reproducibility arises from studies attempted with small population sizes but an additional portion of the variability may also arise from polymorphisms that occur at markedly different frequencies in different ethnic populations. To properly compare results across populations, there must be a good understanding of the variation unique to each population as well as which elements of variation are common across populations. To assess whether there might be undetected common variations in individuals of Asian ancestry that contribute to CETP heterogeneity, all exons were resequenced in 96 individuals. One novel SNP, S332Y, was identified and then characterized in more detail in functional assays and its frequency determined across multiple ethnic groups. This variant is secreted less well than wild type protein but retains significant transfer activity.

Mutations in NIMA-related kinase NEK8 causes nephronophthisis in humans and affects ciliary and centrosomal localization. *E. Otto[1], M. Trapp[2], U. Schultheiss[1], L. Quarmby[2], F. Hildebrandt[1]* 1) Department of Pediatrics, University of Michigan, Ann Arbor, MI; 2) Department of Molecular Biology and Biochemistry, Simon Fraser University, Burnaby, British Columbia, Canada.

Nephronophthisis (NPHP), an autosomal recessive kidney disease, is the most frequent genetic cause of chronic renal failure in the first 3 decades of life. Mutations in 8 genes (*NPHP1-8*) have been identified and homologous mouse models for *NPHP2* and *NPHP3* have been described. Another mouse model of a recessive cystic kidney disease is the *jck* mouse, which is caused by a missense mutation G448V, in a highly conserved RCC1 (regulator of chromosome condensation) domain in Nek8. Under the hypothesis that mutations in *NEK8* might cause NPHP in humans, we performed mutational analysis in a worldwide cohort of 188 patients with NPHP by direct sequencing. We identified 3 different amino-acid changes L330F, H425Y, and A497P, which were absent from at least 80 healthy control individuals. All three mutations are within the RCC1 domain of Nek8, and the mutation H425Y is positioned within the same RCC1 repeat as the murine *jck* mutation. To test their functional significance, we introduced these mutations into full length mouse *Nek8 (mNek8)* GFP-tagged cDNA constructs. In transient overexpression experiments using inner-medullary-collecting-duct (IMCD-3) cells, sub-cellular localization of mutant Nek8 was investigated and compared to wild-type Nek8 expression. All mutant forms of Nek8 showed defects in ciliary localization to varying degrees. The murine mNek8 mutant H431Y (human H425Y) was completely absent from cilia and showed decreased localization to centrosomes. Overexpression of these mutants did not affect overall ciliogenesis, mitosis, or centriole number. Our finding that *Nek8*, when mutated, causes nephronophthisis type 9 strengthens the link between proteins mutated in cystic kidney disease and their localization at cilia and centrosomes.

Effects of maternal-fetal genotype combinations on schizophrenia depend on offspring sex. *C.G.S. Palmer[1], E. Mallery[1], J.A. Turunen[2], H.J. Hsieh[3], L. Peltonen[2,4,5], J. Lonnqvist[2], J.A. Woodward[6], J.A. Sinsheimer[1]* 1) Univ Cal Los Angeles; 2) Natl Publ Hlth Inst; 3) Genentech Inc; 4) Univ Helsinki; 5) Broad Inst MIT; 6) Univ Cal Merced.

Previous studies suggest that maternal-fetal genotype incompatibility (MFG) at RHD and HLA-B loci increases risk for schizophrenia (SZ) in offspring (Palmer et al 2002; Palmer et al 2006; Hollister et al 1996; Insel et al 2005) by creating an adverse prenatal environment, and that the effects may depend on offspring sex. Although not tested by Palmer et al 2002, the effect of RHD MFG may be limited to male offspring (Hollister et al 1996; Insel et al 2005), while that of HLA-B MFG may be limited to female offspring (Palmer et al 2006). If true, this would suggest that sex differences during fetal neurodevelopment should be investigated to fully elucidate the etiology of SZ. The purpose of this study is to use a genetic approach to determine if the effect of RHD MFG is limited to male SZ offspring in the Finnish Schizophrenia Study Sample. The sample contained 277 nuclear families with 1 child affected with SZ or related disorder (affected offspring: 303 males, 202 females). Three models were evaluated using a general joint log-linear conditional model to test for association of RHD MFG and SZ risk in males (Kraft et al 2004). The null model (Model 0) constrains the relative risks for incompatible males ($_M$) and incompatible females ($_F$) to the null value ($_M$=$_F$ =1). Model 1 assumes the relative risk of incompatibility is independent of offspring sex ($_M$=$_F$). Model 2 limits the relative risk to incompatible males ($_F$=1). A significant MFG effect was found in the sample (Model 0 vs Model 1; ^{2} =2.86, 1df, 1-sided p=.04), consistent with earlier analysis of a subset of these families (Palmer et al 2002). Furthermore, there was significant evidence that the effect of RHD MFG incompatibility on SZ is limited to male offspring (Model 0 vs. Model 2; ^{2}=3.27, 1df, 1-sided p=.03), with $_M$=1.4. These results provide further support that RHD MFG increases SZ risk and that the risk is limited to males. Gender differences in fetal neurodevelopment should be considered in future studies of SZ.

Copy number variants detected by array-CGH in a Japanese population and their characteristics. *N. Takahashi[1], Y. Satoh[1], K. Sasaki[1], M. Kodaira[1], Y. Kodama[1], H. Omine[1], Y. Shimoichi[1], K. Sugita[2], H. Katayama[2], N. Tsuyama[3]* 1) Dept Genetics, Radiation Effects Research Foundation, Hiroshima, Japan; 2) Dept Information Technology, Radiation Effects Research Foundation, Hiroshima, Japan; 3) Graduate School of Biomedical Sciences, Hiroshima University, Hiroshima, Japan.

[Purpose] We have studied the effects of atomic-bomb radiation on human germline cells at the DNA level. To conduct this study at the genomewide level, we have introduced DNA micro-array based comparative genomic hybridization (array-CGH). Preliminary experiments revealed that, using the optimum conditions established by us, copy number variants (CNVs) with the size of about 40 kb or more could be detected. Before launching a large-scale study, the feasibility of array-CGH was validated in a pilot study. We will report on various variants identified in the pilot study. [Experiment] We used an array with 2,238 Bac-clones. These target clones were distributed across human autosomes at an interval of about 1.2 Mb. We examined 40 offspring of A-bomb survivors and 40 controls. [Results and Discussion] We found a total of 251 CNVs at 30 different regions in the genome; of these, 14 (termed rare CNVs) were found individually located within distinct genomic regions of 14 individuals, while the remaining 16 CNV regions (termed common CNVs) were observed in two or more individuals. The rare CNVs were confirmed by quantitative PCR, and characterized more precisely than in previous reports using array CGH methods. Distinctive features of these CNVs were observed: Most prominent was that the majority of the rare CNVs presented on Bac-clones that did not overlap with regions of segmental duplication. About 90% of the common CNVs in this population had been previously identified, with the majority of those common CNVs located in regions of segmental duplication. It is likely, therefore, that rare and common CNVs arise through different genetic mechanisms. Since more than half of the rare CNVs are novel, it is also likely that different human populations bear different CNVs, as is the case for single-nucleotide-polymorphisms (SNPs) and insertion-deletion (indel) polymorphisms.

Mutation of FAM20C leads to lethal osteosclerotic bone dysplasia (Raine syndrome), highlighting a crucial molecule in bone development. *M.A. Simpson[1], R. Hsu[1], L.S. Keir[1], J. Hao[2], G. Sivapalan[1], L.M. Ernst[3], E.H. Zackai[3], L.I. Al Gazali[4], G. Hulskamp[5], H.M. Kingston[6], T.E. Prescott[7], A. Ion[1], M.A. Patton[1], V. Murday[8], A. George[2], A.H. Crosby[1]* 1) St George's University of London, London, UK; 2) University of Illinois at Chicago, Chicago, USA; 3) The Children's Hospital of Philadelphia, Philadelphia, USA; 4) UAE University, UAE; 5) Universität Münster, Münster, Germany; 6) St Mary's Hospital, Manchester, UK; 7) Rikshospitalet University Hospital, Oslo, Norway; 8) Royal Hospital for Sick Children, Yorkhill, Glasgow, UK.

The generation and homeostasis of bone tissue throughout development and maturity is controlled by the carefully balanced processes of bone formation and resorption. Disruption of this balance can give rise to a broad range of skeletal pathologies. Lethal osteosclerotic bone dysplasia (Raine syndrome, OMIM:259775) is an autosomal recessive disorder characterized by generalized osteosclerosis with periosteal bone formation and a distinctive facial phenotype. Affected individuals survive only days or weeks. We have identified and defined a chromosome 7 uniparental isodisomy and a 7p telomeric microdeletion in an affected case. The extent of the deleted region at the 7p telomere was established by genotyping microsatellite markers across the telomeric region. The region is delimited by D7S2563 and contains 5 transcriptional units. Sequence analysis of FAM20C in 7 additional affected cases revealed 5 homozygous mutations and 2 compound heterozygotes. The mutations identified include 5 non-synonymous base changes all affecting evolutionarily conserved residues and 4 splice site changes which are predicted to have a detrimental effect upon splicing. FAM20C is a member of the FAM20 family of secreted proteins, and has demonstrated calcium binding properties, we also show by in situ hybridisation its expression profile in mineralising tissues during development. This study defines the causative role of FAM20C in this lethal osteosclerotic disorder and its crucial role in normal bone development.

Genetic and ultrastructural study in congenital glaucoma case with Down syndrome and Axenfeld-Rieger syndrome. *M. Tanwar[1], D. Pathak[1], R. Sihota[2], T. Das[1], T. Dada[2], V. Gupta[2], R. Dada[1]* 1) Anatomy, All India Institue of Medical Sciences, New delhi, India 110029; 2) Dr R.P. Centre for Ophthalmic Sciences, New delhi, India- 110029.

Down syndrome(DS) is a constellation of clinical findings characterized by mental and motor retardation , simian crease, hyperflexiblity, oblique palpebral fissures and enlargement of tongue. Ocular and adnexal findings are quiet common in these cases. In the present study 25 cases of congenital glaucoma were included. One of these cases had Axenfeld-Rieger syndrome(ARS) along with congenital glaucoma and Down syndrome. Materials: 25 cases of congenital glaucoma were enrolled in this study. One case of congenital glaucoma had Down syndrome and ARS. Method: To identify any karyotypic abnormalities, lymphocyte culture were set and 25 well spread G-banded metaphases were analyzed. CYP1B1 gene was screened for six mutations (Termination at 223, Gly61Glu, Pro193Leu, Glu229Lys, Arg368His and Arg390Cys)) by PCR-RFLP. After informed consent surgical trabeculectomy tissues were collected and sent for scanning electron microscopy to identify structural changes in trabecular meshwork.For EM study specimens were fixed in glutraldehyde fixative for 12 hrs and then post fixed in the osmium tetra oxide at 1% for 2 hrs.and processed for Scanning electron microscopy. Result: On cytogenetic analysis 47,XX+21 chromosomal complement was confirmed. This sample was negative for all six CYP1B1 mutations. Ultrastructural study revealed a very compact trabecular meshwork with marked narrowing of intratrabecular spaces. Also the intratrabecular spaces and Schlemm's canal were obliterated by endothelial cells and connective tissue.Conclusion: ARS also known as anterior chamber cleavage syndrome and characterized by mesodermal dysgenesis of cornea and iris. Obliteration of highly compact trabecular spaces and Schlemm's canal by endothelial cells may obstruct the normal aqueous out flow for glaucoma in this case with ARS. Several ocular anomalies are associated with Down syndrome but its association with PCG and ARS has not been documented. Thus it is important to analyze more cases of associated congenital glaucoma.

Mutation of Nkip1 in bovine cardiomyopathy woolly haircoat syndrome. *P. Solanki[1], M.A. Simpson[1], R. Cook[2], A.H. Crosby[1]* 1) Medical Genetics, St George's University of London, London; 2) NWS Agriculture, Camden, NSW, Australia.

In recent years great strides have been made in the understanding of the pathogenic mechanisms of the cardiomyopathies. In particular, genetic studies of both human cardiomyopathies and animal models have identified several molecular pathways which are crucial for normal cardiac function. We present here the identification of the causative mutation in a naturally occurring bovine cardiomyopathy inherited in an autosomal recessive fashion. In 1969, a lethal autosomal recessive cardiomyopathy, known as cardiomyopathy and woolly haircoat syndrome (CWH), was reported in Poll Hereford calves in Australia. The cardiac defect is particularly aggressive and the identification of extensive lesions of myocardial fibrosis in neonates suggests an in-utero onset of myodegeneration. Affected calves are identifiable by a woolly haircoat which cosegregates with the heart condition and death normally occurs within the first 12 weeks either due to sudden cardiac death or congestive heart failure. Assuming that a founder mutation was responsible, we undertook a homozygosity mapping approach in order to identify the underlying genetic defect. This identified a region of homozygosity in the vicinity of the bovine orthologue of the Nkip1 gene. Sequence analysis of this gene revealed the presence of a 7bp duplication in exon 6 of this gene, which cosegregates with the disease status. The duplication is predicted to disrupt the encoded protein product causing a frame shift resulting in the substitution of 55 amino acids and premature termination at position 377. These findings clearly highlight this gene as an important candidate for mutation in human forms of cardiomyopathy.

Ultrastructural changes and genetic study in Associated congenital glaucoma case with Sturge-Weber syndrome.

D. Pathak[1], M. Tanwar[1], R. Dada[1], R. Sihota[2], V. Gupta[2], T. Das[1], T. Dada[2] 1) Anatomy, All India Institute of Medical Sciences. New Delhi, India; 2) Dr. R.P.Centre for Ophthalmic Sciences, AIIMS New Delhi, India.

Congenital glaucoma (PCG) is a genetic disease which manifests at birth or in infancy. Congenital glaucoma may be of primary, secondary or associated. Primary congenital glaucoma (PCG) is characterized by buphthalmos, high intraocular pressure (IOP), corneal edema and photophobia. In secondary congenital glaucoma PCG is associated with other ocular syndrome and in associated congenital glaucoma it is associated with other extra-ocular syndrome. In the present study of 51 cases of congenital glaucoma were enrolled, of these 2 cases had Sturge-Weber syndrome and one case had PCG with Down syndrome and Axenfeld-Rieger syndrome. Clinical diagnosis of Sturge-Weber syndrome was made on the bases of presence of facial port-wine stain on the right side of face. Method: Fifty cases of PCG were enrolled in this genetic and ultrastructure study (Scanning electron-microscopy). For cytogenetic analysis, lymphocyte cultures were set and chromosomes were analysed with GTG banding. CYP1B1 gene was screened for six mutations (Termination at 223, Gly61Glu, Pro193Leu, Glu229Lys, Arg368His and Arg390Cys)) by PCR-RFLP. For ultrastructure study, after informed consent surgical trabeculectomy tissues were collected and sent for scanning electron-microscopy. Results: Cytogenetically all cases of congenital glaucoma and both cases of associated congenital glaucoma were normal. Both sample were negative for all six mutations On ultrastructure analysis all tissues showed trabeculardysgenesis. In both cases of Sturge-Weber syndrome the juxta cannalicular connective tissue had nodular thickenings and deposits of amorphus extra-cellular substance. The trabecular meshwork (TM) had compressed sheets of tissues. In certain areas several layers of TM appeared adherent. Conclusion: Trabecular dysgenesis and the presence of excessive connective tissue, nodular thickenings and adherence of several layers of TM may lead to obstruction of aqueous outflow in associated congenital glaucoma cases causing congenital glaucoma.

Generation of a knock-in spartin (Spg20) mouse, a model for motor neuron degenerative disease. *H. Patel, A.H. Crosby* Medical Genetics, St George's, University of London, London, United Kingdom.

We have previously shown that mutations in spartin underlie a form of motor neuron degenerative disease, the cardinal features of which are spastic paraparesis, dysarthria, distal amyotrophy, mild developmental delay and subtle skeletal abnormalities. The condition is at high frequency amongst the Old Order Amish where a founder 1bp (1110delA) exon 4 deletion mutation is responsible; this mutation results in the substitution of the following 29 amino acids and truncation of the protein by 268 residues (fs369-398X399). In order to learn more about this condition, we have generated a mouse knock-in model of murine spartin that closely represents the human mutation. Unfortunately, as mouse spartin exon 4 is variably spliced, we introduced into the targeting vector a 1bp 1102delA exon 4 deletion that closely corresponds to the human mutation in parallel with two stop codons in exon 5 to ensure the premature termination of both possible spartin transcripts. We have obtained heterozygous animals which are being inter-crossed to generate constitutive homozygous 1102delA *Spg20* knock-in mice. Initial assessment of the breeding program is presented. This knock-in mouse will provide a valuable animal model allowing us to investigate the underlying pathogenic processes of motor neurone degenerative disease.

Cannabinoid therapeutic testing of a Friedreich ataxia mouse model. *R. Mouro Pinto, S. Al-Mahdawi, M.A. Pook*
CCCB/BICGP, Division of Biosciences, School of Health Sciences and Social Care, Brunel University, Uxbridge, UB8 3PH, UK.

Friedreich ataxia (FRDA) is an autosomal recessive disease causing degeneration in the central and peripheral nervous system, cardiomyopathy, skeletal abnormalities and increased risk of diabetes. It is caused by deficiency of the mitochondrial protein frataxin. The genetic mutation found in 98% of FRDA chromosomes is the unstable hyperexpansion of a GAA triplet repeat in the first intron of the *FXN* gene. There is currently no effective treatment for FRDA. A GAA repeat expansion mutation-based transgenic mouse model of FRDA has been developed. The mice exhibit both intergenerational and age-related somatic instability of the GAA repeat, with prominent expansions detected in the cerebellum. In addition, a decreased level of frataxin expression was achieved, which is accompanied by mild oxidative stress. The neurological phenotype of these mice includes a progressive coordination defect, as measured by decreased rotarod performance, and vacuolar pathology within large neurons of the dorsal root ganglia. However, the degree of impairment does not extend to overt ataxia. The antioxidant activity of cannabinoids such as ^{9}-tetrahydrocannabinol (THC) and Cannabidiol (CBD) indicates that they may be effective in preventing and/or treating the development of neurodegenerative disorders such as FRDA. Thus, the potential neuroprotective effect of such cannabinoids is being investigated on the FRDA mouse model available. CBD has been administered in two doses - 10 and 20 mg/kg - over a 3 month period (6-9 and 3-6 months of age respectively). A 20mg/kg dose of CBD:THC (1:1) is currently being administered to test the potential benefits of combining CBD with THC (3-6 months of age). Data will be presented on functional studies (locomotor coordination and activity analysis), together with histological and biochemical analysis to determine more subtle effects, i.e. presence of vacuoles in the DRG, levels of oxidative stress, and aconitase and mitochondrial respiratory chain complex activities.

Breast cancer risk associated with genotype val/val polymorphism of the estrogen metabolizing gene CYP1A1 in Mexican population. *AM. Puebla[1,3], D. Ontiveros[2], M. Gallegos[1]* 1) Medicina Molecular, CIBO, Instituto Mexicano del Seguro Social, Guadalajara, Guadalajara, Mexico; 2) Unidad Médica de alta Especialidad, Hospital de Gineco-obstetricia, Fisiología Obstétrica CMNO, IMSS. Laboratorio de Inmunofarmacología Experimental, CUCEI, Universidad de Guadalajara. Guadalajara, Jal., México; 3) Laboratorio de Inmunofarmacología Experimental, CUCEI, Universidad de Guadalajara. Guadalajara, Jal., México.

Estrogen has been proposed to trigger breast cancer development via an initiating mechanism involving its metabolite, catechol estrogen . We conducted a case-control study to determine whether polymorphism iso/val of CYP1A1 gene that participated in metabolism of estrogen biosynthesis is associated with an elevated risk for breast cancer in Mexican population. In 243 breast cancer patients and 243 healthy controls were determine the genotypes of iso/val CYP1A1 polymorphism. The val/val genotype in breast cancer was 12% and in the control group of 6% ($p<0.05$); the risk factors of breast cancer was associated with a 2.22 fold increase in risk (95% confidence interval, 1.07-4.83). On the basis of comprehensive profiles of estrogen metabolism, this study supports the possibility that polymorphism iso/val of CYP1A1 gene in breast cancer can be play a role in metabolism of estrogen biosynthesis.

Validation of micro-array comparative genomic hybridization (aCGH) from cancer cell lines by fluorescence in situ hybridization (FISH) to provide biomarkers for pharmaceutical development. *J.A. Roseberry Baker[1], E.M. Felke[1], R. Gupta[3], L. Gautier[3], Y. Xiang[3], C. Lopez-Correa[2]* 1) Department of Drug Disposition, Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, Indiana; 2) Department of Functional Genomics, Lilly Research Laboratories, Eli Lilly and Company, Greenfield, Indiana; 3) Lilly Systems Biology, Lilly Research Laboratories, Eli Lilly and Company, Singapore.

Cancer cell lines are an important tool in the discovery of biomarkers and for drug target validation. Array comparative genomic hybridization (aCGH) can be useful for a high throughput characterization of cancer cell lines in which large amounts of data can be generated focusing mainly on amplifications and deletions in the genome. However, cancer cells can have a variety of genetic variations in addition to amplifications and deletions that make aCGH data difficult to interpret. This can include large chromosomal rearrangements and polyploidy. Further limitations to current aCGH technology include limited resolution across the genome, variability across binding strengths for different probes and difficulty with calibration for precise copy number detection. We have demonstrated that FISH can enhance the powerful method of aCGH analysis by overcoming some of these limitations. To exemplify the power of this approach, the aCGH data implied that there was amplification of the ERBB2 gene in three different cell lines. FISH, using a commercially available probe for this region, indicated that the amplification in each cell line was to different levels. In a second example, aCGH data suggested that the CDKN2A gene was deleted in three cell lines. The FISH technique was able to show that all three cell lines were homozygous for this deletion. In many cases these cell lines were polyploid, yet aCGH in combination with FISH was able to quantitate the aforementioned genetic anomalies, which in the past could only be estimated. Thus, the use of aCGH together with FISH can provide significant support to characterization of cancer cells lines (or tumor samples) that can be used as biomarkers or target validation for development of cancer treatments.

GAA repeat expansion-associated epigenetic changes in Friedreich ataxia. *M.A. Pook, O. Ismail, D. Varshney, S. Lymperi, R. Mouro Pinto, S. Al-Mahdawi* CCCB/BICGP, Division of Biosciences, School of Health Sciences & Social Care, Brunel University, Uxbridge, UK.

Friedreich ataxia (FRDA) is an autosomal recessive neurodegenerative disorder that is primarily caused by a GAA repeat expansion mutation within intron 1 of the FXN gene, leading to a decreased level of frataxin protein expression. The mechanism by which this mutation acts is currently unknown, but two models have been put forward. Firstly, it has been suggested that the GAA repeat expansion may adopt an abnormal triplex structure that interferes with FXN gene transcription. Secondly, there is evidence that the GAA repeat expansion is associated with epigenetic changes, such as DNA methylation and modification of histones, producing a heterochromatin-mediated gene silencing effect. In support of this second hypothesis, we have recently obtained data that shows increased DNA methylation of specific CpG sites immediately upstream of the expanded GAA repeat sequence in FRDA patient autopsied brain tissue, compared with non-GAA repeat expansion containing brain tissue. In contrast, no such changes were identified in the FXN promoter region. We have also identified similar DNA methylation increases in brain and heart tissues from our recently established GAA repeat expansion-containing FXN YAC transgenic mouse model, compared with similar non-GAA repeat expansion FXN YAC transgenic mice. These studies will be detailed, together with our more recent investigations to identify potential GAA repeat expansion-associated changes in methylation and acetylation of histones at the FXN locus. Such epigenetic studies to identify the potential GAA repeat expansion mechanism of action will provide valuable information for novel FRDA therapies.

The identification of mutations at the SPG5 locus defines the gene responsible for a pure form of hereditary spastic paraplegia. *M.K. Tsaousidou[1], M.A. Simpson[1], P.A. Wilkinson[1], H. Patel[1], T.T. Warner[3], M.A. Patton[1], T. Siddique[2], A.H. Crosby[1]* 1) Medical Genetics, St George's University of London, London, United Kingdom; 2) Northwestern University Medical School, Chicago, USA; 3) Royal Free & University College Medical School,London, UK.

The hereditary spastic paraplegias (HSPs) comprise a genetically and clinically complex group of inherited diseases of the motor neuron. They are classified according to the mode of inheritance and whether the cardinal clinical feature of leg spasticity occurs alone (pure HSP) or is accompanied by additional neurological or systemic abnormalities (complicated HSP). Despite the mapping to chromosome 8 of the first pure autosomal recessive form (SPG5) of HSP many years ago, the precise nature of the causative gene has remained elusive. In order to refine the chromosomal localisation of SPG5, we undertook linkage studies in a large pure HSP family which maps to this locus. In combination with reports of other families which link to this region, we were able to refine the SPG5 locus to a 21cM (24Mb) interval flanked by markers D8S1115 and D8S1795, a region comprising approximately 100 genes. Systematic sequence analysis of these genes ultimately revealed family specific mutations in all families analysed in a gene located within this region; the identification of this gene defines a novel cause for the motor neuron degeneration characteristic of this disease.

Is family history of osteoporosis associated with osteoporosis preventive behavior in US women? A population-based study. *J. Robitaille[1], P.W. Yoon[2], M. Irizarry-De La Cruz[2], T. Liu[2], C.A. Moore[2], M.J. Khoury[2]* 1) National Center on Birth Defects and Developmental Disabilities, Centers for Disease Control and Prevention, Atlanta, GA; 2) National Office of Public Health Genomics, Centers for Disease Control and Prevention, Atlanta, GA.

Objectives: To assess the relationship between the prevalence of reported doctor-diagnosed osteoporosis and family history in a representative sample of women in the United States, examine whether this association can be explained by other risk factors for osteoporosis, and evaluate whether high-risk individuals based on familial risk are more likely to report preventive behaviors. **Research design and methods:** Prevalence of reported osteoporosis was estimated in a sample of 8073 women aged 18 years and over from the National Health and Nutrition Examination Survey (NHANES), 1999-2004. Respondents reported whether any of their 1st degree relatives and grandparents had ever been diagnosed with osteoporosis. **Results:** The overall prevalence of osteoporosis in women was 8.3%. A positive family history was reported in 19.8% of the participants and was significantly and independently associated with osteoporosis (OR, 95% CI: 2.50, 1.97-3.17). This association was stronger when participants reported having 2 or more affected relatives (OR, 95% CI: 8.31, 4.62-14.94). When stratified by age, the association between family history and osteoporosis was observed only in women aged 35 and over. Women with a positive family history of osteoporosis were more likely to report preventive behaviors such as taking a supplement containing calcium and/or vitamin D (OR, 95% CI: 1.42, 1.17-1.72), being physically active (OR, 95% CI: 1.24, 1.01-1.53) and using estrogen (OR, 95% CI: 1.24, 1.00-1.55) compared to women with no family history of osteoporosis. **Conclusion:** Findings from this study indicate that family history is a significant and independent risk factor for osteoporosis in US women aged 35 and over. In addition to general education campaigns to increase awareness about osteoporosis risk factors and prevention, public health efforts should help identify high-risk women who may benefit most from targeted prevention strategies.

Assessing Departure from Hardy-Weinberg Equilibrium in the Presence of Disease Association. *M. Li[1], C. Li[2]* 1) Department of Biostatistics, University of Pennsylvania School of Medicine, Philadelphia, PA; 2) Department of Biostatistics, Vanderbilt University School of Medicine, Nashville, TN.

Assessing Hardy-Weinberg equilibrium (HWE) is often employed as an important initial step for genotype data quality checking in genetics studies. Since HWE is a population property, tests for HWE often assume the genotypes are randomly sampled from the general population. However, in many human genetics studies, subjects are ascertained through their disease status, and affected individuals (and their relatives in family-based studies) are often overly represented in the ascertained sample than in the general population. As a result, when a marker is associated with the disease, the marker genotypes may no longer be a random sample and this may lead to inflation of type I error rate in HWE tests. Here we develop a general likelihood framework that allows assessment of departure from HWE while taking into account potential association with the disease. The framework can be used for various data structures, including unrelated cases and controls, case-parents trios, and nuclear families with multiple affected offspring. We describe two HWE tests, which are based on likelihood ratio and goodness-of-fit statistics. The type I error rates of these two tests are under control for a broad range of genetic models. When the tested marker is not associated with the disease, our tests have comparable power as the traditional tests for rare diseases and are more powerful for common diseases. When disease association exists, our method can help differentiate departure from HWE caused by disease association from departure caused by other reasons, such as genotyping errors. For nuclear families with one or two offspring, our method can help identify genotyping errors that are not fully detectable by checking Mendelian inconsistencies. We believe our method will provide a valuable tool for researchers in genetics studies of complex diseases.

Accumulation of alpha-synuclein and ubiquitin in Gaucher disease mouse models. *YH. Xu[1], Y. Sun[1], R. Reboulet[1], H. Ran[1], B. Quinn[1], S. Clark[2], B. Wustman[2], GA. Grabowski[1]* 1) Div Human Gen, Children's Hosp Medical Ctr, Cincinnati, OH 45229; 2) Amicus Therapeutics, Cranbury, NJ 08512.

Gaucher disease (GD), the most prevalent lysosomal storage disease, is caused by insufficient activity of acid beta-glucosidase (GCase). Some non-neuronopathic (type I) GD patients have a disease course complicated by Parkinsonism that has an unusually early onset and refractoriness to conventional anti-Parkinson therapy. To understand the pathogenic correlations between GD and Parkinsonism, alpha-synuclein and ubiquitin levels in brain were evaluated by immunohistochemistry of serial brain sections from GCase point-mutated Gaucher mice [D409H (9H) and V394L (4L)] and prosaposin hypomorph together with GCase mutations (4L/PS-NA and 9H/PS-NA). 4L/PS-NA and 9H/PS-NA mice had excess GC accumulation in the brain and the levels were increased with age. In 10-wk old mice, significant alpha-synuclein aggregates were observed in hippocampus, basal ganglia (caudate putamen, substantia nigra, subthalamic nucleus), brain stem, and some cortical/cerebellar regions. Ubiquitin aggregates were also found in these regions and some co-localized with alpha-synuclein. However, alpha-synuclein aggregates were only observed at hippocampal and cerebella regions in >42-wks old 9H and 4L mice that are less severe models. Mouse models for other lysosomal storage diseases were screened in parallel and only sporadic signals were observed, e.g., alpha-synuclein signals in cortex and brain stem of prosaposin deficient (PS-NA) mice and low level in cerebellum (granular cell layer) of lysosomal acid lipase (LAL) knock-out mice; ubiquitin in the midbrain of MPS1 and NPC1 deficiency mice, or in the cortex and mid brain of PS-NA mice. These findings suggested that the defect of GCase activity is a risk factor for alpha-synucleinpathies. Understanding the pathogenic relationship between GCase deficiency and the development of parkinsonian manifestations will provide insights into the genetics, pathogenesis, and treatment of Parkinson disease.

Fragile X syndrome newborn detection--Pilot study. *R. Saul, M. Friez, K. Eaves, G. Stapleton, J. Collins, R. Stevenson* Greenwood Genetic Ctr, Greenwood, SC.

Fragile X syndrome, an X-linked disorder, is the most common form of hereditary mental retardation. Phenotypic detection in the prepubertal period is very difficult, and unfortunately often occurs after families have had a second affected child. Early detection in the newborn period could allow for appropriate developmental intervention and reproductive counseling for the immediate and extended family, and such detection will become increasingly important if specific therapeutic interventions become available. Counseling for potential adult complications in premutation carriers could also be offered. A pilot study was conducted to establish the feasibility of newborn screening for Fragile X syndrome. Over the course of two years, a total of 1458 newborn males at two hospitals in upstate South Carolina (out of a potential pool of 6562 newborn males) were studied after appropriate consent procedures. The blood specimen was obtained via heelstick at the time of the standard newborn metabolic screening sample. Analyses were performed by PCR and questionable or abnormal results were confirmed by Southern blot analysis on a retained cord blood sample or a second sample from the infant. Five (5) of the newborn males had abnormal results2 with full mutations for Fragile X, 2 with premutations for Fragile X, and 1 with sex chromosome aneuploidy (47, XXY). Genetic consultations were provided for all the patients and their families. Our preliminary results suggest a much higher prevalence of Fragile X syndrome (1:729) than that reported (about 1:4,000) in previous population studies. Our study was limited by testing of a relatively small number of males only yet was the first study to test newborns in the United States prospectively over a given period of time. Further studies are suggested in a larger population using automated, high-throughput technologies capable of detecting full mutations and premutations in both sexes to establish the feasibility of adding this analysis to the standard newborn screening panel. In addition, potential benefits and risks should be studied before universal application of this test.

Identification of a modifier gene in heart failure. *F.C. Wheeler[1], T.N. Hadnott[1], O. Marks[1], M.P. Donahue[2], H.A. Rockman[2], D.A. Marchuk[1]* 1) Dept Mol Genet & Micro, Duke Univ, Durham, NC; 2) Dept Medicine, Duke Univ, Durham, NC.

Cardiomyopathy and its resultant clinical outcome of heart failure is a significant cause of death worldwide. Disease progression is highly variable, due in part to undiscovered genetic differences in the population. We have taken an unbiased genetic approach to identify novel genes that contribute to heart disease. In a well-studied calsequestrin ovexpressing transgenic mouse model of dilated cardiomyopathy, we discovered dramatic strain-specific differences in disease progression and survival. Using QTL mapping in multiple crosses, we have identified 7 distinct genetic loci, *Hrtfm1-7* (Heart failure modifier), that modify disease progression and the final outcome of heart failure. Significantly, the phenotypic effects of these loci recapitulate the complexities of human heart disease, with some loci affecting both heart function and survival, and others separately influencing these two phenotypes. In this study, we report the identification of a strong candidate gene for one Hrtfm locus, which affects both heart function and survival. *Hrtfm2* was mapped to the identical location in two different crosses, allowing us to use ancestral haplotype patterns to narrow the candidate interval to 1 Mb. Transcript levels of one gene in the interval were found to be 20-fold different between the strains used to map the locus. Tnni3k is a tyrosine kinase that interacts with cardiac Troponin I, although its precise biochemical function is unknown. We have identified a *Tnni3k* SNP that modulates the observed differences in transcript levels. This SNP, located at the +9 position of intron 19, creates a cryptic splice donor site that leads to a frameshift and a premature stop codon, targeting the message for nonsense-mediated decay (NMD). Experiments in vitro have validated the role of this SNP in aberrant splicing, and blocking NMD restores near normal message levels. We have created a transgenic mouse that expresses high levels of human TNNI3K to study the effect of increasing TNNI3K expression in the original transgenic model of cardiomyopathy. We are also currently investigating the predictive value of *TNNI3K* SNPs in a large human cohort with cardiovascular disease.

Association of SNPs in the 5' Upstream Regulatory Region of the 7 Nicotinic Acetylcholine Receptor Subunit Gene with Schizophrenia, an Endophenotype of Schizophrenia and Alcohol Use. *S. Stephens, A. Franks, S. Leonard*
Department of Psychiatry, University of Colorado Health Sciences Center, Aurora, CO.

The 7 neuronal nicotinic acetylcholine receptor subunit gene (*CHRNA7*) is localized in a region linked to schizophrenia in multiple independent studies and was selected as the best candidate gene for an endophenotype of schizophrenia, the P50 sensory processing deficit, by both genetic linkage to the region and human and animal studies. Mutation screening of the *CHRNA7* coding region and intron/exon splice junctions revealed multiple synonymous variants and rare non-synonmous variants that were not associated with schizophrenia or the P50 deficit; however, this screening also revealed a large number of functional mutations in the upstream regulatory region of *CHRNA7*, particularly, the core promoter. Studies show the prevalence of functional polymorphisms in the *CHRNA7* core promoter to be statistically greater in schizophrenics versus controls. Further, the presence of a promoter polymorphism was associated with the P50 deficit in control subjects. The current study sought to further investigate 12 SNPs in the core promoter and upstream regulatory region of *CHRNA7* via association studies with schizophrenia, the P50 deficit, smoking, smoking in schizophrenia, and alcohol use. Family-based and case-control association studies were performed on samples from 123 families as well as 348 schizophrenic patients and 144 controls. SNP markers upstream of the *CHRNA7* gene were genotyped using Denaturing High-Performance Liquid Chromatography. Family-based association analyses were performed using UNPHASED. Case-control analysis was evaluated by 2, and endophenotypic analyses for P50 ratios by t-tests. The presence of *CHRNA7* core promoter polymorphism(s) was associated with the P50 deficit in control subjects. Additionally, the -1831 bp SNP (rs3087454), located in the upstream regulatory region of *CHRNA7*, is associated with schizophrenia in the case-control sample and supported by results in family members. The -1831 bp SNP was also found to be associated with alcohol use. These data support the 7 nicotinic receptor as a candidate gene for schizophrenia, and the P50 deficit.

Identification of a novel locus (SPG34) responsible for a complicated form of hereditary spastic paraplegia associated with amyotrophy of the hand muscles. *J.A. Reed[1], H. Patel[1], C. Windpassinger[2], M.A. Patton[1], M. Auer-Grumbach[2], P. Hedera[3], A.H. Crosby[1]* 1) Department of Medical Genetics, St Georges University of London, London, United Kingdom; 2) Institute of Medical Biology and Human Genetics, Medical University of Graz, Graz, Austria; 3) Department of Neurology, Vanderbilt University, 465 21st Avenue South, 6140 MRB III, Nashville, United States.

The hereditary spastic paraplegias (HSPs) are an extremely genetically heterogeneous group of disorders. Mutations in BSCL2 encoding seipin, a molecule of unknown function, are causative of around 40% of cases of a complicated form of HSP associated with amyotrophy of the small hand muscles. The same BSCL2 mutations have also been found in other patients with related motor neuron degenerative conditions involving hand muscle wasting. We have undertaken a genomewide screen in three families without BSCL2 mutations but with affected individuals presenting within the clinical spectrum of HSP accompanied by amyotrophy of the hand muscles/dHMNV. Following extensive exclusion mapping a single region compatible with linkage in two of these families as well as two further families was identified. This region, located on chromosome six is situated between markers D6S262 and AL035604, is supported by a maximum multipoint LOD score of 4.81 and has been designated SPG34. Sequencing of candidate genes located within this region has so far failed to reveal any potentially pathogenic sequence alterations.

Translational profiles of neuronal ceroid lipofuscinoses (NCLs). *N. Zhong[1,2], P-R. Wang[2]* 1) New York State Institute for Basic Research in Developmental Disabilities, Staten Island, NY; 2) Peking University Center of Medical Genetics, Beijing, China.

Neuronal ceroid lipofuscinoses (NCLs) are a group of clinically and genetically heterogeneous neurodegenerative disorders. NCLs comprise ten variant forms. Seven genes have being identified. The precise function of all the NCL proteins is currently unclear. One hypothesis is that the proteins defective in NCLs may, at least partially, be involved in a common metabolic pathway. To test our hypothesis, we have investigated protein expression profiles among NCL1, NCL2, NCL3, and NCL8 disease-derived, compared to wild type, fibroblasts. PF2D two-dimensional chromatography was applied. In the first dimension, proteins were separated by chromatofocusing, based on isoelectric point (pI). In the second dimension, proteins with same pI were resolved by reversed-phase chromatography detected by UV. Translational profiles were displayed as an UV/pI map using a ProteoVue* software. Differentially displayed protein pattern was further applied to LC-MS to identify protein sequence. One protein band was found to be at a translational level of 0.166 in wild type fibroblasts but at -0.017 or -0.008 in two NCL1 fibroblast cell lines, at 0.104 in one NCL2 line, 0.066 or 0.047 in two NCL3 lines, and 0.062 in one NCL8 line. Protein sequencing analyses showed this protein has a function of binding calcium and phospholipids to promote membrane fusion. Our results suggested that identification of this protein may open a new avenue to understand the molecular pathogenic mechanism underlying the NCLs.

The Challenges of Treating Patients with Hunter Syndrome and CNS Disease with Enzyme Replacement Therapy (ERT): A Case Report. *A. Paras, R. Katz, B.K. Burton* Division of Genetics, Children's Memorial Hosp, Chicago, IL.

A 7 yo old boy with a severe phenotype of Hunter syndrome began treatment with idursulfase(Elaprase) 9/06. He was given premedication at home with diphenhydramine 1mg/kg. Extreme agitation and anxiety were noted during the initial infusions. During several, BP was noted, even prior to starting Elaprase. Diazepam 0.2mg/kg home pretreatment was added and was effective for several weeks. A few weeks later, BP recurred but this time after Elaprase was initiated and it was accompanied by facial flushing and HR. The infusion rate was slowed and IV diphenhydramine was given with resolution of symptoms. During the following weeks, the infusions was run at a reduced rate and no further symptoms were observed. Two months later, there was an infusion-related reaction (IRR) with mottling of the skin, BP(193/115), HR, and trembling. The infusion was interrupted and IV diphenhydramine given. Since then the patient has received prednisolone 1mg/kg the day before infusion and solumedrol 1mg/kg immediately before infusion along with his other premeds. On one occasion he was extremely irritable, agitated and combative during an infusion for no apparent reason. VS were normal. There was no response to slowing of the infusion, IV diphenhydramine or diazepam. The infusion had to be terminated early. Except for that one occasion, he has done well. He has had a good response to ERT with increased activity, decreased diarrhea and decreased hepatosplenomegaly on PE.

Patients with MPS II with CNS involvement present unique challenges in administering ERT, including the fact that they are often non-verbal and cannot describe symptoms of IRR's. In addition, they may have problems with agitation and combativeness, requiring medication to make the infusion experience acceptable. In this case, we had difficulty initially distinguishing between the patient's situational hypertension and the hypertension accompanying his IRR. Nonetheless, we were able to overcome these hurdles to enable him to benefit from this important therapy.

Information Bottleneck Method for Biomedical Paper Clustering. *H. Siu[1], L. Jin[1], M. Xiong[1,2]* 1) Genetics, Fudan University, Shanghai, China; 2) Human Genetics Center, University of Texas, School of Public Health.

Biomedical literature on complex diseases dramatically grow day by day in the internet. Without automatic clustering the articles we will be lost in the huge biomedical literature. We apply Information Bottleneck Method in our research work, and find a good way to shorter time in identifying articles containing complex diseases, genes or markers. Our datasets are download from PubMed databse, we pick out five classes, every classes include 500,1000,2000 three levels articles, each of the accuracy is over 75%, when we pick out 10 classes of articles for the document clustering, accuracy is about 55%. We propose to use information bottleneck to cluster literatures. Our results show that it is possible to develop a method to automatic cluster biomedical articles and that a more powerful software can be design to classify these large data set by disease, genes and pathways, linking disease with pathways.

Rare Case of Siblings with Childhood Follicular Thyroid Neoplasia and a *PTEN* Promoter Deletion. *J. Stein[1], K. Zbuk[1], A. Stettner[2], D. Wargowski[2], C. Eng[1]* 1) Genomic Medicine Institute, Cleveland Clinic, Cleveland, OH; 2) Clinical Genetics Center, University of Wisconsin, Madison, WI.

Cowden syndrome (CS) is characterized by macrocephaly, cutaneous lesions, and an increased risk for breast, thyroid and endometrial neoplasia. About 85% of those with classic CS have detectable *PTEN* mutations. Promoter mutations are detected in approximately 10% of individuals with CS without an identifiable mutation in the *PTEN* coding region. We report a family with a unique promoter deletion (-1087~ -1062 del 26) detected in three generations. A 9-year-old girl presented with follicular thyroid cancer, and subsequently her sister was diagnosed with a follicular thyroid adenoma at age 6; both carried the promoter deletion. Recent data from the largest cohort of patients with CS has shown a mean age of 31 at thyroid cancer diagnosis, 10-20 years younger than sporadic cases. Additionally, the 40-year-old father tested positive. Previously considered asymptomatic, the father was evaluated further and consequently underwent total thyroidectomy, which revealed extensive adenomatous nodules. The paternal grandfather underwent partial thyroidectomy at age 19 for multiple nodules and also tested positive. *PTEN* promoter point mutations were previously found to have a mild phenotype as defined by number of organ systems involved, but with considerable risk of breast and thyroid cancers. As no other features of CS have been described in this family, only the thyroid appears to be involved. NCCN guidelines for CS recommend annual comprehensive physical examination and consideration of baseline thyroid ultrasound starting at age 18 for most families, but additionally recommend physical examinations 5 years younger than the youngest age of diagnosis. This family illustrates the importance of providing personalized healthcare in the context of the family, as screening should begin in the first year of life in this case. Furthermore, if specific *PTEN* mutations provide evidence for childhood onset cancer, this could have important medical surveillance implications for a subset of families.

Sequence analysis of small non-coding RNAs present in preimplantation mouse embryos. *Y. Ohnishi[1,2,4], A. Toyoda[3], Y. Sakaki[3], K. Tokunaga[1], H. Hohjoh[2]* 1) Department of Human Genetics, Graduate School of Medicine, Univ. Tokyo, Tokyo, Japan; 2) National Institute of Neuroscience, NCNP, Tokyo, Japan; 3) RIKEN Yokohama Institute, Yokohama, Japan; 4) JSPS Research Fellow.

Small non-coding RNAs (18-30 nucleotides in length) including small interfering RNAs (siRNAs) and microRNAs (miRNAs) are thought to play an essential role in biological functions related to development, differentiation and proliferation. Recent studies suggested that such small-sized RNAs most likely contributed to gametogenesis and embyogenesis in vertebrates. In this study, we focused on the early development of mouse embryos and investigated small-sized RNAs present in the course of the development of the mouse preimplantation embryos. We cloned and sequenced small-sized RNAs isolated from unfertilized mouse eggs, morula-stage embryos (2.5 d.p.c.) and blastocysts (3.5 d.p.c.). A total of 2880 clones derived from the mouse eggs and embryos were isolated and sequenced. After annotation of the clones, we found that 531, 342 and 490 clones isolated from unfertilized mouse eggs, morula-stage embryos, and blastocysts, respectively, were mapped to the mouse genome. In addition, 20 clones (4%) derived from 19 miRNA genes, 19 clones (6%) from 9 miRNA genes, and 239 clones (49%) from 54 miRNA genes were detected in unfertilized mouse eggs, morula-stage embryos, and blastocysts, respectively. Interestingly, we noticed that there was a difference in size population of the cloned sequences among the three stages. The small-sized RNA clones in unfertilized eggs and blastocysts appeared to have a peak around 21-24 nucleotides in length, which were similar to those of repeat-associated siRNAs (rasiRNAs) and microRNAs. In contrast, the small-sized RNA clones in morula-stage embryos displayed a bimodal distribution peakede around 20-24 nucleotides and 30 nucleotides in length. Altogether, the data present here suggest that a dramatical alteration of small-sized RNA molecules most probably occurs in the course of the mouse preimplantation embryos.

The quantification of the allelic variations of gene expression in peptidylarginine deiminase type 4 (PADI4). *A. Suzuki[1], Y. Kochi[1], K. Kobayashi[1], R. Yamada[1, 2], M. Mori[3], K. Yamamoto[1, 3]* 1) SNP Research Ctr, RIKEN, Yokohama City, Kanagawa, Japan; 2) Human Genome Center, The Institute of Medical Science, The University of Tokyo,Minato-ku, Tokyo, Japan; 3) Department of Allergy and Rheumatology, Graduate School of Medicine, the University of Tokyo, Bunkyo-ku, Tokyo, Japan.

Multiple studies have shown that human single nucleotide polymorphisms (SNPs) affect gene regulation, resulting allelic imbalances of gene expression. The finding of these regulatory SNPs leads to understanding phenotypic diversity and the identification of alleles that modify disease risks. Therefore, it is important to quantify the allelic variations of gene expression in vivo for identification of regulatory SNPs. Monitoring of these variations is possible in tissues and cells of heterozygous individuals using informative markers within the genes. For measurement of these variations, we performed TaqMan real-time RT-PCR system using cDNA from tissues or cell lines of heterozygous individuals. In this study, we examined allele-specific gene expression in PADI4, which was reported to be associated with rheumatoid arthritis (RA), and of which allelic imbalances of the gene expression were observed. We used TaqMan probes, rs11203366 (G/A) as a marker located in exonic region of PADI4. We measured the signal intensity using cDNA and DNA from heterozygous individuals, and we calculated allele-specific gene expression ratio. We also indicated that two major haplotypes with 4SNPs in PADI4 exonic region including rs11203366 were different stability in vitro and in vivo. We performed the gene expression analysis using cDNA from peripheral blood leukocyte of each genotype individuals and showed that PADI4 expression actually was different in peripheral blood leukocytes with each genotype. These data supported the hypothesis that expression levels of PADI4 are associated with RA susceptibility1, 2 . 1) Nat. Genet. 2003, 34:395-402, 2) Nat. Genet. 2003, 37:478-485.

Multi-plexed TaqMan-based miRNA Profiling of Cancer and Stem Cells. *Y. Wang[1], C.Y. Park[2], I.L. Weissman[2], J. Weidhaas[3], O. Loudig[4], R. Tan[1], C. Chen[1]* 1) Molecular Biology, Applied Biosystems, Foster City, CA; 2) Stanford Institute for Regenerative Medicine and Stem Cell Biology, Stanford University, Palo Alto, CA; 3) Yale University School of Medicine, New Haven, CT; 4) Albert Einstein College of Medicine, Bronx, NY.

Developing microRNA (miRNA) profiling strategies that are efficient and quantitative has proven to be challenging because of their small sizes and the sequence similarity among family members. We have developed multi-plexed TaqMan-based MicroRNA Assays and TaqMan Arrays that provide simple, rapid, quantitative and sensitive tools for miRNA profiling. We have applied such strategy to profile expression of 366 miRNAs in seven breast cancer cell lines as well as paired samples derived from FFPE and fresh frozen breast tumor tissues. Unsupervised hierarchical analysis separated the stromal-derived and luminal epithelial-derived breast cancer cell lines into two distinct groups. Cell-type specific miRNA signature includes miR-200, miR-203 and miR-222 etc, representing potential miRNA biomarkers for characterization of sub-types of breast cancer. In addition, the FFPE sample showed similar miRNA profiles as the paired freshly frozen samples, demonstrating our miRNA profiling strategy can be successfully applied to analyze archived FFPE samples. Coupled with multiplex preamplification, the sensitivity of the multi-plexed TaqMan-based miRNA assays can be further extended to quantifying single or very few cells. We demonstrated the application of this method in studying the development of human hematopoietic stem cells (HSC). We have evaluated the expression profile of 315 human miRNAs using FACS-purified normal human bone-marrow derived HSC and three committed progenitor populations. Distinct miRNA signatures were identified that distinguish each of these cell populations. Characterization of these candidate miRNAs may lead to better understanding of the regulatory roles of miRNAs in development of hematopoiesis.

Molecular cytogenetic characterization of cryptic chromosomal abnormalities in infants and children with Congenital anomalies. *S.K. Murthy[1], A.K. Malhotra[1], P.S. Jacob[1], S. Naveed[1], E.E. Al Rowaished[1], S. Mani[1], S. Padariyakam[1], S.A.H. Al Banna[1], A. Ridha[2], M.T. Al Ali[1]* 1) Molecular Cytogenetics unit, Genetics Department, Al Wasl Hospital, DOHMS, Dubai, U.A.E; 2) Department of Pathology, Dubai Hospital, DOHMS, Dubai, U.A.E.

Congenital anomalies contribute to a significant proportion of infant morbidity and mortality. It affects 3-7% of all live born (new born to five years of age). 10-15% of them are due to chromosomal reasons, which is one of the major cause of congenital anomalies. In Dubai, of the total 1246 referrals for cytogenetic testing during 2005 and 2006, 345 (27.68%) new born and pediatric children were referred for having multiple congenital anomalies(MCA) and/or dysmorphic features. Chromosome abnormalities were detected in 110/345 (31.88%) cases. Of all the abnormal cases, 82.73% were aneuploidies (trisomy 21, 13,18, Turner, Klinefelter) and the remaining 17.27% had unbalanced structural abnormalies . Majority of them were cryptic, which were identified and characterized by molecular cytogenetic techniques - fluorescence in situ hybridization (FISH) and microarray (oligo array-CGH). Such cryptic abnormalities are normally missed by the routine cytogenetic methods. Down syndrome and cryptic unbalanced chromosomal abnormalities are the major genetic causes of congenital anomalies in this referred population of Dubai. Significance of efficient genetic diagnosis, prenatal diagnostic services and genetic counseling is discussed.

FBN2, FBN1, TGFBR1, and TGFBR2 analyses in congenital contractural arachnodactyly. *N.M. Matsumoto[1,2], A.N. Nishimura[1], H.S. Sakai[1], H.S. Saitsu[1], T.M. Mizuguchi[1]* 1) Dept Human Genetics, Yokohama City Univ Grad Sch Med, Yokohama, Japan; 2) SORST, JST, Kawaguchi, Japan.

FBN2, FBN1, TGFBR1, and TGFBR2 were analyzed by direct sequencing in 15 probands with suspected congenital contractural arachnodactyly (CCA). A total of four novel FBN2 mutations were found in four probands (27%, 4/15), but remaining 11 patients did not show any abnormality in either of the genes. This study indicated that FBN2 mutations were major abnormality in CCA, and TGFBR and FBN1 defects may not be responsible for the disorder. FBN2 mutations were only found at introns 30, 31, and 35 in this study. Thus analysis of a mutational hotspot from exons 22-36 (a middle part) of FBN2 should be prioritized in CCA as previously suggested. Collaborating doctors are acknowledged: Drs. Shiro Ikegawa, Hiroshi Kitoh, Nobuyuki Haga, Satoshi Ishikiriyama, Toshiro Nagai, Fumio Takada, Takako Ohata, Fumihiko Tanaka, and Hotaka Kamasaki.

A case of spinocerebellar ataxia type 17 (SCA17) associated with homozygous 46/47 repeats of the TBP gene. *P. Tarantino[1], E.V. De Marco[1], F. Annesi[1], D. Civitelli[1], S. Carrideo[1], M. Caracciolo[1], E. Pisano[2], G. Annesi[1]* 1) Inst Neurological Sci, National Research Council, Mangone, Cosenza, Italy; 2) Neurology Unit, Annunziata Hospital-Cosenza, Italy.

Spinocerebellar ataxia type 17 (SCA17) is a dominant progressive neurodegenerative disorder, caused by a triplet repeat expansion within the TATA-binding protein gene (TBP); normal expansions range from 29 to 42 repeats, whereas abnormal expansions range from 43 to 63 repeats. A reduced penetrance is associated to 43-48 repeats. The disease is characterized by progressive limb and gait ataxia, dysarthria, motor, cognitive and psychiatric abnormalities. In this study, we describe a new homozygous SCA 17 patient from Southern Italy. We observed a patient, son of consanguineous parents, affected by autosomal dominant ataxia, pyramidal and extrapyramidal signs and peripheral neuropathy. He was investigated for repeat expansions in the genes of the spinocerebellar ataxias SCA1, SCA2, SCA3 SCA6, SCA7, SCA8, SCA12, SCA17 and DRPLA. Genomic DNA was amplified with fluorescent primers spanning the SCA expansions. PCR products were separated onto a capillary sequencer. We identified an abnormal CAG/CAA repeat expansion of 46/47 size, within the TBP gene, confirmed by direct sequencing. This is the third case of homozygous expansion described in a patient with SCA17. The first case reported, carrying a homozygous 47 repeat expansion, showed a very severe phenotype with a late onset but rapidly progressing ataxia associated with dementia caused by an apparent partial isodisomy 6. The second case, carrying a homozygous 48 repeat expansion, presented rapidly progressive dementia and chorea implying a HD-like disease. Moreover, previous studies report that homozygotes for SCA2, SCA3 and SCA6 disease show earlier onset and more severe manifestations than heterozygotes. Currently, clinical analysis of the patient and genetic and clinical analysis of other family members are ongoing to evaluate the genotype-phenotype correlation in this family. The addition of one more homozygous case is useful to clarify the molecular mechanisms underlying the gene dosage effects in the polyQ diseases.

G-463A myeloperoxidase polymorphism and Parkinsons disease. *F.E. Rocca[1,2], P. Tarantino[1], E.V. De Marco[1], D. Civitelli[1], I.C. Cirò Candiano[1], S. Carrideo[1], F. Annesi[1], G. Provenzano[1], V. Greco[1], V. Scornaienchi[1], G. Nicoletti[1,2], G. Annesi[1]* 1) Inst Neurological Sci, National Research Council, Cosenza, Italy; 2) Institute of Neurology, University Magna Graecia, Catanzaro.

Parkinson's disease (PD) is a neurodegenerative disorder characterized by a loss of substantia nigra pars compacta (SNpc) dopaminergic neurons, and can be modeled by the neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). A recent study shows that myeloperoxidase (MPO), a key oxidant-producing enzyme during inflammation, is upregulated in the ventral midbrain of human PD and in MPTP mice. Moreover was suggested that inhibitors of MPO may provide a protective benefit in PD. A functional G-463A polymorphism (SNP) in the promoter of the MPO gene is associated with a number of diseases with inflammatory components. In the present study we investigated the association of this SNP with Parkinsons disease. We analyzed 233 PD cases and 100 controls. All patients were screened for this SNP in the MPO gene promoter by combination of PCR and RFLP analysis. The PCR product was digested with AciI restriction enzyme. We did not find significant differences in allele or genotype distribution between PD cases and controls (p=1,00). The MPO gene encodes an antimicrobial enzyme that produces oxidative free radicals. It is normally not present in brain tissue but is expressed under pathological conditions. The signals responsible for the induction of this expression in the brain have not been elucidated. Genetic findings show that the less common A allele decreases myeloperoxidase expression, apparently by destroying a binding site for the transcription factor. The reactive oxygen species play an important role in PD and individual susceptibility to PD may be modulated by G-463A MPO SNP. The precision of our study is limited by small number of controls. Our preliminary data will be completed by increasing the number of the controls analysed to provide a more powered study. If we confirm the present results, we will successively performed an haplotype analysis based on polymorphic markers in the MPO gene promoter, to examine the involvement of a more extended region.

Molecular characterization of Leber congenital amaurosis in Korea. *M.W. Seong[1,2], S.Y. Kim[1], Y.S. Yu[3], J.M. Hwang[4], H.S. Ko[1], J.Y. Kim[1], S.S. Park[1]* 1) Department of Laboratory Medicine, Seoul National University College of Medicine & Seoul National University Hospital Clinical Research Institute, Seoul, Korea; 2) Department of Laboratory Medicine, National Cancer Center, Goyang, Korea; 3) Department of Ophthalmology, Seoul National University Hospital, Seoul, Korea; 4) Department of Ophthalmology, Seoul National University Bundang Hospital, Seongnam, Korea.

Leber congential amaurosis (LCA) is the most severe form of all the inherited retinal dystrophies leading to congenital blindness. LCA is genetically heterogeneous disorder as well as clinically. Although more than 8 genes have been identified with an association of LCA so far, these genes are estimated to account for about half of LCA. We performed the comprehensive mutation analysis of known LCA genes in 20 unrelated Korean patients. All exons and flanking regions were analyzed by direct sequencing for nine genes: the *AIPL1, CRB1, CRX, GUCY2D, RDH12, RPE65, RPGRIP1, LRAT and TULP1*. We identified 9 different mutations in six patients (31.6% of all cases): one frameshift, one nonsense, one splicing and six missense mutations. Seven except one nonsense and one splicing mutation were novel mutations. None of them was recurrent. Mutations were most frequent in the *RPGRIP1* (13.2%) gene, and followed by *RPE65* (5.3%) and *CRB1* (5.3%). Three patients were compound heterozygte harboring two different mutations. The other three patients were found to be single heterozygous for a missense mutation. All novel missense mutations were predicted to be harmful to protein structure or function by analysis of amino acid conservation, characteristics of substituted amino acid and protein structural information. Similar predictions were obtained by in-silico analysis softwares such as Polyphen, SIFT and PMut. These results showed severe genetic heterogeneity in Korean LCA patients and different mutation spectrum from previous reports, suggesting that different strategy might be applied to molecular diagnosis of LCA in Korea.

Parkin mutation analysis in patients with sporadic early-onset Parkinsons disease. *G. Provenzano[1], F. Annesi[1], M.T. Pellecchia[2], F.E. Rocca[1], E.V. De Marco[1], D. Civitelli[1], P. Tarantino[1], P. Barone[2], L. Morgante[3], M. Zappia[4], G. Annesi[1]* 1) Inst Neurol Sciences, National Research Council, Mangone, Cosenza, Italy; 2) Department of Neurological Sciences, University Federico II, Napoli, Italy; 3) Department of Neuroscience, Psychiatry and Anesthesiology, University of Messina, Italy; 4) Clinica Neurologica I, Department of Neuroscience, University of Catania, Italy.

Mutations in the parkin gene (PARK2) are responsible of familial autosomal recessive early onset (45 years) Parkinsons Disease (EOPD) and sporadic EOPD. Recently, a novel parkin mutation, consisting of a deletion of the promoter and exon 1 of parkin, was described in a family with autosomal recessive EOPD and in an isolated case with EOPD. The promoter region is shared by parkin and the neighboring parkin coregulated gene (PACGR). The aim of this study is to perform mutational analysis of the coding regions of the parkin gene in sporadic EOPD and subsequently to investigate whether rearrangements within both the shared promoter region and the parkin gene are present in the patients with only one or no mutations. A total of 53 index cases with sporadic EOPD from Southern Italy were screened for parkin mutation. DNA was exstracted from peripheral blood and each exon of parkin was amplified and sequenced. Absolute quantification was perfomed by real time PCR 7900 HT-SDS, using TaqMan probes for exons 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12 and shared promoter region. For exon 1 we utilized MGB (Minor Groove Binder) probes. Among 53 patients screened for parkin mutations, 8 carried single heterozygous mutations, 4 had simple homozygous mutations, 1 was a compound heterozygous and 40 had no mutations. Gene dosage experiment failed to reveal an exonic rearrangement of the parkin gene in patients with single heterozygous mutations. In our study the gene dosage of core parkin promoter is still in progress. The recent discovery of parkin promoter deletions has not only extended the spectrum of mutations in this gene but has also proved that deletions affecting the promoter should be looked for in patients with a single or no parkin mutation.

Genome-wide linkage analysis for circulating levels of inflammatory markers in the Quebec Family Study (QFS).

S.-M. Ruchat[1,5], J.-P. Després[2], S.J. Weisnagel[1,5], Y.C. Chagnon[3], C. Bouchard[4], L. Pérusse[1,5] 1) Social and Preventive Medicine, Laval University, Quebec, Quebec, Canada; 2) Quebec Heart Institute, Hopital Laval Research Centre, Quebec, Canada; 3) Laval University Robert-Giffard Research Center, Beauport, Quebec, Canada; 4) Human Genomics Laboratory, Pennington Biomedical Research Center, Baton Rouge, Louisiana, USA; 5) Lipid Research Center, CHUL Research Center, Quebec, Canada.

Background: Adipose tissue synthesizes and secretes a wide range of biologically active molecules considered as inflammatory markers which dysregulation in obesity plays a role in the development of insulin resistance and vascular disorders. Thus, finding genes that influence circulating levels of inflammatory biomarkers may provide insights into genetic determinants of obesity-related metabolic diseases. Objective: Search for genes influencing plasma levels of adiponectin (APM1), C-reactive protein (CRP), interleukin-6 (IL6) and tumor-necrosis factor-alpha (TNFA) through a genome-wide linkage analysis. Design: Fasting plasma levels of APM1, CRP, IL6 and TNFA were measured in 764 subjects from QFS. APM1, IL6 and TNFA were measured by ELISA (R&D System Inc., Minneapolis, Minnesota) and CRP by nephelometry (BN Prospec, Dade Behring). After log10 transformation, phenotypes were adjusted for age and sex and tested for linkage with a total of 443 markers using the Haseman-Elston method. A maximum of 393 sibpairs from 211 nuclear families were available for analyses. Results: The peak linkages were found on chromosomes 9q34.3 for APM1 (markerD9S158; nominal p-value = 0.000001), 12q24.2 for CRP (D12S375; 0.0004312), 17q11.2 for IL6 (D17S1294; 0.0000133) and 4p15.2 for TNFA (D4S2397; 0.0000122). Significant evidence of linkage ($p < 0.0001$) was also found on chromosomes 1p36.3 (D1S468; 0.0000305), 3q13.33 (D3S3023; 0.0000446), 14q32.2 (D14S1426; 0.0000097) and 15q21.1 (D15S659; 0.0000013) for APM1, 11q25 (D11S2359; 0.0000136) for IL6 and 5q35.3 (D5S408; 0.0000834) for TNFA. Conclusion: These results suggest that several QTLs can influence plasma levels of inflammatory markers. The genes underlying these QTLs need to be identified.

Exclusion of APC and VHL gene deletions by array based comparative hybridization in two patients with microscopically visible chromosomal aberrations. *G. A. Toruner[1,3], R. J. Wallerstein[2,3], S. Sklower Brooks[4], D. L. Streck[1,3], R. Kuravthi[2]* 1) The Center for Human and Molecular Genetics, UMDNJ-New Jersey Medical School, Newark, NJ 07103, USA; 2) Genetics and Genetic Counseling Program, Hackensack University Medical Center, Hackensack, NJ 07601; 3) Department of Pediatrics, UMDNJ-New Jersey Medical School, Newark, NJ 07103; 4) Department of Pediatrics and Obstetrics, Gynecology and Reproductive Sciences UMDNJ-Robert Wood Johnson Medical School, New Brunswick, NJ 08901.

Karyotyping is a major component of the genetic work-up of patients with dysmorphism. Cytogenetic aberrations, which are close to a known tumor suppressor gene, raise important clinical issues, since deletion of that tumor suppressor gene can cause genetic predisposition to cancer. We present two cancer-free dysmorphic patients with karyotypes of del 46,XX, del (5)(q15q22.3) and del 46,XX,del(3)(p25.2-pter). These deletions are close to the APC and VHL genes that confer susceptibility to Familial Adenomatous Polyposis (OMIM #17510) and Von-Hippel-Lindau syndrome (OMIM #193300) respectively. The array-CGH analysis using a custom Agilent 44K oligonucleotide array demonstrated an interstitial 20.7 Mb deletion on 5q (chr5: 89,725,638-110,491,345) and a terminal 9.45Mb deletion on 3p (chr3:pter-9,450,984). According to the March 2006 human reference sequence, the APC gene is located at chr5: 112,101,483-112,209,835 and the VHL gene is located at chr3: 10,158,319-10,168,746. These results indicate that the APC gene is 2,300 kb and VHL gene is 700 kb away from the respective deletion. Southern blot analysis for APC and VHL genes were negative, consistent with array-CGH findings. These results demonstrate the power of array-CCH for the assessment of potential tumor suppressor gene involvement and cancer risk in patients with microscopically visible deletions in areas near tumor suppressors.

PINK1 mutations and the risk of Parkinsons disease in family members of Southern Italy. *V. Scornaienchi[1], I.C. Cirò Candiano[1], D. Civitelli[1], S. Carrideo[1], F. Annesi[1], P. Tarantino[1], F.E. Rocca[1], E.V. De Marco[1], G. Provenzano[1], G. Nicoletti[1], G. Salemi[2], P. Ragonese[2], V. Terruso[2], M. D'Amelio[2], G. Savettieri[2], G. Annesi[1]* 1) Institute of Neurological Sciences, National Research Council, Piano Lago di Mangone, Cosenza, Italy; 2) Department of Clinical Neurosciences, University of Palermo, Italy.

Mutations in the PTEN-induced kinase 1 (PINK1) gene have been identified in recessively inherited and sporadic early-onset parkinsonism (EOP). The PINK1 gene comprises 8 exons and codes for a 581 amino acid protein (PTEN-induced kinase 1 protein) with a catalytic serine/threonine kinase domain. Functional studies have shown that PINK1 protein may have a neuroprotective role as wild-type PINK1 protects cells against proteasomal inhibition. This protective effect is abrogated by mutations in the PINK1 gene. Herein we investigated a possible association of PINK1 gene mutations in Southern Italy family members with monogenic parkinsonism. 14 family members diagnosed for PD were investigated for the presence of PINK1 mutations. Of them, 5 participants had EOP (mean age at onset 36 years); the remaining 9 had familial late-onset disease (mean age at onset 65 years). DNA was extracted from blood samples following standard procedures. All eight PINK1 exons were amplified by PCR with primers flanking intronic sequences. Sequencing was performed using BigDye Terminator V.1.1. We characterize a novel homozigous mutation (889delG, D297fsX318) in the exon 4 of PINK1 gene occurring in a patient with familiar EOP. None of the other examined patients carried homozygous or heterozygous mutations. We also identified known polymorphic intronic and exonic variants, although none seemed to be associated with disease risk. In conclusion, PINK1 mutations are rare in our Southern Italy patients with EOP and familial Parkinsons disease. However, we found a novel homozigous deletion (889delG, D297fsX318) that causes a premature stop codon and a protein lacking in most of the kinase catalityc domain confirming that recessive mutations in PINK1 might increase the risk of developing PD.

Association of 1494del6 polymorphism of Thymidylate Synthase gene (TYMS) in colorectal cancer of Mexican population. *V. Peralta[1], G. Morgan[2], M.P. Gallegos[1]* 1) Medicina Molecular, CIBO, Instituto Mexicano del Seguro Social, Guadalajara, Guadalajara, Mexico; 2) Departamento de Radiodiagnostico, UMAE, CMNO, IMSS.

The polymorphism 1494del6 of Thymidylate Synthase gene (TYMS) has been associated with decreased levels of mRNA in patients with colon cancer. In this study has been determined the frequency 1494del6 polymorphism of the TYMS gene and it association with colon cancer in patients and controls of Mexican population. DNA of 317 patients and 200 controls was extracted. PCR fragment of 152pb was amplified and were digested with DraI, the products were separated on a 8% polyacrylamide gel. The genotypic frequency in patients and controls for the wild-type genotype was of 56% and 46%; heterozygotes of 27% and 43%; and homozygous was 17% and 11% respectively. When the statistical analisis were performance, not significant differences was observed ($p<0.05$). However, when was compared both groups by sex distribution, we observed that female gender showed association with genotype 1494del6, with OR 2.16(95% CI;1.07-4.53). The polymorphism 1494del6 of TYMS gene was associated with female colon cancer.

Congenital absence of teeth in families. *E. Severin, C. Albu, D.F. Albu, R. Purcarea* Dept Human Genetics, Carol Davila Univ Med Pharm, Bucharest, Romania.

Background - Congenital absence of permanent teeth is a genetic condition which tends to run in families because relatives share genetic material. Objectives - to analyze the pattern of familial hypodontia and to find evidence that mutation of PAX9 gene may cause some family members to be at risk for hypodontia. Setting and sample population - the study was conducted in two families with non-syndromic hypodontia in successive generations. Methods - The diagnosis of hypodontia has been made by clinical and radiographic examinations. A pedigree analysis was performed to determine the pattern of inheritance of the hypodontia phenotype. For DNA analysis, blood samples were collected and isolated DNA was analyzed by PCR. Results - The parents and their siblings did not share similar pattern of hypodontia with regard to the tooth class, region, symmetry and number of teeth involved. In the families, hypodontia followed a similar pattern of inheritance: autosomal-dominant with variable expression and reduce penetrance. Our study failed to confirm the association between the presence of a certain mutation in PAX9 and the resulting pattern of hypodontia as previously suggested some studies. Conclusions - The individual analyses of cases showed great diversities in the hypodontia pattern and degree of severity. Parents, sibs and other family members showed different clinical features of congenital absence of teeth. The cause of severe hypodontia cases - missing both frontal and back teeth - is not explained by PAX9 mutations.

Investigating Linkage to Chromosome 10 in Familial Interstitial Pneumonia (FIP). *A.L. Wise[1,3], M.C. Speer[3], M.P. Steele[3], L.H. Burch[1], A. Herron[3], J.E. Loyd[4], K.K. Brown[5,6], J.A. Phillips III[4], S.H. Slifer[3], M.I. Schwarz[5,6], D.A. Schwartz[1,2]* 1) National Institute of Environmental Health Sciences, Research Triangle Park, NC; 2) National Heart, Lung, and Blood Institute, Bethesda, MD; 3) Duke University, Durham, NC; 4) Vanderbilt University School of Medicine, Nashville, TN; 5) National Jewish Medical and Research Center, Denver, CO; 6) University of Colorado Health Sciences Center, Denver, CO.

The Idiopathic Interstitial Pneumonias (IIPs) are complex conditions, with limited treatment options and unknown etiology. Through a whole genome microsatellite screen for FIP (the familial form of IIP), two regions of interest on chromosome 10 (maximum multipoint LOD score 2.3) and chromosome 11 (LOD score 3.0) were identified. Given the complex nature of both IIP and FIP, we sought to determine if accounting for the chromosome 11 locus and/or phenotypic classification could improve evidence for linkage to chromosome 10. To begin with, families were classified into two phenotypic groups: homogeneous families, with only idiopathic pulmonary fibrosis (IPF) (N=42), and heterogeneous families, with multiple IIP phenotypes including at least one case of IPF (N=40). After phenotypic stratification, ordered subset analysis (OSA) was performed using chromosome 11 family-specific LOD scores as the covariate. Fine-mapping of chromosome 10 revealed 2 linkage peaks in all 82 families strongly defined by phenotypic classification upon stratification (LOD scores 1.5 and 2.1). Homogeneous families showed evidence of linkage to the centromeric peak (LOD score 1.8), while heterogeneous families exhibited evidence of linkage to the telomeric peak (LOD score 1.6) as well as a third peak seen in only the heterogeneous families (LOD score 1.7). Applying OSA, lower chromosome 11 family-specific LOD scores also maximized linkage to chromosome 10 within a subset of 39 of the 82 families (LOD score 3.3, p=0.01) and 22 of the heterogeneous families (LOD score 3.6, p=0.006). Thus, our investigations support possible genetic heterogeneity within FIP, with evidence for linkage to chromosome 10 strengthened in families with lower chromosome 11 LOD scores and a heterogeneous phenotype.

Genetic analysis of sporadic and familial ataxia in Wales. *E. Majounie[1], M. Wardle[1], M. Muzaimi[1], W. Cross[1], H.R. Morris[1], N. M. Williams[2], N.P. Robertson[1]* 1) Department of Neurology, Cardiff University, Cardiff, United Kingdom; 2) Department of Psychological Medecine, Cardiff University, Cardiff, United Kingdom.

Autosomal dominant cerebellar ataxias (ADCAs) are a clinically and genetically heterogeneous group of neurodegenerative disorders. To date, 13 autosomal dominant ataxia genes have been identified from familial studies. However, the majority of cases of adult onset ataxia are sporadic. Our aim was to determine whether non-pathogenic repeat length size influences the risk of ataxia. We used a fluorescent PCR approach using both flanking and intra-repeat primers, to analyze 10 candidate genes (SCA1, SCA2, SCA3, SCA6, SCA7, SCA8, SCA10, SCA12, SCA17, DRPLA) in 112 sporadic ataxia patients, 26 unrelated patients with a family history of ataxia and 306 Welsh Caucasian blood donor controls. Patients with pathogenic SCA or DRPLA expansions were excluded, and we identified SCA6 and DRPLA as the two commonest causes of ADCA in Wales. We observed that the distribution of the larger normal allele (top 10%) in the Welsh population was similar to that previously reported in other Caucasian populations. Generally, the alleles most commonly represented in other Caucasian groups were also most common in the Welsh population. For each of the repeat expansion genes, there was no difference between repeat lengths in cases and controls, for either familial or sporadic ataxia cases. Testing for an additive effect of CAG repeats from the different genes also showed no difference between the cases and controls. Of note however, the proportion of DRPLA alleles over 19 repeats in the Welsh control samples reached 4.2% (13/306). While not as high as that reported in the Asian population (7.4%), this proportion considerably differs from that found in North American Caucasian populations (0%) and corresponds to a high prevalence of DRPLA amongst Welsh ADCA families. In conclusion, large normal repeat expansion size in known ataxia genes is not a risk factor for ataxia in the Welsh population.

Identification of chromosomal rearrangements in children with mental retardation by CGH and FISH. *R. Ruiz-Esparza, A.C. Velazquez-Wong, C. Hernandez-Huerta, M.C. Palacios-Reyes, D. Arenas-Aranda, M.A. Araujo-Solis, F. Salamanca-Gomez* Unit of Investigation In Human Genetics, Instituto Mexicano del Seguro Social, Mexico City, Mexico.

Introduction: Mental retardation (MR) is the most common handicap in childhood, affecting about 3% of the general population. The etiology of MR is unexplained in 30-50% of all cases. Researchers have identified multiple causes including genetic disorders, environmental factors, traumatic accidents, prenatal events such as maternal infection or exposure to alcohol. It has been estimated that chromosomal anomalies account for 4-28% of cases of MR. Recent advances in cytogenetics have shown that subtelomeric rearrangements are involved in 5-7.4% of cases of MR, being deletion 1p36 the most frequent chromosomal rearrangement. In this work, children with idiopathic mental retardation were studied utilizing a FISH assay to detect deletion 1p36 and CGH to identify chromosomal rearrangements. Methods: 55 children with MR were screened using a multicolor FISH assay using probe 1p36 (D1Z2) developed at LLNL, and 11 of them were also analyzed by CGH. A peripheral blood sample was obtained from every patient and lymphocytes cultures were used to obtain metaphase chromosome spreads to perform the FISH assay. A blood sample was also used to obtain total genomic DNA to carry out CGH. At least 25 metaphases were analyzed for each patient for each methodology. Results: CGH results revealed one patient with a deletion in the region 8q24.3. Interestingly, FISH assay did not showed any patients with deletion 1p36. Discussion: These results confirm that the application of molecular cytogenetic methods opens up a promising way to identify chromosomal rearrangements and, therefore genes related to the etiology of MR. This work was conducted with support from the Instituto Mexicano del Seguro Social and Conacyt 2005-01-13947.

Assessment of Liquid Microbead Arrays for the Newborn Screening of Spinal Muscular Atrophy. *R.E. Pyatt, D.C. Mihal, T.W. Prior* Dept Pathology, Ohio State Univ, Columbus, OH.

Spinal muscular atrophy (SMA) is common neurodegenerative disorder with an incidence of 1 in 6,000 births. Ongoing clinical trials are evaluating therapeutic agents, and recent reports have suggested that motor denervation occurs within weeks of birth especially for the most severely affected. The success of these agents depends on identifying individuals as early as possible in order to begin treatment before irreversible neuronal loss. Identification during the newborn period can only be accomplished by direct DNA testing since SMA has no biochemical marker. DNA analysis has been described as the next innovation in newborn screening, but currently in the United States it is used primarily for reflex testing. The object of this study was to validate liquid microbead arrays for the identification of affected individuals by direct DNA analysis. Assays were created to detect the homozygous deletions in SMN1 exon 7 found in approximately 95% of affected individuals using two different microbead chemistries on the Luminex 200: MultiCode-PLx and Tag-It. A series of 367 blood spots including 164 affected, 46 known carrier, and 157 unaffected individuals were then analyzed with each assay. The MultiCode-PLx assay required 4.2 hours and provided correct identification of all 164 affected samples demonstrating 100% sensitivity. Correct exclusion was also made for all 46 carrier and 157 unaffected samples demonstrating 100% specificity. Conversely, the Tag-It assay required 6.8 hours and demonstrated 100% sensitivity and 99.5% specificity. A single false positive sample was observed with the Tag-It chemistry which upon repeat analysis presented values for SMN1 exon 7 which were intermediary between unaffected and affected samples. Neither chemistry displayed sensitivity to increasing copy numbers of the SMN2 pseudogene. Both chemistries showed high levels of sensitivity and specificity for the detection of SMA affected patients. Furthermore ample DNA was extracted from all bloodspots for analysis and SMN2 levels did not interfere with either assay. Liquid bead arrays represent a robust methodology for DNA analysis in newborn screening laboratories.

Genetic defects in patients with X-linked Lymphoproliferative Syndrome in North American. *K. Zhang[1], JA. Johnson[1], J. Villanueva[2], B. Tinkle[1], J. Bleesing[2], AH. Filipovich[2]* 1) Division of Human Genetics, Cinncinnati Children's Hosp, Cincinnati, Ohio, USA; 2) Division of Hematology /Oncology, Childrens Hospital Medical Center, Cincinnati, Ohio, USA.

X-linked Lymphoproliferative Syndrome (XLP) is an immunodeficiency disorder, characterized by fatal infectious mononucleosis, hypogammaglobulinemia, lymphohistiocytosis and B-cell lymphomas. Historically, mutations in the signaling lymphocyte activation molecule (SLAM)-associated protein SAP (SH2D1A gene) have been associated with XLP. More recently, a study of 18 XLP families from a French group reported mutations in the X-linked inhibitor-of-apoptosis XIAP (BIRC4) gene. The mutation spectrum of BIRC4 gene in XLP patients in the North American is not known. In the last three year, we tested more than 200 patients with suspected clinical diagnoses of XLP. We identified 41 patients who were hemizygous for mutations in the SH2D1A gene, of which 12 are previously unreported novel mutations. Interestingly, gross deletions involving one or multi exons, account for more than 30% of the mutations found in SH2D1A. SAP protein analysis by flow cytometry was also performed whenever the sample is available for testing. Very good correlation was observed between the type of mutation and the level of SAP expression. However, the correlation between the genotype of SH2D1A gene and the disease phenotype is much more complex. The type of mutation itself can not predict the course and severity of the disease. We also tested 20 XLP patients who have normal SH2D1A analysis for the presence of BIRC4 mutations. We found two patients who carried gross deletions in BIRC4 gene. Both patients have hepatosplenomegaly, one patient has had a liver transplant, and the other will undergo HCST. Our findings highlight the importance of molecular diagnosis in patients with XLP especially the great indication for their family members with atypical late onset XLP. Farther elucidation of the molecular basis for XLP will continue to provide an expanded understanding of the immune systems role in responding to EBV infection and the biological function of SAP and XIAP in adaptive immune responses and development.

Atypical 22q11.2 Deletions - What Have We Been Missing? *D. McDonald-McGinn[1], S. Saitta[1], C. Catania[1], P. Kaplan[1], J. Coppinger[2], L. Shaffer[2], B. Emanuel[1], E. Zackai[1]* 1) Div Human Gen, Children's Hosp Philadelphia, Philadelphia, PA; 2) Signature Genomics, Spokane, WA.

The majority of patients with a 22q11.2 deletion have the same large >3Mb/A-D deletion identified using N25/TUPLE probes. Nonetheless, there is significant inter & intra familial variability with minimal evidence of genotype-phenotype correlations. In addition, many patients are referred with clinical symptoms of the deletion whose FISH studies are negative. We identified 7 patients with atypical deletions using research probes or clinical CGH. These include one with pulmonary valve stenosis, cleft palate, scoliosis, feeding difficulties, developmental delay & dysmorphia with a 2.6 Mb/midA-D deletion including UFD1L & TBX1 & another with recurrent URIs, VPI, developmental delay, & dysmorphia with a 1.4 Mb/midA-C deletion including TBX1. Both were studied using research probes as the patients clearly had clinical features of the deletion. In addition, 3 others, including one with cleft palate, developmental delay & dysmorphia; another with FTT, microcephaly, aplasia cutis congenita, feeding difficulties & developmental delay; & another with microcephaly, a preauricular tag, micrognathia, dysphagia, & polymicrogyria all had a B-D deletion distal to TBX1 using CGH. Lastly, one patient with scoliosis, speech delay/hypernasality, OCD, and dysmorphia had a C-D deletion and an infant with preauricular tags, VSDs, and dysmorphia had a midE-midF deletion just beyond the classic 22q11.2 deletion region using CGH. So, in summary, we have identified 7 patients with atypical 22q11.2 deletions whose diagnoses would have been missed using conventional FISH. Thus, other individuals with findings ordinarily associated with the deletion may in fact have atypical deletions requiring alternative methods of identification such as CGH. Conversely, a new subset of patients is being elucidated via CGH & although the clinical findings in this latter cohort are variable, not unlike the patients with the standard deletion, these individuals will likely be key in advancing the search for genotype-phenotype correlations & in providing answers to the question What have we been missing?.

The efficacies of clozapine and haloperidol on refractory schizophrenia are related to DTNBP1 variation. *L. Zuo[1,2], X. Luo[1,2], R.A. Rosenheck[1,2], J. Krystal[1,2], J. Cramer[1,2], D.S. Charney[3], J. Gelernter[1,2,4,5]* 1) Dept Psychiatry, Yale Univ Sch Medicine, West Haven, CT; 2) VA CT Healthcare System, West Haven, CT; 3) NIMH (DSC), Bethesda, MD, USA; 4) Dept Genetics, Yale Univ Sch Medicine, West Haven, CT; 5) Dept Neurobiology, Yale Univ Sch Medicine, West Haven, CT.

The prototypical atypical antipsychotic agent clozapine is more efficacious for refractory schizophrenia than the typical antipsychotics, but the mechanism is still under investigation. Since 2002, at least 18 association studies have demonstrated that the DTNBP1 is involved in the cause of schizophrenia. Thus, the DTNBP1 product is hypothesized to be the potential target of antipsychotics. The present study aimed to investigate the relationship between the DTNBP1 and the effects of clozapine and haloperidol on refractory schizophrenia. One thirty-nine patients with refractory schizophrenia were assigned to clozapine (n=62) or haloperidol (n=77) and followed for 3 months. Symptom improvement was evaluated by total PANSS score. Six markers at DTNBP1 and 38 ancestry informative markers (AIMs) were genotyped in all subjects. The relationships between the effects of antipsychotics and the diplotypes, haplotypes, genotypes, and alleles of DTNBP1 were tested by ANCOVA, ANOVA, and t-test. The results show that the patients with diplotype ACCCTC/GTTGCC, genotypes T/T+T/C, or allele T of marker P1333 have better response to clozapine (0.005p0.029), but the patients with diplotype ACCCTC/GCCGCC, genotype A/G, or allele A of marker P1583 have better response to haloperidol (0.007p0.080), in European-Americans, African-Americans, or the combined sample. The present study demonstrated that the DTNBP1 gene modulates the effects of both the atypical antipsychotic clozapine, and the typical antipsychotic haloperidol. Subjects with different DTNBP1 diplotypes, haplotypes, genotypes, or alleles may have different responses to these antipsychotics. Clozapine and haloperidol may have different pathways or efficacy although both are related to DTNBP1.

Flow cytometric study of leukocytes and cell markers from Fabry disease patients. *P. Rozenfeld[1,3], E. Agriello[2], P. Martinez[2,3], N. De Francesco[1], I. Kisiniovsky[3], C. Fossati[1]* 1) LISIN (Immunolgia), Univ Nacional de La Plata, Buenos Aires, Argentina; 2) 2Servicio de Hematología, Hospital Penna, Bahía Blanca, Argentina; 3) 3AADELFA (Asociación Argentina de Fabry y otras enfermedades lisosomales).

There is much evidence linking glycolipids with the immune system. However, studies of immune cells and molecules in glycolipidosis are scarce, specially in Fabry disease. Aims: To analyze whether the disorder of glycolipid catabolism in Fabry patients is associated with changes in leukocyte subpopulations and their cell markers. Methods/Patients: nine Fabry patients were included in the study, 4 pediatric (median age=10 years) and 5 adults (median age=43 years). Four of the patients were on ERT with agalsidase alfa. Whole peripheral blood samples from Fabry patients and 3 normal controls were used for flow cytometric analysis, using the following monoclonal antibodies: CD4-FITC, CD8-PE, CD3-PerCP, CD56+16-PE, CD19-PerCP, Lin1-FITC, CD14-FITC, CD31-PE, CD1d-PE, TCR V24-FITC, CD77-FITC (intracellular staining). Results: The percentages of T and B lymphocytes were within the normal range. A significantly reduced percentage of NK ($p=0.0005$) and dendritic cells ($p= 0.038$) was observed, as compared to controls. ERT treated patients showed a higher level of V24+ cells compared to non treated Fabry patients ($p=0.049$) and controls ($p=0.045$). CD31 expression was lower in granulocytes, monocytes and lymphocytes, being statistically significant in the latter population ($p= 0.0058$). However, no difference was observed in CD38 expression in any subpopulation. Cell surface expression of CD1d showed lower levels in Fabry patients when compared to the control group ($p<0.001$). On the contrary, HLA-DR expression was elevated ($p= 0.01$). Intracellular content of Gb3/CD77 was also analyzed and increased amounts of Gb3 was detected in monocytes ($p=0.001$), lymphocytes ($p= 0.02$) and granulocytes ($p=0.033$). Conclusions: These results suggest that glycolipid disorders may cause changes in leukocyte populations and in expression of cell markers.

Identification of four novel mutations determined EDA gene as one of the major defects for sporadic non-syndromic oligodontia. *S-J. Song[1,2], D. Han[2], M. Yan[1,2], H-L. Feng[2], N. Zhong[1,2,3]* 1) Peking University Center of Medical Genetics, Beijing, China; 2) Peking University Health Science Center, Beijing, China; 3) New York State Institute for Basic Research in Developmental Disabilities, Staten Island, NY.

Recently mutations in the EDA gene have been shown to result in non-syndromic hypodontia in two families inherited in an X-linked recessive manner. It is noteworthy that all affected males exhibited oligodontia (congenital absence of six or more permanent teeth, third molars excluded) in these families. To determine the prevalence of EDA mutations in sporadic non-syndromic oligodontia, we investigated 14 unrelated male probands and their familial members. Mutation screening of the EDA gene was performed by direct sequencing of eight PCR fragments, which spun the entire exons and intron-exon junctions with more than 100 bp. Analyses of the complete coding region of the EDA gene identified four novel missense mutations, Ala259Glu, Arg289Cys, Arg334His and Thr338Met. These mutations account for 37% (5 out 14) of probands we studied, indicating that EDA is a major gene involved in genetic defects of sporadic congenital oligodontia. Our results provided evidence that for non-syndromic sporadic oligodontia, genetic defects in EDA gene should be considered in order to facilitate clinical diagnosis and genetic counseling.

Lack of association between genotypes or haplotypes of ADRB2 and Juvenile Idiopathic Arthritis. *G. Pont-Kingdon[1], K. Sumner[1], B. Clifford[3], A. Whiting[3], E. Lyon[1,2], J. Bohnsack[3], S. Prahalad[3]* 1) Institute for Clinical and Experimental Pathology, ARUP Laboratories, Salt Lake City, UT; 2) Pathology Dept, University of Utah, Salt Lake City, UT; 3) Pediatrics Dept, University of Utah, Salt Lake City, UT.

The 2 adrenergic receptor (2-AR) is present in numerous cell types and ADRB2 polymorphism(s) has been associated with asthma severity, response to beta agonist drugs, and rheumatoid arthritis (RA). The 2-AR has also been shown to contribute to the initiation and progression of joint damage in animals with experimental arthritis.. Our objective was to investigate ADRB2 variants for association with juvenile idiopathic arthritis (JIA) or major JIA subtypes. SNPs at position 46 and 79 result in substitution of glycine to arginine at position 16 (G16R), and of glutamine to glutamic acid at position 27 (E27Q). Both of these have been shown to have functional consequences. ADRB2 haplotypes were established in a cohort of 348 children with JIA and 448 autoimmunity free controls matched for ethnicity by direct molecular haplotyping using melting-curve analysis of a fluorescently labeled loci-spanning probe (LSProbe) that analyzed both SNPs simultaneously. Both ADRB2 SNPs were in Hardy-Weinberg equilibrium among controls. The minor allele frequencies in the controls at positions 16 and 27 were 36.7 % and 41.1% respectively. No association was found between JIA and the genotypes of the 2 ADRB2 SNPs as well as ADRB2 haplotypes. Specifically the haplotype that demonstrated a strong association with RA (R16-Q27) was not associated with JIA (36.7 % among cases, 38.3% among controls). Furthermore none of the variants demonstrated association after stratification by JIA subtypes, including the rheumatoid factor positive polyarticular JIA, although the number of patients with this subtype (~9%)was underpowered to replicate results in adults with RA. Our results indicate that ADRB2 variants are not associated with JIA or major JIA subtypes. These observations suggest that although they share several clinical and pathological features, JIA and RA have unique genetic associations.

Detection of deletion and duplication of dystrophin gene with MLPA in a subset of Chinese DMD/BMD patients.

X-Z. Wang[1,2], Z. Wang4[4], M. Yan[1,2], S-J. Song[1,2], Y-Z. Zhang[1,2], J-H. Zou[1,2], S-Z. Huang[4], T.J. Chen[5], N. Zhong[1,2,3] 1) Peking University Center of Medical Genetics, Beijing, China; 2) Peking University Health Science Center; 3) New York State Institute for Basic Research in Developmental Disabilities, Staten Island, NY; 4) Peking Union Medical College, Beijing, China; 5) University of South Alabama, Mobile, AL.

Duchenne muscular dystrophy (DMD) and Becker muscular dystrophy (BMD) are common X-linked recessive neuromuscular degeneration diseases. DNA rearrangement including deletion and duplication was determined as the major mutation underlying the DMD/BMD. To further investigate the details of deletion and duplication, we applied multiplex ligation-dependent probe amplification (MLPA) analyzed 143 unrelated Chinese DMD/BMD patients and 19 obligated female carriers. The overall detection rate was 72%, which includes 67.1% deletion and 4.9% of duplication. We determined that exon 51 was the most common exon deleted in single-exon deletion, and exons 48-50 and exons 45-50 are the most common in multi-exons deletion. We observed that about 90% of clinically diagnosed DMD/BMD cases carry small size deletion that involves 10 exons or less, including 25% cases carry a single-exon deletion. The most common region of the DMD gene deletions was further determined between exon 48 and exon 51. There is no 5 hotspot region can be characterized in this study, however, the 3 hotspot region was between exon 45 and exon 55. Most of small deletion, as well as the larger duplication, resulted in out-of-frame mutation. The rate of deletion and duplication in dystrophin gene is similar to that of western countries in Chinese population, however we did not find the 5 hotspot region in this study. We conclude that MLPA is a sensitive and effective method to detect duplication and deletion mutation, which should be applied as a first line screening for DMD/BMD in clinical practice.

Over expression of Klotho (KL) gene in fibroblast cell line of Hutchinson-Gilford progeria syndrome (HGPS) does not rescue the phenotypes of HGPS cells. *L. Wang*[1,2], *N. Zhong*[1,2,3] 1) Peking University Center of Medical Genetics, Beijing, China; 2) Peking University Health Science Center, Beijing, China; 3) New York State Institute for Basic Research in Developmental Disabilities, Staten Island, NY.

HGPS is a premature senile disease of children caused by de novo mutation of LMNA gene that encodes a nuclear envelope protein of lamin A/C. The lamin A/C is an important component involved in nucleus membrane skeleton structure. As a new gene related with aging process, KL could prolong the life of mice and also lead to, if deleted, similar symptoms in mice with HGPS features such as growth depletion, lipopenia, adermotrophia etc. In this study, we have investigated whether KL gene could ameliorate the abnormal phenotype of HGPS cells. An expression plasmid was constructed with a full length of coding sequence of KL gene, followed by transfected into three HGPS skin fibroblast cell lines which were determined to carry a G208G mutation. Parameters on cell morphous, levels of protein expression and cell cycle were detected by use of confocol, western-blot and FACS, respectively, to present the effects of KL-encoded protein on HGPS cells. Our data showed that there was no significant improvement on morphous abnormality of HGPS cells nucleus membrane as well as effective reduction on the expression of progerin, the defect lamin A protein observed in HGPS cells. Neither were distinct changes of cell cycles found between KL-treated and untreated HGPS cells. Our results indicated that KL gene does not rescue the pathogenic alterations in the development of HGPS.

CHARGE Syndrome Masquerading as the 22q11.2 Deletion Due to Significant Immunodeficiency. *K.E. Sullivan[1], D.M. McDonald-McGinn[1], S. Bale[2], E.H. Zackai[1]* 1) Pediatrics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) GeneDx, Gaithersburg, MD.

CHARGE syndrome occurs in approximately 1:9000 births and is associated with a CHD7 mutation in 60% of cases. CHD7 is a chromatin remodeling protein expressed at low levels in many tissues including the thymus. There are few data describing the immune system in patients with CHARGE although the second most common cause of death is infectious. Individual case reports with CHARGE-like features and profound immune deficiency have sometimes been referred to as DiGeorge syndrome. Of note, the expression of CHD7 in pharyngeal mesenchyme parallels that of TBX1, the major gene contributing to the phenotype of DiGeorge syndrome/the 22q11.2 deletion. With this in mind, we carefully defined the immune deficiency in four patients who presented in infancy with phenotypic features of CHARGE as well as significant infection leading to a concern for a 22q11.2 deletion. All patients had normal 22q11.2 deletion studies by FISH but were in fact found to have CHD7 mutations. Three of four patients had total T cell counts of less than 20% of normal. In spite of dramatically depressed T cell counts, two patients had relatively normal T cell function as measured by proliferative responses to T cell mitogens. Two patients also had markedly impaired antibody production presumably due to decreased T cell production. In an effort to determine how frequently T cell decrements are found in patients with CHARGE, we subsequently measured absolute lymphocyte counts (comprised largely of T cells) in eight other patients with a CDH7 mutation. Of these, three had persistently low absolute lymphocyte counts which are strongly suggestive of T cell compromise. Thus, in summary, patients with CHARGE/CHD7 mutations appear to have an immune deficiency which resembles that seen in the 22q11.2 deletion, i.e., diminished T cell counts with preservation of function. Given the high frequency of infection in these patients, screening for immune deficiency may well be warranted. Conversely, patients with this particular immune deficiency may benefit from CHD7 testing following normal 22q11.2 deletion studies.

Assessment of the MMRpredict model for prediction of DNA mismatch repair gene mutations. *K.G. Rabe[1], S.K. Nigon[2], N.M. Lindor[2]* 1) Div Biostatistics, Mayo Clinic, Rochester, MN; 2) Dept of Medical Genetics, Mayo Clinic, Rochester, MN.

Background: The MMRpredict model is a web-based model developed to predict which patients diagnosed with colorectal cancer (CRC) under age 55 years have germline mutations in a DNA mismatch repair (MMR) gene [Barnetson et al., NEngJMed 2006;354:2751-63]. Stage 1 MMRpredict estimates the probability for MMR mutations from clinical parameters (age of diagnosis, proximal versus distal site, family history, multiple primary CRCs). We evaluated the performance of Stage 1 of this model in a cohort of colorectal cancer patients. **Methods:** Cases with CRC were identified through Mayo Clinic Rochester. All were consented participants in the Mayo Colon Cancer Family Registry. dHPLC followed by sequencing and MPLA were conducted on the 3 genes. **Results**: We defined 4 probability risk groups:0-10%, 11-25%, 26-50%, and 51-100%. The number of cases in each of these groups was 112, 28, 20, and 31, respectively. The corresponding percent of mutations in each group was 3.6%, 7.1%, 10.0% and 29.0%. The observed/expected ratio in the 4 groups was 1.0 (95% CI 0.27-2.56); 0.40 (95% CI 0.04-1.44) 0.29 (95% CI 0.03-1.03) and 0.39 (95% CI 0.18-0.74). Overall, 17/191 patients were found to have mutations (8.9%), compared to 20.5% predicted (95% CI 0.25-0.70%. **Conclusion:** The MMRpredict Stage 1 predicted a percentage of positive MMR gene mutations carriers was greater than what was found. In the lowest predicted risk group the model performed well, while in the higher risks groups, a trend toward over prediction was seen. Larger studies will be required to further explore the prediction properties of this model. **Acknowledgements:** This work was supported by the National Cancer Institute (NCI), National Institutes of Health (NIH) under RFA #CA-95-011 and through cooperative agreements with members of the Colon Cancer Family Registry and P.I.s. The content of this manuscript does not necessarily reflect the views or policies of NCI or any of the collaborating centers in the CFR nor does mention of trade names, commercial products or organizations imply endorsement by the US Government or the CFR.

Using the MFG Test to Assess ABO Maternal Fetal Incompatibility as a Risk Factor for Schizophrenia. *E.J. Lockwood[1], J.A. Turunen[2], C.G.S Palmer[1], J.A. Woodward[3], J. Lonnqvist[2], L. Peltonen[2,4,5], J.S. Sinsheimer[1]* 1) UCLA, Los Angeles, CA; 2) Natl Publ Hlth Inst, Helsinki, Finland; 3) UC Merced, Merced, CA; 4) Univ Helsinki, Helsinki, Finland; 5) Broad Institute, MIT, Cambridge, MA.

Maternal-fetal genotype (MFG) incompatibility arises from maternal-fetal genotype combinations that adversely affect the developing fetus by inducing a maternal immunological attack, and thereby increasing disease susceptibility. Previous studies have found RHD incompatibility is a risk factor for schizophrenia (e.g. Palmer et al 2002). This study sought to determine if MFG incompatibility originating at another blood group locus, ABO, is also a risk factor for schizophrenia. Since the effect of RHD incompatibility on schizophrenia risk appears to be limited to males, we also hypothesized that the effects of ABO incompatibility on schizophrenia may differ by gender. We analyzed 282 independent nuclear Finnish families with at least one ABO genotyped parent and affected child (296 affected male offspring, 207 affected female offspring) to test for MFG incompatibility. Our hypotheses were tested using the extension of the MFG test (Sinsheimer et al. 2003) proposed by Kraft et al. (2004) that allows for multiple siblings. We adapted the multiple sibling MFG test to include gender specific MFG incompatibility effects and offspring allelic effects. We did not find a significant effect of ABO incompatibility as a risk factor for schizophrenia (RR to incompatible offspring=1.05, p=0.67). We did not find a significant gender effect on ABO incompatibility (RR to incompatible males and incompatible females respectively is 1.21 and 0.85, p=0.19). There is no evidence for offspring allelic effects (RR of having one O allele or two O alleles 1.02 and 1.22, p=0.38). Power calculations show that the sample size was sufficient to detect moderate effect sizes if they were present. Our results are qualitatively consistent with findings by an independent investigation of ABO incompatibility as a schizophrenia risk factor (Insel et al. 2005). Our study demonstrates that the MFG test is an easily implemented and flexible method for examining maternal-fetal genotype combinations in the context of potential covariates.

Mutual Information for Testing Gene-Environment Interaction. *X. Wu[1], L. Jin[1], M. Xiong[1,2]* 1) Dept Genetics, Fudan Univ, Shanghai, China; 2) Human Genetics, University of Texas, School of Public Health.

Abstract Despite current enthusiasm for investigation of gene-gene interactions and gene-environment interactions, the essential issue of how to define and detect gene-environment interaction remains unresolved. In this report, we define gene-environment interaction as a stochastic dependence in the context of the effects of the genetic and environmental risk factors on the cause of phenotypic variation among individuals. We use mutual information that is widely used in communication and complex system analysis to measure gene-environment interaction, and reveal its relationship with the classical concept of interaction odds ratios. We show that the information definition of interaction covers more broad cases of interactions than the logistic regression models. We investigate how gene-environment interaction generate the large difference in information measure of gene-environment interaction between the general population and disease population, which motives us to develop mutual information-based statistics for testing gene-environment interaction. We validate the null distribution and type 1 error rates of the mutual information-based statistics for testing gene-environment interaction using extensive simulation studies. By extensive simulations, we found that the new test statistics were much more powerful than the traditional logistic regression. Finally, in order to further evaluate the performance of our new method, we applied the mutual information-based statistics to three real examples. Our results showed that P-values of the mutual information-based statistics were much smaller than that obtained by other approaches including logistic regression models.

Multifocal pheochromocytoma in a patient with Beckwith-Wiedemann syndrome: A case report and review of the literature. *L. Palma[1], L. Feldman[2], G. Domanowski[3], E. Shoubridge[4], W.D. Foulkes[1,5]* 1) Division Medical Genetics, McGill Univ Health Ctr (MUHC), Montreal, Canada; 2) Dept Surgery, MUHC, Montreal, Canada; 3) Dept Pathology, MUHC, Montreal, Canada; 4) Depts Neurology & Neurosurgery, McGill University, Montreal, Canada; 5) Program in Cancer Genetics, Depts Oncology & Human Genetics, McGill University, Montreal, Canada.

We report the case of a 23-year-old girl with Beckwith-Wiedemann syndrome (BWS) who presented with multifocal pheochromocytoma. The patient was investigated at age 21 for hypertension and headaches. A 24-hour urine collection had high norepinephrine and normetanephrine. CT scan revealed a 2.9 cm left adrenal mass and a 2.3cm mass anterior to the aortic bifurcation. After alpha blockade, the patient underwent a laparoscopic left adrenalectomy and excision of the left para-aortic mass. Postoperative pathological findings included a 5.0 cm left adrenal pheochromocytoma and a 3 cm para-aortic mass consistent with either a completely replaced metastatic lymph node or, more likely an extra-adrenal paraganglioma arising in the organs of Zuckerkandl. At nearly two years follow-up, the patient has no further sequeale or radiologic evidence of recurrent disease. Family history was negative for pheochromocytoma/ paraganglioma, von Hippel-Lindau, and multiple endocrine neoplasia type A/B. To rule out co-existing nonsyndromic pheochromocytoma due to a germline mutation in the *VHL* , *RET*, or *SDHD* genes, molecular testing of all genes was performed and no mutations were identified. To our knowledge, this is the third reported case of pheochromocytoma occurring in a patient with BWS. Two additional cases of pheochromocytoma in association with congenital hemihypertrophy have been reported. Interestingly, all five patients had hemihypertrophy; either isolated or in association with BWS. Our case provides further evidence that pheochromocytoma may be a part of the clinical spectrum of BWS, though in light of the rarity of this tumour type, the need for regular screening is at present, unclear. An awareness of the clinical sequeale of pheochromocytoma among physicians caring for patients with congenital hemihypertrophy or BWS is of utmost importance.

Two Stage State-Space models for genetic networks. *X. Sun[1], L. Jin[1], M. Xiong[1,2]* 1) Dept Genetics, Fudan Univ, Shanghai, China; 2) Human Genetics Center, University of Texas, School of Public Health.

An essential issue for modeling genetic networks is how to model regulation of a gene. The genes are key components of the genetic networks. To address importance of the model of regulation of a single gene, in this report we propose two stage state-space models for genetic networks. Specifically, state-space models for genetic networks are decomposed into two parts. One part is to model its intrinsic regulation within the gene in which state space equations with two unobserved state variables are used to model a transcriptional process of the gene. Second part is to model the regulations between genes in which observed expressions of the other connected genes will be inputted to the state equations to regulate the expression of the gene. The extended Kalman filter is used to estimate the parameters in the models. However, the classical extended Kalman filter does not consider constraints due to the structure of the networks. To incorporate the structure of the networks into identification of the genetic networks we develop a new version of extended Kalman filter in which the constraints of the network structure are imposed in the parameter estimation. The proposed two-stage state-space models with constrained extended Kalman filter are applied to three published gene expression time course datasets. Our preliminary results show that the propose models and algorithms have much accurate precision in prediction of the gene expressions than the traditional methods.

Evolutions of Dynamic Metabolic Networks. *Q. Zhou[1], L. Jin[1], M. Xiong[1,2]* 1) Dept Genetics, Fudan Univ, Shanghai, China; 2) Human Genetics Center, University of Texas, School of Public Health.

In the past, molecular evolution and population genetics have focused on using DNA sequences as tools for studying evolution. Recently, some researchers begin to study evolution of the biological networks such as metabolic, signal transduction, gene regulation and protein-protein interaction networks. However, all these researches mainly study evolution of the network structures and individual enzymes and proteins. Evolution of dynamic properties of the biological networks have never been studied. It is important to know how the evolution of the network structure affects the dynamic behavior of the biological networks. In this report, we treat a biological network as a dynamic system. We study the evolution of glycolysis. Based on our recent development of network alignment algorithms and permutation group graph theory, we identify the typical structure of the metabolic network for each species. Then, we study the evolution of the structure of glycolysis for more than 200 species. For each structure, we derive the kinetic models of glycolysis. We take the yields of ethanol as an objective function and apply the constrained nonlinear control theory to these evolved kinetic models from which we calculate the optimal yields of ethanol For each species, we investigate how the structure of the network affects the yields of the ethanol and other dynamic properties of the networks. These analyses allow us to link the structure of the metabolic network with function of the cell. Finally, we identify the optimal structures of glycolysis pathway which produce the largest yields of ethanol.

Multi-information and Interaction Information for Testing Total Interaction and High-Order Interaction. *G. Peng[1], L. Jin[1], M. Xiong[1,2]* 1) Genetics, Fudan University, Shanghai, China; 2) Human Genetics, University of Texas, School of Public Health.

In the past, most researches mainly focus on studying pair-wise interaction (gene-gene interaction or gene-environment interaction). However, there is increasing evidence to demonstrate that high-order interactions (gene-gene-gene, gene-gene-environment, gene-environment-environment interactions) play an important role in the development of the diseases. The purpose of this report is to develop definition of total interaction and high-order interactions, and statistics for testing total interactions and high-order interaction. Interaction among several genetic and environmental factors is a fundamental concept we often encounter in genetic epidemiology, but rarely specify with precision. In this report, we define high-order interaction as inseparable genetic and environmental effects of the multiple variables. From information point of view, the interaction can be understood as sharing common information causing disease among several genetic and environmental factors. The total interaction is defined as included all interactions from pair-wise interactions to high-order interactions. We use multi-information to measure total interaction and interaction information to measure high-order interaction. The statistics based on information measure are developed to test for total interaction and high-order interaction. Estimation of distribution algorithms is developed to incorporate the test for interaction among more than three genetic and environmental factors into genome-wide association studies. The type 1 error rates and power of the statistics are calculated by large-scale simulations. We show that the power of the newly developed statistics is much higher than that of the logic regression analysis. The developed statistics are applied to the published genome-wide association studies and our current genome-wide association studies of atherosclerosis. Our preliminary results show that the developed statistics have high power to detect high-order interactions.

BubR1 deficiency causes centrosome amplification in PCS (MVA) syndrome. *S. Matsuura[1], H. Izumi[1], Y. Matsumoto[1], T. Ikeuchi[2], H. Saya[3], T. Kajii[4]* 1) Dept. Rad. Biol., RIRBM, Hiroshima Univ., Hiroshima, Japan; 2) MRI, Tokyo Med. Dent. Univ., Tokyo, Japan; 3) IAMR, Keio Univ., Tokyo, Japan; 4) Hachioji, Tokyo, Japan.

Spindle attachment to the kinetochores is monitored by mitotic spindle checkpoint to ensure accurate chromosome segregation in mitosis. Spindle checkpoint operates by delaying the onset of anaphase until all chromosomes have established bipolar microtubule attachment. PCS (MVA) syndrome is a disorder with premature chromatid separation (PCS), mosaic variegated aneuploidy (MVA), Dandy-Walker complex and other anomalies, and a high risk of childhood cancer. Patients with the syndrome are known to have mutations of the BUB1B gene and reduction of its product BubR1, a component of mitotic checkpoint. We found that cells from the patients with the syndrome show amplification of the centrosomes, multipolar mitoses, reduced centrosomal localization of BubR1, and increased activities of Polo-like kinase 1 (Plk1). Normalization of BubR1 expression or reduction of Plk1 in these cells corrected these abnormalities. Induction of overexpression of Plk1 in HeLa cells resulted in centrosome amplification. In view of these findings, we propose that BubR1 operates to prevent centrosome amplification through negative regulation of Plk1.

Highly cost efficient genome wide association studies using DNA pools and dense SNP arrays. *S. Macgregor[1], Z.Z. Zhao[2], A. Henders[2], N.G. Martin[1], G.W. Montgomery[2], P.M. Visscher[1]* 1) Genetic Epidemiology, Queensland Institute of Medical Research, Brisbane, Queensland, Australia; 2) Molecular Epidemiology, Queensland Institute of Medical Research, Brisbane, Queensland, Australia.

Recent advances in large scale genotyping have made genome-wide association (GWA) possible. GWA is one of the primary tools for the identification of loci contributing to susceptibility to complex common disease. However, the major limiting factor in many GWA studies is cost. Individually genotyping GWA samples is often prohibitively expensive, with genome scans of suitable size (hundreds/thousands of cases and controls, hundreds of thousands of markers) typically costing over US$1 million. Alternative approaches which reduce the genotyping cost are therefore highly desirable. We will demonstrate that DNA pooling offers a means of dramatically reducing the cost of GWA studies. Building on previous work on Affymetrix arrays, new methodology will be outlined for statistical analysis of data from the Illumina platform, including a novel quality control metric. The method is based upon contrasting case and control pools and hence does not require independent estimates of rates of unequal amplification of alleles. Illumina and Affymetrix arrays were applied to the same pools; Illumina arrays were found to offer an order of magnitude decrease in pooling error variance compared with Affymetrix arrays. With Illumina arrays concordance with individual genotyping data is excellent; in terms of effective sample size it is possible to extract >80% of the information available with individual genotyping. Guidance will be given on best study design for pooling based GWA studies. It will be shown that even after taking into account pooling error, one stage scans can be performed for >100 fold reduced cost compared with individual genotyping. With appropriately designed two stage studies, individual genotyping can provide confirmation of pooling results whilst still providing ~20 fold reduction in total cost compared with individual genotyping based alternatives. The large cost savings with Illumina based pooling imply that future studies need only be limited by the availability of samples and not cost of arrays.

Robertsonian translocation in infertile North Indian population. *M. Jena[1], D. Pathak[1], M. Tanwar[1], R. Kumar[1], R. Kumar[2], M.B. Shamsi[1], R. Dada[1]* 1) Department of Anatomy, All India Institute of Medical Sciences, New Delhi, India-110029; 2) Department of Urology, All India Institute of Medical Sciences, New Delhi, India- 110029.

Robertsonian translocations (RT) are the most common structural chromosomal abnormalities observed in humans with a total frequency of 1.23 per thousand. Among them translocation (13q;14q) and the translocation (14q;21q) are the most common, with an estimated frequency of 0.97 and 0.20 respectively. It is well known that in infertile male cases, the frequency of chromosomal aberrations is increased and varies from 1.9-4.0% among them, Robertsonian translocations and numerical sex chromosomal aberrations are the most frequent. Of these, 60% inherit the rearrangement from one of their parents and 40% occur denovo. This study was planned with the aim to determine the incidence of RT in men with spermatogenic arrest and to corelate if cases with such structural aberrations lead to recurrent ART failure. Our finding of chromosomal aberrations (3.7%) in the infertile males are in good agreement with literature of 3.3%. In this study of infertile men with non-obstructive azoospermia and oligozoospermia, three cases had 13q14q fusion. Thus the frequency of robertsonian translocation in our study was nearly 30 fold higher than in general population (0.1%). Although robertsonian translocation is likely to be found in chromosomes investigation of infertile men, their role in oligospermia is not clear. The testicular histology of the men carrying such a rearrangement shows a variable picture, ranging from severe impairment to near normality. Individuals carrying each of the ten possible nonhomologous robertsonian translocations of the five humans acrocentric chromosomes (13,14,15,21, & 22) have been reported, but two combinations, rob(13;14) & rob (14;21) are observed at a greater frequency than the rest (73% & 10)%,respectively. Since there is a high frequency of robertsonian translocations in infertile men drawing a genotype and phenotype correlation in these studies will help to acess the severity of spermatogenic arrest in these cases.

Promoter polymorphism of iNOS gene and their influence on essential hypertension in Chinese. *Y. Zhao[1], L. Fu[1,2], Y. Gao[1], J. Shi[2], J. Liu[1], M. Qi[1], H. Liu[1]* 1) Dept Medical Genetics, China Medical Univ, Shenyang, Liaoning, China; 2) Dept Clinical Epidemiology, First Affiliated Hospital, China Medical University, Shenyang, China.

Inducible nitric oxide synthase (iNOS) catalyzes L-arginine to NO, a potent vasodilator which participates in the development of hypertension. iNOS expression is induced by many factors in various tissues including brain, heart, vessel and kidney. To determine the relationship of genetic variation in the regulatory region of the iNOS gene with hypertension in Chinese population, we performed case-control study with 610 subjects, 308 normal controls and 302 hypertensives. The iNOS-1026C/A polymorphism was detected by real-time PCR. The -1026A allele and the -1026AA genotype had significantly lower frequency in hypertensives than in controls ($P<0.05$). After the non-conditional Logistic analysis, -1026AA genotype was an independent predictor for hypertension (OR=0.129, 95% CI 0.053~0.318), and it would be a protective factor for hypertension. We reported for the first time that iNOS -1026C/A is associated with hypertension. Further research is necessary to identify the functional consequence of the variant that modify the susceptibility to hypertension.

Novel *MMP20* mutation underlying autosomal recessive hypomaturation amelogenesis imperfecta. *S-K. Lee[1], F. Seymen[2], K. Gencay[2], B. Tuna[2], J-W. Kim[1,3]* 1) Department of Cell and Developmental Biology & Dental Research Institute, Seoul National University, Seoul, Korea; 2) Department of Pedodontics, Istanbul University, Istanbul, Turkey; 3) Department of Pediatric Dentistry & Dental Research Institute, Seoul National University, Seoul, Korea.

Autosomal recessive hypomaturation amelogenesis imperfecta can be caused by two genes (*KLK4* and *MMP20*). Both proteinases involved in enzymatic degradation of structural enamel matrix proteins. So far only 3 mutations have been identified (one in *KLK4* and two in *MMP20*). Here we report a novel *MMP20* mutation in a consanguineous kindred in Turkey. The identified mutation was g.18,742G>A, c.910G>A, p.A304T in the exon 6 (based on NT_033899.7, NM_004771.3, and O60882). Sequence analysis of 100 healthy normal controls did not reveal this sequence alteration, indicating that this mutation is not a common variation. The proband and his affected brother were both homozygous for this mutation, consistent with consanguinity. The parents and one unaffected sister were carriers of the mutation. The enamel thickness was normal. Lots of enamel of primary teeth and permanent first molar were lost due to hypomaturation combined with caries lesions. Newly erupted teeth had chalky white hypomaturation enamel with mild discoloration. Discoloration was getting dark with increasing ages. This study shows phenotypic variation according to patients age and may lead us better understanding molecular basis of the disease. This work was supported by a grant from the Korea Health 21 R&D Project, Ministry of Health & Welfare, Republic of Korea (A060010) and the Korea Science and Engineering Foundation (KOSEF) through the Biotechnology R&D program (#2006-05229).

Swedish adenomatous polyposis families: Notably High mutation detection rate and colorectal cancer morbidity in probands. *M. Nordling[1], A. Rohlin[1], K. Fritzell[2], G. Kanter Smoler[1], J. Meuller[1], J. Björck[2]* 1) Dept Clinical Genetics, Sahlgrenska Univ Hosp, Goteborg,Sweden; 2) Dept of Medicin, Karolinska Institute, Stockholm, Sweden.

Background and aims: Using a range of different molecular genetic techniques our purpose was to achieve as high mutation detection rate as possible. Our intention was further to uncover any not at yet described genotype-phenotype correlation. Participants and methods: Mutation screening of APC and clinical characterization of 95 unrelated FAP patients from the Swedish Polyposis Registry was performed. In addition to ordinarily used mutation screening methods analyses of splicing affecting mutations and investigations of the presence of low-frequency mutation alleles, indicating mosaics, have been performed as well as quantitative real-time PCR to detect lowered expression of APC. Results: A number of novel mutations were detected and characterised including a case with reduced APC expression The nonsense mutation, c.70 C>T in exon 1, was detected, to our knowledge the most 5 situated APC mutation reported. In total, 60 different APC mutations in 80 of the 95 families where identified in this study and 27 of those are novel. We have previously shown that 6 of the 95 patients carried biallelic MUTYH mutations. The mutation-negative cases all display an atypical FAP phenotype, indicating that the detection frequency for mutations in the APC gene in patients with classical FAP is 100%. Probands with mutations upstream from codon 1309 had a median age at diagnosis of 36 (range, 14-57) years compared to 20.5 (range, 11-34) years among those with mutations downstream of codon 1309 ($P < 0.0014$). The morbidity in CRC among probands, of whom more than 80 percent were diagnosed during the last three decades, was 43 and 18 percent respectively, and in total 34 percent. Conclusion: With a variety of mutation detection techniques it is today possible to achieve a 100% detection frequency in classical FAP. Despite a lower fraction of patients with dense polyposis among those with mutations upstream of codon 1309, CRC at diagnosis occurred more often.

SNP Analysis of the PHF11 gene in Italian families with Allergic Asthma. *P. Zorzi, C. Bombieri, G. Malerba, L. Xumerle, E. Trabetti, P.F. Pignatti* Department of Mother and Child, Biology and Genetics, University of Verona, Italy.

Asthma is a chronic inflammatory disorder of the airways characterized by reversible obstruction, and bronchial hyper-reactivity. Asthma has an important genetic component but no clear pattern of inheritance. In a previous genome scan for asthma, conducted on 123 Italian families, characterized for clinical asthma, rhinitis, elevated total serum IgE, positive Skin Prick Test, and bronchial hyper-responsiveness (BHR) to methacholine, it has been observed the presence of linkage between region 13q14 and elevated total serum IgE. Two studies, recently reported in literature, Zhang et al., 2003, and Jang et al., 2005, identified an association of the PHF11 gene with elevated IgE and atopic dermatitis, respectively. An association study was performed by Transmission Disequilibrium Test (TDT) on 23 Italian families (144 individuals) presenting positive linkage to elevated total serum IgE, using 7 SNPs on the PHF11 gene, reported in literature associated with elevated IgE and atopic dermatitis. 5 SNPs (rs2031532 G/A, rs1046295 G/A, 185752b5_2 C/T, 185306b7_1 A/C, and 185752b4_2 A/G) have been analyzed in multiplex by ddNTP Primer Extension technique, using the SNaPshot Multiplex kit (Applied Biosystems) on the ABI PRISM 310 Genetic Analyzer with the Genescan software. Two SNPs (rs2247119 C/T, and rs2274276 C/G) have been analyzed through PCR and enzymatic restriction. The observed frequencies for the minor allele were rs2031532 A 12%, rs1046295 A 25%, 185752b5_2 T 37%, 185306b7_1 C 38%, e 185752b4_2 G 27%, rs2247119 T 10%, and rs2274276 G 29%. Linkage analysis through the Merlin program showed presence of linkage for atopy (p=0.001) and IgE (p=0.002). TDT did not show any significant association between the analyzed SNPs and IgE in allergic asthma. No significant preferential transmission of the haplotype was observed for any of the analyzed phenotypes. The analysis in our population suggests that association could be linked to the presence of other polymorphisms in the PHF11 gene or neighbouring genes. It may be appropriate to further extend the analyzed region to other neighbouring region, which demonstrated positive linkage to asthma and related phenotypes.

Investigation of rare alleles in MODY genes and their implication in controlling the level of fasting blood glucose.

B. Oh[1], H.R. Han[1], M.J. Go[1], Y.J. Kim[1], S.J. Yang[2], J.E. Lee[3], H.R. Kim[1] 1) Center for Genome Science, National Institute of Health, Seoul, Korea; 2) Macrogen Co., Seoul, Korea; 3) DNA Link, Inc., Seoul, Korea.

Since the prevalence of complex traits such as hypertension and diabetes is high, according to the hypothesis of common disease common allele genetic variations such as SNP having the high frequency in the population have been favored to search the genetic cause of the common diseases. However recently researches have been published to support that rare alleles contribute the expression of complex traits such as HLD or LDL level of blood. In this study rare alleles were identified by resequencing 6 MODY genes, HNF1 (MODY1), GCK (MODY2), HNF1 (MODY3), HNF1 (MODY4), IPF1 (MODY5), NeuroD1 (MODY6), in 120 unrelated Koreans, 60 each in the group of low fasting blood glucose level and in the group of high level. Total 126 alleles were discovered and 46 among them were novel, however only 7 nonsynonymous alleles were discovered from these genes, suggesting that these metabolism-related genes are highly conserved in a repect of protein structure in the population. In addition to the nonsynonymous alleles 41 alleles located upstream of the initiation site were discovered and 9 alleles were selected from these nonsynonymous and promoter alleles for the further study. The selected alleles were genotyped in 7400 individuals collected from the prospective cohort in Korea in order to investigate their relationship to the level of fasting blood glucose by regression analysis. In addition to the analysis the distributions of fasting blood glucose level in carriers were compared with those of total population.

A comparison of the proximal promoter regions of the *PAX3* and *PAX7* genes. *E. Möller, M. Isaksson, N. Mandahl, F. Mertens, I. Pangopoulos* Dept. of Clinical Genetics, University Hospital, Lund, Sweden.

The *PAX3* and *PAX7* genes are rearranged through the common chromosomal aberration t(2;13)(q35;q14) and less frequent variant t(1;13)(p36;q14), respectively, in the pediatric soft tissue tumor alveolar rhabdomyosarcoma (ARMS). The resultant hybrid *PAX3-FOXO1A* and *PAX7-FOXO1A* genes are expressed in ARMS and encode chimeric transcription factors that are more potent than the wildtype transcription factors. Previous studies have suggested that the expression of *PAX7-FOXO1A* is copy-number dependent whereas that of *PAX3-FOXO1A* is not, and it has been suggested that this may be due to a weaker *PAX7* promoter compared to *PAX3*. The aim of the present study was to compare the abilities of the *PAX3* and *PAX7* proximal promoters to drive *Photinus Pyralis* (firefly) luciferase expression. The *PAX3* and *PAX7* promoter fragments were analyzed with the dual-luciferase reporter assay using three vector systems, pGL3-Basic, pGL4.10[*luc2*] and pFhRL. The following eight cell lines were included in the study: HEK293, NIH3T3, HeLa, embryonal rhabdomyosarcoma cell line RD and alveolar rhabdomyosarcoma cell lines RH-30, SJCRH30, RH-41 and RC2. The *PAX3* promoter fragment was found to be capable of more efficient transcriptional activation than that of *PAX7*, irrespective of vector system or cell line used. Our findings are consistent with the notion that an amplification event might be required for the *PAX7-FOXO1A* chimeric transcript to reach a critical expression level for oncogenic activity.

HLA-DRB1 is associated with disease susceptibility and severity of rheumatoid arthritis in Japanese. *S. Tsukahara, K. Ikari, S. Momohara, T. Tomatsu, M. Hara, H. Yamanaka, N. Kamatani* Inst Rheumatology, Tokyo Women's Medical Univ, Tokyo, Japan.

The disease susceptibility to rheumatoid arthritis (RA) has been estimated to have a genetic component of up to 60%, and one-third of the genetic component has been estimated to depend on the human leukocyte antigen (HLA) locus. Several prospective studies suggest that particular HLA-DRB1 alleles encoding a conserved sequence of amino acids called shared epitope (SE) are associated with severe radiographic damage or functional impairment of RA. A recent meta-analysis shows the value of SE for predicting radiographic damage varies among ethnicity. In the present study, we examine whether SE is associated with disease susceptibility and severity of RA in Japanese.

The diagnosis of RA was established using the classification criteria of ACR. Sharp/van der Heijde (SvdH) method was used to assess radiographic joint damage in patients with 5-year disease duration. DNA samples of patients were obtained from IORRA study and population-based control samples were from the Pharma SNP consortium. Sequencing-Based Typing of HLA-DRB1 was performed on 147 cases and 470 controls using the Atria AlleleSEQR HLA-Sequencing-Based Typing Kit. Assign-SBT software was used to determine HLA-DRB1 alleles, and subjects were categorized as having 0, 1 or 2 copies of the SE, defined by the following alleles: 0101, *0401, *0404, *0405, *0410, *1001 or *1406. Association between RA susceptibility and HLA-DRB1 SE were examined by Fisher's exact test. Differences in SvdH scores among copies of the SE were analyzed by linear regression analysis. All statistical analyses were carried out using the R software package.

HLA-DRB1 SE was strongly associated with RA ($P = 5.1 \times 10^{-7}$). Mean SvdH score was 45.0, 50.1 and 77.9 for homozygous negative, heterozygous, homozygous positive individuals for SE allele, respectively. SE had a significant effect on radiographic damage in Japanese RA patients ($P = 0.01$). We conclude that HLA-DRB1 SE is associated with RA susceptibility and severity in Japanese.

Job Syndrome masquerading as Non-Accidental Injury. *W. Reardon[1], F. Stewart[2]* 1) Dept Clin Gen, Ctr Medical Gen, Our Lady's Hosp Sick Children, Dublin, Ireland; 2) Dept Medical genetics, City Hospital, Belfast BT9 7AB.

Syndrome diagnosis, particularly in the absence of objective laboratory analysis, is challenging, requiring specialist insights and experience. Job syndrome is a rare primary immunodeficiency disorder, classically described in association with recurrent staphylococcal skin abscesses, eczema and a predisposition to mucocutaneous candidiasis. IgE levels are massively elevated. Awareness of the syndrome is low among paediatricians, even among geneticists, many of the cases diagnosed having had several years of symptoms prior to recognition. Spontaneous bone fractures are a recognised aspect of the syndrome, even in the absence of an associated demonstrable osteoporosis. This predisposition to fractures was pivotal to our recent recognition of a case of Job syndrome at an advanced stage in child protection proceedings, when a permanent care order was being sought in respect of an 18 month old girl with unexplained fractures. Radiological, child protection and orthopaedic experts all agreed that the findings were consistent woth non-accidental injury. Several aspects of the history, including eczema, has been assumed to be co-incidental. The confirmation of IgE levels in excess of 100 fold the normal age range strongly supported the diagnosis of Job syndrome and led to the withdrawl of the case against the parents.

Significant Locus Heterogeneity in Turkish Families with Autosomal Recessive Nonsyndromic Sensorineural Hearing Loss. *M. Tekin[1], H. Ozdag[2], A. Sirmaci[1], F.B. Cengiz[1], I. Aslan[1], S. Tasir-Yilmaz[2], D. Duman[1], B. Ozturk-Hismi[1], Z.S. Arici[1], A. Incesulu[3], S. Erbek[4], I. Yilmaz[5]* 1) Division of Clinical Molecular Pathology and Genetics, Department of Pediatrics, Ankara University School of Medicine, Ankara, Turkey; 2) Biotechnology Institute of Ankara University, Ankara, Turkey; 3) Department of Otorhinolaryngology, Osmangazi University School of Medicine, Eskisehir, Turkey; 4) Department of Otorhinolaryngology, Baskent University Hospital, Konya, Turkey; 5) Department of Otorhinolaryngology, Baskent University Hospital, Adana, Turkey.

Ninety-five percent of individuals with early-onset genetic deafness demonstrate autosomal recessive transmission in Turkey. Although mutations in GJB2 are responsible in 22% of all deaf families, their frequencies are much lower in affected subjects with consanguineous parents. In this study, we screened 5 large families having parental consanguinity with nonsyndromic sensorineural hearing loss for known autosomal recessive deafness loci. All families were tested and found to be negative for GJB2 mutations. Affymetrix GeneChip 10K or 50K arrays were used for genotyping. Homozygous genotype blocks flanking the known recessive deafness genes were explored in affected subjects. Additional microsatellite markers were also used. Two and multipoint linkage analyses using easyLinkage software package were later performed. Genomic loci for TMIE, CDH23, and MYO15A genes were shown to be linked in single families. A previously reported p.R84W (c.250C>T) mutation in TMIE, and a novel, c.3595-13C>T, mutation in CDH23 were demonstrated to be co-segregating with deafness as a completely penetrant autosomal recessive phenotype in each family. The c.3595-13C>T mutation in CDH23 was predicted to alter the binding of a splicing enhancer protein and was not found in 125 healthy Turkish controls. All known deafness genes were excluded in the remaining 2 families based on heterozygous genotypes of flanking SNPs or microsatellites in affected subjects. These results demonstrate that the etiology of autosomal recessive deafness is remarkably heterogeneous in Turkish families with parental consanguinity.

The -A2518G polimorphism of Monocyte Chemoattractant Protein 1 (MCP-1) is associated with Crohn's disease.

A. Latiano[1], O. Palmieri[1], E. Salvatori[2], M.R. Valvano[1], F. Bossa[1], T. Latiano[1], G. Corritore[1], A. Andriulli[1], V. Annese[1] 1) IRCCS CSS Hospital, San Giovanni Rotondo, Italy; 2) Angelini Farmaceutici ACRAF S.p.A., Pomezia, Italy.

MCP-1 is a chemokine able to promote monocytes migration in sites of chronic inflammation. The -A2518G variation in the MCP-1 gene has recently been implicated in the pathophysiology of many autoimmune diseases. Aim: To investigate MCP-1 SNP and protein plasma levels in patients with inflammatory bowel disease (IBD). Methods: The -A2518G SNP was genotyped by RFLP in 671 IBD patients (435 with Crohns disease [CD], 236 with ulcerative colitis [UC]), 151 CD trios, and in 310 controls (HC). Family-based (TDT) and case-control association analyses were performed. Plasma levels of MCP1 protein in 105 CD patients (48 with active and 57 with inactive disease), 39 UC (19 with active and 20 with inactive disease), and 37 HC were assessed by ELISA. The R702W, G908R, and L1007finsC variants of the CARD15 gene were also genotyped by pyrosequencing. Results: Compared to the frequency in HC (29.5%), the frequency of the risk allele (G) was significantly decreased in the IBD population (24.6%; p=0.02), and more specifically, in the subset with CD patients (23.2%; p=0.006)(TDT: p=0.004). Homo and heterozygous carriers of risk allele were significantly less frequent in IBD (44.1%; p=0.01), and in CD patients (41.6; p=0.003), than in HC (52.6%). No significant difference for the allele (27.3%) and risk genotype (48.7%) frequencies was found in UC. Mean (and median) plasma levels of MCP-1 were not significantly different in IBD patients and controls, irrespective of different genotypes and disease activity. All UC patients had their MCP-1 levels within normal ranges. Conversely, 19 CD patients (18%) had a higher (2 SD) MCP-1 plasma levels, irrespective of disease activity, localization, or MCP-1 genotypes. Conclusion: The investigated variant of MCP-1 gene is a protecting factor for CD. No interaction with CARD15 SNPs, nor a correlation with any clinical sub-phenotypes was found. CD patients carriers of the G allele have a significantly higher MCP-1 plasma levels, which may deserve therapeutic implication.

Identification of novel small molecules suppressing rCGG-repeat-mediated neuronal toxicity. *A. Qurashi, H. Liu, P. Jin* Department of Human Molecular Genetics, Emory University School of Medicine, Atlanta, GA.

Fragile X-associated tremor/ataxia syndrome (FXTAS) is a progressive neurodegenerative disorder recognized in fragile X premutation carriers. Using Fruit fly, we have previously demonstrated that elongated noncoding CGG repeats in FMR1 allele as the pathogenic cause of FXTAS. Here we are utilizing this FXTAS fly model to identify small molecules that can ameliorate rCGG-mediated neuronal toxicity. We have found that neuronal overexpression of rCGG repeats could lead to lethality during early stages of development. Using this lethal phenotype, we have screened a collection of 2,000 FDA-approved, biologically active and structurally diverse compounds. We identified 20 compounds that could reverse the lethality caused by rCGG repeats, with several of them having the potential to target glutamatergic pathways. Of particular interest among them are 5-fluoroindole-2-carboxylic acid and 6, 7-dichloro-3-hydroxy-2-quinoxalinecarboxylic acid, known NMDA receptor antagonists, suggesting that over-activation of NMDA receptor could be involved in rCGG-mediated neurodegeneration observed in FXTAS. Candidate drugs are being further evaluated in rescuing locomotor and brain morphological anomalies observed in FXTAS fly model. Our results demonstrate the utility of a Drosophila model for screening small molecule libraries. This approach may identify potential therapies, and reveal the cellular and molecular pathways involved in FXTAS.

Functional and biophysical characterisation of wild type fibulin 5 and mutants associated with age-related macular degeneration. *C.E. Ridley[1], R.P.O. Jones[1], K. Mellody[2], A.C. Lomas[2], T. Wang[1], M. Howard[2], T. Jowitt[2], C. Baldock[2], A. Lotery[3], P.N. Bishop[2], C.M. Kielty[2], D. Trump[1]* 1) Medical Genetics, University of Manchester, Manchester, UK; 2) Wellcome Trust Centre for Cell-Matrix Research, School of Biological Sciences, University of Manchester, UK; 3) Clinical Neuroscience, University of Southampton, UK.

Introduction Age-related macular degeneration (AMD) is the leading cause of visual loss in the Western world. The pathogenesis is complex, and missense mutations in *Fibulin 5 (FBLN5)* are implicated in up to 2% of patients. The pathogenicity of these missense mutations has been questioned. *FBLN5* mutations also cause cutis laxa. The aim of our study is to investigate wild type (WT) and mutant FBLN5 using functional and biophysical assays to determine the effects of the 9 AMD associated missense changes, 2 cutis laxa missense changes and 2 missense polymorphisms. **Methods** We expressed WT and mutant *FBLN5* in retinal pigment epithelial cells to determine the distribution and secretion of FBLN5. Full length and fragments of WT and mutant FBLN5 were His tagged and expressed in EBNA 293 cells. Purified protein was used in solid phase binding assays and biophysical studies using size-exclusion chromatography (pH7.4) online to multi-angle laser light scattering and circular dichroism (CD). **Results** 4 of the AMD and the 2 cutis laxa mutations led to a reduction in FBLN5 secretion. Studies of UPR activation are underway. Both AMD and cutis laxa mutations led to reduced binding affinity for elastin and the polymorphism G202R increased binding affinity. A WT fragment comprising residues 127-287 (four EGF-like repeats) dimerised and proteins containing this fragment self-associated. The hydrodynamic radius (Rh) for monomeric full-length WT FBLN5 was approximately 3nm, suggesting a compact structure. Several mutants caused increases in Rh, reflecting perturbations to the shape of FBLN5. Recently acquired CD data may reveal associated secondary structure changes. **Discussion** These results indicate missense changes in FBLN5 associated with AMD lead to changes in the structure and function of FBLN5 suggesting they are pathogenic.

A Homozygous Splicing Mutation in PMS2 Causes Early Onset Tumors in an Inuit Family. *L. Li[1], B. Balachandra[2], K. Baker[2,4], J. Jarry[3], L. Kasprzak[4], J. Zhu[5], G. Chong[3], J.R. Jass[2], W.D. Foulkes[1,4]* 1) Dept Cancer Genetics, Lady Davis Inst, Montreal, PQ, Canada; 2) Department of Pathology, McGill University; 3) Dept Pathology, SMBD-Jewish General Hospital; 4) Div Med. Genet, McGill Univ Health Centre; 5) Institute for Genome Sciences & Policy, Duke University, Durham, North Carolina.

Early onset tumors (duodenal, stomach and colorectal cancer as well as an astrocytoma, all diagnosed before the age of 30) have occurred in 4 siblings from an Inuit family living in northern Quebec. No evidence of malignancies was found in the parental generation. Immuno-histochemical staining for MLH1, MSH2 and MSH6 showed positive normal staining of tumor and adjacent non-neoplastic tissue with adequate internal controls. There was absence of staining with PMS2 in all neoplastic as well as in normal tissue from all affected siblings, indicating PMS2 is the cancer-causing gene in this family. The presence of highly homologous PMS2 pseudo-genes on chromosome 7 made conventional exon-by-exon sequencing difficult. Long range PCR was employed to specifically amplify the genuine PMS2 gene from blood DNA, followed by exon amplification and sequencing. A homozygous mutation (C.2002A>G, NM_000535.3) was found in individuals affected by cancer and both parents were found to be heterozygotes. The mutation creates a cryptic 5 splice site causing a 5 bp deletion in exon 11, consequently introducing a premature stop codon. Polony (polymerase colony) assay showed the 5 bp deletion is exclusively located in transcripts derived from the genuine PMS2 locus, but not those derived from the pseudo-locus resembling the C-terminus of PMS2. The predicted truncated form of PMS2 lacks the carboxyl terminus (amino acid residues 668-862), which is required for nuclear localization and endonucleolytic activity. Western blot utilizing an antibody recognizing PMS2 carboxyl terminus showed no expression of the wild-type PMS2 in transformed lymphocytes from a homozygous mutation carrier. Further work is undergoing to elaborate the pathogenic mechanism of this mutation.

Optimal Control as a Tool for Drug Development. *S. Lai[1], H. Xiong[2], F.C. Arnett[3], X. Zhou[3], M.M. xiong[4]* 1) Department of Pathology, Michael E. DeBakey VA Medical Center and Baylor Collage of Medicine, Houston, TX; 2) Department of Computer Science, Texas A&M University, College Station, TX; 3) Department of Internal Medicine, University of Texas Health Science center at Houston, Houston, TX; 4) Human Genetic Center, University of Texas Health Science Center at Houston, Houston, TX.

It is increasingly recognized that understanding of biological processes and biochemical pathways at the systems-level will lead to smarter drug development. Model-based drug design is emerging as a new powerful tool for treatment and drug development. Model-based drug development requires mathematic models that take biological networks as a dynamic system and allow a detailed understanding of the drug mechanism of action, and strategies that optimize drug efficacy and minimizes its side effect. Mathematical models of dynamic systems and optimal control theory have been widely used in the engineering and industries for product design and plant control. The rapid development of systems biology is building momentum for application of the mathematical models and optimal control theory to the pharmaceutical industry. In this report, we propose to use state-space equations for modeling biological networks and apply EM algorithms and extended Kalman filter to the estimation of the parameters in the state-space model of the biological networks. We formulate the drug development as a multi-objective optimal nonlinear control problem and develop algorithms for solving constrained multi-objective optimal control problems. We apply the developed methods to the development of the treatment of Systemic sclerosis (SSc) that is a typical complex disease in which fibrosis occurs in multiple organs. The major source of fibrosis in SSc is over production of collagens from fibroblasts. We developed mathematical model for TGFB pathway that produces collagens. We also developed optimal control strategies which reduce the concentration of collagens to the normal level. The results are confirmed by the experiments of siRNA.

Association of the endothelial nitric oxide synthase gene polymorphism (4a/4b) with the risk of coronary artery disease in mexican population. *R.P. Mariaud[1,2], M. Zuñiga[3], M.P. Gallegos[2]* 1) Instituto de Investigación en Odontología, Departamento de Clinicas Odontologicas Integrales,Centro Universitario de Ciencias de la Salud, Universidad de Guadalajara; Guadalajara, Jalisco, Mexico; 2) Centro de Investigación Biomédica de Occidente, Instituto Mexicano del Seguro Social; Guadalajara, Jalisco, Mexico; 3) Unidad de Terapia Intensiva de Cardiología, Hospital de Especialidades, Centro Medico Nacional de Occidente, Instituto Mexicano del Seguro Social; Guadalajara, Jalisco, Mexico.

BACKGROUND: The vascular endothelium is now recognized as an important participant in a healthy cardiovascular system, and dysfunction of this cellular monolayer might be an initiating event in many or most cardiovascular disease states. The eNOS gene harbours a common polymorphism in intron 4 (4a/b), and some clinical studies have suggested an association of the rare a-allele with coronary artery disease (CAD) and myocardial infarction (MI). However, contradictory results have also been reported. OBJECTIVE: Determinated the association of eNOS polymorphism 4a/4b in CAD patients from Mexican population. MATERIAL AND METHODS: We studied the association of eNOS polymorphism with CAD in 153 patients and 112 controls. For the polymorphisms analysis we amplified a 420bp segment of intron 4. RESULTS: We not observed a significant differences between patients carrying the a-allele (ba+aa) compared with control group, (odds ratio 1.01, 95% confidence interval 0.60-1.61, P>0.05). CONCLUSION: The eNOS gene 4a/b polymorphism was not associated with Mexican patients with CAD.

Upregulation of transthyretin in the brain of a Phenylketonuria mouse model. *J.W. Park, E.S. Park, M.H. Lee, H.Y. Park, S.C. Jung* Department of Biochemistry,School of Medicine, Ewha Womans University, Seoul, Korea.

Phenylketonuria (PKU) is an autosomal recessive disorder that arises from deficiency of phenylalanie hydroxylase (PAH), which catalyzes the conversion of phenylalanine to tyrosine. The resultant hyperphenylalanemia causes mental retardation, seizure, and behavior and movement abnormalities. The high levels of phenylalanine affect brain development in PKU, but the mechanism of neuropathogenesis has not been fully elucidated. Therefore, gene expression profiling was performed in the brain of a mouse model for PKU. Microarray expression analysis revealed overexpression of transthyretin (TTR), early growth response 2 (Egr2), sclerostin domain containing 1 (SOSTDC1), prolactin receptor (PRLR) and klotho (KL) by gene-dosage dependent manner in the brain of the PKU mouse. Among them, transthyretin (prealbumin) is a thyroid hormone-binding protein that transports thyroxine from the bloodstream to the brain. Upregulation of transthyretin and other genes was confirmed by real-time PCR. Western blot analysis also showed increased levels of transthyretin in the brain of the PKU mice, compared to the wild type. This study could be a clue to understand the mechanism of neuropathogenesis and to find a useful biomarker of PKU.

Five genes are associated with colonic ischaemia and serious complications of constipation in a sample of diarrhoea predominant Irritable Bowel Syndrome patients treated with alosetron hydrochloride. *L.C. McCarthy[1], K.J. Davies[1], L.R. Budde[1], C.M. Vignal[1], S.W. Stinnett[1], C.J. Cox[1], A.J. Nelsen[1], D.P. Yarnall[1], H.C. Hollyfield[1], A.A. Flynn[2], I.E. Johnson[3], S.H. Gordon[3], V.Z. Ameen[4], J.S. Almenoff[5], S.S. Sundseth[1], E.H. Lai[1], M.G. Ehm[1]* 1) Pharmacogenetics, GlaxoSmithKline; 2) Drug Discovery Sciences, GlaxoSmithKline; 3) Clinical Development, GlaxoSmithKline; 4) CPDM, GlaxoSmithKline; 5) MIGU MDC, GlaxoSmithKline.

Objective: Determine whether there are any genetic biomarkers associated with the occurrence of ischaemic colitis (IC) or serious complications of constipation (SC) in diarrhoea predominant IBS (d-IBS) patients treated with alosetron. Patients & Methods: A 611,000 SNP whole genome screen and extensive sets of candidate genes were analysed for association with IC and/or SC, in 10 IC cases, 8 SC cases and 305 controls. All cases and controls were d-IBS patients and received alosetron treatment. All cases reported IC or SC following marketing of alosetron. Results: Five genetic biomarkers associated with IC and/or SC have been identified in this case sample, all with sensitivity and/or specificity >80%. HTR7 shows significant association with susceptibility to IC and SC; CAV2 is associated with susceptibility to IC; NR1I3, CSMD1 and COMMD10 are associated with susceptibility to SC. Six significant associations with polymorphisms in genomic loci which do not currently contain known genes were also identified for IC and SC phenotypes. HTR7, CAV2, NR1I3, CSMD1 and COMMD10 gene products have been previously implicated in the mechanisms of inflammation, ischaemia and/or Inflammatory Bowel Disease (IBD). Conclusion: We provide evidence that is consistent with the presence of genetic factors associated with the occurrence of IC or SC in d-IBS patients treated with alosetron. Due to the small case sample sizes in this study, all association results should be considered exploratory and require validation by independent replication and/or additional supporting evidence. If replicated in an independent sample, any validated genetic associations could contribute to a prognostic test to identify patients at increased risk of developing IC and/or SC.

Mutual Information Theory Based Multilocus LD Measure and Its Application to Haplotype Block Partitioning.

L. Zhang[1,2], *J.F. Liu*[1], *HW. Deng*[1,2,3] 1) The Key Laboratory of Biomedical Information Engineering of Ministry of Education and Institute of Molecular Genetics, School of Life Science and Technology, Xi'an Jiaotong University, Xi'an, Shanxi 710049, P.R. China; 2) Departments of Orthopedic Surgery and Basic Medical Science, School of Medicine, University of Missouri-Kansas City, 2411 Holmes Street, Kansas City, MO 64108; 3) Laboratory of Molecular and Statistical Genetics, College of Life Sciences, Hunan Normal University, Changsha, Hunan 410081, P. R. China.

In association studies, it is helpful to evaluate the pattern of linkage disequilibrium (LD) across the human genome for partitioning haplotype block as well as searching for disease genes. Commonly used pairwise measures for assessing LD between two loci, such as D and r2, may lose power in either using multilocus data or precisely describing LD patterns. Meanwhile, most existing multilocus LD measures, such as Normalized Entropy Difference (NED), do not consider the LD heterogeneity in the genome. Consequently, a unified LD measure for multiple loci may result in an ambiguous LD boundary. Additionally, these existing multilocus LD measures can not handle distant regions which may render long range LD patterns. In this study, we proposed a novel multilocus LD measure based on mutual information theory. The measure can largely overcome the drawbacks of both pairwise and multilocus previous LD measures. Using mutual information, our proposed measure describes LD pattern between two multilocus regions each as a compact unit. As such, the proposed measure can better characterize LD patterns between two arbitrary regions. We further applied this LD measure to haplotype blocks partitioning using both simulation and empirical data sets. The results show that the developed LD measure herein has distinct advantages over both traditional pairwise and multilocus LD measures. Compared with the other measures, our LD measure is more robust, which can capture well the LD information between neighboring regions as well as regions with a long distance from each other. Furthermore, haplotype block boundaries can also be precisely detected via our proposed method.

Mapping and identification of genes underlying autosomal dominant non-syndromic sensorineural hearing loss in Chinese families. *H. Yuan[1], J. Cheng[1], Q. Sun[1], H. Sun[1], P. Dai[1], D. Han[1], X. Liu[3], L. He[2]* 1) Institute Of Otolaryngology, Chinese PLA General Hospital, Beijing 100853, China; 2) Bio-X Life Science Research Center, Shanghai Jiao Tong University, Shanghai 200030, China; 3) Department of Otolaryngology, University of Miami, Miami, FL 33136 USA.

In this study, we have identified two novel mutations in two Chinese DFNA families. A maximum two-point LOD score of 6.69 at theta=0 was obtained for marker D14S1040 in family SD-Z001. Haplotype analysis placed the locus within a 7.6 cM genetic interval defined by marker D14S1021 and D14S70, overlapping with the DFNA9 locus on chromosome 14q12-q13. DNA sequencing of coding exons and exon/intron boundaries of the COCH gene identified a c.1625G>A mutation in exon 12 that co-segregates with auditory dysfunction in the pedigree. The mutation results in a predicted C542Y substitution at an evolutionarily conserved cysteine residue in the vWFA2 domain of cochlin. The predominant feature of these Chinese families is that all the affected subjects harboring COCH mutations in the vWFA2 domain do not suffer the vestibular symptoms during their life time. A comprehensive vestibular assessment reveals only subtle vestibular hypofunction in some affected members of these families. In family NMG-L024, the disease locus was mapped to a 12 cM region of chromosome 7p15 between marker D7S629 and D7S526, with a maximum two point LOD score of 5.39 for D7S2457, overlapping with DFNA5 locus. A novel heterozygous mutation,IVS8+4A>G, in the splice donor site of intron 8 was identified in this family. Messenger RNA studies indicated that the identified mutation leads to skipping of exon 8 in the mutant transcript. The IVS8+4A>G mutation is predicted to create a shift in the reading frame and introduce a stop codon at position 372, resulting in a prematurely truncated DFNA5 protein. Thus far, a total of four mutations have been identified in DFNA5 families, all of them result in skipping of exon 8 at the mRNA level. This is the first mutation that is identified in intron 8 in DFNA5 family. Our findings provide further support for the hypothesis that DFNA5-associated hearing loss is caused by gain-of-function mutation.

Genetic discrimination by phenotype: the law versus the insurers in health. *A. Ordonez, F. Suarez, E. Diaz* Inst de Genetica Humana, Pontificia Univ Javeriana, Bogota, DC, Colombia.

The epidemiologic transition in Colombia is the main reason by which in the country, the second cause of mortality in the newborns, is the birth defects. Nevertheless, birth defects are not covered by the insurances of health. Objectives: to determine the set of laws that guarantees the access to the health services to the individuals affected by birth defects and to determine causes by which the attention in clinical genetics is not a priority of the health system. Methods: systematic revision of the legal regulations of the Colombian system of health. Revision of the norms of the insuring companies in health, and of the health maintenance organizations (HMOs), in relation to the attention of birth defects. Results: the Colombian law through the act of the childhood and adolescences, Colombian congress Law 1098 2006, stipulates that the affected with birth defects must receive appropriate medical attention, diagnostic, treatment and counseling. In contrast, the basic plan of health insurance and the HMOs in Colombia only cover one consultation to the geneticist, and no diagnostic test or genetic test asked for, by the geneticist, are covered. The insurers warn to the parents of the patient, about this situation and explain that this restriction is based on the pre-existence of the pathology, which means that the diseases exist before the individual were assured, a situation that prevents him/her the access to the health insurance and attention to the congenital or genetic diseases. The Colombian law of security in health, Colombian congress law 100-1993, prohibits the implementation of this concept (pre-existence), but the insurers apply it currently. Conclusion: the birth defects constitute, in the affected individuals, a discrimination mark into the health system which moves them away of an suitable attention, a discrimination that we have denominated genetic discrimination by phenotype, in which the people with congenital malformations, are warned by the insurers about the supposed limitations that the health plans have in relation to their pathology, a warning based on a concept that the Colombian law prohibits.

A boy with 46,XY,dup(16)(q22.1q23.1) and the ATR-X phenotype. *T. Tokutomi[1, 2, 3], T. Wada[4], M. Sasaki[3], E. Nakagawa[1, 3], S. Saitoh[5], M. Mukaida[2], Y. Goto[1]* 1) Dept. Mental Retardation & Birth Defect Research, National Institute of Neuroscience, NCNP, Kodaira, Tokyo, Japan; 2) Dept. Forensic Medicine, National Defense Medical College, Tokorozawa, Saitama, Japan; 3) Dept. Child Neurology, Musashi Hospital, NCNP, Kodaira, Tokyo, Japan; 4) Dept. Medical Genetics, Shinshu Univ., Matsumoto, Nagano, Japan; 5) Dept. Pediatrics, Hokkaido Univ., Sapporo, Hokkaido, Japan.

INTRODUCTION: The combination of -thalassemia and mental retardation (ATR) is recognized in two distinct syndromes; ATR-X (MIM #301040) and ATR-16 (MIM #141750). ATR-X results from mutations of a putative chromatin remodeling factor encoded by *ATRX* at Xq13.3. ATR-16 is caused by a contiguous gene deletion involving the -globin genes at 16p13.3. The presence of -globin tetramers (HbH inclusions) in peripheral blood was originally used to define ATR-X. An ATR-X phenotype without -thalassemia, however, was reported to be associated with *XNP* mutation, splicing mutation in *ATRX*, or a segmental duplication spanning chromosome 16p13.11-p13.3.

CLINICAL REPORT: The patient, a 10-year-old boy, closely resembled the phenotype of ATR-X except -thalassemia. He showed characteristic clinical features including severe mental retardation, hypotonia, short stature, and characteristic facies. He had no evidence of HbH inclusions.

CYTOGENETIC ANALYSIS: G-banding and high-resolution chromosome analysis in the boy demonstrated an abnormal chromosome 16 with q22.1-q23.1 duplication. His parents had normal karyotypes. FISH using an internal BAC clone RP11-485F09 at 16q22.2 confirmed the duplication. Subtelomeric FISH analyses for 16p and 16q were intact.

DISCUSSION: We report a potential association between ATR-X phenotype and dup(16)(q22.1q23.1) in a patient. ATR has not previously been associated with duplication of 16q. Further precise analysis of the genomic region spanning this segmental duplication may identify novel genes possibly involved in pathways regulated by ATRX.

Characterization and AAV2/8-mediated gene therapy for maternal PKU syndrome in a PKU mouse model. *E.J. Lee, H. Kim, J.W. Park, J.O. Choi, E.S. Park, H.Y. Park, S.C. Jung* Department of Biochemistry, School of medicine, Ewha Womans University, Seoul, Korea.

Phenylketonuria (PKU) is an autosomal recessively inherited metabolic disorder caused by a deficiency of phenylalanine hydroxylase (PAH). The accumulation of phenylalanine leads to severe mental and psychomotor retardation, and uncontrolled female patients present maternal PKU syndrome. Recently, we reported the cognitive outcome of biochemical and phenotypic reversal of PKU mouse model, Pahenu2, by the AAV 2-mediated gene delivery of a human PAH transgene. However, the therapeutic effectiveness had been limited only in male PKU mice. In this study, we generated pseudotyped rAAV2/8-hPAH vector and infused into female PKU mice via the hepatic portal vein or the tail vein. Two weeks after injection, the complete coat color change to black was observed in female PKU as in male. The PAH activities in the liver increased to 65-70% of wild-type in female PKU mice, to 90% in male PKU. Plasma phenylalanine level in female PKU mice decreased to normal value. In addition, the offsprings of the treated female PKU mice can completely overcome the maternal PKU syndrome. The crown-rump length and body weight of fetuses from treated female PKU mice were recovered to the wild type values. Also, the spontaneous abortion rate of treated female PKU mice was normalized. These results indicate that recombinant AAV2/8 mediated gene therapy might be a promising therapeutic strategy for PKU.

Characterization of a novel asymmetrical isodicentric chromosome 18. *C.C. Lin[1,4], P.P. Liu[2], Y.C. Li[3], L.J. Hsieh[1], Y.C. Liu[1], Y.M. Cheng[1], S.L. Shi[4], C.H. Tsai[4], F.J. Tsai[4]* 1) Lab for Chromosome Research, China Medical Univ & Hosp, Taichung, Taiwan; 2) Womens Clinic, Taichung, Taiwan; 3) Dept. of Biomedical Sciences, Chung Shan Medical University, Taichung, Taiwan; 4) Dept. of Medical Genetics and Pediatrics, China Medical University Hospital, Taichung, Taiwan.

Molecular cytogenetic analysis identified a new type of isodicentric chromosome involving different breakpoints at 18q in a female fetus; the anomaly was termed asymmetrical pseudoisodicentric chromosome 18 [46,XX,dic(18)(pterq11.2:: q21.3pter)]. A series of BAC clones for 18q11.2 and q21.3 regions were used to identify one breakpoint within the region q11.2 between 19.8Mb and 21.6 Mb from the telomere of 18p and another breakpoint within q21.3 between 55.4 Mb and 56.9 Mb from the telomere of 18p by FISH analysis. Real-time quantitative PCR and microsatellite analysis further verified that the dicentric chromosome was maternal in origin and resulted from break-a reunion between sister chromatids of a single maternal chromosome. We propose that a loop-type configuration of sister chromatids took place and that the break-reunion occurred at cross sites of the loop to form an asymmetrical isodicentric during either in mitosis or meiosis. In this case, the asymmetrical pseudoisodicentrics resulted in an 18pterq11.2 duplication and an 18q21.3qter deletion, which could lead to certain dysmorphic features of 18q- syndrome in the fetus. Particularly, we presented here a severe form of congenital aural atresia (common feature of 18q- syndrome), anotia associated with an 18q terminal deletion and identified the breakpoint occurred at 18q somewhere between 55.6 Mb and 56.9 Mb from the 18p telomere.

Characterization of junction sites of deletion type variants detected by Array-CGH in Japanese populations. *Y. Satoh[1], N. Tsuyama[1, 2], K. Sasaki[1], M. Kodaira[1], H. Omine[1], Y. Shimoichi[1], H. Katayama[3], N. Takahashi[1]* 1) Dept Genetics, RERF, Hiroshima, Japan; 2) Dept Anal Mol Med Dev, Hiroshima Univ Grad Sch Biomed Sci, Hiroshima, Japan; 3) Dept Info Tech, RERF, Hiroshima, Japan.

We have investigated the effect of atomic bomb radiation to human germ cells at the DNA level, that is, whether mutation rate of atomic bomb survivor's offspring increase significantly more than control group. In order to examine whole human genome, we introduced array CGH method that a comparative genomic hybridization was performed on a microarray system. A population study was performed using genomic DNA from 40 offspring of atomic bomb survivors and 40 offspring of control group. A total of 251 variations was detected using arrays on which about 2,300 human BAC clones were printed. 14 of these variation were rare variant, which were identified in only one offspring among the population. 8 variation was amplification type and 6 variation was deletion type. We report the characterization of deletion type variation. The characterizations of variations were done as follows: (1) Estimations of fragment length of deletion variations by pulse field gel electrophoresis, (2) Narrowing down of junction site by quantitative PCR, (3) Determination of sequence of which junction site was amplified by PCR. Junction site sequences of five kinds of deletion type variation were determined. Average length of deletion region was about 134 kb, and shortest one was 84 kb and longest was 239 kb. Alu- family like sequences were existed in two breaking points in the junction sites and LINE sequence was existed in one breaking point, and the others showed unique sequences at the breaking points. Some variations had a insertion or a inversion inside the deletion region. We report conceivable mechanisms that may produce these deletion variants.

CATSHL Syndrome: Report of Three New Families and Further Delineation of the Phenotype. *R. Toydemir[1], M. McMillin[2], P. Kezele[2], S. Felscher[2], D. Eunpu[3], K. Aleck[4], C. Marques[5], M. Bamshad[2]* 1) HHMI, Dept. of Human Genetics, University of Utah, Salt Lake City, UT, USA; 2) Dept. of Pediatrics, University of Washington, Seattle, WA, USA; 3) Nemours Childrens Clinic, Jacksonville, FL, USA; 4) Section of Medical and Molecular Genetics, Dept. of Pediatrics, University of Arizona, Phoenix, AZ, USA; 5) University of Sao Paulo, Sao Paulo, Brazil.

CATSHL Syndrome (OMIM 610474) is a recently described skeletal dysplasia characterized by camptodactyly of the hands and feet, tall stature, and hearing loss. Less frequent clinical features include kyphoscoliosis, mental retardation, learning disabilities, and microcephaly. CATSHL is caused by substitution of a histidine for a highly conserved arginine residue in the kinase domain of the FGFR3 (p.R621H) that is predicted to result in loss of function. Accordingly, the clinical features of CATSHL recapitulate those found in the *Fgfr3* knockout mouse. To date, CATSHL syndrome has been reported in only a single large pedigree from the U.S. We now report the clinical characteristics of 3 additional families with CATSHL syndrome. The first case is a 7-month-old boy who has camptodactyly, tall stature (96%ile), and bilateral moderate sensorineural hearing loss. His head circumference is at the 25%ile. He also has scoliosis, dysplastic femurs, adducted left knee, and a valgus deformity of the left tibia with new periosteal bone formation. Neither parent is affected. The second case is a 12-year-old girl who has camptodactyly, height more than 95%ile for age, and bilateral sensorineural hearing loss. She has a large forehead and wide set eyes, and developmental delay. She has a 7-year-old brother, who also has camptodactyly and adducted thumbs. Their father reportedly has similar features but was unavailable for study. The third case is an 8-month-old girl born in Brazil who has camptodactyly and tall stature (97%ile). Her hearing appears to be normal. Her father is also affected and has camptodactyly, scoliosis, and tall stature. Phenotypic analysis of these 3 new families further delineates the clinical characteristics of CATSHL syndrome. Screening of *FGFR3* in these families is underway.

Dysregulation of sodium channel 4 expression in the striatum of Huntington Disease transgenic mice. *F. Oyama[1], H. Miyazaki[1], M. Kurosawa[1], T. Kaneko[2], N. Nukina[1]* 1) Lab Structural Neuropathology, RIKEN Brain Science Inst, Saitama, Japan; 2) Department of Morphological Brain Science, Graduate School of Medicine, Kyoto University, Kyoto, Japan.

Sodium channel 4 (4), a recently identified auxiliary subunit of the voltage gated-sodium channels, is significantly downregulated in the striatum of Huntington Disease (HD) model mice and patients. We examined 4-expressing neurons in striatum using in situ hybridization with 4 probe, followed by immunohistochemistry with anti preproenkephalin (PPE) or anti preprotachykinin A (PPTA) and found that 4 mRNA is expressed in two groups of striatal neurons projecting to globus pallidus (marker protein: PPE) and substantia nigra (marker: PPTA). TaqMan RT-PCR analysis indicated that both 4 and PPE mRNAs are preferentially decreased in striatum at a presymptomatic stage of HD mice, while PPTA mRNA and its peptide are unaltered even at the symptomatic stage. These results indicate that there is a difference in downregulation of mRNA and its product among striatal projection neuron proteins.

Polymorphisms of *RIG-I* are associated with adult bronchial asthma. *M. Tamari[1], T. Hirota[1], M. Harada[1], M. Sakashita[1], S. Doi[2], A. Miyatake[3], Y. Nakamura[4]* 1) Lab Genetics Allergy, RIKEN SNP Research Center, Yokohama, Japan; 2) Osaka Prefectural Medical Center for Respiratory and Allergic Diseases, Osaka, Japan; 3) Miyatake Asthma Clinic, Osaka, Japan; 4) The institute of Medical Science,University of Tokyo,Tokyo, Japan.

Bronchial asthma is a complex disorder caused by combination of genetic and environmental factors, and clinical and experimental evidence suggest an important role for respiratory viral infections in the development of asthma. An epidemiologic study showed that ~50% of adult asthma attacks ware associated with viral upper respiratory infections. Recent study has shown that retinoic-acid inducible gene-I (RIG-I) is a helicase-domain-containing protein and plays a crucial role in the host response to viral infection. These findings implicated *RIG-I* as a candidate gene for involvement in asthma. To assess genetic functional variants of *RIG-I* related to susceptibility and clinical phenotypes in adult asthma in a Japanese population, we screened for polymorphisms in *RIG-I* and conducted association studies of 465 subjects with adult asthma and 744 controls. We identified a total of 25 variants, and two non-synonymous substitutions, 19C/T (Arg7Cys) and 33636C/T (Ser144Phe), were found in *RIG-I* with minor allele frequencies of 4%. We characterized the linkage disequilibrium (LD) mapping of the gene by using the Haploview 3.2 program and three variants were selected for genotyping with regard to the LD pattern. We found significant associations between two 3UTR polymorphisms (69438T/C and 70483T/del) and adult asthma susceptibility ($P = 0.026$ and $P = 0.015$, respectively). These findings suggest that the *RIG-I* gene might be involved in the development of adult asthma and the genetic polymorphisms might affect the sensitivity to viral infections. Further investigations off the connection between genotypes and the functional role of RIG-I will be helpful to clarify the etiology of asthma.

Evaluation of Critical Genetic Variation in Idiopathic Recurrent Miscarriages among South Indian Women- a Genomic and Proteomic Approach. *L. Rao[1], V. Suryanaryana[1], M. Kanakavalli[1], V. Padmalatha[1], T. Raseswari[1], D. Mamata[2], S. Lalji[1]* 1) E409,Centre for Cellular and Molecular Biology, Hyderabad, India; 2) Infertility Institute and Research Centre, Hyderabad, India.

Title: Evaluation of Critical Genetic Variation in Idiopathic Recurrent Miscarriages among South Indian Women- a Genomic and Proteomic Approach Lakshmi Rao1, Venkata Suryanarayana1, Kanakavalli Murthy1, Venkata Padmalatha1, T Raseswari1, Mamata Deenadayal2, Lalji Singh 1 1. Centre for Cellular and Molecular Biology, Uppal Road, Hyderabad, India 2. Infertility Institute and Research Centre, Hyderabad, India 3. Corresponding author Statement of purpose Recurrent early pregnancy loss (REPL) is defined as three consecutive first-trimester miscarriages. Reasons include increased maternal age, genetic, anatomical, immunological, endocrine and environmental or life style factors like smoking, caffeine-intake, alcohol, drug-intake and stress. We present genomic and proteomic analysis of women with idiopathic REPL to find etiological factors involved. Methods Well-defined REPL subjects (n=200) and control women (n=99) were included for genotyping studies. For platelet proteome analysis, 25 cases and 10 controls were included. Polymorphisms in detoxification genes (NAT,NAT2,CYP1A1,CYP2D6,SULT1A1,CYP19,aryl hydrocarbon receptor, aryl hydrocarbon receptor repressor), vasoregulatory genes (eNOS,VEGF, anadamide hydrolase), genes involved in blood homeostasis (Prothrombin,Factor V Leiden) were analyzed and their significance was estimated using a two tailed Fishers P-value at 95% significance level. Platelet proteome-analysis was carried out after isolation and solubilization of platelets. Summary of results: Polymorphisms in CYP1A1 (C4887A and T6235C) showed significant association with REPL as evidenced by logistic regression and haplotype analysis. Novel variants in CYP2D6,anadamide hydrolase,eNOS were associated with REPL. Proteomic analysis of platelets revealed a differential expression pattern in three proteins with approximate molecular masses of 65kDa, and 20kDa which were present in REPL women.

Characterization of the Finnish prostate cancer susceptibility locus HPCX. *T. Wahlfors[1], H. Mattila[1], K. Ivori[1], K. Chang Sik[2], M. Vihinen[2], H. Oja[4], T. Tammela[3], T. Ikonen[1], J. Schleutker[1]* 1) Lab of Cancer Genetics,Inst of Medical Technology,Univ of Tampere and Tampere Univ Hospital, Tampere,Finland; 2) Bioinformatics,Inst of Medical Technology,Univ of Tampere, Tampere,Finland; 3) Division of Urology,Tampere Univ Hospital and Medical School,Tampere,Finland; 4) Tampere School of Public Health,Univ of Tampere,Tampere,Finland.

Prostate cancer is the most common male cancer in the Western world but its etiology is still unclear. While most of the cancer cases are sporadic, there is evidence suggesting that 42% of the cases have a hereditary component. A locus that has been shown to be important in the Finnish population is HPCX on Xq27-28. To date, the susceptibility gene has not been found because of the complex structure of the chromosomal region. We are applying the NMD microarray technique for the analysis of HPCX. In this technique the patient sample is compared to itself after inhibition of NMD. Microarrays are then used to identify nonsense transcripts that are increased in abundance after loss of NMD. Inactivation of tumor suppressor genes is a two-step process involving mutation of the target gene and loss of the other allele. In lymphoblastoid cell lines the other normal wild type allele can mask the effect of a germline mutation. Because males have one X-chromosome, there is only one allele of the X-chromosomal genes. Therefore, tumor suppressor genes may be caught using lymphoblastoid cell lines. Cell lines for analysis were selected from six affected and six healthy persons in HPCX linked families. mRNA was isolated from cells after treatment and the altered levels of mRNA expression were studied using Agilent 44K oligoarrays. In data analysis the limma package from Bioconductor was used for differential expression analysis using the linear models. First, ten genes were selected for direct sequencing and afterwards five genes more by using different linear model. So far the following genes have been sequenced:RBMX, CSAG2, RAP2C, SOX3, MBNL3, ZNF75, MAGEC1, MAGEA1,MAGEA11, MAGEC3, RAB39B, SUHW3, RAB9A and ZBTB33. No truncating mutations were found. However, a few interesting missense mutations were detected and these genes are now under further study.

Identification of marker chromosomes using FISH-based technology and DNA polymorphic marker. *Y.C. Li[1], L.J. Hsieh[2], C.P. Chen[3], F.J. Tsai[4], C.C. Lin[2]* 1) Dept. of Biomedical Sci, Chung Shan Medical Univ, Taichung, Taiwan; 2) Dept. of Medical Research, China Medical University and Hospital, Taichung, Taiwan; 3) Dept. of Obstetrics and Gynecology, Mackay Memorial Hospital, Taipei, Taiwan; 4) Dept. of Medical Genetics and Pediatrics, China Medical University Hospital, Taichung, Taiwan.

Marker chromosomes are chromosome or chromosome fragment which their origin can not be resolved by conventional cytogenetic analysis. Marker chromosome account for about 1:1,100 cases at amniocentesis, 1:4,000 in live born and approximately 1:400 in mentally retarded patients. We performed 24 colors spectral karyotyping (SKY) analysis and/or FISH study with chromosome region specific probes to identify 33 cases of marker chromosome (19 cases were prenatal). All but 3 cases, the origin of marker chromosome can be unequivocally identified (success rate: 90.9%). Among those marker identified, 10 cases were derived from chromosome 15 (33%), 6 cases involved chromosome 22 (20%), 3 cases originated from chromosome 9 (10%), 3 cases involved chromosome 18 (10%), 3 cases were derived from X chromosome (10%) and 2 cases from Y chromosome. The remaining 3 cases were each from chromosome 2, 3 and 14 respectively. In some of the cases, QF-PCR assays with STR markers on specific chromosome regions were also conducted to reveal the paternal or maternal origin of the marker chromosomes. Three of 33 cases had been reported as case reports (Chen et al. 2004; Lin et al. 2006; Chen et al. 2006). The study demonstrated the importance of clinical cytogenetic and molecular analysis for diagnosis of marker chromosome and showed how crucial it was for prenatal counseling and management of the pregnancies. The study was supported by grants from the National Health Research Institute (NHRI-EX92-9207SI) and from the National Science Council (NSC95-2311-B-040-001), Taiwan.

The dual role of HLA-DRB1*13 in ACPA positive and ACPA negative Rheumatoid Arthritis. *E. Lundström[1], H. Källberg[2], J. Rönnelid[3], L. Alfredsson[2,4], L. Klareskog[1], L. Padyukov[1]* 1) Department of Medicin, Karolinska Institutet and Hospital, Stockholm, Sweden; 2) Environmental Medicin, Karolinska Institutet, Stockholm, Sweden; 3) Oncology, Radiology and Clinical Immunology, Uppsala University, Sweden; 4) Stockholm Center for Public Health, Sweden.

Objective. Since the discovery of the importance of HLA-DRB1 alleles as risk factors for development of rheumatoid arthritis (RA), major interest to shared epitope (SE) alleles remains dominant and very little has been studied regarding influence on RA from non-SE HLA-DRB1 alleles. In this study we investigate the impact of several different DRB1 alleles in two major subgroups of RA defined by the presence or absence of anti-citrullinated protein antibodies (ACPA). Methods. HLA typing was performed by SSP-PCR for 1352 patients (820 anti-CP positive and 532 anti-CP negative) and 922 controls from the Epidemiological Investigation of Rheumatoid Arthritis (EIRA) material. Odds ratios (ORs) for HLA-DRB1 allele frequencies were calculated with 95% confidence intervals (95% CI) and interpreted as relative risks (RR), since the study was population-based. Results. We show that DRB1*13 is protective against anti-CP positive (RR 0.57, 95% CI 0.37-0.88) but not anti-CP negative RA (RR 1.10, 95% CI 0.81-1.50) when using dominant model. Further we confirm that DRB1*03 contributes to anti-CP negative (RR 1.37, 95% CI 1.01-1.87) but not anti-CP positive RA (RR 0.94, 95% CI 0.63-1.40). However, this was not true when we analyzed DRB1*03 using recessive model (RR: 1.60 95% CI 0.81-3.14). In opposite, we show that DRB1*03 together with DRB1*13 reveal significant risk for anti-CP negative disease, (RR: 1.75 95% CI: 1.04-2.94) suggesting a possible interplay between these two alleles. Conclusion. Our data show complex relations between different DRB1 alleles in development of RA. DRB1*13 is playing a dual role, being protective against anti-CP positive but increasing risk of anti-CP negative arthritis in combination with DRB1*03. Interestingly, DRB1*13 might be involved in protecting against virus infections, which may support the hypothesis concerning the viral etiology of RA.

Aberrant DNA methylation of multiple genes in myeloid leukemia. *K. Uhm, Y. Lee, E. Lee, H. Kim, S. Park* Dept Anatomy, Col Medicine, Korea Univ, Seoul, Korea.

DNA methylation in the promoter region of a gene plays an important role in gene silencing. To examine whether promoter methylation is involved in the tumorigenesis of hematologic malignancies, I investigated promoter methylation status of the 6 multiple genes in 20 acute myeloid leukemias (AML) and 20 chronic myeloid leukemias (CML) by methylation-specific PCR (MSP) method. Fifty-five of normal peripheral blood samples were included as controls. The frequencies of DNA hypermethylation in AML were: 43% for SFRP1, 85% for SHP1, 86% for Integrin a4, 93% for RUNX3, 29% for H-cadherin, and 0% for DAB2IP, respectively. The DNA methylation frequencies in CML were; 6% for SFRP1, 25% for SHP1, 13% for Integrin a4, 31% for RUNX3, 35% for H-cadherin, 0% for DAB2IP, respectively. In contrast, DNA hypermethylation of genes, excepted H-cadherin, was not detected in 55 normal peripheral blood samples. The DNA methylation frequencies of SFRP1, SHP1, Integrin a4, and RUNX3 genes were higher in AML than in CML, significantly ($p<0.05$). These results suggest that the transcriptional inactivation by aberrant methylation of SFRP1, SHP1, Integrin a4, and RUNX3 genes may contribute to the tumorgigenesis of AML and CML. Also, the aberrant DNA methylations of these 4 genes are more frequent event in AML than CML.

Lack of association between HFE gene mutations and breast cancer in Azorean patients. *P.R. Pacheco[1,2], H. Polena[1], C. Ballart[1], T. Eloi[3], C.C. Branco[1,2], R. Cabral[1,2], V. Santos[3], V. Carneiro[4], L. Mota-Vieira[1,2]* 1) Mol Genetics Pathol Unit, HDES; 2) IGC, Oeiras; 3) Cirurgic Dept, HDES; 4) Anatomic Pathology Dept, HDES, Azores, Portugal.

Iron overload, caused by HFE mutations, may be carcinogenic because it can catalyse the formation of free radicals, suppress the immune system and increase tumour cells growth. Hence, HFE mutations have been evaluated as risk factors for cancer. The purpose of this study was to assess if HFE mutations are related to the risk of breast cancer (BC). To that end, we compared frequencies of C282Y and H63D mutations in 86 Azorean BC women and in 183 healthy controls. Samples were obtained after written informed consent. The C282Y allele frequency in the BC group was 4.07%, higher than in control group, 3.28%; with an OR=1.25 (95% CI, 0.48 - 3.24). Regarding H63D mutation, the allele frequency in the BC group was 21.51%, very similar to the frequency found in the control group, 21.04%; OR=1.03 (95% CI, 0.66 - 1.6). The mean age at diagnosis for BC patients was 60.4 yr (range, 33-87) and 54.8 yr (range, 31-84) in the healthy control group. As age is known to influence breast cancer risk and thus could be a confounding factor, we stratified the BC and the healthy control groups into three age stratum, according to the menopausal status (<48, 49-58 and >59 yr). Odds ratio for breast cancer risk associated with H63D mutation was 1.29 (95% CI, 0.54 - 3.13) in women bellow 48 yr; 0.69 (95% CI, 0.24 - 2.01) in the range of 49-58 yr, and 0.97 (95% CI, 0.53 - 1.78) in women above 59 yr. On the other hand, odds ratio for breast cancer risk associated with C282Y mutation increased with age, from 1.14 (95% CI, 0.29 - 4.52) in women bellow 48 yr to 2.03 (95% CI, 0.44 - 9.27) in women above 59 yr. The risk for breast cancer was higher in older women bearing the C282Y mutation than in healthy controls, although not statistically significant. In conclusion, the results suggest that HFE gene mutations are not associated with an increased risk for breast cancer and do not significantly contribute to the community prevalence of breast cancer in the Azorean population (paularpacheco@hdes.pt). Azorean Government founded.

Functional interactions of conserved non-coding (CNCs) sequences with other CNCs using circular chromosome conformation capture (4C). *D. Robyr, G. Duriaux-Sail, S. Polti, C. Wyss, S. Deutsch, S.E. Antonarakis* Genetic Medicine and Development, University of Geneva Medical School, Geneva, Geneva, Switzerland.

The comparison of human chromosome 21 (Hsa21) sequences with the mouse syntenic regions led to the identification of roughly 3500 regions displaying an identity of 70% over a length of a least 100 nucleotides of ungaped alignment. About 65% (~ 2300) of these are conserved non-coding sequences (CNCs).Very little is known about the function of most CNCs. We speculated that a functional CNC may interact with its genomic target (i.e. an enhancer would bind to its cognate gene promoter). Thus, the identification of any part of the genome that interacts directly with a CNC could provide clues on the function of the latter. We have generated libraries of CNC-interacting DpnII fragments by chromosome conformation capture (4C) whose identity is determined by subsequent sequencing. We have generated initial results concerning crosslinking of 18 Hsa21 CNCs with DNA fragments mapping hundreds of kilobases away from the bait on the same chromosome, or with fragments on other chromosomes. A total of 245 such potentially interacting DpnII DNA fragments have been identified so far. Interestingly, the median distance from the cloned DpnII fragments to the nearest conserved region is 767bp with a pvalue of 0.045 when compared to the distribution of the median of the distances of 1000 random samples of 245 fragments. These results provide initial evidence that the function of CNCs is mediated by their interaction with other conserved regions. We are now using high-throughput sequencing technology in order to increase the pace of characterization of the CNCs-interacting loci.

Parkes Weber syndrome, vein of Galen aneurysmal malformation, and other fast-flow vascular anomalies, and specific neural tumors, associated with CM-AVM and RASA1 mutations. *N. Revencu[1], L.M. Boon[1], J.B. Mulliken[2], O. Enjolras[3], M.R. Cordisco[4], D. Chitayat[5], M. Vikkula[1]* 1) Lab Human Molec Genetics, Christian de Duve Inst, Brussels, Belgium; 2) Vascular Anomalies Center, Children's Hospital, Boston, USA; 3) Centre Multidisciplinaire des Angiomes de lenfant, Hôpital denfants Armand-Trousseau, Paris, France; 4) Department of Pediatric Dermatology, Hospital de Pediatria Dr. J.P. Garrahan, Buenos Aires, Argentina; 5) Medical Genetics Program Mount Sinai Hospital, Toronto, Canada.

Background: Mutations in RASA1 were documented in 6 families (39 individuals) with autosomal dominant multifocal capillary malformations (CMs). Nine individuals had an associated arteriovenous malformation/fistula (AVM/AVF). One patient had Parkes Weber syndrome (PKWS), a disorder considered to be sporadic and non-genetic. Methods: We collected clinical information and DNA samples for 61 probands (from 21 centers) and their families with a phenotype similar to that observed in the original study: 56 had multifocal CMs, and 35 also a fast-flow vascular anomaly: 19 AVM/AVF and 16 PKWS; 5 had PKWS without multifocal CMs. RASA1 was screened by DHPLC followed by sequencing. Results: We identified 42 distinct mutations in 44/61 probands: 16/19 with AVM/AVF, 13/16 with PKWS, 15/21 with multifocal CMs only, and 0/5 with PKWS without multifocal CMs. RASA1 mutation was also found in 57 relatives. Overall, 17 individuals with a RASA1 mutation had an AVM/AVF: 8 were intracranial, 2 of which were vein of Galen aneurysmal malformations. Moreover, 7 patients had either a benign or a malignant tumor, 3 of which are known to occur in neurofibromatosis type I and/or type II. Penetrance of RASA1 mutations was 98% and de novo occurrence was 32%. Conclusions: Multifocal CM is the hallmark of RASA1 mutation. These patients often have extra- or intracranial AVM/AVF. This study confirms the original association designated capillary malformation-arteriovenous malformation (CM-AVM). In addition, PKWS, as well as vein of Galen aneurysmal malformation are genetic diseases, part of the CM-AVM spectrum. Specific neural tumors also may be linked to RASA1. (miikka.vikkula@uclouvain.be).

Global transcript profiles of adipose tissue in weight-discordant MZ twin pairs: Pathways behind acquired obesity. *J. Naukkarinen[1], K.H. Pietiläinen[2,3,4], A. Rissanen[2], J. Saharinen[1], P. Ellonen[1], H. Yki-Järvinen[3], M. Oresic[5], J. Kaprio[4], L. Peltonen[1,6]* 1) Dept Molecular Medicine, National Public Health Inst., Finland; 2) Obesity Research unit, HUCH, Helsinki, Finland; 3) Dept of Medicine, Division of Diabetes, HUCH, Helsinki, Finland; 4) Finnish Twin Cohort Study, Dept of Public Health, University of Helsinki, Finland; 5) VTT Technical Research Centre of Finland, Espoo, Finland; 6) The Broad Institute, MIT, Cambridge, MA, USA.

The metabolic consequences of obesity arise from a complex interaction of genes and environment, the contributions of which are difficult to discern. We aimed to expose biological pathways affected by acquired obesity using a unique study design of deeply phenotyped MZ twin pairs discordant for recent onset of obesity (n=14 pairs, age 25 years, 15.2 kg mean weight difference). This design facilitates identification of obesity-induced changes in biological pathways independent of genetic background. Body composition was carefully assessed using DEXA, MRI and spectroscopy, and insulin sensitivity by the euglycemic clamp technique. Transcript profiles of abdominal subcutaneous fat was done by Affymetrix U133 Plus 2.0 arrays. Lipidomics and amino acid measurements in serum and adipose tissue were done by liquid chromatography/mass spectrometry. The obese co-twins subcutaneous fat revealed marked reductions in the mtDNA copy number. Our novel pathway analysis of transcript profiles reveal significant downregulation of mitochondrial branched-chain amino acid (BCAA) catabolism and upregulation of inflammatory pathways. The pathway changes correlate with liver fat accumulation, insulin resistance and hyperinsulinemia. Additional support was obtained from parallel changes in serum levels of insulin secretion-enhancing BCAAs and proinflammatory lipid species in serum and fat. The data provide compelling evidence for the inflammatory character of acquired obesity associated with significant defects in BCAA catabolism. These aberrations are closely associated with ectopic fat accumulation and insulin resistance, hallmarks of obesity from early on in young healthy adults.

Independent NF1 and PTPN11 mutations in a family with Neurofibromatosis-Noonan syndrome. *C.T. Thiel[1], M. Wilken[2], M. Zenker[1], R. Fahsold[3], A. Rauch[1]* 1) Institute of Human Genetics, University Hospital Erlangen, University of Erlangen-Nuremberg, Erlangen, Germany; 2) Private pediatric clinic, Eppenreutherstr. 28, Hof, Germany; 3) Private clinic Prager & Junge, Dresden, Germany.

Neurofibromatosis-Noonan syndrome (NFNS), an entity which combines both, features of Noonan syndrome (NS) and Neurofibromatosis type 1 (NF1), was etiologically unresolved until recent reports demonstrating NF1 mutations in the majority of patients with NFNS. The phenotypic overlap was explained by the involvement of the RAS pathway in both disorders. 95% of patients with NF1 show loss of function mutations of the NF1 gene, encoding a GTPase-activating protein which terminates Ras-GTP signalling, whereas NS is genetically heterogeneous with activating mutations in genes of the RAS pathway, in particular PTPN11. We report on an 18 month old girl with developmental delay, mild pulmonary stenosis and craniofacial anomalies suggestive of NS. In addition she had 11 café-au-lait spots, compatible with a diagnosis of LEOPARD syndrome. The development of bilateral optical gliomas at 19 month, though, suggested NF1. An otherwise healthy brother had 5 café-au-lait spots and mild craniofacial anomalies (broad nasal bridge) while the mother had about 10 café-au-lait spots without any further signs of neurofibromatosis. Mutational analysis of the NF1 and PTPN11 genes in the proband revealed a maternally inherited heterozygous splice-site mutation c.4661+1GC in intron 27a of the NF1 gene and a de-novo PTPN11 missense mutation c.5CT (p.T2I). The NF1 mutation was also present in the brother and the mother and interestingly was distinct from the recently described recurrent 3-bp inframe deletion in exon 17 described as the cause of absence of neurofibromas in Neurofibromatosis. In contrast to published cases, in the probands mother and brother the NF1 mutation resulted in only a mild NF1 phenotype without major signs of Noonan syndrome, despite its location within the GAP domain forming region. However, the unexpected additional PTPN11 mutation explains the index patients craniofacial NS features.

Frequent 22q11 aberrations in patients with non-syndromic autism spectrum disorders shown by SNP array based segmental aneuploidy screening. *M. Poot[1], N. Verbeek[1], R. van 't Slot[1], M.R. Nelen[1], B. van der Zwaag[3], E. van Daalen[2], W. Staal[2], J.A.S. Vorstman[2], M.V. de Jonge[2], P.F. Ippel[1], M.J. van den Boogaard[1], F.A. Beemer[1], J. van der Smagt[1], E.H. Brilstra[1], G.R. Jalali[4], B.S. Emmanuel[4], H. van Engeland[2], J.P.H. Burbach[3], H.K. Ploos van Amstel[1], R. Hochstenbach[1]* 1) Dept. Medical Genetics, UMC Utrecht, Utrecht, Netherlands; 2) Child and Adolescent Psychiatry, UMC Utrecht; 3) Pharmacology and Anatomy, Rudolf Magnus Institute of Neuroscience, UMC Utrecht; 4) The Division of Human Genetics, The Children's Hospital of Philadelphia and the Joseph Stokes Jr Research Institute, Philadelphia, USA.

Autism spectrum disorders (ASD) are neurodevelopmental conditions characterized by impaired reciprocal social interaction, communicative deficits, and restricted behavioral patterns. ASD occurs in syndromic forms (e.g. FRAX, del(22q13), Rett), and as non-syndromic cases frequently involving cytogenetic abnormalities. Recently, array-based genome-wide screens have demonstrated frequent copy number variation in non-syndromic ASD. Screening 50 patients with autism and additional major or minor anomalies with the Infinium HumanHap300 SNP platform (Illumina, Inc., San Diego, CA) we found in 17 patients 10 regions with deleted and 19 with duplicated signals. Aberrant signals were distributed among 26 distinct chromosomal loci. Eleven of those have previously been reported as regions of significant linkage to or association with ASD. Apart from 14 patients with unique aberrations, 2 patients carried duplications and a 3rd patient a deletion within the 22q11 region, of 0.726, 2.966, and 0.388 Mb, respectively. The duplications were confirmed by multiplex ligation-mediated probe amplification and are likely to involve LCRs A, B and D. We conclude that SNP array-based screening of ASD patients uncovers an appreciable number of CNVs, which in part overlap with loci already discovered by other approaches. Our finding that 3 out of 50 ASD patients carried aberrations within the 22q11 region is highly unexpected. The relatively small size of CNVs found in this study may allow us to pinpoint candidate genes for ASD.

Deletions in GCH1 are a frequent cause of Dopa-responsive dystonia. *U. Müller[1], D. Steinberger[2], C. Troidl[1], K. Brockmann[3], M. von der Hagen[4], C. Feiner[5], J. Henke[6], B. Zirn[1]* 1) Institut für Humangenetik, Justus-Liebig-Universität, Giessen, Germany; 2) Bioscientia, Ingelheim, Germany; 3) Pädiatrie II, Universität Göttingen, Germany; 4) Neuropädiatrie, Universität Dresden, Germany; 5) Neurologische Praxis, Tuttlingen, Germany; 6) Institut für Blutgruppenforschung, Köln, Germany.

Molecular diagnosis of Dopa-responisve dystonia (DRD) is usually done by sequencing the six exons of the gene GCH1. This method does not detect heterozygous deletions which have been reported in DRD. We therefore assessed the frequency of deletions and point mutations in GCH1 in a large cohort of patients with Dopa-responsive dystonia (DRD). A total of 136 dystonia patients were studied. These were divided into two groups according to clinical criteria. Group 1 included dystonia patients with a dramatic therapeutic response to L-Dopa plus/or circadian fluctuation of symptoms (definite or probable DRD). Group 2 included those dystonia patients in whom clinical data were incomplete and L-Dopa response was not striking or not tested (possible DRD). 57 patients were assigned to group 1 and 79 to group 2. We found a GCH1 point mutation in 27 patients of group 1 (47.4%) and in 4 of group 2 (5.1%). Of these, nine single and one double mutation have not been recognized before. GCH1 deletions were detected by qPCR in four patients of group 1 (7.0%) and in one patient of group 2 (1.3%). The entire GCH1 gene (exons 1 to 6) was deleted in four patients, and a partial deletion (exons 3 to 6) was found in one. Three of the four complete GCH1 deletions were familial and one had occurred de novo. The partial deletion was familial. The high frequency of deletions of GCH1 demonstrates that deletion analysis should be included in the routine molecular diagnosis of DRD.

Biological and genetic interplay between the asthma susceptibility genes Neuropeptide S receptor 1 and Tenascin C. *C. Orsmark-Pietras[1], E. Melén[2], J. Vendelin[3], M. van Hage[4], F. Nyberg[2], G. Pershagen[2], A. Scheynius[4], M. Wickman[2], J. Kere[1,4], and the PARSIFAL Genetics Study Group* 1) Dept. of Biosciences and Nutrition, Karolinska Institutet, Sweden; 2) Institute of Environmental Medicine, Karolinska Institutet, Sweden; 3) Dept. of Medical Genetics, University of Helsinki, Finland; 4) Dept. of Medicine, Karolinska Institutet, Sweden.

Neuropeptide S receptor 1 (NPSR1, GPRA) was recently identified as a susceptibility gene for asthma and high total serum IgE levels. The ligand for NPSR1, Neuropeptide S (NPS), activates signalling through NPSR1 and microarray analysis has identified Tenascin C (TNC) as a target gene of NPS-NPSR1 signalling. Several studies have linked TNC to asthma through its altered expression in asthmatic tissue but few genetic analyses have been performed. As both NPSR1 and TNC have been implicated as susceptibility genes for asthma, and since TNC is upregulated by NPSR1 activation, our objective was to study the joint risk modifying effect of different TNC and NPSR1 allele combinations. Regulation of TNC was investigated using NPS stimulated NPSR1 transfected cells. Using the cross-sectional PARSIFAL study (n=3,113) we genotyped 12 TNC SNPs and performed single SNP association, haplotype association and TNC and NPSR1 gene-gene interaction analysis. Our results confirm and show a NPS dose-dependent expression of TNC. The genotyping results indicate single SNP and haplotype associations to several SNPs in TNC for asthmatic phenotypes with the most significant association for haplotype TGGT (p=0.0005) in rhinoconjunctivitis. Evidence of significant gene-gene interaction was found between several of the TNC and NPSR1 SNPs. We here show that the asthma susceptibility gene TNC, previously thought of as a phenotypic marker for inflammation also contributes to the asthmatic phenotype on a genetic level. We show an example of gene-gene interaction, based on both a regulatory relationship between NPSR1 and TNC and genetic interaction between NPSR1 and TNC, modifying the phenotype in asthma-related traits. These results join previously independent pathways of importance in the development of asthma and allergic diseases.

Association between *TNF receptor 2* gene polymorphisms and anti-TNF treatment response in a large cohort of patients with rheumatoid arthritis. *C. Potter[1], J. Bowes[1], K.L. Hyrich[1], BRAGGSS[2], A. Morgan[3], A.G. Wilson[4], J. Isaacs[5], J. Worthington[1], A. Barton[1]* 1) University of Manchester, UK; 2) Biologics in Rheumatoid Arthritis Genetics and Genomics Study Syndicate; 3) University of Leeds, UK; 4) University of Sheffield, UK; 5) Newcastle University, UK.

Purpose: To investigate association between response to anti-TNF therapy and genetic variation in the gene encoding the type 2 TNF receptor (*TNFR2*) in a large UK cohort of patients with rheumatoid arthritis (RA).
Methods: UK-wide multi-centre collaborations were established to recruit a cohort of 642 patients treated with anti-TNF drugs for RA (46% received Infliximab, 43% Etanercept and 11% Adalimumab). Pairwise tagging and random single nucleotide polymorphisms (SNP) spanning the *TNFR2* gene were identified from the phase II Hapmap dataset (www.Hapmap.org). Genotyping was performed using a Sequenom MassArray platform. Linear regression was performed to investigate association between SNPs and response to anti-TNF therapy at 6 months, defined as the absolute change in disease activity score (DAS28), under a genotypic model.
Results: Twenty SNPs were successfully genotyped and conformed to Hardy-Weinberg expectations. Associations of borderline significance were demonstrated between drug response and 3 SNPs, mapping to the promoter and 5' region of the *TNFR2* gene (rs520916: p=0.04, rs652625: p=0.04, rs3766730: p=0.04). Strong linkage disequilibrium was exhibited between two of these SNPs (rs520916-rs652625: r^2=0.72) but not the third (rs520916-rs3766730: r^2=0.01, rs652625-rs3766730: r^2=0.02). No association with the remaining SNPs was demonstrated. In particular, a tagging marker for a potentially functional polymorphism (M196R, rs1061622) mapping to exon6 of the gene did not demonstrate association with drug response.
Conclusion: Association between 2 independent effects within the *TNFR2* gene and anti-TNF treatment response was demonstrated in a cohort of patients with RA. These findings require replication in other series and, if confirmed, further fine mapping to identify the causal variant.

Parkinson Disease in Russia: Analysis of Genetics Markers in Patients with Sporadic Parkinsons Disease. *S. Limborska[1], M. Shadrina[1], E. Semenova[1], G. Bagyeva[2], M. Partola[1], S. Illarioshkin[2], P. Slominsky[1]* 1) Human Molecular Genetics Dept, Institute of Molecular Genetics, Russian Academy of Sciences, Moscow, Russian Federation; 2) Department of Neurogenetics, Institute of Neurology of Russian Academy of Medical Sciences, Moscow, Russian Federation.

Sporadic Parkinsons disease (PD) is a common neurodegenerative disorder, characterized by the loss of midbrain dopamine neurons and Lewy body inclusions. It is thought to result from a complex interaction between multiple predisposing genes and environmental influences, although these interactions are still poorly understood. A major breakthrough in recent years was identification of mutations in multiple genes causing inheritable form of the disease such as parkin, leucine-rich repeat kinase 2, DJ-1, PINK1 and other loci. Mutations in the parkin gene (PARK2) are a frequent cause of autosomal recessive, early onset Parkinsonism. Various mutations have been identified. s of PD development is mutations in this gene. The mains types of mutations in this gene are deletions and duplications of single exons or exon groups. We analyzed rearrangements in exons 1-12 of the PARK2 gene in 140 patients with early-onset Parkinsons disease (EOPD) and in 200 patients with classical sporadic Parkinsons disease. All the patients were from Russia. The frequency of these mutations in EOPD patients was 11,8%, in classical sporadic PD patients - 4,5%. Most frequent rearrangments were detected in exons 3, 4 and 5. Mutations in the gene Leucine-Rich Repeat Kinase 2 (LRRK2) have been identified in both dominant and sporadic cases affected by Parkinson's disease (PD). The LRRK2 Gly2019Ser mutation is the most frequent substitution in Caucasians, accounting for approximately 5-6% of familial and 0.5-2.0% of apparently sporadic PD cases. We investigated the frequency of the LRRK2 G2019S mutation in our sporadic PD patients and 13 autosomal dominant PD patients. We established that the frequency of this mutations in female patients was 7,7% and in sporadic patients was 0,8%.

Molecular Analysis of Progressive Familial Intrahepatic Cholestasis In Israel. *T. Yardeni[1], Y. Anikster[2], R. Shapiro[3], Y. Bujanover[4], D. Bercovich[1,5]* 1) Genetics, migal, Kiryat-shmona, Israel; 2) Metabolic Disease Unit Sheba Medical Center Tel-Hashomer; 3) Institute of Gastroenterology,Schneider Children's Medical Center; 4) Paediatric Gastroenterology Unit Sheba Medical Centre; 5) Tel Hai Academic College, Israel.

Progressive familial intrahepatic cholestasis (PFIC) syndromes are a rare autosomal recessive disorder, characterized by defects in the mechanisms involved in bile formation. PFIC leads to death in the first decade of life if liver tranplant is not preformed. This disorder has multi-phenotypes which are divided in to subtypes PFIC:1,2,3. The correlation between genotype and phenotype are not always clear. There are three known suspected genes which could be involved in this disorder: The PFIC1 (ATP8B1) gene that codes the P-type ATPase protein, which is expressed in the liver parenchymal cells; the PFIC2 (BSEP) gene codes for ATP-binding cassette (ABC) transporter protein, which is expressed only in the liver canalicular membrane. The MDR3 is the third gene that codes a different ATP-binding cassette (ABC) transporters protein, which plays a key element in the availability of phospholipids to the canalicular bile. The aims of this study were to characterize the genetic molecular basis of patient with PFIC subtypes. Blood samples collection & DNA extraction were preformed on 14 different families, 10 of the children had PFIC1 or PFIC2 and 4 children with PFIC3 phenotypes. Mutations screening were preformed using DNA chromatography (DHPLC) of patient samples and controls, loci SNP's linkage study was preformed. Out of the 10 families with the PFIC1 or PFIC2 phenotypes, for two of them, a novel mutations were found in the BSEP gene, one (G877R) was homozygous in the patient from family number 2 and the two missense mutations (G19R & S226L) were compound heterozygous in the patient from family number 3. In family number 14 with the same phenotype, another heterozygous missense mutation was fond in the ATP8B1 gene (R600W), which is in the most conserve region of the protein. These findings have clinical and epidemiological aspects and may lead to a better understanding of the correlation between genotype and phenotype.

Identification of candidate genes common to bleomycin and radiation induced pulmonary fibrosis in mice. *A-M. Lemay, C. K. Haston* Dept Human Genetics, McGill Meakins-Christie, Montreal, PQ, Canada.

The genetic basis of susceptibility to pulmonary fibrosis is largely unknown. We previously identified bleomycin-induced and radiation-induced pulmonary fibrosis quantitative trait loci (QTL) in crosses of susceptible C57BL/6J (B6) mice with resistant A/J or C3H/fKam mice. We hypothesized that the genes involved in bleomycin induced pulmonary fibrosis would be the same as those of radiation-induced pulmonary fibrosis and this overlap would allow for the identification of a small number of candidate genes for further investigation. The linkage regions identified to be common to bleomycin and radiation response are on chromosomes 6, 17 and 18 (LOD= 2.4, 4.2 and 3.5). To further investigate these putative linkages, chromosome substitution strains [C57BL/6J-Chr 4A/NaJ (n=11), C57BL/6J-Chr 6A/NaJ (n=19) and C57BL/6J-Chr 17A/NaJ (n=19)], were treated with the bleomycin and the radiation protocols. The fibrosis phenotype of these strains was different from the B6 response for each treatment (% fibrosis of Chr6A=0.7 0.9, Chr17A=0.2 0.06, p>0.23) supporting the existence of A/J derived fibrosis protective alleles on chromosomes 6 and 17. To identify potential fibrosis candidate genes in the putative linkage intervals, gene expression studies with microarrays were completed on control and treated B6 mice. This analysis revealed 1012 genes to be differentially expressed in lung tissue in bleomycin treated mice and 118 differentially expressed genes in the study of radiation-induced pulmonary fibrosis. Of these, 48 genes were differentially expressed in both types of treatments. Pulmonary genes differentially expressed in bleomycin and radiation treated B6 mice included those of chemotaxis, proteolysis and immune response. Of the 48 genes differentially expressed in bleomycin and radiation-treated mice, 4 were located within the linkage regions. These genes were *Fkbp4* (FK506 binding protein), *Fkbp5*, *Angpt14* (angiopoietin-like 4) and *Lox* (lysyl oxidase). Genomic approaches were combined to produce a set of candidate genes which may influence susceptibility to pulmonary fibrosis regardless of the induction treatment.

Incorporating endophenotypes into family-based allelic association studies. *W.C. Wang[1], I.S. Chang[2], C.H. Chang[1], C.A. Hsiung[1]* 1) Division of Biostatistics and Bioinformatics, National Health Research Institutes, Taiwan; 2) Institute of Cancer Research, National Health Research Institutes, Taiwan.

For a genetic study in which there are concordant and discordant sibpairs for a complex disease trait and there are also available the measurements of other endophenotypes for each of the individuals, we describe a test for association that utilizes nonparametrically the additional endophenotypes. The usefulness of this method is evaluated in simulation studies, which show that the gain in power is influenced by not only the endophenotypic value but also the correlation between the diagnosis-based phenotype and the endophenotype. Comparison with multivariate FBAT in terms of power will be presented. An additional benefit of our approach is that it provides a method to evaluate the usefulness of endophenotypes. This study is partly motivated by the Stanford Asian Pacific Program in Hypertension and Insulin Resistance (SAPPHIRe) study, which included both concordant sibpairs (both sibs being hypertensives or hypotensives) and discordant sibpairs (one hypertensive and one hypotensive sib) and collected several biochemical assay data on metabolic variables. Data from the SAPPHIRe study are used to illustrate the method.

Paternal transmission and resistance against selection of mutant alleles associated with late-onset ornithine transcarbamylase deficiency in male patients. *M. Yoshino[1], E. Harada[1], A. Yanagawa[2], Y. Watanabe[1], S. Numata[1], C. Fujii[1]* 1) Pediatrics, Kurume University School of Medicine, Kurume, Fukuoka, Japan; 2) Institute of Biostatistics, Kurume University, Kurume, Fukuoka, Japan.

In 13 families with late-onset ornithine transcarbamylase (OTC) deficiency in male patients, 3 mutant alleles - R40H, R277W and Y55D - were identified. In a total of 22 informative parent-offspring pairs, father-to-daughter transmission and mother-to-offspring transmission occurred in 5 (23%) and 17 (77%), respectively, indicating that paternal transmission would substantially contribute to the pool of these mutant alleles. Relative reproductive fitness of males and females carrying these mutant alleles were calculated to be 0.49 and 0.89, respectively. Comparison of life-span of these mutant alleles estimated on the basis of these fitness values with those associated with 'classical' phenotype (neonatal onset), in which reproductive fitness of male patients was nil, revealed that the former was selected against much slowly. This would allow these late-onset phenotype mutant alleles to be retained more frequently than those associated with classical phenotype in a population. Although heterozygous female carrying these late-onset phenotype mutant alleles were generally asymptomatic, one female carrying R40H allele died after a hyperammonemic episode at the age 18 years. Such heterozygous female should be alerted to possible hyperammonemic crisis.

Maternal uniparental disomy 14 detected in patients suspected to have Prader-Willi syndrome. *S. Saitoh, K. Hosoki* Dept Pediatrics, Hokkaido Univ Sch Medicine, Sapporo, Japan.

Maternal uniparental disomy 14 [upd(14)mat] is characterized by intrauterine growth retardation, neonatal hypotonia, precocious puberty, and truncal obesity. The phenotypes of upd(14)mat resemble those of Prader-Willi syndrome (PWS) which is characterized by neonatal hypotonia, small hands and feet, mental retardation, and hyperphagia resulting in obesity beyond the infancy. Mitter et al. (2006) recently reported that upd(14)mat was detected in 4 out of 33 patients who were suspected to have PWS, and raised the question that upd(14)mat could be underestimated in patients with features resembling PWS. However, other studies have failed to detect upd(14)mat in cases resembling but lacking PWS. Therefore, we examined fifty eight Japanese patients initially suspected to have PWS based on clinical features, but for whom normal results of the *SNURF-SNRPN* DNA methylation test excluded the diagnosis of PWS. Using these samples, we examined DNA methylation status at the promoter region of the imprinted *MEG3* gene, located in 14q32.2. If aberrant DNA methylation was identified, we carried out a microsatellite polymorphism study and determined the parental origin of each chromosome 14. We identified abnormal hypomethylation at the *MEG3* promoter in 3 out of 58 patients. An almost complete lack of methylation was found in 2 patients, but 1 patient demonstrated a faint methylated signal. The polymorphism study demonstrated that the 2 patients lacking *MEG3* promoter methylation had complete upd(14)mat, whereas the patient with partial hypomethylation was mosaic for upd(14)mat. All 3 patients with upd(14)mat had intrauterine growth retardation, neonatal hypotonia and feeding difficulty, with PWS suspected during infancy. Our results further support the resemblance of upd(14)mat and PWS phenotypes, particularly during infancy, and demonstrate the significance of *MEG3* methylation testing for PWS-like patients in whom PWS is excluded.

RNAi of human transcription factors for analysing regulatory networks. *M. Sultan[1], I. Piccini[1], D. Schmidt[1], D. Balzereit[1], A. Fiebitz[1], W. Wruck[1], R. Herwig[1], I. Ulitsky[2], F. Buchholz[3], H. Lehrach[1], M.L. Yaspo[1]* 1) Max Planck Institute for Molecular Genetics, Berlin, Germany; 2) Tel Aviv University, Tel Aviv, Israel; 3) Max Planck Insitute for Molecular Cell Biology and Genetics, Dresden, Germany.

Systematic analysis of transcription factors (TFs) and associated gene regulation networks are of central relevance to developmental biology and medicine. In order to get insights into the nature and complexity of gene regulatory networks we analysed global gene expression profiles after knocking down specific transcription factors by means of RNAi technology in human cell lines. We initially focused on the TFs encoded by human chr.21 (TFs21) that are endogenously expressed in Hek293T17 cells. In order to evaluate off-target effects affecting the expression of unintended gene targets, we performed independent experiments using three different types of silencing molecules (siRNAs, esiRNA). Silencing efficiencies for the different molecules were evaluated by qRT-PCR, and whenever possible by Western blot. We retained for further analysis samples showing a knock-down at the mRNA level of at least 75%. Global transcriptome analysis are carried out on the Affymetrix platform. The subset of genes that are found dysregulated with all silencing molecules represent a high-confidence set of potential direct as well as indirect TF target genes. For BACH1 we identified a subset of 157 genes that are found dysregulated with all silencing molecules, representing a high-confidence set of potential target genes. Among those we observed the up-regulation of HMOX1 (Heme oxygenase 1), a known target of BACH1. We will present data on the set of 10 knocked down TFs21, and show how the data sets are used to chart potential regulatory networks, integrating other levels of information of ChIP on chip experiments and promoter informatics. In a systematic effort, we are currentely knocking down the expression of ca. 200 additional human transcription factors potentially involved in key developmental processes and human pathologies for understanding associated gene regulation networks.

Identification of a novel PD locus on chromosome 6q in Norwegian and Tunisian kindreds. *C. Vilariño-Güell[1], K. Haugarvoll[1], M.M. Hulihan[1], J.M. Kachergus[1], L. Ishihara-Paul[2], S. Oldham[2], R. Amouri[3], S.B. Ahmed[3], M. Kefi[3], R.A. Gibson[2], F. Hentati[3], J. Aasly[4], M.J. Farrer[1]* 1) Dept of Neuroscience, Mayo Clinic, Jacksonville, FL; 2) Research and Development, GlaxoSmithKline, USA and UK; 3) Dept of Neurology, Institut National de Neurologie, Tunis, Tunisia; 4) Dept of Neurology, St Olavs hospital, Trondheim, Norway.

Parkinsons disease (PD) is a prevalent, late-onset movement disorder affecting ~2% of the population by 70 years of age. To date, mutations in 5 genes (SNCA, PARKIN, DJ-1, PINK1, and LRRK2) have clearly been implicated in familial forms of PD. In addition, seven other chromosomal loci have also been mapped for inherited forms of PD. Here we report a new locus for late-onset, levodopa-responsive, autosomal dominant parkinsonism in families from Norwegian and Tunisian populations. Genome-wide genotyping and statistical analysis of 63 multiplex kindreds with familial parkinsonism from Tunisia, North Africa, identified significant linkage to chromosome 6q23.1-q24.2 (MLS=4.5). The same chromosomal 6q23.1-q24.2 locus was concurrently identified by linkage analysis of autosomal dominant parkinsonism in a large Norwegian pedigree (MLS=2.3). Combined, the statistical evidence for a novel gene mutation(s) is unequivocal (MLS=6.), for which the LOD-1 peak spans a genomic interval of 10.8Mb. The geographic origin of linked families in Tunisia and Norway suggests the prevalence of chromosome 6q23.1-q24.2 linked disease may be globally widespread. LRRK2 G2019S provides a good precedent as the mutation appears to have originated in the Tunisian Arab Berber community, but is now found throughout the world and is a major contributor to risk. Preliminary data implicates nine kindreds in total, in which affected families members have been screened for all other known genetic causes of parkinsonism. High resolution molecular genetic mapping in linked pedigrees, including STR, high-density SNP genotyping and copy number assessment have refined the disease-linked genomic interval. Gene sequencing is being pursued in affected family members of the largest Norwegian kindred, for which there is significant linkage to identify the novel causative gene mutation.

Van Allen-Myhre Syndrome: Report of a New Case with Chondrodysplasia Punctata. *S. Parkash[1,2], S. Keating[3], E. Kolomietz[3], D. Chitayat[1,2]* 1) Clinical and Metabolic Genetics, Hospital for Sick Children, Toronto, Ontario, Canada; 2) Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital, Toronto, Ontario, Canada; 3) Department of Laboratory Medicine and Pathobiology, Mount Sinai Hospital, Toronto, Ontario, Canada.

Van Allen-Myhre Syndrome consists of ectopia cordis, exomphalos, ectrodactyly, oligodactyly, absent sacrum, radial hypoplasia, microphthalmia, hemifacial microsomia, and cutis aplasia, among other findings. The syndrome was first described in a female infant of Mexican-American first cousins (Van Allen and Myhre, 1991). A second case was reported by Zolotukhina et al (1993). A third case, though not labeled as having Van Allen-Myhre Syndrome, describes a fetus with many features of the syndrome (Pivnick et al, 1998). Hancock et al (2002) reported a case initially thought to be suggestive of Van Allen-Myhre Syndrome, however was later felt to have features of Goltz Syndrome (Hancock et al, 2002). Goltz Syndrome, a presumed X-linked dominant disorder linked to Xp22, is associated with defects in the skin, skeleton, soft tissues, and eyes. We report a fetus with ectopia cordis, omphalocele, hyperlordosis, scoliosis, and ectrodactyly. Karyotype and microarray analysis was normal, with no deletion in the Xp22 region. Xrays revealed changes consistent with chondrodysplasia punctata. To our knowledge, this is the 4th case of Van Allen-Myhre Syndrome reported in the literature, and the first case with chondrodysplasia punctata, which adds to the confusion regarding overlap between this condition and Goltz Syndrome.

(1993) Unusual Complex of Congenital Malformations. Am J Med Gen 46: 728-729.

Hereditary pancreatitis caused by a double gain mechanism. *C. Le Marechal[1,2,3,4], E. Masson[1,2], J. Chen[1,3], C. Férec[1,2,3,4]* 1) INSERM, U613, 29220 Brest, France; 2) Faculté de Médecine de Brest et des Sciences de la Santé, Université de Bretagne Occidentale, 29238 Brest, France; 3) Etablissement Français du Sang - Bretagne, 29220 Brest, France; 4) Laboratoire de Génétique Moléculaire et dHistocompatibilité, Centre Hospitalier Universitaire de Brest, Hôpital Morvan, 29220 Brest, France.

Hereditary pancreatitis was often reported to be caused by 'gain-of-function' missense mutations in the cationic trypsinogen gene (PRSS1). Recently, we have reported that triplication of a ~605-kb segment containing the PRSS1 gene on chromosome 7 was responsible for the disease in five French Caucasian families (Le Marechal et al. Nat Genet 2006;38:1372-4). This triplication, which seems to result in a gain of trypsin through a gene dosage effect, represents a previously unknown molecular mechanism causing hereditary pancreatitis. Here, we further identified a hybrid trypsinogen gene due to unequal homologous recombination in a new French family. This mutational event was initially revealed by quantitative fluorescent multiplex PCR (QFM-PCR) and then fully characterized by long-range PCR at the nucleotide level; it resulted in the formation of an additional copy of trypsinogen that fused the anionic trypsinogen gene (PRSS2) with the PRSS1 gene. The resulting hybrid gene seems to be apparently functional because its expression was detected from the peripheral blood cells by RT-PCR. Most importantly, the hybrid gene was predicted to encode a protein with a known missense mutation that has been previously reported to cause hereditary pancreatitis. In summary, this mutation appears to cause the disease through a new mechanism viz. a double gain of trypsin through an increased trypsinogen copy that in turn encodes a clearly gain of function mutant protein.

Ignoring Temporal Trends in Genetic Effects Substantially Reduces Power for Detection of Quantitative Trait Loci. *G. Shi[1], D.C. Rao[1, 2]* 1) Division of Biostatistics, Washington University, St. Louis, MO; 2) Departments of Genetics and Psychiatry, Washington University, St. Louis, MO.

As individuals grow from birth, many physiological and biological changes take place in the pathways underlying human diseases, increasing risk for many diseases as a result of accumulating changes with age. Biological evidence of temporal trends in genetic effects have been demonstrated in animal studies. We propose a systematic variance components linkage analysis method incorporating temporal trends in QTL effects as well as in polygenic effects. Heritabilities are no longer constant over all ages, but instead are functions of the appropriate ages and depend in turn upon a few additional unknown temporal trend parameters. Using the generalized variance component model, we evaluate the gain in power of the linkage test in the presence of temporal trends. In our extensive simulations, we find that ignoring this gene-by-age interaction, when present, substantially reduces power thereby jeopardizing gene discovery. On the other hand, modeling such trends explicitly enhances gene discovery for complex traits. For example, when the average (over age) QTL heritability is 0.10 and the peak QTL heritability is 0.4, the empirical power is only 43% when trends are ignored, which increases to over 99% when the temporal trend is appropriately modeled.

Genome stability in SMC1A-mutated Cornelia de Lange Syndrome patients. *A. Musio[1], M. Paulis[1], M. Deardoff[2], M.L. Focarelli[1], K. Maninder[2], I. Krantz[2], P. Vezzoni[1]* 1) Human Genome Department, Istituto di Tecnologie Biomediche, CNR, Segrate, Milan, Italy; 2) Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, USA.

Cornelia de Lange syndrome (CdLS) is a clinically heterogeneous developmental disorder characterised by facial dysmorphia, upper extremity malformations, cardiac defects, growth and cognitive retardation. Due to the often severe presentation of CdLS, most cases arise sporadically as a consequence of de novo mutations, while the milder familial cases are rare. Recent reports showed that mutations in NIPBL, which codes for a cohesin-associated factor, as well as in two cohesin subunits, SMC1A and SMC3, cause CdLS . These findings demonstrate that CdLS is a heterogeneous disorder, in agreement with the fact that the severity of the symptoms varies greatly among the patients, although the cellular basis of this diversity only now is beginning to be elucidated. Among the cohesin complex factors, SMC1A seems to play important and different roles. In fact, in addition to a structural function, it is involved in gene expression, in genome stability and in DNA repair and recombination. Recently, it has been observed that some CdLS patients carrying mutations in NIPBL gene show increased chromosome breakage and Premature Sister Chromatid Separation, suggesting that there may be some predisposition to chromosomal fragility in CdLS. This information is lacking in patients carrying mutations in the SMC1A gene. To address this point, Epstein-Barr virus immortalized lymphoid cell lines and primary human fibroblasts from CdLS patients have been established and analysed for both spontaneous and induced genome instability by standard cytogenetic methods. This work will allow us to further investigate the ability of CdLS cells to block the cell cycle and to repair damaged DNA providing, for the first time, a direct link between CdLS and genome instability.

Developing genetic competency in undergraduate nursing students: Follow-up to a 2006 study. *L. Tribble*
Education Division, Greenwood Genetic Center, Greenwood, SC.

Background: The largest group of healthcare providers is registered nurses whose work allows a unique and holistic view of patients. In the 21st century of genomic medicine, nurses need to understand basic genetic concepts, to identify patients in need of genetic services through the collection of family histories, and to provide information regarding genetic testing.

Objective: To determine if the instructional content from a 3 hour nursing elective in human genetics for third year students was useful and encountered in students' senior level coursework and clinical experiences.

Methods:A six question survey was developed and posted on electronic Blackboard for access by 35 students who had completed a semester elective in human genetics in early 2006. Questions were designed to assess which instructional topics were identified by students as being encountered in their senior coursework and clinical rotations.

Results: Eleven of the 35 (31.4%) students completed the survey.

1. Students identified the topics of newborn screening, prenatal testing and family history as being the most useful in their current classes and rotations.

2. Students reported that genetic information proved useful in senior level courses, specifically obstetrics and gynecology, pediatrics, maternal/newborn nursing, medical-surgical nursing,and in clinical work.

3. Participants indicated an opinion that genetics will play an important role in modern healthcare and expressed confidence in their ability to locate genetic services and information for patients.

Conclusion: Based on survey results, it is suggested that a specific course in human genetics at the undergraduate level is both needed and beneficial in professional nursing preparation. Curriculum should emphasize relevancy and application to nurses' work and attention should be noted to emphasize specific topics of genetic instruction.

Response to neo-adjuvant chemotherapy in women with BRCA1-positive breast cancers. *J. Lubinski[1], T. Byrski[1], J. Gronwald[1], T. Huzarski[1], E. Grzybowska[2], M. Budryk[2], M. Stawicka[3], T. Mierzwa[4], M. Szwiec[5], R. Wisniowski[6], M. Siolek[7], S.A. Narod[8], The Polish Hereditary Breast Cancer Consortium* 1) Dept. of Genetics and Pathology, International Hereditary Cancer Center, Pomeranian Medical University, Szczecin; 2) Department of Tumor Biology, Maria Skłodowska-Curie Memorial Institute Gliwice, Poland; 3) Prophylactic and Epidemiology Center, Poznań, Poland; 4) Department of Clinical Genetics, Bydgoszcz Medical University, Poland; 5) Regional Oncology Hospital, Opole, Poland; 6) Regional Oncology Hospital, Bielsko Biała, Poland; 7) Holycross Oncology Center, Kielce, Poland; 8) Centre for Research in Women`s Health, University of Toronto, Canada.

PURPOSE: There have been no studies to date which look at the relative effectiveness of different regimens of chemotherapy in women who have breast cancer and who carry a BRCA1 germ-line mutation. We wished to compare rates of response to neo-adjuvant chemotherapy in BRCA1 mutation carriers and non-carrier controls. EXPERIMENTAL DESIGN: From a registry of 3,479 patients, we identified 44 Polish women who carried a BRCA1 founder mutation and who had been treated with neo-adjuvant chemotherapy for breast cancer, and 41 age- and hospital-matched controls. RESULTS: 35 of the 44 BRCA1 mutation carriers (80%) experienced a partial or complete response to neo-adjuvant chemotherapy, compared to 39 of the 41 (95%) non-carriers (P = 0.05). In the hereditary subgroup, response rates differed depending on whether or not a taxane (docetaxel) was given. Six of the 15 BRCA1 carrier women given docetaxel with doxorubicin responded (complete or partial), compared to 29 of 29 given other (DNA-damaging) therapies (P = 0.001). Among the non-carriers, the rates of response to the two categories of chemotherapy were similar. CONCLUSIONS: Breast cancers among BRCA1 carriers frequently do not exhibit sensitivity to docetaxel in the neo-adjuvant setting. It is likely that normal BRCA1 is required for clinical response to mitotic spindle poisons.

Cleidocranial dysplasia: the use of a specific protocol to detect atypical cases and new findings in eight Brazilian cases. *P.J.G. Pereira, L.A.N. Oliveira, D.R. Bertola, R.S. Honjo, C.A. Kim, L.M.J. Albano* Genetics Unit, Instituto da Criança, Sao Paulo, SP, Brazil.

Cleidocranial dysplasia (CCD) constitutes a generalized autosomal dominant skeletal dysplasia with variable expression, affecting membranous bone ossification. It is characterized by short stature, patent fontanels, tooth anomalies, hypoplastic clavicles and other skeletal changes. We applied a specific radiological protocol in eight cases with clinical diagnosis of CCD from 4 families to amplify the CCD phenotypic spectrum and also to detect atypical cases. Six out of eight patients were females, and two were males. All cases were familial but one (7/8 - 87.5%). Main clinical findings were: short stature (3/7 - 43%); typical face (6/8 - 75%); midfacial hypoplasia (6/8 - 75%): delayed closure of the fontanels (5/7 - 71.5%); patent fontanels (2/7 - 28.5%); late teeth eruption (7/8 - 87.5%); delayed eruption of permanent teeth (7/7 - 100%); approximation of the shoulders (6/8 - 75%); genu valgus (6/8 - 75%); flatfeet (5/8 - 71.5%). Main X-ray findings were: hypoplasia of the clavicles (6/8 - 75%); aplasia of clavicles (1/8 - 12.5%); small scapulae (5/7 - 71.5%); hypoplasia of the iliac wings (4/7 - 57%); wide pubic symphysis (6/7 - 86%); delay of the pubic bone ossification (6/7 - 86%); broad femoral head and short femoral neck (6/7 - 86%); coxa valga (4/8 - 50%); coxa vara (2/8 - 25%); underpneumatization of the sinuses air cells (4/7 - 57%); lack of ossification of the calvaria (4/8 - 50%). No atypical CCD case was found. However, one case presented a duplication of the calcaneus, which is an unusual finding. We consider that integrated radiological and genetic evaluations are important to a better delineation of this skeletal dysplasia. Thus, atypical cases and new findings would be easily and promptly detected.

MTHFR and E-selectin gene polymorphism towords genetic predisposition of coronary artery disease (CAD). *R. Tripathi[1,2], S. Agarwal[2]* 1) Genetics, SGPGIMS, Lucknow, India; 2) Genetics prof.

MTHFR (5,10 methylene tetrahydrofolate reductase) is a regulatory enzyme of homocysteine metabolism whereas E-selectin (CD62E) mediates the adhesion of circulating leukocytes and play a role in pathogenesis of atherosclerosis. The aim of the study to determine the influence of C677T polymorphism of MTHFR gene and A561C polymorphism of E-selectin gene in North Indian population.The C677T polymorphism and A561C polymorphism were genotyped by PCR-RFLP in n=112 angiographically documented CAD patients and n=127 age/sex matched healthy individuals as control.The T allele frequency of MTHFR gene were 13.56% in CAD patients Vs 7.4% in control,this indicate significant association ($p<0.05$, OR=1.94, 95%CI=1.076-3.778) of MTHFR gene C677T polymorphism with CAD. The C allele of E-selectin gene ($p>0.05$, OR=1.15) shows insignificant association.Our study shows that MTHFR can be used as genetic marker for predisposing CAD. However, largesample size is needed to confirm the results.

Data mining and comparison of measures of informativeness for ancestry in admixture mapping. *T.B. Mersha[1], H.W. Wiener[2], H.K. Tiwari[1], D.T. Redden[1,3], D.B. Allison[1, 3,4], R.C.P. Go[2]* 1) Section on Statistical Genetics, Department of Biostatistics, UAB, Birmingham, AL; 2) Department of Epidemiology and International Health, UAB, Birmingham, AL; 3) Clinical Nutrition Research Center, UAB, Birmingham, AL; 4) Department of Nutrition Sciences, UAB, Birmingham, AL.

Given the huge amount of single nucleotide polymorphism (SNP) data available from high-throughput sources such as HapMap, data mining is a reasonable approach to identify SNPs that are informative for genetic ancestry. The distribution and density of the SNPs across the genome of African and European populations were extensively investigated using three SNP databases of HapMap, Affymetrix and Illumina. We have exploited these resources by web mining the data available from each of these databases to prioritize potential candidate SNPs useful for admixture mapping. About 4 million SNPs were compared between Africans and Europeans using various measures of ancestry informativeness in use today viz. absolute allele frequency differences (), Fisher Information Content (FIC), Shannon Information Content (SIC), and Fixation Index (FST). Each method provides different sets of candidate ancestry informative markers (AIMs) within and across the databases. The selected SNPs represent valuable resources for admixture mapping studies. The overlap and non-overlap between selected AIMs by different measures of informativeness, and in the different platforms are discussed.

Identification of transcobalamin as the cobalamin-binding protein in crude mitochondrial fractions in fibroblasts from patients with inborn errors of vitamin B_{12} metabolism. *L. Yamani[1,2], A. Hosack[2], B.M. Gilfix[2], D. Watkins[2], D.S. Rosenblatt[1,2]* 1) Department of Human Genetics, McGill University, Montreal, Quebec, Canada; 2) Division of Medical Genetics, Department of Medicine, McGill University Health Centre, Montreal, Quebec, Canada.

Vitamin B_{12} (Cobalamin, Cbl) binds two enzymes intracellularly. The cytosolic enzyme, methionine synthase (MS), utilizes methylcobalamin (MeCbl) as a cofactor in the conversion of homocysteine to methionine. The mitochondrial enzyme, methylmalonyl-CoA mutase (MCM), utilizes adenosylcobalamin (AdoCbl) as a cofactor in the conversion of L-methylmalonyl-CoA to succinyl-CoA. A defect in MeCbl metabolism or MS (*cblD variant 1, cblG,* and *cblE*) results in homocystinuria. A deficiency in AdoCbl synthesis or MCM (*cblA, cblB, cblD variant 2,* and *mut*) results in methylmalonic aciduria. A defect in steps common to the two pathways causes both conditions (*cblC, cblD,* and *cblF*). We have recently shown that at least one Cbl-binding protein of 28 kDa besides MCM exists in crude mitochondrial fractions. Human fibroblasts were incubated for 96 hours in 25 pg/mL [^{57}Co]CNCbl bound to human transcobalamin (TC). Crude mitochondrial fractions were isolated and analyzed by gel filtration chromatography. The presence of a Cbl-binding protein with an estimated molecular weight of 28 kDa was confirmed. The amount of labelled Cbl bound to this 28-kDa protein was increased in cells from *mut, cblB,* and *cblD var.2* patients, as opposed to wild-type cells. In an attempt to identify this protein, crude mitochondrial fractions from a *cblB* cell line were incubated with anti-TC antibody-coated beads. It was found that the protein was precipitated by the anti-TC antibody. Analysis of labelled Cbl from a *cblF* cell line, where all Cbl is trapped in lysosomes, showed that 22-28 % of the Cbl counts were in the crude mitochondrial fractions, suggesting our mitochondrial fractions contain lysosomal material. This also suggests that the previously identified Cbl-binding protein is in fact lysosomal TC that is present in the crude mitochondrial fractions. The reason for differences in Cbl-bound TC levels among complementation groups remains to be determined.

A candidate gene association study of refractive error in the 1958 British Birth Cohort. *C.L. Simpson[1,2], P. Hysi[1], S.S. Bhattacharya[2], C.J. Hammond[3], A.R. Webster[2], C.S. Peckham[1], P.C. Sham[4], J.S. Rahi[1,2]* 1) Ctr Pediatric Epid & Biostat, Inst Child Health, London, WC1N 1EH, United Kingdom; 2) Institute of Ophthalmology, University College London, London EC1V 9EL, UK; 3) Twin Research and Epidemiology Unit, Kings College London, London UK; 4) Genome Research Center, University of Hong Kong, Hong Kong SAR China.

Refractive error (RE) is a common complex quantitative trait, with myopia affecting up to 60% of some populations. Development is influenced by multiple genes and environmental factors. Many genetic studies focus on rare extreme RE phenotypes such as high myopia, which is inherited in a Mendelian fashion. However most commonly occurring RE is not extreme, has complex inheritance and may have different underlying causes. We aimed to identify variants which affect common RE in a well characterised national population, the 1958 British Birth Cohort. The distribution of RE is leptokurtic and skewed towards myopia. 1196 individuals were selected at random from the two outer tertiles of the cohort RE distribution. Candidate genes were chosen based on recently published linkage peaks and further selected by biological relevance. 1536 tagSNPs were selected across 111 candidate genes and genotyped on the Illumina GoldenGate platform. This experiment had 80% power to exclude any candidate gene contributing >10% of the variance of RE in this cohort, which is reasonable given the assumption of the common disease, common variant hypothesis. All SNPs were in Hardy Weinberg equilibrium and genotyping failure rate was <5%. Using single SNP and moving-window haplotype-based analyses, interim findings provide statistically significant association (p-values range from 0.0007 to 0.01) between multiple SNPs and RE in multiple genes. Two strong candidates based on biological function, PAX6 and SOX2, have already been definitively excluded as being associated with RE. A replication study of the most promising results, consisting of 292 SNPs in 4 novel candidate genes, is currently close to completion. We will present our novel findings and discuss the implication of these associations and the involvement of these candidate genes in the pathogenesis of RE.

Screening of point mutations in genes implicated in spinocerebellar ataxia (SCA) type 13, 14, 27 and SCA linked to chromosome 16q in a large group of SCA families. *I. Silveira[1], E.M. Ramos[1], I.F. Bento[1], I. Alonso[1], P. Magalhães[2], P. Coutinho[3], J. Sequeiros[1,4]* 1) UnIGENe, IBMC - Univ Porto, Portugal; 2) CCGen, IBMC - Univ. Porto, Portugal; 3) Hosp. S. Sebastião, Sta Maria da Feira, Portugal; 4) ICBAS, Univ. Porto, Portugal.

The autosomal dominant spinocerebellar ataxias (SCAs) are clinically and genetically very heterogeneous diseases, mainly characterized by gait and limb ataxia, dysarthria, and a variable degree of oculomotor impairment, usually of adulthood onset. Seven autosomal dominant SCAs (SCA1, SCA2, MJD/SCA3, SCA6, SCA7, SCA17 and dentatorubro-pallidoluysian degeneration or atrophy, DRPLA) are caused by a (CAG)n expansion within the coding region, producing an extended polyglutamine tract in the mutant protein. In SCA12, the disease results from an expanded (CAG)n, but in the 5-UTR of the *PPP2R2B* gene. In SCA8 there is an expanded (CTG)n tract in an untranslated region. A pentanucleotide expansion is implicated in SCA10, caused by a tract of hundreds of ATTCT repeats in an intron of a gene with still unknown function. In five dominant forms, including SCA5, 13, 14, 27 and SCA linked to chr. 16, the disease is originated by point mutations or small deletions in the responsible gene. The SCAs are individually rare worldwide, though some may show a high clustering in certain geographic areas. We ascertained 270 SCA families of Portuguese origin and performed mutation analysis for all SCAs caused by a repeat expansion as well as for SCA13, 14, 27 and the single-nucleotide substitution in puratrophin-1 gene implicated in SCA linked to chr. 16q. In our group of families, MJD was the most frequent SCA (52%), followed by DRPLA (4%); SCA1, 2, 6, 7, 8, and 17 were together the cause of only a few cases (less than 8%); a point mutation was found responsible for SCA14 in one family (less than 1%), whereas no mutations where identified in SCA13, 27 and puratrophin-1 genes. In conclusion, point mutations in known autosomal dominant SCA genes seem to be rare in Portuguese families with SCA.

Stability of Placental RNA using Dried Maternal Blood Spots. *D. Marquez-Do, C. Jorgez, F. Bischoff* OB/GYN, Baylor College of Medicine, Houston, TX.

Introduction Circulating plasma RNA appears to be associated with subcellular particles, rendering stability under different preanalytical conditions. Circulating levels of several transcripts in maternal plasma have been shown to correlate with poor pregnancy and/or fetal outcome. Thus, RNA analysis for prenatal diagnosis and pregnancy related complications using dried blood spots (DBS) could provide an economical and simple way to collect, ship, store, and process samples. **Objetive** Having demonstrated successful recovery and detection of placental mRNA from DBS, we further explore the role of other factors, including temperature (4C vs. 25C) and processing time (from 24h to 8 weeks), that may interference stability and detection of placental transcripts. **Methods** mRNA fragments encoding human GAPDH (internal control) and hCG (placental transcript) were analyzed by real-time PCR using DBS from 7 pregnant women (GA=9.092.50). **Results** GAPDH and hCG transcript were detected in all samples 24h after collection. After one week of storage, we observed decrease in the amount of RNA recovered; however, the decrease was influenced by target transcript, temperature and storage time. For GAPDH, no significant reduction at either temperature was observed when processed at 1 week. Reduction of GAPDH was only significant ($p=0.033$) after 8 weeks storage at 25C. For HCG, following 1 week, a 50% reduction at both temperatures was observed. After 2 weeks at 25C, 90% reduction was reached and held constant by 8 weeks. However, HCG transcripts were significantly more stable over 2-8 weeks at 4C ($p=0.051$). Though HCG levels decrease with time at 4C, transcript levels were not significantly lower than levels measured at 1 week ($p=0.254$). **Conclusions** Although placental mRNA can be isolated from DBS, only 50% of the mRNA appears to be protected from degradation following long storage times. Further studies are warranted to identify additional fetal/placental transcripts amenable to detection and prenatal screening.

Computational identification of candidate loci for recessively inherited mutation using high-throughput SNP arrays. *M. Laakso[1,3], S. Tuupanen[2,3], A. Karhu[2,3], R. Lehtonen[2,3], L.A. Aaltonen[2,3], S. Hautaniemi[1,3]* 1) Computational Systems Biology Laboratory, Institute of Biomedicine; 2) Department of Medical Genetics; 3) Genome-Scale Biology Research Program, Biomedicum Helsinki, University of Helsinki.

Single nucleic polymorphisms (SNPs) are one of the most abundant genetic variations in the human genome. Recently, several platforms for high-throughput SNP analysis have become available, capable of measuring thousands of SNPs across the genome. Tools for analyzing and visualizing these large genetic datasets in biologically relevant manner are rare. This hinders effective use of the SNP-array data in research on complex diseases, such as cancer. Our major objective is to develop methods for identifying DNA regions that likely harbor recessive mutations. We describe a computational framework to analyze, integrate and visualize SNP-array data. First, the methods to identify biologically interesting regions are implemented as a module (CohortComparator) that can be used for the rapid and integrated analysis of SNP-microarray data. Second, we have constructed a framework (RegionAnnotator) for annotating the genes emerging from CohortComparator analysis. The algorithms are designed to have high sensitivity and the identified regions are ranked using a scoring algorithm. Our method does not assume a close relatedness between the samples. We have also developed annotation tools that automatically query gene IDs, microarray probe IDs, gene ontology information etc. Annotations of the DNA regions are used to integrate genotype information into other sources of data such as gene expressions and literature searches. The methodology has been tested both with simulations and real data. In our case study we analyze 50k and 100k SNP-data from 41 patient samples, from which two samples harbored a MYH mutation, and 51 reference samples. Our results show that the methodology presented here is effective and capable of identifying and ranking loci with recessive mutations, if such exist in the data. In summary, our new software provide means to speed up the process to transform high-throughput SNP data set to biomedical knowledge.

Recurrent genomic rearrangements of 17q12 are involved in a wide range of phenotypes: renal disease, diabetes and epilepsy. *H. Mefford[1,2], S. Clauin[3], A. Sharp[1], R. Moller[4,5], R. Ullmann[6], R. Kapur[7], D. Pinkel[8], G. Cooper[1], M. Ventura[1,9], H. Ropers[10], N. Tommerup[5], E. Eichler[1,10], C. Bellanne-Chantelot[3,11]* 1) Genome Sciences, University of Washington, Seattle, WA; 2) Division of Medical Genetics, University of Washington, Seattle, WA; 3) Center of Molecular Genetics and Cytogenetics, AP-HP Pitié-Salpetrière, Paris, France; 4) Danish Epilepsy Centre, Dianalund, Denmark; 5) Wilhelm Johannsen Centre for Functional Genome Research; 6) Max-Planck Institute of Molecular Genetics, Berlin, Germany; 7) Department of Laboratories, Childrens Hospital and Regional Medical Center, Seattle, WA; 8) Comprehensive Cancer Center, University of California San Francisco; 9) Department of Genetics and Microbiology, Universitá di Bari, Italy; 10) Howard Hughes Medical Institute, Seattle, WA; 11) University Pierre et Marie Curie, Paris, France.

Most studies of genomic disorders have focused on patients with cognitive disability and/or peripheral nervous system defects. In an effort to broaden the phenotypic spectrum of this disease model, we assessed 155 autopsy samples from fetuses with well-defined developmental pathologies in regions predisposed to recurrent rearrangement by array CGH. We found that 6% of fetal material showed evidence of microdeletion or microduplication, including 3 independent events that likely resulted from unequal crossing-over between segmental duplications. One of the microdeletions, in a fetus with multicystic dysplastic kidneys, encompasses the *TCF2* gene on 17q12, previously shown to be mutated in maturity-onset diabetes as well as a subset of pediatric renal abnormalities. Fine-scale mapping of the breakpoints in different patient cohorts reveals a recurrent 1.5 Mb *de novo* deletion in individuals with phenotypes ranging from congenital renal abnormalities to maturity-onset diabetes of the young type 5. Breakpoints lie in flanking polymorphic segmental duplications. The reciprocal duplication was also identified and is enriched in samples from patients with epilepsy and mild mental retardation. We describe the first example of a recurrent genomic disorder associated with diabetes.

Analysis of variation in the pituitary adenylate cyclase-activating polypeptide (PACAP/ADCYAP1) gene and susceptibility to bipolar disorder. *F.W. Lohoff, A.E. Weller, P.J. Bloch, T.N. Ferraro, W.H. Berrettini* Department of Psychiatry, Univ Pennsylvania, Philadelphia, PA.

Background: Linkage studies in bipolar disorder (BPD) suggest that a susceptibility locus exists on chromosome 18p11. The pituitary adenylate cyclase-activating polypeptide (PACAP/ADCYAP1) gene maps to this region. PACAP is a neuropeptide involved in PNS and CNS neurotransmission and is required for catecholamine secretion. Animal models of PACAP mutations show remarkable behavioral defects, including hyperactivity and increased exploratory behavior. We hypothesize that genetic variations in the human PACAP gene contribute to BPD. **Methods:** Genotypes for 4 SNPs (rs2846811; rs8192595; rs2856966; rs1610037) across the PACAP gene in BPD patients (n=570) and healthy controls (n=710) were obtained. Genotypes and allele frequencies were compared between groups using Chi square contingency analysis. LD between markers was calculated and estimated haplotype frequencies were compared between groups. **Results:** We did not observe any significant differences between groups on the allele, genotype or haplotype level for any of the tested SNPs. **Conclusion:** Our results provide no evidence for an association of the PACAP gene with BPD in this group of patients and controls. Additional studies are necessary to elucidate the BPD susceptibility locus on chromosome 18p.

Changes in Phenotype of Bloom's Syndrome with New Manifestations in Adult Individuals. *E. Passarge, H. Löser*
Human Genetics, Inst Humangen, Univ Essen, Essen, Germany.

Bloom's syndrome results from autosomal recessive mutations in the BLM gene located on human chromosome 15 at 15q26.1, encoding a DNA helicase with homology to RecQ in E. coli (MIM 210900). Its phenotype includes (i) pre- and postnatal growth retardation, (ii) facial features with dolichocephaly and a narrow face, (iii) light-sensitive facial telangiectasia in most patients, (iv) manifestations of genomic instability as revealed by a 10-fold increase of spontaneous sister chromatid exchanges, breaks and homologous exchanges between chromosomes, and an increased rate of somatic mutations. Affected individuals develop similar types of cancer as in the population, but at a much younger age (about 1 in 4).

We report data of a longterm study of the natural history of 15 individuals with Bloom's syndrome observed during the past 38 years in Germany. We found that the phenotype in adult individuals becomes less distinctive with age than it is in children. In spite of persistent feeding difficulties, such as lack of appetite or regurgitation, adult individuals tend to gain weight. A new finding is development of diabetes mellitus type 1 or type 2. This has been observed in 27 of 117 patients (23%) of individuals in the Bloom's Syndrome Registry (J. German, M. Sanz, E. Passarge, unpublished data). The skin manifestations tend to improve with age. We diagnosed Bloom's syndrome prenatally in a family known to be at risk. When the parents were informed about this diagnosis they changed their mind and decided to carry the pregnancy to term. Retarded growth was evident during all stage of the pregnancy and the affected infant weighed only 2000 g at birth at 40 weeks of gestation. However, he lacked the typical appearance of Bloom's syndrome. We conclude that the phenotype of Bloom's syndrome is wider than recorded previously. It remains to be seen whether the molecular type of mutation present in an individual influences the phenotype.

Acknowledgement: We thank J. German, M. Sanz, and N.A. Ellis, New York, for cooperation and mutational analysis.

Direct Brain Delivery of Iduronate 2-Sulfatase Reduces Glycosaminoglycan Accumulation and Improves Histopathology in the CNS and Peripheral Tissue of Hunter Mice. *Y. Lu, J. Pan, AR. Garcia, A. Stronge, M. Tonini, C. Neal, J. Lamsa* Preclinical Research, Shire HGT, Cambridge, MA.

Hunter syndrome, or mucopolysaccharidosis (MPS) II, is an X-linked inherited disorder caused by the deficiency of the enzyme iduronate 2-sulfatase (I2S), which is involved in the lysosomal catabolism of the glycosaminoglycans (GAG) dermatan and heparan sulfate. To evaluate the effect of I2S on GAG accumulation and CNS pathology, we injected I2S (0.1mg) or vehicle directly into the right striatum of the Hunter mouse brain. We found that a single injection of I2S caused an improvement of histopathology of the brain and liver, comparing wild-type, vehicle treated, and I2S treated Hunter mice. Specifically, in the brain we found a reduction of abnormally high lysosomal activity in microglial, meningial and perivascular cells using LAMP-1 immunostaining; decreased glial fibrillary acidic protein (GFAP) immunostaining with reduced astrocyte cell size and its processes, possibly reflecting a reduction of inflammation in the CNS; and reduced intracytoplasmic vacuolization in Purkinje cells. In the liver, we found that central I2S delivery caused a significant increase in I2S levels as measured by ELISA. We also found a significant decrease of LAMP-1 staining in hepatocytes, sinusoidal cells and connective tissues; reduction of GAG accumulation, to a degree similar to wild type controls; and a marked reduction of intracytoplasmic vacuolization in all hepatocytes. Our data demonstrate that CNS I2S delivery is effective in reducing GAG accumulation and improving histopathology in the brain. It also indicates that central delivery of I2S not only distributes to, and affects the brain, but also peripheral organs. These data suggest that I2S injected directly into the CNS is able to improve the histopathological markers described here and provides a basis for establishing levels of I2S effective in improving biochemical and histological markers of MPS II in future studies.

Evidence for *BACH2* in chromosomal region 6q14-6q16.3 with nonsyndromic cleft lip and palate. *A. Mostowska[1], T.H. McHenry[2], M.E. Cooper[2], M. Govil[2], D.R. FitzPatrick[3], V.J. Vieland[4], M.L. Marazita[2], J.C. Murray[1]* 1) Department of Pediatrics, University of Iowa, Iowa City, IA; 2) Center for Craniofacial and Dental Genetics, University of Pittsburgh, Pittsburgh, PA; 3) University of Edinburgh, Edinburgh, U.K; 4) Columbus Children's Research Institute, Columbus, OH.

Isolated cleft lip with or without cleft palate (NSCL/P) is a common congenital anomaly in humans, the etiology of which is complex and associated with both genetic and environmental factors. Prior linkage scan analysis from 7 different NSCL/P populations identified a substantial probability of linkage to 6q14-6q16.3 region (two-point PPL=0.43, multipoint PPL=0.88; multipoint maximum HLOD=3.0). To fine map this region, 65 SNPs in candidate genes were selected and genotyped on 275 multiplex families from Southeast Asia. TDT analysis revealed modest associations with SNPs in two genes: *BACH2* (p=0.02 for rs1065273, rs9359876, rs404256; and p=0.04 for rs10455512) and *EPHA7* (p=0.02, rs535926). Pairwise and multi-locus haplotype analyses, in sliding windows up to 5 SNPs, also revealed a significant transmission distortion for different combination of markers. The highest departure from random sharing was observed for markers located in *BACH2* gene. Sequence analysis of *BACH2* in 96 NSCL/P cases revealed a number of mutations and novel gene variants specific only for affected individuals including 163delEEDE or Val820Met. The number of DNA changes identified in cases was statistically higher than in controls. To confirm these findings sequencing analysis was performed in 96 NSCL/P cases from North America, revealing significant results, as well. BACH2 is an oxidative stress-responsive transcription factor containing a basic leucine zipper BTB domain and cytoplasmic localization signal. It functions as a positive regulator of cell death and may act as a tumor suppressor. We also show that in mice, *Bach2* is specifically expressed in craniofacial structures during development. This report provides evidence for an association of chromosomal region 6q14-6q16.3 with NSCL/P and indicates that BACH2 may be a novel transcription factor playing a role in etiology of this common anomaly. NIH grants:R37-DE08559,R01-DE016148,P50-DE016215.

The use of genome-wide eQTL associations to identify novel genetic pathways involved in complex traits. *J.L. Min[1], J.M. Taylor[1], T. Watts[2], K.R. Ahmadi[3], J.B. Richards[3], J. Broxholme[1], F. Pettersson[1], I. Ragoussis[2], T.D. Spector[3], K.T. Zondervan[1], L.R. Cardon[1]* 1) Bioinformatics & Statistical Genetics, Wellcome Trust Centre for Human Genetics, University of Oxford, United Kingdom; 2) Genomics Laboratory, Wellcome Trust Centre for Human Genetics, University of Oxford, United Kingdom; 3) Twin Research & Genetic Epidemiology Unit, St Thomas Hospital Campus, Kings College London, United Kingdom.

Despite recent successes of genome-wide association studies in several complex traits, many associations between clinical phenotypes and genetic variants will remain difficult to uncover because of phenotypic heterogeneity. In such cases, the use of downstream biological phenotypes may provide a more powerful approach. Gene expression levels are highly variable and heritable, and are known to be strongly associated with genetic variants. This study investigates the association between a range of quantitative metabolic phenotypes and gene expression levels in twins, followed up by targeted SNP association analysis. Expression profiling was conducted in lymphoblastoid cell lines from 119 monozygotic pairs and 60 dizygotic pairs from the St. Thomas UK adult twin registry, and 60 unrelated CEU HapMap individuals, using the Illumina Sentrix Human-6 version 2 BeadChip. Out of the 46,713 transcripts measured, the 5,070 most variable probes in twins, and 4,918 probes in the HapMap individuals, were selected. To find SNPs associated with expression levels, we performed a genome-wide SNP analysis in the HapMap individuals between 946,479 non-redundant SNPs (HapMap Phase II) and 4,918 probes. Significance was assessed through permutation; consistency of the associations is being investigated through comparison with other published genome-wide eQTL analyses. Of the 5,070 selected probes in the twins, 1648 (32%) showed at least moderate heritability. These heritable probes are being examined for association with metabolic traits. Those that show significant association are cross-referenced with the genome-wide association HapMap results for identification of associated SNPs. These SNPs will be genotyped in the present twins, and a replicate sample, to test the association.

Role of an intermediate SCA2 allele in a patient with spinocerebellar ataxia. *E.M. Ramos[1], S. Martins[1,2], I. Alonso[1], L.B. Jardim[3], P. Coutinho[1,4], J. Sequeiros[1,5], I. Silveira[1]* 1) UnIGENe, IBMC, Univ. Porto, Portugal; 2) IPATIMUP, Porto, Portugal; 3) Hosp. Clínicas de Porto Alegre, Brasil; 4) Hosp. S. Sebastião, St. M. Feira, Portugal; 5) ICBAS, Univ. Porto, Portugal.

Spinocerebellar ataxia type 2 (SCA2) is a neurodegenerative disorder of autosomal dominant inheritance. It is caused by the expansion of an unstable CAG repeat within the exon 1 of the *ATXN2* gene (12q24.1), coding for a polyglutamine (polyQ) tract, in ataxin-2 protein. The interspected repeat is highly polymorphic in length and configuration, with CAA interruptions varying in number and position within the sequence. Normal chromosomes have usually 14 to 31 repeats interrupted by one or more CAAs, whereas expanded alleles display 34 to 59 pure repeats. In this study, ten SCA2 families from different ethnic origins, namely of Portuguese (4), Brazilian (3), Italian (1) and Asian (2) ancestry, were studied. We have analyzed two previously reported single nucleotide polymorphisms (SNPs), proximal to the CAG repeat, along with the CAA interruption pattern. The GT haplotype was described as mainly associated with normal alleles, whereas the CC is shared by all expanded alleles. Expanded haplotypes were reconstructed by cloning a region of 462 bp, encompassing the deleterious repeat and flanking SNPs. All normal chromosomes carrying the GT haplotype shared the $(CAG)_8CAA(CAG)_4CAA(CAG)_8$ repeat pattern, whereas normal alleles with the CC haplotype lack the first CAA interruption. The only expanded chromosome (50 CAGs) assessed showed the CC haplotype. In addition, we found an intermediate allele of 32 repeats in a patient with atypical symptoms of spinocerebellar ataxia. Although sharing the CC haplotype with expanded alleles, the intermediate allele was interrupted at the 3-end of the repeat: $(CAG)_{23}CAA(CAG)_8$. This pattern may confer increased instability to the repeat tract, predisposing to expansion and disease expression. Since our finding points to the importance of the haplotype and configuration patterns on disease penetrance of intermediate alleles in SCA2, further studies in additional alleles are now proceeding.

Partial maternal isodisomy of chromosome 17p in a case of infantile cystinosis. *A.S. Lebre[1], V. Morinière[1], O. Dunand[3], N. Morichon[1], C. Antignac[1,2]* 1) Département de Génétique, Hôp Necker-Enfants Malades, Paris, France; 2) Inserm U574, Hôp Necker-Enfants Malades, Paris, France; 3) Hôpital Trousseau, Paris, France.

Cystinosis is an autosomal recessive disorder characterized by an accumulation of intra-lysosomal cystine due to a defect in cystine transport across the lysosomal membrane. Three clinical forms of cystinosis (infantile, juvenile and ocular cystinosis) have been delineated based on severity of symptoms and age of onset. The causative gene, CTNS, maps to 17p13, spans 23 kb of genomic sequence, and encodes the lysosomal cystine transporter, cystinosin. CTNS mutations have been detected in individuals affected with all forms of cystinosis. The most common mutation is a large 57 kb deletion spanning exons 1 to 10, detected in ~60-70% of affected northern European individuals.

Here, we report a maternal uniparental disomy of chromosome 17 (mat UPD17) in a 2.5-year-old girl presenting with isolated infantile cystinosis. This patient was detected homozygous for a 57-kb deletion of the CTNS gene. The mothers proband was found heterozygous for the deletion but surprisingly the father did not bear the deletion. Haplotype analysis with polymorphic markers spanning the whole chromosome 17 demonstrated no paternal contribution for all the markers of chromosome 17 and only one maternal contribution for markers of chromosome 17p. As a deletion 17p would not be viable, these results suggest a maternal uniparental disomy 17 with an heterodisomy of 17q and a isodisomy of 17p. They are the first evidence of mat UPD of chromosome 17 and in cystinosis.

Are VEGF and Interleukin Haplotypes risk factors in prostate cancer etiology among African Americans? *K. Yanamandra[1], M. Ankem[2], D. Napper[1], P.B. Boggs[3], H. Chen[1], S.A. Ursin[1], G. Mills[4], J.A. Bocchini Jr.[1], R. Dhanireddy[5]* 1) Dept Pediatrics, LSU Health Sciences Ctr, Shreveport, LA; 2) VA Medical Center, Shreveport, LA; 3) Allergy Clinic, Shreveport, LA; 4) Feist-Weiller Cancer Center, Shreveport, LA; 5) Dept Pediatrics, UT Health Sciences Center, Memphis, TN.

Angiogenesis is a major feature and is an essential process in the development, growth and metastasis of malignant tumors. A host of genetic factors also influence the tumorigenesis and cancer etiology, especially the combination of low-penetrance gene polymorphisms. We have been studying the influence of genetic single nucleotide polymorphisms (SNP) for the past five years including the interleukins (IL), vascular endothelial growth factor (VEGF), prothrombin gene, Methylenetetrahydrofolatereductase (MTHFR), etc.in the tumorigenesis and the etiology of various cancers including multiple myeloma, breast, lung, head and neck cancers. In the present investigation we have studied the influence of IL-1, IL-8, IL-10, and VEGF SNPs in the etiology of prostate cancer in seventeen prostate cancer patients and one hundred and seventy four controls among African Americans,using microplate PCR RFLP and allele specific PCR genotyping methods. Among the genetic markers studied, mutant allele in the promoter region of VEGF gene showed a significant difference (OR 2.8, p value 0.03 for -460T). Among the haplotypes studied, the IL-1 beta -511C/IL-8 -251T/IL-10 -1082G/ VEGF-460T/VEGF-1154G haplotype frequency was found to be significantly higher among the Prostate cancer patients compared to the controls (OR 1.4, p value 0.04). Based on our experimental data we conclude that the IL-1 beta -511C/IL-8 -251T/IL-10 -1082G/VEGF -460T/VEGF-1154G haplotype could be a significant risk factor in the etiology of prostate tumorigenesis among African American population. Data and statistics on different markers will be presented.

Some Mathematical, Statistical, and Computational Issues Behind the Hardy-Weinberg Equilibrium in the Tri-allelic Case. *M. Rao, X. Liu, R. Chakraborty* Ctr Genome Information, Univ Cincinnati, Cincinnati, OH.

The Hardy-Weinberg equilibrium phenomenon is well-understood in the bi-allelic case. Formidable mathematical, statistical, and computational problems arise in the tri-allelic and higher-order-allelic cases. Behind the equilibrium phenomenon in the tri-allelic case lies a 3x3 bivariate symmetric distribution of the alleles with identical marginal distributions. Exploiting the fact that the collection of all such distributions is a compact convex set, we produce six basic bivariate distributions on whose edifice inbreeding, equilibrium, estimation, and power calculations revolve around. Each bivariate distribution represents a specific type of mating.

Possible interaction between gap junction proteins Cx26 and Cx31 to cause non-syndromic deafness in Chinese patients. *D. Yan[1], P. Dai[2], X. Lin[3], Y. Yuan[2], W.X. Tang[3], X.M. Ouyang[1], H. Yuan[2], L.L. Du[1], X.Z. Liu[1]* 1) University of Miami, Miami, FL, USA; 2) PLA General Hospital, Beijing, China; 3) Emory University School of Medicine, Atlanta, GA, USA.

Congenital deafness in humans occurs in approximately 1 in 1000 live births, and at least 50% of these cases are hereditary. It is estimated that roughly 70% of all cases of hereditary hearing loss (HL) are non-syndromic, approximately 80% of which are inherited in an autosomal recessive fashion. Mutations in a single gene encoding connexin 26 (Cx26) or gap junction beta 2 gene (GJB2) are the leading cause of non-syndromic sensorineural HL (NSHL). GJB3 (Cx31) mutations have also been shown to cause deafness in the Chinese population. To determine if mutations at these two gap junction proteins can interact to cause HL, we have screened 108 Cx26 heterozygous Chinese patients for mutations in Cx31 by sequencing. A total of 3323 NSHL patients, consisting of 314 familial and 3009 sporadic cases, were initially analyzed for GJB2 mutations. In all cases the HL was congenital and severe to profound. After exclusion of the SLC26A4 (Pendred syndrome) caused HL and the A1555G mutation in the 12SrRNA gene, the full GJB3 coding region was analyzed. Two different mutations (N166S and A194T) occurring in compound heterozygosity with the 235delC and 299delAT of GJB2 were identified in 3 sporadic cases (235delC/N166S, 235delC/A194T and 299delAT/A194T). Western blots analysis identified both Cx26 and Cx31 in the mouse cochlea, which are known to be able to form heteromeric GJs. We are currently using an in vitro expression system to investigate functional consequences of compound Cx26 and Cx31 mutation on GJ functions. Acknowledgement: The work is supported by NIH DC 05575 *Cx26GJB2*.

MLPA identification of whole exon and single nucleotide deletions in the CFTR gene of Hispanic individuals with cystic fibrosis. *I. Schrijver[1], K. Rappahahn[1], L.M. Pique[1], M. Kharazzi[2], L-J. Wong[3]* 1) Pathology, L235, Stanford Univ, Stanford, CA; 2) Genetic Disease Branch, California Department of Health Services 850 Marina Bay Parkway, Room F175, Richmond, CA 94804; 3) Molecular and Human Genetics, Baylor College of Medicine One Baylor Plaza, NAB 2015, Houston, TX 77030.

Identification of CFTR mutations in Hispanics with cystic fibrosis (CF) can facilitate diagnosis, improve management, and guide genetic counseling. In both carrier screening panels and molecular diagnostics, however, a disparity between Caucasian and Hispanic mutation detection continues to exist. In order to more fully characterize the Hispanic CFTR mutation spectrum, we aimed to identify exonic deletions in 39 self-identified Hispanic patients who had previously completed extensive mutation analysis. Using a commercial multiplex ligation-dependent probe amplification (MLPA) assay, exon deletions appeared present in 10/39 patients. Two recurrent pathogenic deletions (of exons 2 and 3 and of exons 22 and 23) were identified in 3 patients each (15.4%). Based on MLPA results, 3 apparently novel deletions were identified in 4 additional patients. However, during the process of confirmation, single nucleotide deletions at the probe binding sites were identified (exon 6b: 935delA, exon 19 : 3791delC and exon 20 : 3961delA). All resulted in false positive deletion signals with MLPA and all were close to the ligation site. Interestingly, none of the 3 deletions are common in Caucasians and the 935delA mutation is one of the most common mutations identified in U.S. Hispanics. A total of 76 mutations and 5 silent variants reported in the Cystic Fibrosis mutation database (http://www.genet.sickkids.on.ca/cftr/app) are located under the sequences that immediately surround the MLPA ligation sites in this assay. Twenty-three occur in non-Caucasians, including 9 Hispanic, 6 from the greater Middle-East, 4 Asian, and 4 African. These mutations are not all rare. Thus, apparent exonic deletions by MLPA may indicate both large deletions and point mutations, with important implications for pan-ethnic MLPA testing in CF and other genetic conditions.

Family-based association studies of congenital heart defects. *L. Scheinfeldt[1], E. Goldmuntz[2], J. Campanile[1], M. Devoto[1,3], D.A. Driscoll[1,4]* 1) Department of Human Genetics, CHOP, Philadelphia, PA; 2) Department of Cardiology, CHOP, Philadelphia, PA; 3) Department of Biostatistics and Epidemiology, University of Pennsylvania, Philadelphia, PA; 4) Department of OBGYN, University of Pennsylvania, Philadelphia, PA.

Congenital heart defects (CHD) are the most common birth defects occurring in as many as 1% of live births, and approximately 15% of these are outflow tract malformations. Studies have identified several genes and chromosomal regions associated with syndromic CHD; however, the genetic contribution to isolated CHD remains to be elucidated. We utilized a family-based candidate gene association study to identify genes involved in cardiac outflow tract malformations. Initially, 47 tag single nucleotide polymorphisms (SNPs) in 18 candidate genes were studied in 355 trios with outflow tract malformations; the transmission disequilibrium test was used to test for association. We found significant association in one Jagged 1 (JAG1) SNP (rs1997814) with a corrected p-value of 0.012. However, an expanded validation study with 7 additional SNPs and 120 additional trios failed to confirm an association. We did not find association between JAG1 SNPs and outflow tract malformations upon replication, but have not excluded the possibility of an association. The sample size may have been too small to detect a modest genetic contribution to CHD. Further, the population is heterogeneous and until we examine sub-groups of outflow tract malformations we cannot exclude an association with JAG1 variants. The lack of association with JAG1 SNPs is surprising given previous animal and human studies. JAG1 is one of two serrate-like ligands involved in the Notch gene pathway and is expressed in the aorta. Notch2 and JAG1 double heterozygote mice have cardiac defects, and human studies have found JAG1 mutations in patients with Alagille syndrome as well as patients with isolated tetralogy of Fallot, a classic outflow tract anomaly. We conclude that further studies with larger and more homogeneous populations of patients with cardiac defects will be required to successfully identify the genes responsible for isolated CHD.

Genealogical relations and genetic distance between an Otomi-speaking community and a Tepehua-speaking community in the state of Hidalgo, Mexico. *A. Sanchez-Boiso[1], R. Peñaloza[3], R. Sanchez-Urbina[1], E. Castro-Sierra[2], R.I. Ortiz de Luna[1], L. Buentello[4], F. Salamanca[3], M.P. Flores[6], J. Aguirre-Hernandez[5], V. Moran-Barroso[1]* 1) Department of Genetics, Hospital Infantil de Mexico Federico Gomez (HIMFG), Mexico City, Mexico; 2) Laboratory of Psychoacoustics, HIMFG; 3) Medical Research Unit in Genetics, Hospital de Pediatria del CMNSXXI-IMSS; 4) Anthropological Research Institute, UNAM; 5) Department of Clinical Veterinary Medicine, University of Cambridge; 6) Department of Social Work, HIMFG.

Mitochondrial DNA (mtDNA) of native Mexican populations has been studied in the context of the settling of the American continent, analyzing the frequencies of the four Amerindian haplogroups: A, B, C and D. mtDNA haplogroup frequency was determined in 2 Mexican populations: an Otomi-speaking (Otomanguean; San Antonio el Grande) population and a Tepehua-speaking (Penutian; Huehuetla) population living within 3 miles from each other in Eastern Mexico. IRB approval and informed consent were obtained. Blood samples for mtDNA analysis were taken from 38 unrelated subjects in San Antonio el Grande and 36 unrelated subjects in Huehuetla. DNA extraction was carried out using commercial kits. Amplification of four Amerindian mtDNA haplogroups was achieved using previously reported primers. PCR products of haplogroups A, C and D were digested with specific restriction enzymes. Haplogroup B was analyzed using polyacrylamide gels. San Antonio el Grande: highest frequency (percentage) was 39 for haplogroups A and C, 11 for B and 3 for D. Huehuetla: highest frequency was 39 for B, 33 for A, 14 for C and 6 for D. In both populations, 8 percent of samples did not correspond to any of the analyzed haplogroups and were classified as other. Haplogroups A and C predominated in San Antonio el Grande, the latter haplogroup with a frequency similar to one reported for a Raramuri population (Uto-Aztecan) in Northwestern Mexico. In Huehuetla, predominant haplogroup was B followed by haplogroup A. Results reveal distribution of B and C haplogroups differing between both populations, in agreement with their belonging to different language stocks, despite living within close proximity from each other.

SNP genotyping in the presence of copy number polymorphisms. *T. LaFramboise[1], M. Kothari[1], L. Macconaill[2], M. Gould[1]* 1) Genetics, Case Western Reserve University, Cleveland, OH; 2) The Broad Institute of Harvard and MIT, Cambridge, MA.

Genotyping SNPs using microarrays has become increasingly high-throughput and cost-effective. The methods associated with these arrays generally assume two copies of each SNP locus per cell, for a diallelic genotype. Given the recent discovery of widespread copy number variation in the human genome, however, this assumption is no longer always valid. For example, if an A/G SNP is contained within a genomic region that is duplicated in a significant proportion of the human population, this SNP's genotype may be AAA, AAG, AGG, or GGG for some individuals. Similarly, an individual may carry an A- or G- genotype in a region harboring a germline deletion, or a -- genotype if chromosomes harboring the deletion are inherited from both parents. This generalized genotype is unrestricted by the usual diallelic assumption that results solely in AA, AG, and GG genotypes, and succinctly provides both copy number and SNP allelic information.

Most available software would call an AAG genotype as AA or AG, an A- genotype as AA, and a -- genotype as No Call. These erroneous calls can lead to incorrect phasing and apparent Hardy-Weinberg deviations. Moreover, the impending growth in genome-wide association studies will heavily rely on accurate SNP genotyping, whether the SNPs are used as markers or as putative causal variants.

We have developed methods to infer generalized genotypes from both the Affymetrix and Illumina arrays. Each of these platforms interrogates over 500,000 human SNPs across the genome. Our generalized genotypes were verified using a variety of experimental assays, and demonstrated a high level of accuracy. The interrelationship between SNP allele and copy number variation provides insight into the history of the point mutation and duplication events that resulted in these variants. Our analysis of thousands of duplicated SNPs implies that the duplication is more recent than the point mutation in most, if not all, cases. Furthermore, the duplication events seem to be recurrent in human history in many cases.

Linkage study in Puerto Rican families with Endometriosis. *E.M. Ledet[1], R. Thouta[2], J.E. Bailey-Wilson[3], I. Flores[4], D. Mandal[1]* 1) Department of Genetics, Louisiana State University Health Sciences Center, New Orleans, LA; 2) Department of Pathology, Louisiana State University Health Sciences Center, New Orleans, LA; 3) NHGRI/NIH, Baltimore, MD; 4) Department of Microbiology, Ponce School of Medicine, Ponce, PR.

Endometriosis is a disease which has affected millions of women; yet, much is still unclear about this often misunderstood condition. Endometriosis is defined by the growth of endometrial tissue, both endometrial stroma and endometrial glands, outside of the uterine cavity. Currently, the exact number of women suffering with endometriosis is unknown, but some, epidemiological studies have indicated a prevalence of 5-20% in women of reproductive age.

Our previous linkage studies on 39 Puerto Rican families produced a LOD score of 1.75 at one of the candidate regions on chromosome 10. For this study, 41 Puerto Rican families with two or more patients with surgically diagnosed endometriosis were recruited; blood samples and patient histories were obtained. Marker genotypes were obtained on chromosomes 1, 3, 7, 8 and 10. Specifically, Mendelian inconsistencies were screened and cleaned from the data set using Sib-Pair and PedCheck, and allele frequencies were calculated utilizing Sib-Pair. Significant allelic association was revealed with an empiric p value of 0.0095 at one of the candidate regions. The marker allele frequencies have been estimated from the data though Sib-Pair. The data would be further utilized to do linkage analysis to identify any susceptibility loci. Additionally, utilizing patient histories, the presence and incidence of other conditions, namely ovarian, lymphoma, breast, and prostate cancers, within the families with respect to endometriosis will be assessed and analyzed. In this study we intend to identify any markers associated with endometriosis on chromosomes 1, 3, 7, 8, or 10, identify and document any correlation, especially with relation to cancer, between family disease history and endometriosis, and, in general, characterize the histories and disease symptoms within this Puerto Rican population.

Clinical and Molecular Characterization of a patient with Langer-Giedion syndrome mosaic for del(8)(q22.3q24.13). *A..L. Shanske[1], A. Patel[2], S. Saukam[2], O. Nahum[4], H.J. Luedecke[3], B. Levy[4]* 1) Children's Hosp Montefiore, Albert Einstein College of Med,Bronx, NY; 2) Dept of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 3) Institut fur Humangenetik, Universitatsklinikum, Essen, Germany; 4) Dept of Pathology, Columbia U College of Physicians & Surgeons, New York, NY.

The tricho-rhino-phalangeal syndrome type II(TRPS II)is characterized by sparse scalp hair,a long nose with a bulbous tip, a long flat philtrum, cone-shaped epiphyses, and multiple cartilaginous exostoses. Almost all patients have a hemizygous deletion on chromosome 8q24.1 affecting at least the contiguous *TRPS1* and *EXT1* genes. Here we describe a mentally retarded 14 year old girl with features of TRPS II who is mosaic for an interstitial deletion in 8q24.1. Her birth weight,length, and head circumference were all 2-4 SDs beneath the mean. Her height, weight, and HC were all 2-4 SDs beneath the mean. She had brachycephaly, thick brows with a synophrys and a bulbous nasal tip. She had a duplicated right lower lateral incisor. A bone age done at chronological age 9 years and 4/12 years showed a bone age 6-7 SDs beneath the mean. Cone-shaped epiphyses were present at many phalanges. She had multiple exostoses of the humeri,femora,tibia and the scapula. A WISC-R administered when she was 6 and ½ years of age revealed a full-scale IQ of 62. She has always attended a special education program and is now able to converse in complete sentences in English. A female karyotype with two cell lines was found in blood and skin. Seven of 105 peripheral blood cells exhibited an interstitial deletion in the long arm of chromosome 8 and the remaining cells yielded a normal karyotype, 46,XX,del(8)(q22.3q24.13)[7]/46,XX [98]. The del(8) cell line was present in a much higher percentage (71%) in skin fibroblasts. Deletion of the *TRPS1* and *EXT1* genes was confirmed by FISH. SNP oligonucleotide microarray analysis indicated the deleted region to be 19.59Mb in size with over 50 genes including *TRPS1*, *EXT1* and a number of disease genes on either side of the *TRPS1-EXT1* interval. Mosaicism as this case illustrates, must be considered in patients with TRPS II.

Novel ciliary function for TOPORS (RP31 gene) associated with autosomal dominant retinitis pigmentosa. *A.Z. Shah[1], C. Chakarova[1], H. Khanna[2], S. Parapuram[2], P. Munro[1], M. Cheetham[1], K. Matter[1], R. Koenekoop[3], A. Swaroop[2], S.S. Bhattacharya[1]* 1) Institute of Ophthalmology, London, United Kingdom; 2) The University of Michigan, Kellogg Eye Center, Ann Arbor, Michigan, USA; 3) The McGill Ocular Genetics Laboratory, McGill University Health Centre, Montreal, Canada.

Purpose: We have recently identified mutations in *TOPORS* (RP31 gene) responsible for autosomal dominant retinitis pigmentosa (unpublished data). *TOPORS* is a ubiquitously expressed gene; a protein showing polyfunctional character. The purpose of our work is to characterise the role TOPORS plays in the photoreceptors, which may explain the retinal degeneration seen with mutations in this gene. Methods: *TOPORS* was cloned from human retinal cDNA into FLAG-tagged vector pCATCH, and identified mutations were introduced by site-directed mutagenesis. The WT and mutants were transfected into cell lines and imaged using fluorescent microscopy. A commercially available antibody for TOPORS was acquired and used to localise endogenous TOPORS in cell lines, and for immunoblot analysis. Mouse cryo-sections were used to find the specific protein localization in the retina. Results: Both mutations result in frameshift, prematurely terminating the TOPORS protein. To identify the functional consequences of the mutations we created mutant constructs with an N-terminal tag and transfected MDCK and 661W cells. The WT showed the expected pattern of expression within the nucleus in MDCK cells, but an increased cytoplasmic presence in 661W cells. Localisation studies in WT mouse retinal cryo-sections show a discreet signal from the inner-outer segment boundary (connecting cilium) of the photoreceptor layer. TOPORS also localises to the primary cilia of MDCK cells. Immunoblot analysis confirmed the expression of TOPORS as a 150 kDa band in cell lines and retinal tissue extracts. Conclusion: Given the specific signal from the connecting cilium of the retina, identification of mutations in *TOPORS,* an otherwise predominantly nuclear protein, suggests a new function within photoreceptor cells. Mutation carriers only manifest retinal degeneration with no other symptoms therefore suggesting a novel mechanism for photoreceptor degeneration.

A Frequent TGFRII PolyA tract mutation that downregulates the TGF- signal pathway results in inactivation of CDK2-AP1 expression in human MSI CRC. *Z. Yuan[1], J. Shin[2], K. Fordyce[3], P. Sreeramoju[3], T. Kent[4], J. Kim[3], V. Wang[3], K. Sacchini[5], TK. Weber[1,2]* 1) Molecular Genetics; 2) Surgery,Einstein College of Medicine,NY; 3) IBM; 4) Surgery,U.of Pittsburgh,PA; 5) Irvington High School,NY.

Background:A frequent(~90%)frameshift mutation in the PolyA tract of the type II transforming growth factorreceptor(TGFRII)has been reported only in MSI colorectal cancer(CRC)inhibiting the growth suppressive effect of the binding of its ligand,TGF-.Recently,we reported significant decreased expression of the growth suppressor gene Cyclin Dependent Kinase2-Associated Protein1(CDK2-AP1)in 85%of MSI CRC and its association with decreased apoptosis and increased S-phase.This study tests the hypothesis that inactivation of CDK2-AP1 in MSI CRC results from the absence of growth-inhibitory signal via TGFRII due to the inactivating polyA tract mutation.Methods:We utilized a transient transfection of RNAi to target TGFRII in the CRC cell lines SW620(Wild type:WT)and Dld1(mutant receptor:MT).We induced over-expression of TGFRII by transfection of the WT receptor into these lines.A reporter construct(p3Tu-Lux)of TGF-signal was cotransfected into the same lines to assess response.mRNA and protein of CDK2-AP1 were measured by real-time PCR and Western blot assays.The effect of modulating the TGF-signal on cell proliferation,apoptosis,and differentiation was measured with an MTT,FACS,and Matrigel assay.Results:The methods demonstrated the transfection of RNAi targeting the WTTGFRIIin SW620 resulted in a substantial decrease in CDK2-AP1 expression.Conversely introduction of WT TGFRIIinto the mutant Dld1 cell line resulted in a significant increase in CDK2-AP1 expression and its association with decreased proliferation,increased apoptosis and cell differentiation.Discussion:The results support our hypothesis that down-regulation of CDK2-AP1 in MSI is the result of impaired TGF-signaling due to inactivating mutations of the PolyA tract in TGFRII and the broader concept of different pathways of malignant transformation and progression in MSI vs MSS which suggests further study of TGFRII modulation of CDK2-AP1 is indicated.

Haplotype and nucleotide diversities in two hypervariable regions of mtDNA in world populations and their forensic implications. *W. Niu[1], N. Wang[2], B. Budowle[3], R. Chakraborty[1]* 1) Ctr. Genome Information, Univ. Cincinnati, Cincinnati, OH; 2) Div. Allergy and Human Genetics, Cincinnati Children's Hospital Med. Ctr., Cincinnati, OH; 3) Lab. Div., FBI Academy, Quantico, VA.

Sequence data from hypervariable regions HV1 and HV2 of mtDNA are used in DNA forensics. MtDNA sequence match arises from three scenarios: 1) the two samples are of a single origin, 2) donors of the two samples are of the same maternal lineage, or 3) the observed match is coincidental. The match probability is generally obtained by the counting method (i.e., relative frequency of the target sequence in a database). Merging of populations in such a database requires evaluation of mtDNA diversity within and between populations. We addressed this by using HV1 and HV2 sequence data from 5,944 individuals belonging to 17 populations encompassing 638 nucleotide sites. Elimination of sequences with ambiguous sites resulted in 5,295 sequences, spanning both HV1 and HV2. Two measures of diversity can be defined for mtDNA: haplotype diversity (in which each distinct haplotype is treated as an allele, irrespective of their sequence dissimilarity) and nucleotide diversity (extent of nucleotide mismatches between sequences). The former is directly relevant to forensic inference. A comparison of these two measures of diversity shows that the within-population diversity at nucleotide level varies more widely across world-wide populations (observed mean mismatch 6.6 in Greece to 15.9 in Kenya) than that at haplotype level (haplotype diversity of 0.9126 in Apache Indians to 0.9992 in Spain and China). Consequently, the coefficient of nucleotide diversity among the 6 population groups of the world is considerably larger (N_{ST}=8.9%) than the coefficient of haplotype diversity (G_{ST}=0.95%). G_{ST} between populations within group is even smaller (G_{ST} almost zero for Caucasians to 1.8% between the two populations of Native Americans). Comparative data on autosomal STRs yield larger G_{ST} values, suggesting that a broader merging of populations may be enough for mtDNA database to get a count-based estimate of rarity of any specific haplotype observed in forensic case work. (Research supported by NIH grant GM 41399).

Reduced nuclear -catenin may suppress intestinal tumorigenesis in Dnmt1 hypomorphic ApcMin/+ mice. *M. Luo[1], M.A. Renelt[1], J. Chen[1], Y. Chen[1], B. Zheng[1], L. Wang[1], X. Hao[2], P.W. Laird[3], C. Shao[1], J.A. Tischfield[1]* 1) Department of Genetics, Rutgers University, Piscataway, NJ; 2) Department of Chemical Biology, Ernest Mario School of Pharmacy, Rutgers University, Piscataway, NJ; 3) Department of Surgery and Biochemistry and Molecular Biology, University of Southern California, Los Angeles, CA.

Intestinal tumorigenesis is substantially suppressed in Dnmt1-hypomorphic ApcMin/+ mice, but the mechanism by which DNA hypomethylation contributes to tumor suppression remains to be determined. Apc is known to be a negative regulator of the Wnt signal transduction cascade. Mutation or loss of Apc is found in a vast majority of human colorectal carcinomas and in the adenomas of ApcMin/+ mice. Dysregulation of the Wnt pathway caused by Apc inactivation allows -catenin to translocate to and accumulate in the nucleus, where it functions as a co-activator of transcription. In the current study, we examined intestinal tumorigenesis and -catenin distribution in the Dnmt1 hypomorphic ApcMin/+ mice model. We find that while tumor formation can still be initiated, manifested as microadenomas, in those mice, tumor progression is significantly suppressed. Macroscopic tumors were rarely observed, even in relatively old mice. While the absence of Apc is correlated to an intensive accumulation of -catenin in macroscopic tumors of Dnmt1 wild-type mice, the macroscopic adenomas, but not microadenomas, formed in Dnmt1 hypomorphic mice showed little accumulation of -catenin protein in their nuclei even though Apc is absent. Meanwhile, intensive nuclear -catenin staining was observed in Paneth cells from the same mice. There was no significant difference in the -catenin mRNA level between mice with different Dnmt1 status, though the -catenin protein level was lower in Dnmt1 hypomorphic mice. Our results suggest that the reduced nuclear accumulation of -catenin, which can be a consequence of reduced expression, accelerated degradation and/or impaired transport, may be responsible for the suppression of tumor progression in ApcMin/+ mice with DNA hypomethylation.

True hermaphroditism with a 46,XX/46,XY karyotype. *A.L. Zaslav[1], L. Mehta[2], J. Jacob[3], T. Mercado[1], L. Palmer[4]*
1) Cytogenetics, State University of New York at Stony Brook, Stony Brook, N.Y; 2) Schneider Children's Hospital, LIJ, New Hyde Park, N.Y; 3) Division of Cytogenetics, Dept. of Lab Medicine, LIJ, New Hyde Park, N.Y; 4) Department of Urology, Schneider Children's Hospital, LIJ, New Hyde Park, N.Y.

True hermaphroditism (TH) is a rare condition in which the external genitalia are ambiguous and the gonads have both ovarian and testicular elements. We present a newborn infant with TH and a 46,XX/46,XY karyotype. At birth the infant presented with ambiguous genitalia, no palpable testes and clitoromegaly. Two different surgical procedures (S1,S2) were performed. Endoscopic evaluation revealed a 1cm urogenital sinus and a vagina with a single cervical os posteriorly. Laparoscopy (S1) showed a single uterus with two gonads. Gonadal biopsy revealed predominantly testicular tissue with normal appearing seminiferous tubules (ST). Close to the surface ST appeared smaller and poorly formed indicating gonadal dysgenesis. On the left was a fallopian tube. The biopsy of this structure revealed ovarian tissue, with a mixture of germ cells consistent with gonadoblastoma. At the second surgery the child underwent bilateral gonadectomy and awaits vaginoplasty and clitoroplasty. Chromosome analysis and FISH analysis performed on peripheral blood (BL) and skin (S), left (LG) and right (RG) gonadal tissue from the two surgical procedures showed 46,XX/46,XY in BL, S, LG, RG (S2). Only 46,XX cells were observed from the RG from S1. The LG from S1 failed to grow. FISH on 200 nuclei, S and G using the CEP X/CEP Y probes and SRY/CEP X probe (Vysis, Downers Grove, IL) on BL was performed. All tissues except RG (all XX) from S1 revealed a XX/XY signal pattern in varying proportions. Metaphase FISH on BL revealed that 7/10 cells were positive for one X centromere and the SRY critical region of the Y. TH is rare with only 10% having a 46,XX/46,XY karyotype. Patients present with significant diagnostic and management challenges involving various disciplines. This case study will assist in increasing knowledge of long-term genetic, physical and psychosocial care for patients with TH.

Truncating *BMPR2* mutation in a patient with pulmonary arterial hypertension and hereditary hemorrhagic telangiectasia. *C.M. Rigelsky[1], R. Lehtonen[2], C. Eng[1], M.A. Aldred[1]* 1) Genomic Medicine Institute, Lerner Research Institute, Cleveland Clinic, Cleveland, OH; 2) Department of Medical Genetics, University of Helsinki, Finland.

Pulmonary arterial hypertension (PAH) and hereditary hemorrhagic telangiectasia (HHT) are two distinct clinical entities that overlap in some individuals. PAH is characterized by elevated mean pulmonary arterial pressure. *BMPR2* is the only gene that has been associated with familial PAH; mutations are associated with autosomal dominant inheritance with reduced penetrance. HHT is an autosomal dominant condition characterized by epistaxis, telangiectasia and visceral lesions. HHT has been shown to be caused by mutations in *ACVRL1*, *ENG* or *SMAD4*. To date twenty-four families have been described with features of PAH and HHT. Eighteen of these were caused by mutations in *ACVRL1* and two by *ENG* mutations. We report here a 36-year-old woman diagnosed with PAH and HHT and a *BMPR2* mutation. She was initially diagnosed with PAH at the age of 24. At the age of 35, a computed tomographic scan of the chest revealed pulmonary AVMs, suggesting the possible diagnosis of HHT. Physical exam and review of her medical history revealed nasal telangiectasia and spontaneous nighttime epistaxis. She met HHT diagnostic criteria based on the presence of pulmonary AVMs, epistaxis and nasal telangiectasia. She was adopted, so no family history was available. In this patient, mutation analysis of *ACVRL1*, *ENG* and *SMAD4* were all normal. However, analysis of *BMPR2* revealed a germline nonsense mutation in exon 10, designated c.1297C>T (p.Q433X). This is the first known report of a patient with a clinical diagnosis of PAH and HHT who has a germline mutation in *BMPR2*. It is currently not clear how a *BMPR2* mutation could result in an HHT phenotype. *BMPR2*, *ACVRL1*, *ENG* and *SMAD4* are all members of the TGF-beta/BMP superfamily; however, crosstalk between the TGF-beta and BMP signaling pathways is not fully understood. While HHT is not common among individuals with *BMPR2* mutations, this case highlights that analysis of the *BMPR2* gene is indicated in patients affected with both HHT and PAH who do not harbor *ACVRL1*, *ENG* or *SMAD4* mutations.

Tracing the Selection on Human ADH1B Gene. *H. Li, S. Gu, K.K. Kidd* Department of Genetics, Yale School of Medicine, New Haven, CT.

Alcohol dehydrogenase (ADH) is a widely studied enzyme as is the gene family encoding the focus of this enzyme. Previous studies have shown that the *ADH1B*47His* allele is associated with a decrease in the risk of alcoholism and the core region with this allele has undergone positive selection in some populations. A literature review identified studies reporting allele frequencies of this polymorphism for 131 population samples (for a total of 168 when combined with our new data on 37 populations. The derived *ADH1B*47His* allele reaches high frequencies only in West and East Asia, but has a low frequency in the region between East and West Asia, suggesting that the derived allele increased in frequency independently in the two regions. We tested seven single nucleotide polymorphisms (SNPs) and two short tandem repeat polymorphisms (STRPs) in the *ADH1B* region in the world sample to form the haplotypes. Seven haplogroups were defined with different SNP allele patterns. H5, H6, and H7 are haplogroups with the derived *ADH1B*47His* allele. H5 is restricted in West Asia and H6 is in East Asia and Pacific region. H7 has in addition to H6 the derived allele of rs3811801 in the regulatory region, and is restricted to East Asia. We analyzed 24 population samples from East Asia covering six ethnic families and find H7 is enriched in the Hmong, Han Chinese, and Altaic families. We typed 23 more SNPs in about 170kb flanking region of *ADH1B*. The extended haplotype homozygosity (EHH) and relative EHH tests for the *ADH1B* core were consistent with selection for the haplogroups with derived SNP alleles in the Hmong and Altaic. Other populations showed only a weak signal at best. The selection distribution is significantly correlated with the frequency of the derived regulatory polymorphism rs3811801, not the derived amino-acid altering allele *ADH1B*47His*. Thus, the real focus of selection may be the regulatory region of H7. The *ADH1B* downstream STRP provides relative age estimates for the SNP-based haplogroups that are in general agreement with the Out of Africa pattern and a recent expansion of H7 in East Asia. The refined pattern of variation for *ADH1B* haplogroups will help design studies to understand the selective force(s) that may have operated.

ATM gene deletion in children with _TEL-AML1_-positive acute lymphoblastic leukemia. *M. Shago[1,2], S.H. Hong[1,2], G. Nie[1], M. Abdelhaleem[1,2], I. Teshima[1,2], O. Abla[1,2]* 1) Departments of Paediatric Laboratory Medicine and Paediatrics, The Hospital for Sick Children, Toronto, ON, Canada; 2) Departments of Laboratory Medicine and Pathobiology and Pediatrics, University of Toronto.

The t(12;21) translocation, which results in the fusion of the *TEL* and *AML1* genes, is present in ~25% of pediatric B-precusor acute lymphoblastic leukemia (ALL) patients. Although initially thought to be a favorable prognostic indicator, the t(12;21) was associated with a similar rate of relapse as t(12;21)-negative pre-B ALL in subsequent studies. While secondary cytogenetic abnormalities are often present, their prognostic significance is unknown. We characterized cytogenetic changes in 57 patients diagnosed with t(12;21)-positive ALL between 2000-2005. One of the recurrent changes was a deletion of 11q, detected in 3/57 (5%) of patients.

Using FISH analysis, we determined that the 11q deletions in these 3 patients included the *ATM* gene. *ATM* (11q22.3) is one of the master genes controlling signaling pathways for DNA repair. *ATM* mutations, deletions, or loss of heterozygosity have been reported in a number of sporadic cancers. In CLL, ATM protein deficiency is associated with aggressive disease, while in adult ALL, loss of heterozygosity of the *ATM* gene is associated with a favourable prognosis. Our aim was to further characterize the incidence and significance of the *ATM* deletions. In total, *ATM* deletions were detected in 16 of 56 patients. In 10 of the 16 *ATM*-deleted patients, the deletion extended distally to the *MLL* gene region (11q23). Five of the 57 children (9%) in this cohort have developed a relapse of ALL. None of the patients with *ATM* deletions have relapsed.

Our data support the speculation that *ATM* gene deletion may have a positive impact on patient survival. In the majority of *ATM*-deleted cases in our cohort, the deletion in 11q was not detected by conventional G-band analysis. This emphasizes the significance of procedures such as FISH and microarray analyses in more accurate definition of genomic alterations in childhood ALL.

Two cases of deletions of the derivative chromosome 9 in CML. *T.A. Mercado[1], A. Zaslav[1], S. Richard[2], D. Tully[1], E. Knorr[1], M. Dahir[1]* 1) Cytogenetics, SUNY, Stony Brook, Stony Brook, N.Y; 2) Blood and Marrow Stem Cell Cell Transplantation Program, SUNY Stony Brook, Stony Brook, N.Y.

Ph results from a reciprocal (R) translocation (T) of chromosomes 9 and 22. The BCR-ABL gene is formed on the der(22) and ABL-BCR on the der(9). FISH identified unexpected deletions (D) of the T product in 10-15% of patients (PTS) with CML. Studies have demonstrated atypical (AT) abnormal (AB) findings were associated with a more rapid progression (P) to blast crisis and shorter survival (OS) time. We report 2 cases of CML with a D of ABL-BCR on 9. PTS were male (PT 1 25y, PT 2 44y), diagnosed with chronic CML. PTS were placed on hydroxyurea and allopurinol awaiting imatinib therapy. PTS were evaluated using standard cytogenetic & molecular techniques: PT 1: 24H BM; PT 2: BM & unstimulated blood (UB). The T was seen in all cells of both PTS. PT 2 also had a del(6)(q21) in 6/20 cells (BM & UB). FISH using the BCR/ABL DF DC probe (200 nuclei) revealed an AT AB signal pattern of 2O:1G:1F: PT 1:194/200; PT 2:121/200 BM; 157/200 UB. FISH on 10 G-banded metaphases: PT 1: 6 BM cells; PT 2: 9 UB cells. All cells showed the AT AB pattern. Evidence showed that DS occur at the time of the Ph T and the recombination that generated the RT can also produce large DS. It has been demonstrated that DS on the 9 may be a significant prognostic indicator (Lee,Y et.al., 2006, Ca Genet Cytogenet 166(1):65; Huntly,B et.al., 2003, Blood 102(4):1160; 102(6):2205). Early studies were based on the der(9) PT treatment with hydroxyurea or interferon-based regimens. Data on D status in PTS receiving imatinib, although preliminary, appear to indicate that PTS with the DS have shorter P-free S in both chronic &/or advanced phases of CML. The PTS reported here have AT DS on the der(9). Since they are newly diagnosed and in the preliminary stages of treatment they will be monitored as to disease P and OS. It is possible that these DS are associated with the loss of one or more tumor suppressor genes within the deleted region on the der(9). This may be related to accelerated P to blast crisis in these PTS. These findings will be used to assist in determining prognosis and treatment for PTS with AT DS.

Molecular analysis of the CHD7 gene in CHARGE syndrome: identification of 22 novel mutations and evidence for a low contribution of large CHD7 deletions. *P. Vuorela[1], S. Ala-Mello[2], C. Saloranta[2], M. Penttinen[3], M. Pöyhönen[4], K. Huoponen[1], W. Borozdin[5], B. Bausch[6], E.M. Botzenhart[6], C. Wilhelm[5], H. Kääriäinen[1,7], J. Kohlhase[5,6]*
1) Department of Medical Genetics, University of Turku, Turku, Finland; 2) Department of Clinical Genetics, Helsinki University Hospital, Helsinki, Finland; 3) Clinical Genetics Unit, Department of Pediatrics, Turku University Central Hospital, Turku, Finland; 4) Department of Medical Genetics, University of Helsinki, Finland; 5) Praxis für Humangenetik Freiburg, Germany; 6) Institut für Humangenetik und Anthropologie, Universität Freiburg, Freiburg, Germany; 7) Department of Molecular Medicine, National Public Health Institute, Helsinki, Finland.

Autosomal dominant CHARGE syndrome (OMIM #214800) is characterized by choanal atresia and/or cleft lip/palate, ocular colobomas, cardiovascular malformations, retardation of growth, ear anomalies and deafness, and caused by mutations in the CHD7 gene. Here we describe the outcome of a molecular genetic analysis in 18 Finnish and 56 German patients referred for molecular confirmation of the clinical diagnosis of suspected CHARGE syndrome. In this group of 74 patients, we found mutations in 30 cases. 22 mutations were novel, including 11 frameshift, 5 nonsense, 3 splice site and 3 missense mutations. One de novo frameshift mutation was found in the last exon and is expected to result in a minimally shortened CHD7 polypeptide. Since the mutation is associated with a typical CHARGE syndrome phenotype, it may indicate the presence of an as yet unknown functional domain in the very carboxyterminal end of CHD7. qPCR or MLPA assays did not reveal deletions in mutation negative cases, suggesting that larger CHD7 deletions are not a major cause of CHARGE syndrome. Our mutation detection rate of 40.5% is relatively high in an unselected cohort of patients, who were referred to DNA analysis because of suspected diagnosis of CHARGE syndrome, and one can expect it to be markedly higher in a cohort of patients who meet strict criteria of the disorder.

A WT1 exon 6 truncation mutation causes ambiguous genitalia in a patient with Denys-Drash syndrome. *A. Tsai[1], P. Chiang[2], S. Kopinsky[2], E. Spector[2]* 1) Div Clinical Gen & Metabolism, Childrens Hosp, Denver, CO; 2) DNA Diagnostic Lab, Department of Pedatrics, UCDHSC.

Denys-Drash syndrome (DDS) is a rare genetic disorder featuring the triad of congenital nephropathy, Wilms tumor, and intersex disorders (XY pseudohermaphroditism or XY female). DDS is associated with constitutional mutations in the Wilms tumor suppressor gene, WT1. Of 30 patients with reported mutations, 24 had mutations at exons 8 or 9; 21 of these were missense mutations in the zinc-finger region of WT1. Six patients had mutations outside exons 8 and 9. Only seven of the 30 were truncation mutations: one each in exons 1, 3 and 8; two each in exons 6 and 9. Unlike WAGR syndrome, with its complete deletion of one copy of WT1, DDS is most likely caused by a dominant-negative mode of action of mutant DDS proteins. We present here a new case of DDS with a novel nonsense mutation in exon 6, leading to a stop codon and hence a truncated protein. The patient was initially diagnosed with ambiguous genitalia/partial androgen insensitivity syndrome (46, XY). Orchiectomy was performed at age 5 days, and the patient was raised as a girl. At 8 months, she presented with a one-week history of vomiting, fever and abdominal distension. Huge bilateral Wilms tumors were detected. The entire coding region of the WT1 gene was sequenced from genomic DNA isolated from peripheral blood. A mutation was identified at exon 6 (Y339X; numbering is based on isoform B, NP_077742). Lessons learned: (1) Always consider a diagnosis of DDS in the presence of ambiguous genitalia and androgen insensitivity. Offer Wilms tumor protocol (quarterly renal ultrasound until age 12) until proved otherwise. Due to the rarity of DDS, our patients ambiguous genitalia didnt initially raise suspicion of DDS, so she was not monitored for Wilms tumor. (2) The mutation identified represents the first report of an exon-6 truncation mutation in a patient with ambiguous genitalia. (3) Molecular diagnosis of WT1-related conditions like DDS, Frasier Syndrome, familial Wilms tumor and isolated diffuse mesangial sclerosis is now available clinically, and will greatly facilitate genotype-phenotype correlation studies.

Confronting Complexity in Late-Onset Alzheimer Disease: Application of Two-Stage Analysis Approach Addressing Heterogeneity and Epistasis. *T.A. Thornton-Wells[1], J.H. Moore[3], E.R. Martin[4], M.A. Pericak-Vance[4], J.L. Haines[2]* 1) Vanderbilt Kennedy Center for Research on Human Development, Vanderbilt University Institute of Imaging Science, Vanderbilt University, Nashville, TN; 2) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 3) Departments of Genetics and Community and Family Medicine, Dartmouth Medical School, Lebanon, NH; 4) Miami Institute of Human Genomics, Miller School of Medicine, University of Miami, Miami, FL.

Common diseases with a genetic basis are likely to have a very complex etiology. A new comprehensive statistical and computational strategy for identifying the missing link between genotype and phenotype has been proposed, which emphasizes the need to address heterogeneity in the first stage of the analysis and gene-gene interactions in the second stage. We applied this two-stage analysis strategy to late-onset Alzheimer disease (LOAD) from 654 families and an independent set of 451 cases and 699 unrelated controls. Bayesian Classification found significant clusterings ($p<0.002$) for both datasets, which used the same five SNPs in LRRTM3 as the most influential in determining cluster assignment. In subsequent analyses to detect main effects and gene-gene interactions, SNPs in three genesPLAU, ACE and CDC2were found to be associated with LOAD in particular subsets of the data based on their LRRTM3 multilocus genotype ($p<0.05$). All of these genes are viable candidates for LOAD based on their known biological function. Further studies are needed to replicate these statistical findings and to elucidate possible biological interaction mechanisms between these genes and LRRTM3.

Disruption of an AP-2 binding site upstream of *IRF6* is commonly associated with nonsyndromic cleft lip and palate. *F. Rahimov[1], M.J. Hitchler[2], F.E. Domann[2], A. Jugessur[3], R.T. Lie[3], A.J. Wilcox[4], K. Christensen[5], E.D. Green[6], M. L. Marazita[7], B.C. Schutte[1], J.C. Murray[1]* 1) Dept Pediatrics, Univ Iowa; 2) Dept Rad Onc, Univ Iowa; 3) Univ Bergen, Norway; 4) NIEHS, Durham, NC; 5) Univ Southern Denmark; 6) NHGRI, NIH; 7) Center Craniof Dent Genet, Univ Pittsburgh.

Nonsyndromic cleft lip and palate (NSCLP) is a common craniofacial birth defect. We discovered that mutations in *IRF6* underlie Van der Woude syndrome (VWS), an orofacial clefting disorder where lower lip pits are the only features distinguishing VWS from NSCLP. Subsequently, we reported a strong association between SNPs in the *IRF6* locus and NSCLP. We observed a particularly strong overtransmission of the ancestral allele V of the rs2235371 (V274I) SNP in individuals of Asian and South American ancestry. However, the frequency of the risk allele is over 97% in European and African populations making it an unlikely candidate for the etiological mutation. Direct sequencing of the coding regions of *IRF6* did not detect potential causative mutations. We postulated that the causative variant(s) are in linkage disequilibrium with V274I and could reside in the regulatory element(s) of *IRF6*. Using comparative genomic sequence analysis from 14 vertebrate species, we detected a highly conserved region 9.7kb upstream of *IRF6*. Family-based association analysis in Norwegian, Danish and Filipino populations showed strong overtransmission of a conserved SNP (rs642961) in this region ($p<2x10^{-8}$). The ancestral allele G and the derived allele A of rs642961 split the V allele of V274I into two haplotypes. The V-A haplotype is significantly overtransmitted ($p<3x10^{-8}$), whereas transmission of the V-G haplotype is not distorted ($p<0.7$). Gel shift assays showed that the A allele of rs642961 disrupts binding activity of the transcription factor AP-2 alpha. *TFAP2A* is highly expressed in craniofacial structures and knockout mice have multiple facial anomalies. A ChIP assay showed that AP-2 binds to its consensus binding sites *in vivo* suggesting that it could function upstream of *IRF6*. In total, our data suggests that a common functional variant upstream of *IRF6* contributes to NSCLP and implicates AP-2 in the IRF6 developmental pathway.

African-American gender biased gene flow revealed by mtDNA haplotypes. *N. Wang[1], W. Niu[2], B. Budowle[3], R. Chakraborty[2]* 1) Div. Allergy and Human Genetics, Cincinnati Children's Hosp, Cincinnati, OH; 2) Center for Genome Information, Univ. of Cincinnati, Cincinnati, OH; 3) Laboratory Division, FBI Academy, Quantico, VA.

As an admixed population, African-Americans are the results of gene flow between Africans and Americans of European descent within the last 20 generations. Such admixture histories have advantage in uncovering the genes underlying human complex diseases that have different prevalence in the parental populations (also called admixture mapping). Understanding the gene flow to African-Americans from the parental populations is critical especially for diseases caused by imprinting genes (i.e., genes with parent-of-origin effect). In the present study, sequence data on mitochondrial hyper-variable regions I and II (HV1 and HV2) from 240 Africans (45 from Egypt, 98 from Kenya, and 97 from Sierra Leone), 1303 African-Americans, and 1794 Caucasians (95 from Austria, 107 from France, 43 from Greece, 158 from Spain, and 1391 from the USA) were extensively analyzed to study the gene flow to African-Americans from maternal lineage. Our results show that the haplotype diversities are 0.9979, 0.9984, and 0.9967 for the Africans, African-Americans, and Caucasians, respectively, suggesting that the extent of mtDNA haplotype difference at individual level is large. However, within each population, the mismatch distribution in the African-Americans (observed mean 14.4) is close to that in the Africans (observed mean 14.8), but significantly higher than that in the Caucasians (observed mean 8.0). In addition, our results reveal that common African-American haplotypes cluster closely with haplotypes found in the Africans, strongly suggesting gender-biased gene flow to African-Americans with nearly exclusive African female contributions. Taken together, the results obtained herein should provide important guidelines for studying diseases related to imprinting genes and diseases linked to mitochondrial DNA in the African-Americans. (Research supported by NIH grant GM 41399 to RC).

Detection of gene duplication(s) among Chinese X-linked mental retardation (XLMR) with multiplex ligation probe amplification (MLPA). *X-G. Tao[1], X-Z. Wang[1], J-M. Wang[1], Y-W. Jiang[1], N. Zhong[1,2]* 1) Peking University Center of Medical Genetics, Beijing, China; 2) New York State Institute for Basic Research in Developmental Disabilities, Staten Island, NY.

Mental retardation (MR) is defined as a significant impairment of cognitive and adaptive function, with onset before age 18 years. It is estimated to occur in about 3-5% of the population. In a national wide survey conducted in 2000, there are about 30,000,000 MR patients among 0-6 years Chinese children in the mainland China, with an annual increase of 300,000. Because X-linked MR accounts for about 20-30% of the MR population, we anticipated that there must be a large number of XLMR patients. We have initialized a molecular testing among the XLMR patients to exclude fragile X syndrome (see Ju et al., Abstract control number 10089 in this conference). After fragile X syndrome is excluded, we employed multiplex ligation probe amplification (MLPA) to screen for gene deletion or duplication among clinically suspected XLMR patients. A mix of 43 probes (probe kit P106, MRC, Holland) detecting for 14 XLMR genes including FMR1, FMR2, GDI1, and SCL6A8 was hybridized to patients genomic DNA that was amplified. Among 51 cases we studied, two cases were identified to have gene duplication. One is carrying a duplication at exon 11 of FMR2 gene, and another, having a large duplication spinning genes GDI1 and SCL6A8. Here we report the first finding of a gene-duplication at FMR2 locus. Our results indicated that applying MLPA may detect 3.9% of clinically suspected XLMR cases. We believe that the detecting rate may be higher once the size of testing sample is increased.

Risk factors for migraine taking into account family structure in a sample of Portuguese families. *C. Lemos[1,2], M.J. Castro[1,2], I. Alonso[1,2], J. Barros[3], J. Sequeiros[1,2], J. Pereira-Monteiro[2,3], D. Mendonça[2], A. Sousa[1,2]* 1) UnIGENe, IBMC, Porto, Portugal; 2) ICBAS, Univ.Porto, Portugal; 3) Serviço Neurologia, HGSA, Porto, Portugal.

Migraine is a primary, chronic headache and a highly prevalent disease. An increased risk for relatives of migraineurs suggests that genetic factors may be implicated in the most common forms of this disease. In a previous study, we validated the use of family history to classify relatives as migraine sufferers and we found that probands were able to correctly identify their affected relatives although migraine in familial members was underestimated, but not overestimated. In that sample of Portuguese families, we also found evidence of familial aggregation in first-degree relatives of probands. In the present study, we evaluated relatives age at observation and gender as risk factors for migraine, since this is an age and gender-dependent trait. We also included probands age at onset in the model to test if this variable was associated with relatives affection status in our families. A total of 131 Portuguese families were selected for this study. Among 492 first-degree relatives of probands with migraine, 317 were affected and 175 were healthy. Probands age at onset was used as dichotomous variable (<16, 16+ years) and relatives were divided in two groups according to their age at observation (<40, 40+ years). We performed a logistic regression analysis and general estimating equations (GEE) were used to account for residual correlation among members from the same family. After adjusting for the remaining variables, gender was found to be a risk factor for migraine (OR=3.22; 95% CI= 2.13- 4.86), with females at higher risk than males. Probands age at onset and relatives age at observation were not associated with the outcome. No significant interactions were found between these variables. In a previous study, a lower age at onset in probands was associated with relatives affection status. In our study, the proportion of affected relatives was independent of probands age at onset. Our findings showed that, as expected, gender is a risk factor for migraine.

Mutation screening of NOTCH pathway genes in individuals with left ventricular outflow tract defects. *K.L. McBride[1], G. Zender[1], S.M. Fitzgerald-Butt[1], S.D. Fernbach[2], J.A. Towbin[2], J.W. Belmont[2]* 1) Center of Molecular & Human Gen, Columbus Child Res Inst, Columbus, OH; 2) Dept Molecular & Human Genetics, Baylor College of Medicine, Houston TX.

The NOTCH signaling pathway is important for heart development. Multiple receptors (NOTCH 1-4) interact with multiple membrane bound ligands (JAGGED, SERRATE, DELTA) leading to cleavage and release of the intracellular NOTCH domain. This domain interacts with the RBPJK/CBF1/Su(H) transcription factor, changing it from a repressor to an activator of genes from the HES families (e.g. HEY2). JAG1 defects in human (Alagille syndrome) frequently cause tetralogy of Fallot, septal defects, aortic valve stenosis (AVS) and coarctation of the aorta (CoA). The cardiac defects in the mouse HEY2 knockout are similar to human Alagille syndrome, while the zebrafish homologue mutant gridlock recapitulates coarctation of the aorta. Recently, NOTCH1 mutations have been found in 2 families with calcific AVS. We postulated NOTCH pathway genes may be important in the development of congenital left ventricular outflow tract (LVOT) defects in humans. We screened 101 individuals with AVS, CoA or hypoplastic left heart syndrome (HLHS) for mutations in HEY2 and NOTCH1 by denaturing high performance liquid chromatography. Direct sequencing was performed on any amplicons demonstrating an abnormal chromatogram. None of the cases had mutations in HEY2. 64 variants in NOTCH1 were identified, 27 of which were novel. 9/27 variants cause an amino acid substitution, and could be found in the subject and one parent. The missense mutations are scattered throughout the gene, but are not present in the Notch, transmembrane, or ankyrin domains. 6/9 of these involve a highly conserved nucleotide. None of these changes have been observed in 184 control chromosomes. The presence of the variant in both the subject and a parent, and the occurrence in highly conserved amino acids among non-critical domains are characteristic of a susceptibility allele for a complex genetic disease. We believe this supports our hypothesis that NOTCH1 variants are necessary, but not sufficient, to cause LVOT defects in some subjects.

A glucocorticoid receptor gene haplotype is associated with increased risk for low birth weight infants among Kenyan mothers. *D. Smelser[1], A. Grant[2], C. Bean[3], G. Satten[3], S. Kariuki[5], L. Zhang[4], A.A. Lai[4], Y.P. Shi[4], L. Slutsker[4], B. Nahlen[4], F. ter Kuile[4], V. Udhayakumar[4]* 1) National Office of Public Health Genomics; 2) National Center on Birth Defects and Developmental Disabilities; 3) Division of Reproductive Health; 4) Division of Parasitic Diseases, Centers for Disease Control and Prevention, Atlanta, GA; 5) Kenya Medical Research Institute, Kisumu, Kenya.

Background: Inflammatory pathway components play critical roles in mediating preterm and low birth weight births in response to malaria infection. The glucocorticoid receptor mediates cross-talk between the inflammatory response and endocrine pathways. We selected SNPs based on their previous association with glucocorticoid activity, which may be a factor contributing to low birth weight. **Methods:** We examined if three functional SNPs: 3669AG (rs6198), *Bcl*I (intron 2) and *Tth111*I within the *NR3C1* (glucocorticoid receptor) gene were associated with delivery of a low birth weight infant among Kenya mothers in a malaria endemic area. A total of 735 mothers were included in the study: 674 delivered a normal weight (2500g) infant and 61 delivered a low birth weight (2500g) infant. **Results:** Among the *NR3C1* polymorphisms analyzed, only the 3669AG SNP was associated with increased risk for delivering a low birth weight infant (OR 3.3; 95% CI: 1.44-7.54). After adjusting for potential confounders of infant sex, parity, maternal anemia, peripheral and placental malaria parasitemia, the GG genotype of the 3669AG polymorphism was no longer significantly associated with delivery of a low birth weight infant. Haplotypes were constructed for the polymorphisms and are listed here with their population frequencies: AGG (0.691), ACA (0.143), AGA (0.100), ACG (0.40) and GGA (0.026). Only the GGA haplotype was significantly associated with increased risk for delivering a low birth weight infant in both univariate and multivariate analyses [Adjusted OR=4.58; 95% CI: 1.94-10.82]. **Conclusion:** In this Kenyan maternal population, the 3669AG (rs6198), *Bcl*I (intron 2) and *Tth111*I GGA haplotype of the *NR3C1* gene was significantly associated with delivery of a low birth weight infant.

IMPACT OF POLYMORPHISMS IN CANDIDATE GENES FOR PHARMACORESISTANCE IN MESIAL TEMPORAL LOBE EPILEPSY. *M.S. Silva[1], K.M. Siqueira[1], N.C. Ianni[1], E. Bilevicius[2], F. Cendes[2], I. Lopes-Cendes[1]* 1) Medical Genetics, FCM - Unicamp, Campinas, Sao Paulo, Brazil; 2) Neurology, FCM - Unicamp, Campinas, São Paulo, Brazil.

Mesial temporal lobe epilepsy (MTLE) is associated with the highest proportion of the drug-resistant patients. One hypothesis to explain differences in drug response in epilepsy treatment is the association with pharmacogenetic differences present in genes related to drug-metabolism and ion channels. Therefore, allelic variations in these genes could be responsible for degreased efficiency of antiepileptic drugs and failure to control seizures. The purpose of this study was to investigate whether single nucleotide polymorphisms (SNPs) on drug-transporter genes (ATP-binding cassette family: ABCB1, ABCC2, ABCC4; and RLIP76-ralA-binding-protein1) and ion channels (SCN11A-Na+channel subunit; CACNA1B-Ca+2channel 1B subunit) could be associated with pharmacoresistance in a large group of MTLE patients. We chose 11 validated SNPs in dbSNPs database: rs12680, rs 12454987, rs8092935 (RALBP1); rs2235039, rs282564, rs2229109, rs3213619 (ABCB1); 2273697(ABCC2); 2274407(ABCC4); 2298771(SCN11A); 4422842(CACNA1B). Genotyping was carried out using the TaqMan system(Applied Biosystems). We included 90 drug-resistant MTLE patients and compared with 60 drug-responsive MTLE patients. Genotypic frequencies were in Hard-Weinberg equilibrium in both groups and no significant allelic differences were observed, for any of the SNPs tested, between the two groups ($p>0.01$). In addition, no differences were found between the allelic frequencies in both groups and the NCBI SNPs database. In conclusion, we found a lack of correlation between SNPs in candidate genes associated with drug-metabolism and ion channels and pharmacoresistance in MTLE.

Population specificity may not be enough: a case-based investigation of racial generalization in gene-disease association research. *J. Yu, S.M. Fullerton, J. Crouch, K. Fryer-Edwards, W. Burke* Center for Genomics and Healthcare Equality, University of Washington, Seattle, WA.

The use of racial and/or ethnic categories in genetic research has received increasing attention, with editors and other commentators recommending greater care in the choice of racial/ethnic labels and attention to the specificity of population description. Specificity in sample description helps guard against inappropriate generalization of population-specific findings to larger, socially-defined, racial groups. It also helps researchers extend preliminary observations to new settings for the robust replication of gene-disease association. Despite the clear importance of sample specificity with respect to these social and scientific purposes, no studies have examined the use of population sampling and description in a defined literature focused on an established gene-disease association. We therefore examined the nature of population description, and its role in result interpretation, in 80 articles which investigated the association of the PPAR-gamma Pro12Ala polymorphism with diabetes and related phenotypes (published between 1997 and 2005). Our analysis suggests that population description varies widely among the collected articles, with differences related more to investigators country of origin and the source of the study sample than to the journals impact or year of publication. While very few of the reports hypothesized race-based differences in gene-disease association (5%), and only a small proportion of articles explicitly invoked racial genetic differences in their interpretation of association results (15%), findings from a population in a defined location were commonly generalized to a particular racial group (45%). These results suggest that care in population description does not mitigate the practice of racial generalization. To make progress in this area, greater attention will need to be paid to characterizing the conditions under which generalization by nation-of-origin or race is both empirically and socially justified.

PCA-correlated SNPs for structure identification in worldwide human populations. *P. Paschou[1], E. Ziv[2], E.G. Burchard[3], M.W. Mahoney[4], P. Drineas[5]* 1) Dept of Molecular Biology & Genetics, Democritus University of Thrace, Greece; 2) DGIM, Institute for Human Genetics, UCSF; 3) Depts of Biopharmaceutical Sciences & Medicine, Pharmaceutical Sciences & Pharmacogenetics, UCSF; 4) Dept of Mathematics, Yale University; 5) Dept of Computer Science, RPI.

Existing methods to ascertain small sets of markers for the identification of human population structure (, Fst, Informativeness, etc.) require prior knowledge of individual ancestry. Based on Principal Components Analysis (PCA) and recent results in Theoretical Computer Science, we develop a novel algorithm that, applied on genomewide data, selects small subsets of SNPs (PCA-correlated SNPs) that reproduce the structure found by PCA on the complete dataset, without use of ancestry information. Evaluating our method on a previously described dataset (10,805 SNPs, 11 populations), we demonstrate that, achieving in most cases 99% genotyping savings, PCA-correlated SNPs can be effectively used to assign individuals to particular continents or populations. We validate our methods on the HapMap populations and achieve perfect intercontinental differentiation with 14 PCA-correlated SNPs. The Chinese and Japanese populations can be easily differentiated using less than 100 PCA-correlated SNPs ascertained after evaluating 1.7 million SNPs from HapMap. We show that structure informative SNPs are not portable across geographic regions. However, we manage to identify a general set of 50 PCA-correlated SNPs that effectively assigns individuals to one of nine populations. Compared to the measure of Informativeness, our methods, although unsupervised, achieved similar results. Applying our algorithm on a novel Puerto Rican dataset (192 individuals 7,257 SNPs) we show that PCA-correlated SNPs can successfully predict population structure and admixture proportions. We subsequently validate these SNPs for structure identification in an independent Puerto Rican dataset. The algorithm that we introduce runs in seconds, even on genomewide data, and will facilitate the identification of population substructure, the study of admixed populations as well as stratification assessment in multi-stage whole-genome association studies.

High-density genome-wide array CGH in a genetically homogenous population. *J.G. Mulle[1], A.E. Pulver[2], S.T. Warren[1]* 1) Dept Human Genetics, Emory Univ Sch Medicine, Atlanta, GA; 2) Department of Psychiatry and Behavioral Sciences, Johns Hopkins University School of Medicine, Baltimore MD.

Extensive copy number variation (CNV) in the human genome is an exciting new discovery with potentially major implications for complex genetic disease studies. However, robust conclusions about CNV distribution in phenotypically normal populations have been elusive. This is in part because prior studies have used outbred samples, yielding imprecise population-level inferences. Additionally, the limited resolution of previously available technologies has biased estimates of the distribution and frequency of CNV in control genomes. Furthermore, different levels of resolution among technologies have prevented comparison between studies, even when studies investigate the same samples. We sought to improve on prior efforts in two ways; first, we assess CNV in phenotypically normal individuals ascertained from a genetic isolate, the Ashkenazi Jewish (AJ) population. Secondly, we employ CGH using an oligonucleotide array with 2.1 million features, corresponding to a density of 1 oligo every 1.1 kb in non-repetitive genomic sequence, to expand the range of CNV detection. Using this study design, we detect an average of 90 deletions and 112 duplications per genome, of median size 11 kb and 28 kb, respectively. All test samples are compared to one HapMap reference individual (NA12155), in whom CNV has been partially characterized by at least three technologies (McCarroll et al., 2006, Redon et al., 2006). We detect 60 of 81 (74%) unique CNV previously reported to exist in our HapMap reference genome, including 20 of 24 variants found using Affymetrix 500k EA array data (Redon et al., 2006), 37 of 53 variants found using WGTP BAC arrays (Redon et al., 2006), and 10 of 13 deletions found using HapMap genotype data (McCarroll et al., 2006). This 75% overlap with existing datasets (despite their overlap of only 10-25% with one another) implies that as experimental resolution increases, so will detection of true CNV. This characterization of the true CNV distribution in control genomes will be an important tool for understanding susceptibility variants for common, complex disease.

Family and twin studies of Restless Legs Syndrome. *L. Xiong[1], K. Jang[2], J. Montplaisir[3], A. Levchenko[1], P. Thibodeau[1], C. Gaspar[1], G. Turecki[4], G.A. Rouleau[1]* 1) Center for the Study of Brain Diseases, CHUM Research Center - Notre Dame Hospital, University of Montreal, Québec, Canada; 2) Department of psychiatry, University of British Columbia, Canada; 3) Centre d'étude du sommeil, Hôpital du Sacré-Cœur de Montréal and Centre de recherche en sciences neurologiques, Université de Montréal, Québec, Canada; 4) Research Center, Douglas Hospital, McGill University, Québec, Canada.

Background and purpose: Restless legs syndrome (RLS) is a prevalent sensorimotor disorder characterized by an imperative urge to move the legs. It often aggregates in families, indicating a potential genetic component. The purpose of this study is to characterize the clinical features of familial RLS and estimate its heritability. **Subjects and methods:**We undertook a systematic full family study of 259 RLS probands and their family members during a period of 10 years by multidimensional assessments of the probands and structural questionnaire telephone interviews for evaluation of family members using standardized RLS diagnostic criteria. We also conducted a population survey of RLS in 272 adult twin pairs from Canada using the same structured standardized questionnaire. **Results:**Our data confirms that RLS aggregates in families with a familial rate of ~77% by family history. Data from twin study also confirms that RLS is a common disorder with a prevalence of 12.3% in the surveyed population. The concordance rate of RLS is 53.7% in monozygotic and 19.0% in dizygotic twins with same sex, predicting a heritability of 69.4%. There are significant positive correlations of age at onset and severity scores among the concordant twin pairs. However familial RLS is a chronic disorder with average disease duration about 2416 years and a wide range of age of onset (AO: 2815 yr) and variable phenotypic expressivity in terms of severity, clinical course and sleep disturbance. Younger AO seems to be the most decisive factor distinguishing the familial and sporadic forms. Familial RLS is further characterized by higher rate of restless arms, bilateral restless legs, progressive clinical course and higher measurement of periodic leg movements during sleep (PLMS).

The need for continuing care: Patients with BRCA mutations desire follow-up genetic counseling. *J.Gamm Ruschman[1], E. Miller[1], K. Theobald[2], S. Knapke[1]* 1) Div Human Genetics, Cincinnati Children's Hosp Medical Ctr, Cincinnati, OH; 2) St. Elizabeth Medical Ctr, Edgewood, KY.

Patients seen at CCHMC for genetic counseling related to BRCA1/2 testing are seen by a genetic counselor and a geneticist. Traditionally, patients receive pre- and post- test counseling. After BRCA1/2 results are given, patients are referred to their original provider for management. This clinical service has been provided since 1996, with no routine follow-up of mutation carriers. We assessed patients interest in follow-up genetic counseling using a survey designed as a center-specific patient needs assessment. It was sent to 212 patients with positive BRCA test results. We received 89 responses (42%). Of those that responded, 39 (43%) indicated they were interested in a follow-up genetic counseling appointment. The main reasons patients cited for interest in follow-up genetic counseling were: to learn about risks for other family members (33%), to learn about new research related to genetic test result (44%), or to discuss screening or prevention options (15%). We used several Likert scale questions to measure the patients current emotions about her genetic testing. 65% of patients that reported that they had been upset about their testing in the last week were interested in follow-up as compared to 40% of those that did not indicate they were upset ($p=0.064$). Also, 59% of those that reported they had strong feelings about their genetic testing indicated an interest in follow-up genetic counseling as compared to 38% of those that did not report strong feelings($p=0.066$). The results indicate that at our center many patients desire continued follow-up genetic counseling services, especially related to discussing further testing within the family, to learn about new research related to their genetic testing results, or discuss additional management options. Additionally, a trend suggests that the patients seeking these services may be more likely to be having strong emotions about their results, and psychosocial genetic counseling will likely be a very important component of these follow-up sessions.

Identification of the genes modulating the activity of RNAi pathway using whole-genome shRNA library. *C. Pak, P. Jin* Department of Human Genetics and Graduate Program in Genetics & Molecular Biology, Emory University School of Medicine, Atlanta, GA 30322.

RNA interference (RNAi) is a well-conserved mechanism that uses small noncoding RNAs to silence gene expression post-transcriptionally. Gene regulation by RNA interference (RNAi) has been recognized as one of the major regulatory pathways in eukaryotic cells. The endogenous small RNAs can shape diverse cellular pathways, including chromosome architecture, development, growth control, apoptosis and stem cell maintenance. RNAi operates through two post-transcriptional mechanisms: targeted mRNA degradation (siRNA) and suppression of translation (miRNA). The RNAi mechanism has been co-opted by researchers and has achieved broad utility in gene-function analysis, drug-target discovery and validation, and therapeutic development. Although several major components of the endogenous RNAi machinery, including Dicer, Argonaute proteins and TRBP, have been identified, little is known about the regulation of the RNAi pathway itself. In this study, using a cell-based RNAi reporter system to monitor modulation of RNAi activity, we are conducting a genome-wide RNAi screen to identify the genes that could modulate the activity of the RNAi pathway. In this system, an HEK 293-derived stable cell line expressing a GFP reporter gene (293-EGFP) was infected with a lentivirus expressing a short-hairpin RNA (shRNA) that resembles endogenous miRNA precursors and are processed by the endogenous miRNA machinery into siRNAs that specifically target to GFP. Upon transduction of GeneNet^{TM} human 50K siRNA library (200,000 siRNA complexity targeting 47,000 transcripts), target cell populations with selected GFP fluorescence intensity have been recovered by flow cytometry. The corresponding target genes are being identified by sequencing and expression arrays. Subsequently, candidate genes will be further validated using independent siRNA duplexes. This study will assist in further advancement in understanding the importance of small regulatory RNAs in biology and human diseases.

An obese rat model with retinal degeneration. *V. Vasireddy[1], G.B. Reddy[2], M.N.A. Mandal[1], T. Mrudula[2], X. Wang[3], M.M. Jablonski[3], N.V. Giridharan[4], R. Ayyagari[1]* 1) Ophthalmology and Visual Scien, University of Michigan, Ann Arbor, MI; 2) Department of Biochemistry, National Institute of Nutrition,Hyderabad, India; 3) Ophthalmology, University of Tennessee Health Sciences Center, Memphis, TN; 4) National Center for Laboratory Animal Sciences, National Institute of Nutrition, Hyderbada, India.

A strong association between obesity and ocular complications including retinal degeneration has been reported. The molecular basis through which obesity increases the risk of retinal degeneration is not yet known. We have identified a spontaneous obese rat model (WNIN/ob) and evaluated the retinal phenotype. Retinal morphology was studied by histology and ultrastructure analysis of retinal sections from 2 to 12 months old WNIN/Ob rat and lean littermate controls. Immunohistochemistry was performed using retinal cell specific marker antibodies. RNA from retina of 2 and 12 months old WNIN/Ob and its lean littermate rats was used for microarray analysis using Affymetrix Rat Genome 230 2.0 Gene Chip and expression of selected retinal genes was analyzed by real-time PCR analysis. No obvious change in retinal morphology was observed at 2 months age in obese rats as compared to its littermate lean controls. Onset of retinal degeneration appeared to be between 4-6 months of age. By 12 months age there were noteworthy changes in obese rat retina, particularly significant thinning of outer nuclear layer. Immunohistochemical analysis indicated photoreceptor degeneration, particularly rod cell loss, in obese rats. Gene expression analysis identified 429 genes that were differentially expressed in 12 months obese retina. Most of the down-regulated genes were found to be involved in phototransduction and the up-regulated genes are associated with apoptotic and stress response pathways. RT-PCR analysis of selected retinal genes validated the microarray data and further confirmed photoreceptor degeneration phenotype in WNIN obese rats. The spontaneous obese rats developed progressive retinal degeneration, with predominant rod cell loss at the early stages of degeneration.

Gene Selection for Classification of Microarray Data Based on the Bayes Error. *J.G. Zhang[3], H.W. Deng[1,2,3]* 1) Laboratory of Molecular and Statistical Genetics, College of Life Sciences, Hunan Normal University, Changsha, Hunan 410081, P. R. China; 2) The Key Laboratory of Biomedical Information Engineering of Ministry of Education and Institute of Molecular Genetics, School of Life Science and Technology, Xi'an Jiaotong University, Xi'an 710049, P. R. China; 3) Dept Basic Medical Sci, Univ Missouri, Kansas, Kansas City, MO.

Background: With DNA microarray data, selecting a small subset of discriminative genes from thousands of genes is a critical step for accurate classification of phenotypes for, e.g., disease diagnosis. Several widely used gene selection methods often select top-ranked genes according to their individual discriminative power of each gene in classifying samples into distinct categories, without considering correlations among genes. A limitation of these gene selection methods is that they may result in gene sets with some redundancy and yield an unnecessary large number of candidate genes for classification analyses. Some latest studies show that incorporating gene to gene correlations into gene selection can remove redundant genes and improve classification accuracy. Results: In this study, we propose a new method, Based Bayes error Filter (BBF), to remove irrelevant and redundant genes in classification analyses of microarray data. The effectiveness and accuracy of this method is demonstrated through analyses of five publicly available microarray datasets. The results show that our gene selection method is capable of achieving better accuracies than previous studies, while being able to effectively remove irrelevant and redundant genes and obtain efficient and small gene sets for sample classification purposes. Conclusion: The proposed method can effectively identify a compact set of genes with high classification accuracy. This study also indicates that application of the Bayes error is a feasible and effective way for removing redundant genes in gene selection.

Novel genetic association of SOCS3 with adiposity measures in Hispanics of the IRASFS. *M.E. Talbert[1,2], C.D. Langefeld[3], J.M. Norris[4], S.M. Haffner[5], D.W. Bowden[1,2]* 1) Depts of Biochemistry,Wake Forest U School of Med,Winston Salem,NC; 2) Cntr for Human Genomics,Wake Forest U School of Med,Winston Salem,NC; 3) Public Health Sciences,Wake Forest U School of Med,Winston Salem,NC; 4) Dept of Preventive Medicine,U of Colorado Health Sciences Center,Denver,CO; 5) Dept of Medicine,UT Health Sciences Cntr,San Antonio,TX.

Our group has reported genetic linkage on chromosome 17q with BMI, visceral adipose tissue (VAT), and waist circumference (WAIST) in Hispanics of the Insulin Resistance Atherosclerosis Family Study (IRASFS) (Sutton,Int J Obes 30:1433-41,2006). Following high density SNP mapping of the linked region, SNP rs9914220 showed evidence of association with BMI, VAT, and WAIST(P=.001-.01). This SNP is ~10 Kb upstream of the Suppressor of Cytokine Signaling 3(SOCS3) gene, which is critical to the feedback inhibition of the leptin receptor response. We hypothesized that SOCS3 genomic variants lead to reduced leptin effectiveness, promoting obesity by altering regulation of appetite and metabolism. Consequently, we genotyped rs9914220 and 15 additional SOCS3 SNPs in 1425 Hispanics from the IRASFS. CEU/YRI HapMap tagSNPs with minor allele frequency(MAF)>5%; and an r2 threshold of 0.8 were supplemented with SNPs from HapMap and dbSNP. Genotypes were tested for association with adiposity measures (BMI; VAT; WAIST; waist to hip ratio, WHR; subcutaneous adipose tissue, SAT) using SOLAR and QPDT analysis. Using SOLAR, 4 highly correlated promoter SNPs (including rs9914220) showed association under 2df and dominant models with BMI, WAIST, WHR, SAT, and VAT (P=.00003-.03). Rs9914220 had a MAF (allele T) of 14% with C/T and C/C genotype subjects having a ~3.3 unit higher BMI than T/T subjects (similar trends observed with other traits). The 3'-UTR SNP rs7221341 also showed association with all 5 adiposity measures, while 2 other SNPs in the 3'-UTR were associated with 2-3 measures of adiposity using SOLAR (P=.001-.04). QPDT analysis supported the 3-UTR SNP results, identifying haplotypes associated with BMI, VAT, WHR, and SAT (P=.0009-.04). These results suggest a role for genetic variation in SOCS3 in human obesity, and possibly diabetes.

Analysis of T2D-Associated SNPs Identified from Whole Genome Association Studies in the IRAS Family Study: Replication Studies and Quantitative Trait Analysis. *N.D. Palmer[1], C. Langefeld[1], J. Ziegler[1], M. Goodarzi[2], J. Norris[3], S. Haffner[4], M. Bryer-Ash[5], R. Bergman[6], K. Taylor[2], J. Rotter[2], D. Bowden[1]* 1) Wake Forest Univ., Winston-Salem, NC; 2) Cedars-Sinai Medical Center, Los Angeles, CA; 3) Univ. of Colorado, Denver, CO; 4) Univ. of Texas Health, San Antonio, TX; 5) University of California, Los Angeles, CA; 6) University of Southern California, Los Angeles, CA.

Recent advances have facilitated genome-wide association (GWA) studies that systematically search the genome for disease susceptibility loci. In this study we tested the most significant associations with type 2 diabetes (T2D) from 4 recent GWA studies and using quantitative trait analysis, assessed -cell function (acute insulin response; AIR and disposition index; DI) and insulin sensitivity (S_I). Seventeen SNPs in 11 loci were genotyped on 1417 Hispanic Americans (HA) and 605 African Americans (AA) from the IRAS Family Study and analyzed for association with T2D and measures of glucose homeostasis from the FSIGT/MINMOD using SOLAR and QPDT. Association with T2D was observed in two regions: EXT2/ALX4 (chr. 11) (HA P<0.016) also associated with insulin secretion (AIR P<0.008), and IDE/KIF11/HHEX (chr. 10) (AA P<0.04) also associated with insulin secretion (AIR P<0.02). In HA, though not associated with T2D, a SNP in IGF2BP2 (chr. 3) was associated with the disposition index (P<0.004), fasting glucose (P<0.04); the two SNPs in CDKAL1 (chr. 6) were associated with AIR (P<0.005) and the SNP in LOC387761 (chr. 11) was associated with AIR (P<0.005) and fasting glucose (P<0.01). Little evidence of association was observed in AA. Loci with little association evidence with the traits examined include: PKN2 (chr. 1), FLJ39370 (chr. 4), SLC30A8 (chr. 8), CDKN2B/A (chr. 9), an intragenic region of chr. 11 and FTO (chr. 16). These results suggest some T2D susceptibility loci in the HA population that modulate T2D risk through variation in insulin secretion, but provide little support for association with T2D or glucose homeostasis in AA. Extensions of these initial studies are needed to definitively evaluate ethnic-specific susceptibility variants in these populations.

Identification of potential functioning variants in COMT through high frequency derived allele haplotypes. *J.B. Listman[1], H.R. Kranzler[2], R. Anton[3], J. Gelernter[4,5]* 1) Dept. Anthropology, New York Univ., New York, NY; 2) Dept. Psychiatry, Univ. of CT Sch. Medicine, Farmington, CT; 3) Dept. Psychiatry, Med. Univ SC, Charleston, SC; 4) Depts. Psychiatry, Genetics, and Neurobiology, Yale Univ. Sch. Medicine, New Haven, CT; 5) VA CT West Haven, CT.

Variation in the gene encoding the enzyme catechol-O-methyltransferase (COMT) has been investigated in relation to phenotypes including schizophrenia, suicidal behavior, pain response, substance dependence, anxiety, and intelligence, with a focus on the functional val108/158met polymorphism (the val allele is the ancestral allele as determined by comparison with the chimp genome); however, this variant alone cannot account for the effects of the locus on the above phenotypes. We genotyped 149 European Americans (EA) and 165 African Americans (AA) for val108/158met and an additional 14 SNPs spanning 25.583 kb of COMT. The most common reconstructed haplotype extending across all 15 SNPs in EAs (14%) and the second highest in AAs (5%) includes the derived met allele but also the derived alleles at three other SNPs (rs933271, rs5993883, and rs740603). The most common 15-SNP haplotype in AAs (7%) contains the four ancestral alleles at the same loci. In EAs, this haplotype has a frequency of 3%. While we did not find high linkage disequilibrium in this region overall, for a core region spanning these three additional loci we found in EAs higher Relative Extended Haplotype Homozygosity (high LD extending from a high frequency haplotype - a departure from neutrality) for the three-derived-allele haplotype than for the three-ancestral-allele haplotype. In AAs we found the opposite. The three additional derived alleles in the most common EA15-SNP haplotype are potentially functional variants for phenotypes in which the val108/158met allele has been implicated but does not fully explain phenotypic variation, as they may show a signature of positive selection. These findings bear further investigation, particularly in the EA population.

Changes in expression and chromatin structure of Jarid1c are associated with neural differentiation. *J. Xu[1], A.P. Arnold[2], C.M. Disteche[1]* 1) Department of Pathology, University of Washington, Seattle WA; 2) Department of Physiological Science and laboratory of Neuroendocrinology of the Brain Research Institute, University of California, Los Angeles, CA.

The X chromosome encodes a disproportionately high number of genes essential for normal brain development, whose mutations cause various forms of X-linked mental retardation. The dosage difference in X-linked genes between XY males and XX females is largely compensated for by X-inactivation in females; however, some X-linked genes escape X inactivation and therefore would be expressed at a higher level in females. One of these genes, Jarid1c, encodes a histone H3K4 de-methylase and causes mental retardation when mutated in human. We have previously shown that Jarid1c is expressed more highly in female than in male mouse brains, whereas Jarid1d, the Y-linked paralog of Jarid1c, is expressed at a very low level and thus does not compensate for the X-linked gene. Our current in situ hybridization studies indicate that Jarid1c mRNA is abundant in specific brain regions including the olfactory bulb, piriform cortex, habenula, hypothalamic nuclei, hippocampus, cerebellum, triangular septal nucleus, and the interstitial nucleus of Cajal, indicating a role in the development of specific neural structures. We determined that Jarid1c was up-regulated following neural differentiation of plural potent P19 cells, confirming the role of Jarid1c in this developmental process. Histone modifications associated with active transcription, such as H3 and H4 acetylation and H3 di-methylation at lysine 4, were enhanced at the 5end of Jarid1c gene in P19 neurons relative to stem cells. Conversely, no such modifications were detectable at the Y-linked Jarid1d sequence. Thus, specific epigenetic modifications target Jarid1c in the course of neural differentiation.

Constitutional Cytogenetic Analysis in Men with Familial Testicular Germ Cell Tumor. *C.M. Mueller, L. Korde, J. Peters, M.H. Greene* Clinical Genetics Branch, DCEG, NIH, NCI, Rockville, MD.

Testicular germ cell tumor (TGCT) is the most common malignancy in young men. Familial clusters of TGCT, epidemiologic studies demonstrating that family and personal history of TGCT increase disease risk, and the association of TGCT with congenital anomalies all suggest the existence of an inherited predisposition to TGCT. Unfortunately, unraveling the genetic basis of familial testicular cancer through traditional linkage studies has been difficult, in part because families with many affected individuals are exceedingly rare. Several somatic cytogenetic abnormalities have been associated with TGCT, notably isochromosome 12p which is frequently identified in tumor tissue, and the germline chromosome abnormality 47,XXY (Klinefelter syndrome) which is associated with increased risk of mediastinal germ cell tumors. Although somatic and germline cytogenetic abnormalities helped to localize other hereditary cancer syndrome genes (e.g., retinoblastoma, Wilms tumor, familial adenomatous polpyposis), only one previous conventional karyotype analysis has been performed in men with TGCT, with no germline chromosomal rearrangements detected among the 12 subjects studied.

As part of a multidisciplinary familial TCGT study, we performed conventional karyotype analysis and spectral karyotyping (SKY) on peripheral blood lymphocytes from twenty-six affected men from 15 multiple-case TGCT families, with the goal of identifying candidate loci of as-yet-unidentified testicular cancer susceptibility genes. We detected the paracentric inversion 46,XY,inv(7)(q21.2q32) in one subject with an affected father, but this clonal abnormality was inherited from his phenotypically normal mother. Neither this chromosome 7 inversion, nor its related breakpoints, has been associated with any phenotypic abnormalities. We have concluded that this cytogenetic abnormality is not associated with an inherited predisposition to TGCT. Future studies using higher resolution tools, such as array-based comparative genomic hybridization (CGH), may be useful in the attempt to identify high-penetrance TGCT susceptibility genes.

Potential Role of RUNX2 in Nonsyndromic Sagittal Craniosynostosis. *C. Nauta[1], Y. Dong[2], H. Drissi[2], S.A. Boyadjiev[1]* 1) Section of Genetics, Department of Pediatrics, University of California Davis, Sacramento, CA; 2) Musculoskeletal Research Center, University of Rochester, Rochester NY.

Nonsyndromic sagittal craniosynostosis (NSC) is the most common type of craniosynostosis, occurring in approximately 1 in 5000 live births. Despite this high prevalence, the genetic etiology of NSC remains unknown. RUNX2 is a transcription factor necessary for regulation of chondrogenesis and osteogenesis in mesenchymal stem cell-derived osteochondroprogenitors. In an attempt to identify genetic factors implicated in NSC we performed SNP-based association studies with 384 SNPs around 60 candidate genes in a total of 89 sagittal NSC case-parent trios. Association to RUNX2 was established (rs2396441; $p<0.03$) and direct sequencing of RUNX2 in a cohort of 20 patients identified 2 rare familial non-synonomous SNPs, which were not present in 130 control chromosomes - c.709C>T (R237C) and c.1489G>A (G497S). Loss-of-function (LOH) mutations of RUNX2 cause Cleidocranial dysplasia (CCD), resulting in late-closing cranial sutures and decreased skull ossification. We hypothesize that RUNX2 gain-of-function (GOF) mutations may cause the opposite phenotype of increased sutural ossification and synostosis. Analogous situation has been documented for MSX2. Using a multimerized RUNX response element driving the luciferase reporter gene, we examined the transactivating potential of the RUNX2 R237C and G497S expression vectors. A clear GOF effect was observed for R237C but not for G497S in mouse calvarial osteoblasts. Our results indicate that specific mutations in the RUNX2 gene may result in NSC through gain of RUNX2 function. Further studies will delineate the precise molecular mechanisms implicating RUNX2 in the genetic etiology of sagittal NSC.

Glucose homeostasis, adiposity, and Insig2: genetic analysis in the IRASFS. *C.D. Langefeld[1], M.E. Talbert[2], J.M. Norris[4], S.M. Haffner[3], D.W. Bowden[2]* 1) Public Hlth Sci, Wake Forest U School of Med,Winston Salem,NC; 2) Cntr for Human Genomics,Wake Forest U School of Med,Winston Salem,NC; 3) Dept of Preventive Med,U of Colorado Health Sci Cntr,Denver,CO; 4) Dept of Med,UT Health Sci Cntr,San Antonio,TX.

The Insulin-induced gene 2 (Insig2) mediates feedback inhibition of cholesterol synthesis by inhibiting Sterol Response Element Binding Proteins (SREBPs). Insig2 has been the subject of intensive genetic association analysis following strong association of SNP rs7566605 with BMI in Caucasians and African Americans (Herbert Science. 312:279-284, 2006). Insig2 genomic variants may promote abnormal SREBP activation, which could cause altered expression of cholesterol synthesis and glucose homeostasis genes. Additionally, an Insig1 SNP was reported associated with plasma glucose/post-load glucose (Krapivner Diabetologia 50:94-102, 2007). We genotyped rs7566605 and 15 additional Insig2 SNPs in 1425 Hispanics of the Insulin Resistance Atherosclerosis Family Study (IRASFS). CEU HapMap tagSNPs with MAF>5% and r2 threshold of 0.8 were selected and supplemented with HapMap genotyped SNPs, as well as those of dbSNP. SNPs were tested for association with measures of adiposity (BMI, waist circumference, waist to hip ratio, visceral adipose tissue, subcutaneous adipose tissue) and glucose homeostasis (fasting insulin, fasting glucose, insulin sensitivity, disposition index, acute insulin response) using SOLAR. No association was observed between rs7566605 and any adiposity or glucose homeostasis traits. SNPs rs17047718 (Promoter) and rs12623648 (3UTR), however, were consistently associated with glucose homeostasis measures: fasting insulin, fasting glucose, insulin sensitivity, and HOMA (P=.0007-.04). These SNPs were also associated with obesity measures, visceral adipose tissue (P=.002-.04) and subcutaneous adipose tissue (P=.01-.04). Additional association with adiposity measures was observed with 3 SNPs, 2 of which were in the same LD block as rs7566605 (P=.002-.04). These analyses support a role for Insig2 in the regulation of adiposity in Hispanics, but also provides evidence of involvement in glucose homeostasis.

Pathogenesis of the Mucopolysaccharidoses: Differential Effects of Glycosaminoglycan Storage on Cartilage Versus Synovial Tissue. *C. Simonaro[1], X. He[1], E. Eliyahu[1], N. Shtraizent[1], M. Haskins[2], E. Schuchman[1,3]* 1) Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York, NY 10029; 2) University of Pennsylvania School of Veterinary Medicine, Philadelphia, PA 19104; 3) Department of Gene & Cell Medicine, Mount Sinai School of Medicine, New York, NY 10029.

We have previously shown that glycosaminoglycan (GAG) storage in the mucoploysaccharidoses (MPS) leads to inflammation and apoptosis within cartilage, most likely through activation of the lipopolysaccharide (LPS) signaling pathway. We have now extended these findings to synovial tissue, and further explored the mechanism underlying GAG-mediated disease. Gene and protein expression analysis of synovial fibroblasts from rats with MPS type VI revealed that numerous inflammatory molecules were elevated, including several molecules important for LPS signaling (e.g., toll-like receptor 4 and lipoprotein binding protein). Elevation of tumor necrosis factor-alpha, in particular, led to up-regulation of an essential osteoclast survival factor, ligand of receptor activator of NF-kB (RANKL), resulting in the appearance of multinucleated osteoclast-like cells in the bone marrow and osteopenia. Treatment of normal synovial fibroblasts with GAGs also led to production of the pro-survival lipid, sphingosine-1-phosphate, resulting in enhanced cell proliferation consistent with the hyperplastic synovial tissue observed in MPS patients. In contrast, GAG treatment of normal chondrocytes led to production of the pro-apoptotic lipid, ceramide, confirming the enhanced cell death we had previously observed in MPS cartilage. These findings have important implications for the pathogenesis and treatment of MPS, and have further defined the mechanism of GAG-stimulated disease.

Human population stratification and genetic association studies. *X. Sheng, G. Zhang, R. Chakraborty* Ctr Genome Information, Univ Cincinnati, Cincinnati, OH.

Population stratification becomes relevant for case-control association studies when allele frequencies are different in cases and controls due to systematic ancestry differences of subjects classified as cases and controls. This may cause spurious associations, and leads to both false positive and false negative findings. Recently, several statistical approaches have been proposed using genomic markers to control for this confounding effect. In this study, we describe a new method that efficiently corrects for stratification by regressing the pairwise genotypic difference on the pairwise genetic distance (computed from genomic markers) of all case-control pairs. A new test statistic *T* is formulated to measure the genotypic difference between cases and controls, adjusting for stratification contribution. Significance level is determined by the null distribution of *T*, which is generated from the genomic markers by using permutation. The current existing approaches (Genomic Control and Structured Association) are compared to our new method by simulating different disease association studies, under a variety of parameter settings. Allele frequencies from the African and European data of the HapMap project as well as simulated allele frequencies from a uniform distribution were used in such simulation experiments. Results suggest that our procedure has a correct nominal type-1 error rate in the presence of different levels of population stratification. In most scenarios we considered, our method has a larger power and, in some cases, substantially larger power than that of existing methods. In terms of power, the Structured Association method is closest to our new approach, but the latter requires substantially smaller computational time, which implies its ease of application in large-scale or even genome-wide association studies. (Research supported by the NIH grant GM41399 to RC).

Methods to Impute Missing Genotypes for Population Data. *Z. Yu[1], D.J. Schaid[2]* 1) Dept Statistics, University of Irvine, Irvine, CA; 2) Division of Biostatistics, Mayo Clinic, Rochester, MN.

For large scale genotyping studies, it is common for most subjects to have some missing genetic markers, even if the missing rate per marker is low. This compromises association analyses, with varying numbers of subjects contributing to analyses when performing single-marker or multi-marker analyses. In this paper, we consider eight methods to infer missing genotypes, including two haplotype reconstruction methods (local expectation maximization-EM, and fastPHASE), two k-nearest neighbor methods (original k-nearest neighbor, KNN, and a weighted k-nearest neighbor, wtKNN), three linear regression methods (backward variable selection, LM.back, least angle regression, LM.lars, and singular value decomposition, LM.svd), and regression tree, Rtree. Their accuracies were evaluated under a variety of conditions and parameters. Our results indicate that LM.lars had the lowest error rates across different samples. LM.back and fastPHASE gave slightly less accurate estimate of missing genotypes than LM.lars, but both had better performance than the other methods. Our results suggest that either fastPHASE or LM.lars should be used to impute missing marker genotypes.

Replication of a Genome-Wide Mapping Case-Control Study in Esophageal Cancer. *D. Ng[1], N. Hu[1], Y. Hu[2], C. Giffen[3], Z.Z. Tang[4], X.Y. Han[4], H.H. Yang[2], M.P. Lee[2], A.M. Goldstein[1], P.R. Taylor[1]* 1) Genetic Epidemiology Branch, DCEG/NCI/NIH/DHHS, Bethesda, MD, USA; 2) Laboratory of Population Genetics, CCR/NCI/NIH/DHHS, Bethesda, MD, USA; 3) Information Management Systems, Silver Spring, MD, USA; 4) Shanxi Cancer Hospital, Taiyuan, Shanxi, PRC.

Background: Previously, we applied the Affymetrix mapping 10K SNP array in a pilot case-control study to determine differences in genotypes between esophageal squamous cell carcinoma (ESCC) cases and controls from a high-risk area in China and identified 38 SNPs in or near one of 33 genes. The present study attempted to replicate the results of these 38 gene-related SNPs in a new sample of cases and controls. Methods: A subset of 300 ESCC cases and 300 matched controls from a larger case-control study conducted in Shanxi Province, China was selected for the present study. A series of multiplex oligonucleotide ligation assays to genotype these 38 target SNPs were developed and applied to germline DNA from study subjects. Assays were validated by direct sequencing of eight SNPs in 12 pairs of cases and controls, and Hardy-Weinberg equilibrium was examined in control samples. General linear models were used to derive odds ratios (ORs) for dominant, recessive, and additive modes of transmission adjusted for baseline risk factors and one or more SNPs. Factor analysis was used to predict individual risk of ESCC. Results: Among 36 evaluable SNPs, four were significant in one or more analyses, including SNPs in EPHB1, PIK3C3, SLC9A9, and PGLYRP2. Risks were significantly increased for subjects with the T/T genotype in SNPs in EPHB1, PIK3C3, and SLC9A9, and for subjects with the A/A genotype in the PGLYRP2 SNP. The best factor analysis models accurately classified case/control status in approximately half of the subjects. Conclusions: Four of 38 previously identified gene-related SNPs remained significant in this replication study. While EPHB1, a receptor protein tyrosine kinase previously associated with colorectal cancer, merits particular consideration as a candidate tumor suppressor gene for ESCC, further exploration of all four genes in ESCC is recommended.

Informative heterogeneity and failed replication: lessons from genome-wide association data for type 2 diabetes.

M.I. McCarthy[1], T.M. Frayling[2], N.J. Timpson[1,3], M.N. Weedon[2], C.M. Lindgren[1], H. Lango[2], K.S. Elliott[1], J.R.B Perry[2], N.W. Rayner[1], R.M. Freathy[2], A.T. Hattersley[2], E. Zeggini[1], The Wellcome Trust Case Control and UK Type 2 Diabetes Genetics Consortia 1) University of Oxford, UK; 2) Peninsula Medical School, Exeter, UK; 3) University of Bristol, UK.

Replication is central to effective follow-up of putative associations emerging from genomewide association (GWA) analyses: signals which fail to replicate are typically dismissed from further evaluation. Recently, we showed that variants within the *FTO* gene were strongly associated with type 2 diabetes (T2D) in both the Wellcome Trust Case Control Consortium GWA scan (n=4862: OR=1.27 [1.16,1.37], $p=2x10^{-8}$) and replication samples (n=9103: OR=1.22 [1.12,1.32], $p=5x10^{-7}$). This T2D-susceptibility effect was mediated exclusively through an impact on adiposity and was not detected in other well-powered GWA scans for T2D which had explicitly (or implicitly) matched cases and controls for BMI.

To explore the impact of ascertainment scheme on the profile of highly-significant findings, we re-analysed the WTCCC scan comparing the same 2938 common controls separately with lean and obese T2D subgroups (each n~968) stratified by median case BMI ($30.3kgm^{-2}$). In the obese T2D GWA, *FTO* was clearly the strongest T2D-effect (OR=1.48, $p=1.4x10^{-13}$) with only weak evidence for *TCF7L2* (OR=1.21, p=0.001), even though this was the strongest signal in the combined scan. In the "lean-T2D" GWA scan, the contributions were reversed with the *FTO* association undetectable (OR=1.07, p=0.2) and *TCF7L2* predominant (OR=1.52, $p=1.3x10^{-14}$).

These data clearly demonstrate that: (a) the profile of extreme signals emerging from GWAs can be profoundly affected by the ascertainment scheme; (b) failure to detect replication in other well-powered studies does not always indicate a spurious association; (c) "informative" heterogeneity can deliver valuable mechanistic insights (in this example, identification of adiposity as the factor mediating the *FTO* effect on T2D-susceptibility revealed the functional mechanism); (d) from the point of view of major genetic determinants, lean and obese T2D represent quite distinct phenotypes.

Nucleolar Localization of p19Arf Is Important for Tumor Suppressor Function During Transformation by the Abl Oncogene. *R. Stackpole, N. Rosenberg* Graduate Program in Genetics, Sackler School of Graduate Biomedical Sciences, Tufts University School of Medicine, Boston, Massachusetts.

The *Ink4a/Arf* locus is the second most common site of mutation in cancer. Our lab has shown that p19Arf, one of two tumor suppressors encoded by this locus, plays an important role in transformation of lymphoid cells by *abl* oncogenes. Like most oncogenic events, *abl*-mediated transformation is a multi-step process involving an initial proliferative phase, followed by a crisis phase characterized by erratic growth and high levels of apoptosis. During crisis, selection for fully malignant cells occurs. Both the p19Arf and p53 tumor suppressors are required for crisis, and fully malignant transformants usually contain alterations that allow the cells to bypass tumor suppressor responses mediated by these proteins.

To determine if expression of p19Arf is the cellular trigger of the crisis response, we explored the way in which Abl expression affects p19Arf. Consistent with the ability of Abl to stimulate Myc, a transcription factor known to induce p19Arf expression, analyses of normal bone marrow cells soon after stimulation with Abl reveals that both *myc* and *arf* are induced in the cells prior to the onset of crisis. Immunofluroescence analyses reveal that many Abl-positive cells express p19Arf but do not show characteristic signs of apoptosis. Thus, expression of p19Arf is not sufficient to induce crisis. Further examination of the images reveals that localization of p19Arf changes as transformation proceeds. Early after Abl expression, p19Arf is predominantly found in the nucleoplasm; as crisis begins, the protein becomes nucleolar. In addition, the intensity of nucleolar staining increases. These data together suggest that the localization and expression levels of p19Arf modulate the effects of the protein during oncogenesis and that simple expression of the molecule is not sufficient for its anti-tumorigenic effects.

Prenatal False Positive for Trisomy 21 with Fluorescent in situ Hybridization (FISH). *H. Sroka[1], E. Kolomietz[2, 3], E.J.T. Winsor[2,3], J. Ng-Kcomt[2], E. Cappa[2], D. Chitayat[1,3]* 1) The Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital,Toronto, Canada; 2) Pathology and Laboratory Medicine, Mount Sinai Hospital, Toronto, Canada; 3) University of Toronto, Toronto, Canada.

We present a case with clinical information and interphase FISH results consistent with with trisomy 21 and normal male karyotype. A 32-year-old primigravida woman presented with an increased fetal nuchal translucency of 4.1mm at 12.7 weeks gestation. First trimester combined prenatal screening yielded a risk of > 1/8 for Down syndrome and 1/36 for trisomy 13/18. The couple declined CVS and proceeded with amniocentesis at 16 weeks gestation. Rapid FISH analysis on uncultured amniotic fluid cells was performed using AneuVision (Vysis) probes for chromosomes 13, 18, 21, X and Y. Ninety-four percent of nuclei showed 3 signals for chromosome 21 and a normal pattern for the other chromosomes. The couple was informed of the FISH results and arranged for termination of the pregnancy, which was delayed due to the holiday season. Seven days later metaphase chromosome analysis revealed a normal male karyotype and the couple was immediately informed. FISH studies using the same probe mixtures were carried out on metaphase slides and revealed no evidence of a cryptic translocation involving chromosome 21. In retrospect, the most likely explanation for the false positive FISH result was contamination of the probe mixtures during application on the slide. Analysis was performed on two areas of the microscope slide (probes for chromosomes 13 and 21 on one site and 18, X and Y on the other site) and the probes for chromosome 21 and Y are both labelled with SpectrumOrange. Fetal anatomy ultrasound and fetal echocardiography at 19 weeks did not reveal any anomalies. The pregnancy is currently ongoing. The ACMG/ASHG statement (2000) on FISH testing recommends that clinical decision-making should be based on information from 2 of 3 of the following: positive FISH results, confirmatory chromosome analysis, or consistent clinical information. We present this case to warn clinicians and patients that, in rare circumstances, errors occur despite meeting the usual counselling precautions.

Hits from a whole genome associations lead to pathways with substantial genetic contribution to complex traits.

K. Taylor[1,2], S. Targan[2], L. Mei[1], X. Su[1], A. Ippoliti[2], E. Mengesha[1], L. King[1], K. Papadakis[2], J. Rotter[1,2] 1) Medical Genetics Institute, Cedars Sinai Medical Ctr, Los Angeles, CA; 2) Inflammatory Bowel Disease Center, Cedars Sinai Medical Ctr, Los Angeles, CA.

A genome-wide association study identified IL23R as a Crohns disease (CD) susceptibility gene and recent evidence supports a role for the IL17-IL23 pathway, and Th17 cells, in immune disorders including CD. Our aim was to examine the genetic contribution of this pathway to CD susceptibility. **Methods:** 763 CD subjects and 254 controls were genotyped for SNPs in IL17-IL23 pathway genes: IL23A, IL23R, IL17A, IL17RA, IL12B, and IL12RB1; haplotypes were assigned using PhaseV2; and association was tested by chi square and permutation. Synergy, defined as CD risk in excess of that of each individual gene, was tested by logistic regression. **Results:** IL23R, IL17A, IL17RA, and IL12RB1 "risk" and "protective" haplotypes contribute substantially to CD risk as shown by association and by high population attributable risk (PAR; IL23R, 19%; IL17A, 15%; IL17RA, 10%; IL12RB1, 40%). The OR for CD increased with the number of "risk" haplotypes (OR =1 for 0-1 "risk" haplotype, 1.3 for 2, 2.5 for 3, and 4.0 for 4, $p<0.0001$). Synergy was observed between IL23R and IL17A and between IL23R and IL17RA (OR=1 for the IL23R or IL17A "risk" haplotype alone, 2.4 for both, $p=0.047$ for interaction; OR ~1.1 for IL23R or IL17RA "risk" alone, ~3.0 for both, $p=0.036$). In contrast no synergy was observed with other CD susceptibility variants (CARD15, ATG16L1, PHOX2B, OctN, 10q, FAM92B or NCF4). **Discussion:** Substantial CD susceptibility was contributed by genes of the IL17-IL23 pathway together, beyond that identified by genome-wide association. Furthermore, IL23R CD susceptibility required the presence of a risk haplotype from either IL17A or IL17RA. The lack of a synergistic interaction with common CARD15 mutations supports the hypothesis that the IL17-IL23 pathway and CARD15 act separately to increase CD risk. These observations further suggest that hits from genome-wide association studies will lead to pathways harboring genes that, in combination and in interaction, substantially contribute to human complex traits.

Mutations in Wnt5A in Patients with Autosomal Dominant Robinow Syndrome. *J.L. Lohr[1, 7], A.D. Person[2,8], C.M. Sieben[1,7], S. Hermanson[2], A.N. Neumann[1,7], M.E. Robu[2,8], J.R. Schleiffarth[1], H. van Bokhoven[4], J. Hoogeboom[5], J.F. Mazzeu[6], A. Petryk[1,2], H.G. Brunner[4], S.C. Ekker[2,7,8], S. Beiraghi[3]* 1) Department of Pediatrics, University of Minnesota, Minneapolis, MN; 2) Department of Genetics, Cell Biology and Development, University of Minnesota, Minneapolis, MN; 3) Department of Developmental/Surgical Sciences/Pediatric Dentistry, University of Minnesota Minneapolis, MN; 4) Department of Human Genetics, University Medical Center Nijmegen, Nijmegen, The Netherlands; 5) Department of Clinical Genetics, Erasmus University Medical Center, Rotterdam, The Netherlands; 6) Departments of Genetics and Evolutionary Biology, Institute of Biosciences, University of Sao Paulo, Brazil; 7) Institute of Human Genetics, University of Minnesota, Minneapolis, MN; 8) Minnesota Craniofacial Research Training Program (MinnCResT), Minneapolis, MN.

Robinow Syndrome is a heritable condition with both autosomal dominant and autosomal recessive transmission described. Both forms are characterized by short stature, mesomelic limb shortening, craniofacial abnormalities and genital hypoplasia. The recessive form has been associated with mutations in the tyrosine kinase receptor, *ROR2*, a putative mediator of Wnt signaling. We have shown, using a candidate gene approach, that dominant Robinow syndrome in all affected members of the original family described by Dr. Robinow, is associated with a heterozygous missense mutation in a highly conserved region of exon 4 of *WNT5A*. The single living unaffected family member has two wild type *WNT5A* alleles. A second *WNT5A* mutation has been found in exon 3 in an unrelated patient with sporadic Robinow Syndrome with a dominant phenotype. Both mutant proteins show reduced function in a zebrafish cell migration assay. This data suggests that a *WNT5A* signaling pathway dependent on *ROR2* for signal transduction is important in human craniofacial, skeletal and genital development, and that normal development of these structures is sensitive to variations in *WNT5A* function.

Identification of genes that specify human kidney aging. *H.E. Wheeler[1], J. Higgins[2], J.M. Zahn[3], D. Absher[4], J. Li[4], R.M. Myers[1,4], A.B. Owen[5], S.K. Kim[1,3]* 1) Genetics, Stanford University, Stanford, CA; 2) Pathology, Stanford University, Stanford, CA; 3) Developmental Biology, Stanford University, Stanford, CA; 4) Stanford Human Genome Center, Palo Alto, CA; 5) Statistics, Stanford University, Stanford, CA.

Aging is a complex process defined by the gradual decline of a multitude of physiological functions leading to an increasing probability of death and thus best studied using a systems biology approach. We are studying aging of the human kidney, which begins to show functional decline around age 40. Kidneys age at different rates, such that some people show little or no effects of aging whereas others show rapid functional decline of the kidney. We have performed a pilot study to find genes that associate with different rates of kidney aging in humans. We first performed whole-genome transcriptional profiling to find 741 genes that change expression with age in the kidney, and then used these age-regulated genes as candidates in a genetic association study for kidney aging. We genotyped 1041 SNPs in the first set of 346 candidate genes in 261 kidney samples, and found 9 genes that show weak but significant association with kidney aging. We are now screening a new set of 276 candidate genes, which should identify a new set of genes that may be associated with kidney aging. Also, we will test the reproducibility of the pilot screen by performing a second study using ~800 more kidney samples. These studies may provide the first evidence for genes that are associated with kidney aging in humans. Not only will this research uncover basic principles about human kidney aging, but it will also be directly relevant to understanding why some people progress to end stage renal disease whereas others do not. The kidney aging genes could help determine the rate of kidney aging for patients, and mechanistic insight from our studies could eventually lead to treatments that slow down or prevent kidney failure in old age.

Association of *APOH* Promoter Polymorphisms with Lupus Nephritis and Cardiovascular Disease. *S. Suresh[1], E. Jacobs[1], S. Manzi[2], D.K. Sanghera[1], A. Kao[2], F. Bontempo[3], C. Kammerer[1], F.Y. Demirci[1], M.I. Kamboh[1]* 1) Dept of Human Genetics; 2) Lupus Center of Excellence; 3) Dept of Medicine, Univ. of Pittsburgh, Pittsburgh, PA.

Systemic lupus erythematosus (SLE) is a prototypic autoimmune disease that predominantly affects premenopausal women. Cardiovascular disease and nephritis are major cause of death in these patients. Apolipoprotein H ($_2$-glycoprotein I) is necessary for binding of anionic phospholipids to certain antiphospholipid antibodies in SLE and antiphospholipid syndrome. We evaluated the role of 8 *APOH* promoter SNPs for their association with SLE risk and related clinical variables (renal and cardiovascular involvement) in a case-control cohort. DNA from 399 SLE women (350 Caucasians and 49 African Americans) and 496 healthy control women (454 Caucasians and 42 African Americans) were genotyped for 8 *APOH* promoter SNPs using Pyrosequencing. Because of its rare presence (MAF<0.01), rs8178818 SNP was excluded from further analyses. The genotype distributions of rs8178820 and rs3760291 SNPs differed significantly (P<0.001) between Caucasians and African Americans implying a race-specific effect. Due to the small number of African American subjects, association studies were performed only on samples from Caucasian subjects. Haploview analysis of our data revealed strong LD (D'=1, r^2=0.98) between rs8178820 and rs3760291 SNPs, therefore, rs3760291 was excluded from haplotype analysis (6-site analysis was performed) and from multiple regression analyses. The overall haplotype distribution was significantly different (P=0.004) between cases and controls. When 6 SNPs were included in a multiple regression model, 2 SNPs (rs8178819 and rs3760292) showed association with SLE risk (P=0.015 & P=0.046, respectively) and one SNP (rs8178820) with lupus nephritis (P=0.004). Two SNPs, rs3760292 and rs8178822, showed significant association with carotid plaque (P=0.036 and P=0.007, respectively). Our findings support the hypothesis that *APOH* promoter variants are involved in the etiology of SLE, especially the risk for lupus nephritis and cardiovascular disease and merit further investigation.

Weighted Gene Coexpression Network Analysis Identifies Biomarkers in Glycerol Kinase Deficient (GKD) Mice: Systems Biology Informs Pathogenesis. *N. MacLennan[1], J. Dong[2], J.E. Aten[2], S. Horvath[2,3], L. Rahib[4], K.M. Dipple[1,3,4], E.R.B. McCabe[1,3,4,5]* 1) Pediatrics, UCLA, Los Angeles, CA, USA; 2) Biostatistics, UCLA, Los Angeles, CA, USA; 3) Human Genetics, UCLA, Los Angeles, CA, USA; 4) Biomedical Engineering, UCLA, Los Angeles, CA, USA; 5) Bioengineering, UCLA, Los Angeles, CA, USA.

To investigate the pathogenesis of GKD, we identified biomarker genes in a glycerol kinase (Gyk) knockout (KO) mouse using a network analysis algorithm, Weighted Gene Co-Expression Network Analysis (WGCNA) that relates a measure of differential expression to intramodular connectivity. Highly connected, highly correlated intramodular hub genes are associated with disease pathogenesis. We used WGCNA to reduce dimensionality of microarray expression data from livers of day of life (Dol) 1 and Dol 3 KO and wild type (WT) mice and we identified genes involved in pathogenesis using intramodular connectivity. WGCNA revealed significant network overlap between Dol 1 and Dol 3 mice. Both Dol 1 and Dol 3 livers contained network modules enriched with genes involved in organic acid metabolism and cell cycle. Differences in network expression were revealed also. Unlike Dol 3, the Dol 1 gene module containing Gyk as a member was enriched with apoptotic genes. WGCNA identified networked genes that were not anticipated by apriori hypotheses. We examined the validity of these novel genes in tissue culture. Confirmation studies for Acot, Psat and Plk3 identified by WGCNA using nuclear receptor agonists and antagonists, and causality (NEO) analysis validated the results of WGCNA. Acot gene expression preceded Plk3 and Psat gene expression in the inferred dol 3 gene network from NEO analysis. We conclude that WGCNA reduces high dimensionality expression data to a low dimensionality output to identify networks and biomarkers in GKD. We speculate that GK may have an apoptotic moonlighting role that is lost in GKD. These investigations in Gyk KO mice demonstrate that systems biology approaches improve our understanding of disease pathogenesis and may provide insights into treatment through identification of previously unanticipated networks.

Discovery and genotyping of insertion/deletion variants from whole-genome SNP assay data. *T. Zerr[1], G.M. Cooper[1], J.D. Smith[1], E. Tuzun[1], J. Kidd[1], M.J. Rieder[1], E.E. Eichler[1,2], D.A. Nickerson[1]* 1) Department of Genome Sciences, University of Washington School of Medicine, Seattle WA; 2) Howard Hughes Medical Institute, Seattle, WA.

The potential phenotypic effects of common indel polymorphisms remain largely unexplored due to an inability to systematically and accurately genotype such variants. Whole-genome association studies have produced a wealth of data which should in principle allow such analyses; however, segmentation algorithms previously applied to quantitative whole-genome SNP data lack power to detect deletion variants spanning small numbers of probes, despite the fact that common deletions tend to be small in size. We have developed a computational approach to genotype biallelic insertion/deletion polymorphisms. Our algorithm uses mixture likelihood based classification to infer insertion/deletion genotypes from any number of SNP probes, and is capable of both ab initio deletion detection and directed deletion genotyping. We tested our approach by analyzing publicly available Illumina Infinium II SNP assay data from a panel of 120 HapMap samples. Inference of gender from X-linked marker data indicate that our algorithm can produce accurate insertion/deletion genotypes from as few as 60 samples, with as few as two probes within the variant region; in 6910 adjacent X-linked probe pairs, in samples of 54 females and 6 males (simulating a deletion allele frequency of 5%), males were correctly classified with a frequency of 98.3%, and females were correctly classified with a frequency of 99.1%. We were also able to validate our ab initio deletion detection using fosmid-end sequence data for three of the 120 samples. At least 33% of strongly scoring deletion allele predictions were supported by fosmid end sequence mapping, with 20% being supported for more weakly scoring sites. True validation rates are likely to be higher given the limited resolution of deletion detection via fosmid-end sequence mapping; we are sequencing a panel of our deletion predictions to confirm this hypothesis. We anticipate that our approach will facilitate analysis of common deletion polymorphisms in human genotype-phenotype studies.

The role of hMSH5 in DNA double-strand break repair. *J.D. Tompkins, N. Zhao, C. Her* School of Molecular Bioscience and Center for Reproductive Biology, Washington State University, Pullman, WA. 99164-4660.

DNA double-strand breaks (DSBs) constitute the most common and dangerous form of DNA damage frequently occurring during normal DNA metabolism and exposure to chemotherapeutics. Although hMSH5 is generally known for its function in meiotic recombination, recent studies have demonstrated that the interplay between hMSH5 and various interacting partners are involved in mitotic DSB repair and DNA damage response. Specifically, we demonstrate that a DSB triggers the local recruitment of endogenous hMSH5 and hMSH4 proteins in somatic cells, and DSB-induced hMSH5 assembly at the break is dependent on functional hMRE11 and hRad51 proteins. Moreover, hMSH5 RNAi reduces the frequency of DNA recombination triggered by a defined DSB in human cells harboring a chromosomally integrated recombination reporter. The function of hMSH5 in DSB repair is potentially controlled by a dynamic interplay with c-Abl, in which the interaction between these two proteins coordinates the activation of c-Abl kinase and tyrosine phosphorylation of hMSH5 at tyrosine residue 742 (Y742). By disrupting the (Px)5 motif within the hMSH5 N-terminal c-Abl-interacting domain, the common polymorphic hMSH5 P29S variant alters the functional interaction with c-Abl in DNA damage response and repair. Coherent with the fact that compromised recombinational repair renders cells more sensitive to strand break-inducing agents; over-expression of hMSH5 P29S or hMSH5 Y742F mutant proteins sensitizes cells to ionizing radiation and cisplatin, respectively. Taken together, the current evidence strongly suggests an important role for hMSH5 in the process of recombinational repair and DNA damage response.

A high frequency of acyl-CoA dehydrogenase, short chain (ACADS) variant genotypes among healthy Ashkenazi Jews. *S. Pardo, B. Kirmse, M. Wasserstein, S. Scott, R. Kornreich, R.J. Desnick, G.A. Diaz, L. Edelmann* Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York, NY.

Short-chain acyl-CoA dehydrogenase deficiency (SCADD) is a rare autosomal recessive disorder of fatty acid oxidation that results from mutations in the gene encoding acyl-CoA dehydrogenase, short chain (ACADS). The biochemical phenotype includes urinary excretion of ethylmalonic (EMA) and methylsuccinic (MSA) acids, high C4 acylcarnitine levels and an elevated C4/C2 ratio. The clinical phenotype is very heterogeneous, varying from a fatal metabolic decompensation in infancy with metabolic acidosis, failure to thrive, developmental delay, hypotonia and seizures to a more subtle later-onset progressive myopathy or, most commonly, a completely asymptomatic clinical course. To date, few confirmed SCADD patients have been characterized molecularly and little is known about how genotype correlates with the biochemical and clinical phenotype. With the recent addition of tandem mass spectrometry to newborn screening programs, our Program for Inherited Metabolic Diseases has evaluated 27 newborns with a positive C4 acylcarnitine profile. Five patients of Ashkenazi Jewish (AJ) descent were found to be homozygous for the 319C>T founder mutation. None have displayed any symptoms of SCADD as yet, despite continuous excretion of EMA and MSA. To further delineate the relationship between ACADS genotypes and SCADD, we determined the population frequencies of six known pathogenic variants in ACADS in the general (AJ) population from the greater New York metropolitan area. Our screening data of 412 healthy AJ individuals indicates that the frequency of carriers for three of the variants, 511C>T, 625G>A and 319C>T, is high (0.058, 0.422 and 0.019, respectively), an unexpected finding as SCADD does not display a higher incidence in the AJ population. Biochemical analysis is underway to correlate specific genotypes with urinary concentrations of EMA and MSA. In summary, our results contribute to the understanding that pathogenic variants of ACADS do not necessarily lead to clinical manifestations of SCADD and that additional environmental and/or genetic factors may modify disease presentation.

Multi-faceted gene silencing mechanism of MeCP2. *H. Soejima[1], S. Yakabe[1,2], H. Yatsuki[1], K. Joh[1], K. Miyazaki[2], T. Mukai[3]* 1) Division of Molecular Biology and Genetics, Department of Biomolecular Sciences, Faculty of Medicine, Saga University, Saga, Japan; 2) Division of General Surgery, Department of Surgery, Faculty of Medicine, Saga University, Saga, Japan; 3) Saga University, Saga, Japan.

For epigenetic gene silencing, cooperation of methyl-CpG binding proteins (MBDs) and chromatin modification factors, which are recruited to methylated DNA, is required. We have screened genes, which are suppressed by MeCP2, one of the MBDs, by MeCP2 knockdown (KD) experiments combined with microarray gene expression analyses. We found that expression of 46 genes elevated more than three times in common with two independent KD experiments with different siRNA sets. Among the 46 genes, 24 had CpG islands (CGIs) within their putative promoter regions. We examined MeCP2 binding and DNA methylation at promoter CGIs of 10 genes. Three showed MeCP2 binding before KD and release from promoter CGI after KD, whereas others did not show MeCP2 binding even before KD. Among the three genes, two showed promoter DNA methylation but one did not. Furthermore, DNA methylation of the two genes was not changed after KD. These results suggested that a majority of genes are indirectly, rather than directly, suppressed by MeCP2, that DNA methylation itself is insufficient for the silencing when both DNA methylation and MeCP2 are involved, and that MeCP2 can bind to unmethylated CGI, leading to the silencing.

Association between IBD and the TL1A/DR3 ligand/receptor pair. *L. Mei[1], X. Su[1], K. Taylor[1], S. Targan[2], J. Rotter[1]* 1) Dept Medical Genetics, Cedars-Sinai Medical Ctr, Los Angeles, CA; 2) IBD Center, Cedars-Sinai Medical Ctr, Los Angeles, CA.

Background: The TNF-like cytokine, TL1A, binds to the death domain receptor (DR3), and induces NFKB1 expression in Th1 cells. Up-regulation of TL1Aand DR3 is related to the gut inflammation characteristic of Crohns disease (CD). Since TL1A was recently identified as a CD susceptibility gene by genome-wide association and confirmed by our group, our aim was to investigate whether a genetic interaction between TL1A and DR3 contributed to CD. Method: Eight DR3 and 5 TL1A SNPs were genotyped in 763 CD, 351 ulcerative colitis (UC) and 254 controls. Haplotype blocks were constructed by Haploview; individual haplotypes were assigned by PHASE and ordered by frequency; associations were tested by chi-square and permutation. Gene-gene interaction was tested by logistic regression. Results: Two major haplotypes of DR3 were associated with CD. In non-Jews, CD patients had a lower frequency of homozygotes of H1 (66.2% vs. 76.7%, p=0.007) and a higher frequency of H2 carriers (13.1% vs. 7.5%, p=0.035) when compared with controls; however, this association was absent in Jewish CD. In non-Jewish UC, a similar trend of association for H1 and H2 was also observed, though it was not statistically significant. H2 of TL1A has been reported to be negatively associated with CD (39% vs. 50%) and UC (37.3% vs. 50%) recently by our group, and this effect was also seen only in non-Jews. When analyzing DR3 and TL1A together, a significant dose-effect was observed among protective factors (DR3 H1 and TL1A H2) in non-Jewish IBD (p trend <0.0001), odds ratio ranging from 1 to 0.47 (1 protective factor) to 0.19 (both protective factors). No statistical interaction was detected between these two genes. Conclusion: The DR3 association observed supports that idea that the TL1A/DR3 interaction contributes to CD pathogenesis. Hits from genome-wide association studies will identify pathways that may contain other genetic determinants of complex traits.

Analysis of gene expression in familial mesial temporal lobe epilepsy associated with hippocampal atrophy. *C.V. Maurer-Morelli[1], C.S. Rocha[1], R. Secolin[1], R.R. Domingues[1], F. Cendes[2], I. Lopes-Cendes[1]* 1) Department of Medical Genetics, FCM/UNICAMP - Brazil; 2) Department of Neurology, FCM/UNICAMP - Brazil.

Rationale: Hippocampal atrophy (HA) is the most prominent pathological substrate in patients with intractable mesial temporal lobe epilepsy (MTLE) and until recently, this finding was exclusively associated with predisposing environmental factors. However, we identified the first *locus* for familial MTLE associated with HA, which strongly suggests that HA may also have a genetic predisposition. Surgical specimens of patients with intractable MTLE, offer a unique opportunity to address questions related to the pathophysiology of HA in the context of MTLE. The aim of this study was to perform gene expression studies in tissue samples from familial MTLE patients who underwent surgery for medically intractable seizures. **Methods:** This study was performed using Human Genome U133 Plus 2.0 array (Affymetrix). High-quality total RNA from one control hippocampus (from autopsy) and three surgical specimens (from pharmacoresistant epilepsy patients) were isolated by TRIzol (Invitrogen-Life Technologies). We used 6 g of starting material in the one-cycle target labeling protocol (Affymetrix). Data was acquired by GeneChip Scanner 3000 (Affymetrix) and analyzed using MAS5.0 expression measure (Affymetrix). **Results:**Comparison between control and disease hippocampi identified 2300 genes which were differently expressed and they are related to many cell functional classes, such as transcription factors, enzymes, signaling and structural function. Interesting, among these we identified five genes which were present in disease hippocampi, but not present in control specimen and are localized within the candidate region for familial MTLE identified on chromosome 18p: *ADCYAP1, TYMS, DLGAP1, PTPRM* and *YES1*. **Conclusions:** Our study brings functional information related to gene expression profile into the current efforts to unravel the molecular mechanism responsible for familial MTLE associated with HA. Additional studies are underway in order to compare gene expression profile of familial and non-familial MTLE hippocampi. Supported by FAPESP and CNPq.

SNP array mapping of 20p deletions: genotypes, phenotypes and copy number variation. *N.B. Spinner, A.J. Greco, B.T. Thiel, J. Glessner, P. Munoz, X. Gai, D.A. Piccoli, S.F.A. Grant, H. Hakonarson, I.D. Krantz, B.M. Kamath* Dept Pediatrics, The Children's Hosp, of Phila, Phila, PA.

We analyzed 21 patients with deletions of 20p using the Illumina Human Hap550 SNP array to 1) establish genotype/phenotype correlations, 2) identify breakpoints and 3) investigate the use of the HumanHap550 platform for analysis of chromosome deletions. Deletions of 20p are relatively rare, although those that include JAG1 at 20p12 occur in 5% of patients with Alagille syndrome (AGS). The 21 patients had deletions of 20p identified by cytogenetics (N=6), molecular cytogenetics (N=11) or MLPA (N=4). Nineteen patients had clinical features of AGS, and these deletions included the JAG1 gene. Deletions ranged from 100 Kb to 14.62 Mb, and all of the breakpoints were unique. Seven patients had deletions sized between 100kb and 2.83 Mb, and all had normal development, with no clinical anomalies outside of those associated with Alagille syndrome. Apparently, haploinsufficiency for the 10 genes (excluding JAG1) within this region does not cause phenotypic anomalies. Eleven patients had deletions between 3 and 8.3 Mb, and of these, 8/11 had developmental delay. Only one patient was deceased, secondary to complications of AGS. Few additional anomalies were seen in this group, but these included renal anomalies (N=4), conductive hearing loss (N=2) and bifid uvula (N=1). Three patients with large, proximal deletions had the most clinical abnormalities, which included CNS and endocrine anomalies and hearing loss. These 3 patients all had significant delays, and features of autism and/or savant characteristics. In addition to defining the 20p deletions, analysis using the HumanHap550 array identified 31 different genome-wide copy number variants (>20 SNPs), with 1-5 variants called per patient. Deletions of the short arm of chromosome 20 are relatively mild, with limited clinical anomalies. The use of SNP arrays provides accurate high -resolution definition of genomic abnormalities. Copy number variants that are unlikely to be pathogenic were identified in all patients, and careful cataloging of these is crucial to correct interpretation of these studies.

Aortic Root Disease and Myotonic Dystrophy in Two Siblings: A Unique Family with Maternal Connective Tissue Disease and Paternal CTG Expansion in *DMPK*. *J. Platt[1], T. Mozaffar[2], M.V. Zaragoza[1]* 1) Center for Molecular and Mitochondrial Medicine and Genetics and Dept. of Pediatrics, Division of Genetics and Metabolism, University of California, Irvine; 2) Dept. of Neurology, University of California, Irvine.

Diseases of the aorta including dilation and dissection are significant features of inherited defects of connective tissue including most notably, fibrillin 1 in Marfan Syndrome. Myotonic Dystrophy type 1 (DM1) is an autosomal dominant, multisystem disorder characterized by skeletal muscle weakness, myotonia, cataracts and cardiac conduction abnormalities. DM1 is caused by CTG expansion in the gene Myotonic Dystrophy Protein Kinase (*DMPK*). We describe a family consisting of two siblings both with aortic root disease, minor skeletal abnormalities, progressive muscle atrophy, weakness and early-onset cataracts. Their mother has significant aortic root disease. Their father has frontal balding, bilateral cataracts and adult-onset diabetes. DNA testing for Myotonic Dystrophy revealed mutations in *DMPK* for both siblings (>250 and >350 CTG repeats) and for their father (64 CTG repeats). DNA sequence analysis of *Fibrillin 1* (*FBN1*) detected two heterozygous, maternally inherited nucleotide changes: E1283A in exon 31 and IVS58-21G>A in intron 58. The *FBN1* sequence variants have not been previously described as disease-causing mutations; thus, E1283A most likely represents a novel mutation in *FBN1* for aortic root disease. Clinical and molecular evaluation of this unique family provides insight on the genotype-phenotype associations in two individuals with both connective tissue disease and myotonic dystrophy.

Gene-environmental interactions that affect serum IgE levels of urban school children. *Y. Suzuki[1], Y. Mashimo[1], H. Inoue[1], M. Funamizu[1], N. Shimojo[2], Y. Kohno[2], Y. Okamoto[3], A. Hata[1]* 1) Department of Public Health, Chiba University, Chiba, Japan; 2) Department of Pediatrics, Chiba University, Chiba, Japan; 3) Department of Otolaryngology, Chiba University, Chiba, Japan.

Background: Serum IgE level is determined by both environmental and genetic factors and their interactions. Little is known about the specific environmental and genetic factors that show significant interactions.

Aim: To evaluate interactions between environmental factors and interleukin 4 receptor alpha (IL4RA) gene Ile50Val polymorphism on serum levels of total and specific IgE in urban school children.

Methods: Four hundreds and seventy-three school children with 6 to 12 years of age were examined by questionnaires for their life styles in an urban area of Japan. We determined total IgE, specific IgE (mite, cat dander, alternaria, egg white, cedar pollen, orchard grass), and the genotype for IL4RA Ile50Val in the 411 children. Association between categorical data was evaluated with chi-square tests. Screening of factors that affected on IgE values was carried out with Kruskal-Wallis test. Effects on serum IgE levels of the polymorphism, environmental factors and their interactions were evaluated with logistic regression.

Results: Among environmental factors examined, daycare attendance before 2 years of age was associated with total IgE and cat dander-specific IgE; current floor type of bedroom was associated with total IgE and mite-specific IgE; consumption of yogurt was associated with total IgE, mite-specific IgE, egg white-specific IgE; raising pats was associated with cat dander-specific IgE. Significant interaction between raising pets and IL4RA Ile50Val genotype on cat dander-specific IgE level was observed. Effect of daycare attendance on total and cat dander-specific IgE levels was also modified by IL4RA Ile50Val genotype.

Conclusion: Response in total and cat dander-specific IgE serum levels to environmental alterations is affected by IL4RA Ile50Val polymorphism.

Analysis of candidate loci in primary open angle glaucoma families. *J.P.C. Vasconcellos[1], A. Tavares[2], I. Lopes-Cendes[2], C.V. Maurer-Morelli[2], R. Secolin[2], M.R.B. Moraes Silva[3], F.F. Costa[4], V.P. Costa[1], M.B. Melo[5]* 1) Ophthalmology, University of Campinas, Campinas, São Paulo, Brazil; 2) Medical Genetics, University of Campinas, Campinas, São Paulo, Brazil; 3) Ophthalmology, UNESP, Botucatu, São Paulo, Brazil; 4) Hemocentro, University of Campinas, Campinas, São Paulo, Brazil; 5) CBMEG, University of Campinas, Campinas, São Paulo, Brazil.

Purpose: Glaucoma is one of the major causes of irreversible blindness worldwide, characterized by progressive loss of optic nerve ganglion cells, associated with correspondent visual field damage. There are at least 13 loci (GLC1A - GLC1M) associated with POAG identified from genetic mapping studies, most of them involving families that follow a Mendelian inheritance pattern but only three genes were identified: myocilin (MYOC - GLC1A), optineurin (OPTN - GLC1E) and WD Repeat-Containing Protein 36 (WDR36 - GLC1G) genes. The goal of this study was to evaluate nine candidate loci associated with POAG in Brazilian families through linkage analysis. Methods: Seven families with POAG (121 individuals - 47 affected) were enrolled in this study. Thirty three microsatellite markers were used to genotype nine candidate regions linked to POAG (GLC1A - GLC1I). Two-point linkage analysis was performed using the MLINK program of the LINKAGE package. Results: Among the seven families, two (28.6%) presented mutations (Cys433Arg) in the MYOC gene (GLC1A) segregating with POAG. The remaining 5 families did not show evidence of linkage in GLC1A (MYOC gene), GLC1C, GLC1E (OPTN gene), GLC1F, and GLC1G (WDR36 gene) loci, with LOD scores < -2.00. The data related to loci GLC1B, GLC1D, GLC1H and GLC1I were inconclusive (LOD scores between +3.00 and -2.00) being necessary the genotyping of additional markers to narrow the candidate regions. Conclusions: MYOC gene alterations seem to contribute to the development of POAG among Brazilian families with autosomal dominant pattern of inheritance. However, the analysis of the remaining families support the heterogeneity of POAG and stresses the importance of the evaluation of additional families in order to search for different loci and predisposing genes to better understand the genetic basis of glaucoma.

The spectrum of the Factor VIII defects in Taiwanese patients with Hemophilia A. *G.C. Ma[1], S.P. Chang[1], M. Chen[1,2,3], M.C. Shen[1,4]* 1) Center for Medical Genetics and Department of Medical Research, Changhua Christian Hospital, Changhua, Taiwan; 2) Department of Obstetrics and Gynecology, College of Medicine, National Taiwan University, Taipei, Taiwan; 3) Department of Obstetrics and Gynecology, Changhua Christian Hospital, Changhua 500, Taiwan; 4) Department of Internal Medicine, Colleague of Medicine, National Taiwan University, Taipei, Taiwan.

Hemophilia A (HA) is an X-linked recessive bleeding disorder caused by various types of pathological defects in the FVIII gene. With the exception of two intron inversions (IVS22 and IVS1), no mutation hotspots in the FVIII gene were identified in the previous literature. To date, several studies on the spectrum of FVIII defects have been performed in Western populations, but similar studies in Asian races are scarce. Here, we report the distribution of the mutations within the FVIII gene in 31 Taiwanese unrelated patients with HA (19 severe and 10 moderate/mild males, and 2 severe females). Of these, 12 (38.7%) and one (3.2%) severely affected males were genotyped with the recurrent IVS22 and IVS1 inversion, respectively. These frequencies were similar to that in general populations (IVS22: 40-50%; IVS1: 2-5%) reported elsewhere. The FVIII defects in the remaining 18 inversion-negative patients cover a wide spectrum, in which 17 different mutations were identified, including ten missense and three nonsense mutations as well as two small and two large deletions. Twelve of these mutations are novel: seven caused nonsense substitutions and five resulted in truncated proteins. To assess the putative pathogenetic impacts of the newly amino acid substitutions, computer analyses were performed based on the molecular 3D modeling. The degree of conservation in cross-species FVIIIs and the position in known functional FVIII regions were studied. The novel missense mutations found in our series all occurred at evolutionary conserved residues that may carry a functional importance in our analyses. The results of this study add the short list of Taiwanese/Chinese FVIII mutations to the existing literature, and will enhance our understanding of the molecular basis of FVIII protein function and the mechanism underlying HA.

Analysis of the oligonucleotide microarray on placentae of pre-eclamptic pregnancies without labor. *J. Park[1], S. Lee[2], W. Lee[3], C. Ryu[3], K. Lee[2], D. Cha[2]* 1) Ob and Gyn, Bundang CHA hospital, Sungnam, Kyoungki-Do, Korea; 2) Ob and Gyn, Kangnam CHA hospital, Seoul, Korea; 3) Digital Geneomics, Seoul, Korea.

Objective: Preeclampsia is a severe disorder of widespread vascular endothelial malfunction that occurs beyond the 20th week of gestation. But, little is known about its etiology. The aim of this study is to investigate the placental specific mRNAs and the related mechanism associated with the progression of this disease using the genome wide expression profiling. Methods: Placentae from 16 normal pregnancies without labor and 17 pregnancies complicated by preeclampsia without labor were collected. We performed genome-wide expression profiling using CodeLink Human Whole Genome Bioarray (55k). Results: Among the 55,000 genes that were analyzed in the microarray, 467 genes were found to be differentially expressed. Among these candidates, 424 were up-regulated and 43 were down-regulated. The up-regulated genes included Fas, Heat shock protein 1 and TRADD, which are well-known biological markers for apoptosis, as well as plasminogen activator inhibitor type 1. Several biological processes associated with the development of preeclampsia were analyzed by gene ontology classification, including response to oxidative stress (selenoprotein P), apoptosis, immune response, and vascular constriction. Conclusion: mRNA microarray is a high throughput and time-saving method to monitor altered gene expression. The results could provide interesting clues to the etiology of pre-eclampsia and lead to further studies in a more targeted fashion.

Comparing Methods for Association Test of Longitudinal or Multivariate Phenotypes. *H. Wu, Q. Yang* Department of Biostatistics Boston University School of Public Health Boston MA.

Longitudinal or multivariate phenotype data may be frequently encountered in genetic studies. Such data contain more information than independent univariate phenotype data, but how to best analyze them is not always straightforward. We have evaluated three approaches to analyzing longitudinal or multivariate phenotype data in association studies: random effects models, creating a single summary measure of all traits and combining multiple test statistics from the test of each trait. Simulation studies were conducted to assess the validity and efficiencies among these strategies with 1000 replicates. Our results suggested that random effects models performed as good as using mean of multiple quantitative traits if these traits follow the same marginal distribution with exchangeable correlations among them. We are comparing these two strategies for traits that follow different marginal distribution with heterogeneous correlation structure, as well as to the third strategy, combining test statistics from individual univariate analysis. This study will provide insights on choosing strategies for analyzing longitudinal or multivariate phenotype data in association studies.

Spondyloepiphyseal dysplasia, Omani type. A second family and expansion of the phenotype. *S. Robertson[1], M. van Roij[2]* 1) Department of Paediatrics, Otago Medical School, Dunedin, New Zealand; 2) Department of Clinical Genetics, VU University Medical Center, Amsterdam, The Netherlands.

Two siblings, the offspring of a second-cousin union, are presented manifesting a spondyloepiphyseal dysplasia that is progressive from early childhood and results in severe kyphoscoliosis and arthropathy in association markedly variable brachydactyly. Owing to the novelty of the phenotype an Affymetrix 50K genome wide scan was performed seeking regions that were homozygous by descent from a common ancestor of the parents of the two affected children. A region of >15Mb was identified at 10q22 incorporating the CHST3 locus, encoding chondroitin 6-O-sulfotransferase, previously been shown to be mutated in the recessive condition, Spondyloepiphyseal dysplasia (Omani type). Both children were shown to be homozygous for the mutation 857T>C predicting the substitution L286P. The residue 286L is tightly conserved through evolution implying a high likelihood that the observed mutation is causative of the observed phenotype. Clinical descriptions of SED Omani type have been restricted to two Omani families with short stature, progressive kyphoscoliosis, severe arthropathy with joint dislocations but only minimal manifestations in the hands. Our observations extend the phenotype associated with mutations in CHST3, report the first family outside Oman, and add to the wide spectrum of skeletal anomalies that can arise from the dysregulation of the sulfation of cartilage.

A protective variant of the PTPN22 locus in rheumatoid arthritis in the New Zealand Caucasian population. *W. Wan Taib[1], K. Gendall[1], P. Chapman[2], N. Dalbeth[3], P. Gow[3], A. Harrison[2], J. Highton[2], P. Jones[4], L. Stamp[2], J. O'Donnell[2], T.R. Merriman[1]* 1) Biochemistry Department, University of Otago, Dunedin, NZ; 2) School of Medicine, University of Otago, NZ; 3) Middlemore Hospital, Auckland, NZ; 4) QE Hospital, Rotorua, NZ.

Rheumatoid arthritis (RA) is a complex autoimmune disease with a strong genetic contribution to its pathogenesis. The first non-major histocompatibility complex (MHC) gene discovered to be reproducibly associated with RA is the protein tyrosine phosphatase non-receptor 22 (PTPN22) gene in the Caucasian population. The PTPN22 functional variant, R620W, has been associated with RA in many studies in different populations. We have previously published a genome-wide association scan that identified MHC and PTPN22 as major loci in RA. Within the *PTPN22* haplotype block (365kb), there were disease-associated SNPs (rs3789600 and rs3789598) that suggested an association of *PTPN22* independent of *R620W*, possibly related to the disease-protective 'haplotype 5' previously identified by Carlton et al. (OR=0.65; frequency=0.35; *AJHG*, 77:567, 2005). The aim of the study reported here was to extend the previous data on 'haplotype 5', in particular studying variation in other genes mapping in the *PTPN22* haplotype block. The rs3789600 and rs3789598 SNPs were genotyped over 863 NZ Caucasian RA cases and 564 NZ controls. Both were associated with disease (*P*=0.0006 and *P*=0.0003, respectively) and clearly defined a protective haplotype, related to 'haplotype 5'. Subsequent typing of 'haplotype 5' tagging SNPs in the extended *PTPN22* haplotype block identified one SNP (rs1539438) in *C1orf178* that refined the protective haplotype to OR=0.53, $P=1x10^{-5}$, frequency=0.11). These data confirm the presence of a protective RA effect at *PTPN22* independent of *R620W* and possibly mapping outside of *PTPN22*.

Accurate prediction of deleterious protein polymorphisms. *A. Torkamani[1], N.J. Schork[2]* 1) Graduate Program in Biomedical Sciences; Department of Medicine; and Center for Human Genetics and Genomics, University of California at San Diego, La Jolla, CA 92093; 2) Scripps Genomic Medicine and Department of Molecular and Experimental Medicine, The Scripps Research Institute; Departments of Psychiatry and Biostatistics, Center for Human Genetics and Genomics and Stein Institute for Research on Aging, University of Ca.

Contemporary, high-throughput sequencing efforts have identified a rich source of naturally occurring single nucleotide polymorphisms (SNPs), a subset of which occur in the coding region of genes and result in a change in the encoded amino acid sequence (nonsynonymous coding SNPs or nsSNPs). It is hypothesized that a subset of these nsSNPs may underlie common human disease. Testing all these polymorphisms for disease association would be time consuming and expensive. Thus, computational methods have been developed to both prioritize candidate nsSNPs and make sense of their likely molecular physiologic impact. We have developed a sequence-based method to prioritize nsSNPs and have applied it to the human protein kinase gene family. The results of our analyses provide high quality predictions and outperform available whole genome prediction methods (74% vs. 83%; prediction accuracy). Our analyses and methods consider both DNA sequence conservation - which most traditional methods are based on - as well unique structural features of relevant proteins, such as group membership, domain residence, and protein flexibility. We also provide a ranked list of common kinase nsSNPs that have a higher probability of impacting human disease based on our analyses.

The interaction between a functional variant in *F5* gene and maternal smoking during pregnancy on preterm delivery. *Y.X. Yu[1], H.J. Tsai[1], S.C. Zhang[1], X. Liu[1], C. Pearson[2], K. Ortiz[2], X.B. Wang[1]* 1) Mary Ann and J. Milburn Smith Child Health Research Program, Childrens Memorial Hospital, Northwestern University Feinberg School of MedicineCenter, Chicago, IL; 2) Department of Pediatrics, Boston University School of Medicine and Boston Medical Center, Boston, MA.

Introduction: We previously reported that factor 5 (*F5*) genetic polymorphisms were associated preterm delivery (PTD, gestational week <37). *F5* gene plays a critical role in the regulation of blood coagulation. Women smoking during pregnancy had higher levels of blood coagulation than those who did not. We hypothesize that *F5* gene and maternal smoking during pregnancy may synergistically increase the risk of PTD. **Methods:** A functional SNP (rs6019) in *F5* gene was genotyped in 548 PTD mothers and 1,770 mothers who delivered full-term recruited from a case-control study at Boston Medical Center. The individual effects of SNP rs6019 and maternal smoking, and their interactive effect on PTD and gestational age were examined using logistic regression and multiple linear regression models after adjusting potential confounders. **Results:** Maternal smoking was associated with PTD and gestational age. Additionally, SNP rs6019 was associated with PTD (OR [95% CI]: 1.3 [1.1-1.6]) and gestational age ([SE]: -0.5 [0.1]; $p < 10^{-4}$), respectively. More importantly, we found significant interactive effects of SNP rs6019 and maternal smoking on PTD. Comparing with non-smoking mothers with the CC genotype, those with the CG or GG genotype was associated with increased risk of PTD (OR [95%CI]: 1.5 [0.8-2.9] for CG; 2.5[0.8-7.9]) for GG) when smoking intermittently, and even higher risk when smoking continuously (OR [95%CI]: 2.6 [1.7-4.2] for CG; 4.1 [1.9-8.8] for GG). Similarly, significant interactive effects were observed for gestational weeks ([SE]: -1.8 [0.4]; $p < 10^{-4}$ for CG; -2.4 [0.6]; $p = 10^{-4}$ for GG). **Conclusions:** We confirmed that maternal smoking and *F5* genetic variant each was associated with increased risk of PTD. Moreover, we found significant *F5* gene-maternal smoking interaction on the risk of PTD.

The mammalian genome expresses an abundance of small RNAs. *R.J. Taft[1], L.J. Croft[1], M. Askarian-Amiri[1], C. Simons[1], J.M.G. Szubert[2], X. Zhou[3], J.S. Mattick[1]* 1) ARC Special Research Center for Functional and Applied Genomics, Institute for Molecular Bioscience, University of Queensland, Brisbane, Australia; 2) Faculty of Life Sciences, The University of Manchester, Manchester, United Kingdom; 3) LC Sciences, Houston, TX, USA.

We have previously shown that the proportion of non-protein-coding DNA consistently scales with increasing biological complexity. We hypothesize that these vast sections of the mammalian genome encode many vital genetic elements, including small regulatory non-coding RNAs. Using criteria based on known microRNAs, we identified approximately 1.7 million sequences encoding putative stem-loop structures in the mouse genome, which may act as small RNA precursors. Thousands of randomly chosen predictions were tested using custom microarrays containing modified oligonucleotides, and were interrogated with small RNAs less than 300 nt. Controls were included for known small RNAs, particularly miRNAs, and for ubiquitous and highly expressed mRNA contamination. We found that 15% of mouse predictions were detected in whole 10-12 day embryo, and a total of 19% were detected in five separately polled tissues. Many of the predictions were differentially detected between tissues. There was also no difference in the validation rates between sequences exhibiting conservation and those that did not, suggesting that many may be clade-specific. Northern blot analysis of a random selection of 50 of the array-positive mouse predictions confirmed that 75% were detectable as small RNAs whose sizes ranged from ~20-110 nt, and include a potential new class of small RNAs at ~100 nt. Tissue panel expression analysis by Northern indicates that a least a subset of these small RNAs are highly expressed across a range of tissues. We have also performed experiments interrogating a prediction set of ~1.6 million putative stem-loop precursors in human, and found that ~35% returned positive results. We predict that, at a minimum, the mammalian genome expresses hundreds of thousands of small RNAs.

Chemical Chaperone Effect on GLA Gene Mutations in Korean Patients with Fabry disease. *J.Y. Park[1], G.H. Kim[1,2], H.W. Yoo[1,2,3]* 1) Genome Research Center for Birth Defects and Genetic Disorders, Asan Institute for Life Sciences; 2) Medical Genetics Clinic and Laboratory, Asan Medical Center; 3) Department of Pediatrics, Asan Medical Center, University of Ulsan College of Medicine, Seoul, Korea.

Fabry disease, an X-linked inborn error of glycosphingolipid catabolism, results from the deficient activity of GLA (-galactosidase A). We have identified 15 different mutations in the GLA gene in 13 classic and 2 atypical male Fabry patients from 15 unrelated Korean families. Out of 15 identified mutations, 2 were novel mutations, the p.Asp231Gly missense mutation and the p.Leu268delfsX1 deletion mutation. The study was undertaken to evaluate effect of chemical chaperone 1-deoxygalactonojirimycin (DGJ) on GLA missense mutant constructs in vitro. Nine missense mutations including one novel mutation were cloned into a mammalian expression vector. GLA activity and GLA expression were analyzed using fluorescence spectrophotometry and Western blot after transient expression in COS-7 cells. COS-7 cells were cultured for 2 days in DMEM medium with and without of 20 uM DGJ. The addition of DGJ to culture media enhanced GLA activity up to 2.5 fold in p.Met42Val, p.Ile91Thr and p.Phe113Leu. The p.Ile91Thr and p.Phe113Leu were clinically associated with atypical form. While mature form (46 kDa) protein of -Gal A increased markedly in the p.Phe113Leu, it also increased less abundantly in the p.Met42Val and p.Ile91Thr. DGJ treatment in other mutations including p.Glu66Gln, pArg112Cys, p.Cys142Trp, p.Asp231Gly, p.Asp266Asn, and p.Ser297Phe did not show any significant effect both on GLA activity and protein expression. Interestingly, no GLA activity was observed in a novel mutation, p.Asp231Gly, but the protein was normally expressed as wild type GLA. Especially, the p.Glu66Gln showed approximately 40 % GLA activity in the absence of DGJ, and the protein was expressed normally, indicating that it is a mild mutation or functional SNP. In conclusion, the results suggest that chemical chaperone DGJ enhances GLA activity and mature protein expression in milder mutations associated with atypical form of Fabry disease.

Association of *FGF23* Genotype with Lower BMD at the Hip and Spine in the Old Order Amish. *J. Liu, D.J. McBride, B.D. Mitchell, E.A. Streeten, A.R. Shuldiner* Division of Endocrinology, Diabetes and Nutrition, University of Maryland School of Medicine, Baltimore, MD.

As a novel phosphaturic hormone, fibroblast growth factor 23 (FGF23) is mainly produced in bone and affects bone mineral homeostasis by regulating phosphate and vitamin D metabolism. Rare mutations that increase FGF23 levels cause autosomal dominant hypophosphatemic rickets, while disorders associated with reductions in FGF23 are characterized by hyperphosphatemia, elevated production of 1, 25-dihydroxyvitamin D and hyperostosis. We thus hypothesized that common variants in *FGF23* might influence bone mineral density (BMD) and susceptibility to the common forms of osteoporosis. Five tagging SNPs were selected according to Hapmap and genotyped in individuals from the Amish Family Osteoporosis Study (AFOS) (n=1031). In addition, one SNP, rs12812339, was genotyped in a Mexican-American (Mex) cohort from the San Antonio Family Osteoporosis Study (n=857). Significant association between the promoter SNP rs12812339 (-1951C-->A) and BMD was found in the Amish. The frequency of minor allele C was 0.38. Subjects with C/C genotype had lower BMD at the femur and spine than those with C/A or A/A genotypes. In a dominant model, age-, sex- and BMI- adjusted P values at the hip were 0.003 for the intertrochanter, 0.0005 for the femoral neck, 0.006 for the trochanter, 0.001 for the total hip; for spine, 0.007. Narrow neck femur average buckling ratio(an indicator of bending strength) was also strongly associated with C/C genotype (P=0.00006). After stratifying by age or gender, the associations with BMD traits remained only in those men and women over age 50 years suggesting a role in bone loss rather than peak bone mass. The frequency of the C allele was lower in the Mex cohort (allele frequency=0.07). Although there was no statistically significant association with BMD, those few subjects with the C/C genotype tended to have lower hip and spine BMD. Our results showed that the C/C genotype of rs12812339 was strongly associated with decreased hip and spine BMD and with buckling ratio in the Amish. This promoter SNP may act by increasing FGF23 levels and accelerating the rate of bone loss.

Generation of the anti-mouse prosaposin specific antibody: Regional accumulation of prosaposin in the hippocampus of saposin D knockout mouse. *J. Matsuda, A. Yoneshige, K. Suzuki* Institute of Glycotechnology, Future Science and Technology Joint Research Center, Tokai University, Kanagawa, Japan.

Sphingolipid activator proteins (saposins A, B, C, D) are small homologous glycoproteins which are indispensable for *in vivo* hydrolysis of some sphingolipids by lysosomal hydrolases. We generated specific saposin A and D knockout mice that clarified their *in vivo* functions, saposin A as an essential activator of lysosomal galactosylceramidase and saposin D as a lysosomal acid ceramidase activator. In this study, in order to further investigate the biological role of the precursor protein (prosaposin) of the four saposins in the nervous system, we generated an anti-mouse prosaposin-specific antibody by immunizing rabbit with three oligopeptides, selected from the prosaposin sequences that do not encode any saposins and investigated its regional expression in the brain of murine models of lysosomal storage disorders including saposin D knockout mouse (Sap-D-/-). Immunoblotting study of brain homogenates demonstrated a major band at around 65kDa corresponding to the predicted size of prosaposin. Most of the 65 kDa band shifted to 58 kDa by glycoproteinase F treatment. The intensity of the 65kDa band was most dramatically increased in Sap-D-/-. Immunohistochemical study of the brain showed that the expression of prosaposin was observed predominantly in the hippocampus, olfactory bulb and cerebellum. In Sap-D-/-, its immuno-reactivity was dramatically increased with some regional increases, most notably in the hippocampal CA3 pyramidal neurons. By confocal microscopic analysis, hippocampal pyramidal neurons in the CA3 area contained prosaposin immuno-reactive inclusions, co-localizing with an endoplasmic reticulum (ER) marker protein. Immunoelectron microscopic analyses also revealed the retention of prosaposin immuno-reactive products in the ER. These findings indicate that the prosaposin dose exist uncleaved in the specific type of cells suggesting a regional role in the nervous system, especially in the hippocampal CA3 pyramidal neurons. This prosaposin specific antibody may be useful to further investigate regional functions of prosaposin itself in the nervous system.*in vivo*.

Discrepancies of the results between MLPA and FISH, and between MLPA kits, observed in a case of subtelomeric imbalances of chromosome 12. *K. Wakui[1,2], Y. Kinishita[1], Y. Furui[3], K. Shinogi[3], T. Fukui[3], R. Kawamura[1], N. Gondo[3], S. Yokoyama[3], H. Higashi[3], Y. Fukushima[1,2]* 1) Dept Med Genet, Shinshu Univ Sch Med, Matsumoto, Japan; 2) Div Clinical and Mol Genet, Shinshu Univ Hosp, Matsumoto, Japan; 3) Biomedical Business Div. FALCO biosystems Ltd., Kyoto, Japan.

Multiplex Ligation-dependent Probe Amplification (MLPA) has come into wide use for subtelomeric screening as a new molecular cytogenetic technique. We analyzed subjects with known subtelomeric imbalances using 2 kinds of MLPA Kits (SALSA MLPA KIT HUMAN TELOMER, P036B and P070, MRC-Holland), and evaluated the usefulness and limitations of this method compared with subtelomeric metaphase FISH analyses. Of these, some of the results showed discrepancies between MLPA and FISH, and/or between 2 kinds of MLPA kits. We report here one of such cases; a subtelomeric imbalances of chromosome 12. A case was recognized having add(12p) by initial G-banding. The 24 color FISH analysis showed that the entire der(12) was derived from chromosome 12. Subtelomeric FISH analysis performed in 2000 showed that the signals of 12qter were detected at the both chromosome ends of the der(12), and the signals of 12pter were retained at the breakpoint of the der(12). However, we detected not only gain of 12q but also loss of 12pter by MLPA analysis using P036B kit, although only gain of 12q was detected by P070 kit. We re-analyzed this case by FISH using TelVysion 12p/12q FISH Probe (Vysis), and found that the signals of 12qter was detected at the both chromosome ends of the der(12) as well, but the signals of 12pter was not detected around the breakpoint of the der(12). The target gene of the 12pter probe is *SLC6A12* (170kb distance from the 12p telomere) in P036B kit, and *RBBP2* (290kb distance) in P070 kit. The FISH probe for 12pter which we used in 2000 was 90I5/PAC (estimated about 700kb distance), and sAVH27 (90kb distance) was used as TelVysion 12pter probe. Thus, this case was re-diagnosed as having a 12q partial trisomy with 12p subtle deletion (170-290kb in size). Advance in cytogenetic testing is continuous. We always need to consider the resolution of each technique at the cytogenetic diagnosis of the structual chromosomal abnormality.

Patterned cerebellar Purkinje cell degeneration in mouse models of saposin D deficiency and Niemann-Pick type C disease is associated with selective expression of sphingosine kinase. *A. Yoneshige, J. Matsuda, A. Sasaki, K. Suzuki* Institute of Glycotechnology, Future Science and Technology Joint Research Center, Tokai University, Hiratsuka, Kanagawa, Japan.

Selective death of cerebellar Purkinje cells (PCs) is a prominent feature of the neuropathology in several lysosomal storage disorders (LSD). It is well known that both Niemann-Pick type A/B and type C (NPC) show PC death. However there has been no accepted explanation of this selective loss of PCs in these metabolic disorders. We generated saposin D knockout mouse (Sap-D-/-) which is the deficiency of the essential *in vivo* activator of lysosomal acid ceramidase, and found selective PC death with accumulation of -hydroxyl fatty acid-ceramide. In 2004, Terada *et al.* demonstrated a compartmentalized expression of sphingosine kinase 1 (SPHK1), which phosphorylates sphingosine (Sph) to form a bioactive lipid mediator, sphingosine 1-phosphate (S1P), in PCs of wild type mice. In this study, we investigated the relationship between SPHK1 expression and the pattern of PC death in two murine models of sphingolipidosis, Sap-D-/- and mouse model of human NPC disease (NPC1-/-). Immunoblotting study using anti-mouse-SPHK1 antibody revealed that SPHK1 was localized in the cytosolic fraction and its protein level was higher in the cerebellum than that in the cerebrum. By immunohistocemical study, both Sap-D-/- and NPC1-/- showed selective and progressive loss of PCs. The pattern of PC death was symmetrical in stripes in coronal sections corresponding to the expression of SPHK1. Especially in Sap-D-/-, most of the SPHK1-negative PCs were completely lost. In contrast, SPHK1-positive PCs could survive even in the terminal stage. The study with primary cultured PCs also confirmed that PCs from Sap-D-/- die earlier than those from the wild type. In the primary cultured PCs from Sap-D-/- mice, SPHK1 was expressed dominantly in the dendritic spines of PCs. These findings indicate that the intracellular levels of sphingomyelin, ceramide, Sph and S1P have important roles in the survival and maintenance of PCs. Regulating the expression of SPHK1 could be a possible way to protect neurons from cell death in some LSDs.

Clinical phenotype of adult patients with X-linked -thalassemia/ Mental Retardation (ATR-X) Syndrome. *T. Wada[1], Y. Fukushima[1], S. Saitoh[2]* 1) Dept Medical Genetics, Shinshu Univ Sch Medicine, Matsumoto, Japan; 2) Dept Pediatrics, Hokkaido University Graduate School of Medicine, Sapporo, Japan.

[Introduction] The dysregulation of epigenetics is one of the most important causes of mental retardation. ATR-X syndrome (OMIM #301040) is among syndromic X-linked mental retardation (MR), and is characterized by male patients, severe MR, dysmorphic facies, presence of HbH inclusion, genital and skeletal abnormality and characteristic behavior. The mutations of the *ATRX* gene on Xq13 cause this syndrome, as well as non-specific MR in both male and female. The *ATRX* gene encodes ATRX protein, which is thought to be involved in chromatin remodeling. However, the pathogenesis of this syndrome remains to be elucidated. More than 160 patients, including 40 cases in Japan, have been diagnosed as ATR-X, but we have little information about the natural history of this syndrome. Here we report the clinical phenotype of the adult patients with this syndrome. [Subjects] Twelve adult ATR-X patients, (Age range when evaluated 18-35 Yr; mean 23.8Yr), whose mutations in the *ATRX* gene were confirmed, were clinically evaluated. [Results] All patients had severe MR without expression of any meaningful words. Most of all showed autistic-like behavior, including little interest in those around them, avoidance of eye contact, or repetitive stereotype movement. All but one were not able to stand or walk without aid, while the one was able to walk alone, communicate non-verbally with others, and do his minimal daily life by himself. Nobody had psychiatric problems to be needed for medication. [Discussion] Considering that in general not all patients with severe mental retardation show autistic behavior, ATR-X shows a distinctive phenotype with severe MR and autistic behavior. Interestingly, patients with other diseases caused by the disturbance of epigenetics, such as Rett syndrome or Angelman syndrome, also show MR and autistic behavior. This suggests that ATRX may have a role in neurobiological mechanisms for both MR and autism through epigenetic mechanism. It is important to establish the natural history of the syndrome not only for clinical practice but also for basic research.

Molecular evolutionary study of the ionotropic glutamate-receptor gene family as schizophrenia susceptibility genes: human-specific non-neutral pattern observed in *GRIN2B* upstream region. *H. Shibata, K. Tanaka, K. Watanabe, H. Goto, Y. Fukumaki* Med Inst Bioreg, Kyushu Univ, Fukuoka, Japan.

Schizophrenia is a common psychiatric disease with relatively strong genetic background ($_s$ = 10). Typical preadolescent onset characterized by loss of sociality suggests severely reduced fitness. However, the disease prevalence is highly stable to be ~1% in any human populations. We hypothesized that the schizophrenia susceptibility alleles are maintained by non-neutral process such as balancing selection. To test this hypothesis, we started molecular evolutionary analyses on genes reported to be associated with schizophrenia. In this paper, we report the result of upstream regions of ionotropic glutamate receptor gene family. We collected the complete variation data from the target region by resequencing 50 unrelated humans and 50 unrelated chimpanzees as non-human controls. From the analyses of six ionotropic glutamate receptor genes: *GRIN1* (3.2 kb), *GRIN2A* (0.8 kb), *GRIN2B* (3.8 kb), *GRIN2D* (2.4 kb), *GRIA1* (5.1 kb) and *GRIK1* (4.5 kb), we identified, 123, 40, 41, 56, 131, 107 and 23 segregation sites, respectively. By window plot analysis, we identified significant positive values of Tajimas *D* (+2.16) at the 3.0 kb upstream region of *GRIN2B*. Since population contraction is unlikely for humans, this positive Tajimas *D* is a signature of balancing selection. In contrast, we observed no significant departure from neutral evolution in the same region in chimpanzees, suggesting that the pattern is specific to human lineage. The region harbors only two common SNPs closely located (rs12368476 and novel, 49 bp apart) and no other rare polymorphisms. By genotyping additional 250 samples, we observed modest LD (r^2 = 0.4) between the SNPs. We also found that the haplotype with derived alleles on both loci is missing, whereas the other three haplotypes observed in similar frequencies (22-48 %). Neutral process such as population expansion is unlikely to explain this unusual pattern. Since significant association of *GRIN2B* with schizophrenia has been frequently reported, this non-neutral pattern observed in the *GRIN2B* upstream region is potentially associated with schizophrenia.

A novel missense mutation in the cartilage-derived morphogenetic protein 1 (CDMP1) gene of Grebe Type Chondrodysplsia patients in a Saudi Arabian family. *M. Ul Haque[1,3], E.A. Faqeih[2], H. Al-Zaidan[3], A. Al-Shammary[1], S.H.E. Zaidi[4]* 1) Molecular Genetics Lab, DPLM, King Faisal Specialist Hosp, Riyadh, Saudi Arabia; 2) Department of Pediatric Medicine, Children's Hospital, King Fahad Medical City, Riyadh, Saudi Arabia; 3) Department of Medical Genetics, King Faisal Specialist Hospital & Research Centre, Riyadh, Saudi Arabia; 4) Department of Medicine, University Health Network & University of Toronto, Toronto, Ontario, Canada.

Grebe type chondrodysplasia is a rare autosomal recessive skeletal disorder in which affected subjects exhibit markedly shortened limbs and tiny digits without abnormalities of the axial skeleton. This defect results from loss of function mutations in the cartilage-derived morphogenetic protein 1 (CDMP1) gene. Here we report a consanguineous family from Saudi Arabia, in which three children in two sib-ships display this rare disorder. All affected subjects exhibit typical features of Grebe type chondrodysplasia, which include severely shortened hands and legs, and appendage like fingers. In addition, these patients exhibit occipital prominence, bi-temporal narrowing and dental anomalies. Sequencing of the CDMP1 gene of the affected children identified a novel c.1285T>C change in the gene. The unaffected parents, who had no apparent skeletal abnormalities, were heterozygous for this mutation. In the amplified CDMP1 gene, the mutation creates a BstU1 cleavage site. The expected digestion pattern co-segregated in the heterozygous carriers and the affected individuals of this family. No BstU1 digestion was observed in the amplified CDMP1 genes of 100 control subjects. This mutation is predicted to result in a p.Cys429Arg substitution in the 2nd of the seven cysteines, which are highly conserved among various members of the transforming growth factor beta (TGF-beta) super family. It is possible that the replacement of Cys429 with an arginine has caused incorrect disulphide bond formations among the remaining six cysteines, resulting in an altered structure/activity of the mutant CDMP1 protein. It is likely that this has manifested in the children as Grebe-type chondrodysplasia with additional abnormalities that are unique to these patients.

Linkage disequilibrium mapping of a susceptibility gene for Kawasaki disease. *Y. Onouchi[1], T. Gunji[1,2], J.C. Burns[3], C. Shimizu[3], J.W. Newburger[4], T. Kawasaki[5], Y. Nakamura[6], A. Hata[1,7]* 1) Lab. Gastrointestinal Diseases, SNP Research Center, RIKEN, Yokohama, Japan; 2) Dept. Hard Tissue Engineering, Graduate School, Tokyo Medical and Dental Univ., Tokyo, Japan; 3) Dept. Pediatrics, Univ. California San Diego, School of Medicine, La Jolla, CA; 4) Dept. Cardiology, Boston Childrens Hospital, Boston, MA; 5) Japan Kawasaki Disease Research Center, Tokyo, Japan; 6) Lab. Molecular Medicine, Human Genome Center, Institute of Medical Science, the Univ. of Tokyo, Tokyo, Japan; 7) Dept. Public Health, Graduate School of Medicine, Chiba Univ., Chiba, Japan.

Kawasaki disease (KD) is an acute systemic vasculitis syndrome of infants and young children. Although its etiology is largely unknown, genetic factors are considered to play a significant role in the pathogenesis of KD. Our previously performed sib pair linkage study identified signals of linkage in 10 chromosomal regions (MLS 1.14 - 2.69). In one region, we identified a SNP significantly associated with KD by linkage disequilibrium (LD) mapping (637 KD v. s. 1034 control; OR=1.89, 95%CI 1.53-2.33, P=2.2x10^{-9} in dominant model). Association with KD was replicated in 209 U.S. KD patients (T:U=64:30, OR=2.13, 95%CI 1.38-3.29, P=0.00045 by TDT). Furthermore the SNP was associated with formation of coronary artery lesions (OR=2.05, 95%CI 1.37-3.08, P=0.00044 in Japanese, OR=3.36, 95%CI 1.72-6.59, P=0.00018 in the U.S.) and with resistance to intravenous gamma globulin therapy (OR=4.67, 95% CI 1.34-16.24, P=0.0076 in the U.S.). The SNP was located in intron 1 of gene X and in vitro analysis using minigene revealed that the susceptibility allele of the SNP reduces splicing efficiency. Allele specific transcript quantification analysis showed a consistent result that the amount of the transcripts in PBMCs from the susceptibility allele was less than that of non-susceptibility allele of the gene. Interestingly, knockdown and over-expression of the gene enhances and represses the IL-2 production in stimulated Jurkat cells. The gene can be considered as a negative regulator of T-cell activation and the SNP might play a role in immune hyper-reactivity in KD by suppressing the regulating mechanism.

Maple Syrup Urine Disease: Mutation analysis in Filipino patients using the COPPER plate system. *C.L.T Silao[1], H. Samejima[2], C. Torii[2], C. Padilla[1], K. Kosaki[2], M. Matsuo[3]* 1) Institute of Human Genetics, National Institutes of Health Philippines and Department of Pediatrics, University of the Philippines-Philippine General Hospital, Manila, Philippines; 2) Division of Medical Genetics, Department of Pediatrics, Keio University School of Medicine, Tokyo, Japan; 3) Department of Pediatrics, Kobe University Graduate School of Medicine, Kobe, Japan.

Maple Syrup Urine Disease (MSUD) is a recessive metabolic disorder caused by defective function of the branched chain -ketoacid dehydrogenase complex (BCKD). Mutation analysis of the dihydrolipoyl transacylase (E2), the alpha and beta subunits of the branched chain -ketoacid decarboxylase (E1, E1) genes of the BCKD complex was done in 33 Filipino patients. A highly sensitive and specific mutation scanning method, called the COPPER (Condition-Oriented-PCR-primer-Embedded-Reactor) plate system, to analyze the entire coding regions of the E1, E1 and the E2 genes was used. The coding regions were amplified using 31 primer pairs, all with the same cycling conditions, and aliquoted on a 96-well format polymerase chain reaction (PCR) plate. This method allowed simultaneous amplification of all coding regions of the 3 genes using a single block in a thermal cycler. Using this method, 7 novel mutations were identified - 2 missense mutations (G132S, M348K) in the E2 gene, 1 missense mutation (S339L) in the E1 gene and 2 nonsense mutations (Q157X, Q190X) in the E1 gene. We were also able to identify an A to G nucleotide substitution changing the start codon ATG to GTG in the E1 gene. Another novel deletion involving nt 788-790 (TCT) was identified in exon 6 of the E1 gene. These findings show that the COPPER plate system is an ideal tool for mutation analysis.

Delineation of star syndrome (syndactyly, telecanthus, anogenital, and renal anomalies). *S. Unger[1,2], D. Böhm[3], W. Borozdin[1,3], B. Steiner[4], T. Schmitt Mechelke[5], K. Borowski[6], K. Keppler-Noreuil[6], G. Mortier[7], R. Sandford[8], B. Zabel[1,2], A. Superti-Furga[2], J. Kohlhase[3]* 1) Inst Human Genetics, Univ Freiburg, Freiburg, Germany; 2) Centre for Pediatrics and Adolescent Medicine,Univ Freiburg, Freiburg, Germany; 3) Center for Human Genetics Freiburg, Freiburg, Germany; 4) Institute for Medical Genetics, University of Zürich, Zürich, Switzerland; 5) Division of Neuropaediatrics, Children's Hospital Lucerne, Switzerland; 6) Division of Medical Genetics, University of Iowa, Iowa City, Iowa, USA; 7) Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium; 8) Department of Medical Genetics, University of Cambridge, Cambridge, UK.

In 1996, Green et al. reported a mother and daughter with toe syndactyly and anogenital and renal malformations. Here we report four unrelated children with an identical constellation of malformations and an update on the original family. All four new cases came to attention because of anal atresia and pronounced lateral cutaneous syndactyly of the feet. Renal/urinary tract anomalies and abnormalities of the external genitalia were also present in every patient. Minor heart malformations (ASD and pulmonary artery stenosis), reproductive organ malformations (duplication of the vagina and/or uterus), and craniosynostosis were seen in some. All had strikingly similar dysmorphic features including telecanthus and lop ears. Chromosome analysis was normal in all. *SALL1* and *SALL4* were analyzed for mutations and deletions as mutations in these genes have been associated with anal atresia in Townes-Brocks and Okihiro syndromes, respectively, but no mutations were found. Also, as the children had fifth finger clinodactyly, the *MYCN* gene was analyzed to exclude Feingold syndrome and no mutations/ deletions were found. We hypothesize that this pattern of anomalies represents a distinct, possibly dominant syndrome and this was confirmed by detection of deleterious de novo mutations in a novel candidate gene in all four cases as well as detection of a mutation in the same gene in the patients reported by Green. The clinical and the molecular data (currently in preparation for submission) will be presented.

Skull defects, alopecia, and distinctive facies; a new syndrome? *A. Kariminejad[1], B. Bozorgmehr[1], M.R. Ashrafi[2], M.H. Karimi-Nejad[1]* 1) Clinical Genetics, Kariminejad-Najmabadi Pathology & Genetics Center, Tehran, Iran; 2) Markaz Tebi Hospital, Tehran, Iran.

We describe the first and only child of first cousin parents with skull defect, alopecia, sparse eyebrows and eyelashes, hypertelorism, epicanthal folds, wide and flat nasal bridge, notched and hypoplastic alae nasi, short palpebral fissure, and high forehead. Skin appears normal except for very sparse body hair. On examination of the skull, fontanels are wide and skull ossification defect on the frontoparietal region can be detected. Three dimensional maxillofacial and skull MRI revealed large calvarial defect in parietal region. A round smaller defect is noted in the parieto-occipital suture. Superior sagittal suture is widely patent. The association of alopecia and ossification defects of skull has previously been reported by Pinherio et al. (1983). They reported four sisters from a sibship of thirteen with hypotrichosis, enamel hypoplasia, dystrophic nails, supernumerary nipples, pigmented nevi and bony deficiency in the fronto-parietal region. Hyperkeratosis on the palms and mild xeroderma on the limbs was also present. Our patient does not have the enamel hypoplasia, dystrophic nails, supernumerary nipples, pigmented nevi, hyperkeratosis or xeroderma, and has dysmorphic features absent in the reported cases. The association of skull defect and alopecia and dysmorphic features has not previously been reported. We suggest that the association of these features may characterize a new autosomal recessive syndrome.

A latitude dependent positive selection of the polymorphisms of p53 codon 72 and mdm2 SNP309 in Eastern Asian populations. *B. Su[1], H. Shi[1], S. Tan[2], H. Zhong[4], C.J. Xiao[2], Y. Peng[1], X.B. Qi[1], W. Shou[2], R.L. Ma[4], Y. Li[5], X. Lu[1,3]* 1) Kunming Institute of Zoology and Kunming Primate Research Center, Chinese Academy of Sciences, Kunming, Yunnan, China; 2) Human Genetics Center, Yunnan University, Kunming, Yunnan,China; 3) Ludwig Institute for Cancer Research, Oxford Branch, Oxford University, UK; 4) Institute of Genetics and Developmental Biology, Chinese Academy of Sciences, Beijing, China; 5) Qujing Normal College, Qujing, Yunnan, China.

The tumour suppressor p53 is one of the most important tumour suppressors, and mdm2 is the major inhibitor of p53 by acting through an autoregulation loop. Two of the human specific polymorphisms, p53 codon 72 and mdm2 SNP309 respectively, could influence the activities of p53 and mdm2. We screened 4,029 samples from 67 populations across eastern Asia, and we observed a tight link between p53Arg72 frequency and latitude ($r = 0.64$, $p<0.01$, two-tailed t test). Further analysis on ultraviolet radiation also indicated a strong correlation between UV strength and mdm2SNP309 polymorphism. This pattern suggests that the two genetic variations have recently been undergone positive selection in human populations due to the sensitivity of p53 and mdm2 to environmental stress. The data reported here is informative to a better understanding of cancer epidemiology in human populations.

Type 2 diabetes whole genome association study in four populations: the DiaGen Consortium. *J.T. Salonen[1], P. Uimari[1], J.-M. Aalto[1], M. Pirskanen[1], B. Todorova[1], T.-P. Tuomainen[2], J. Luedemann[3], M. Nauck[3], W. Kerner[4], R.H. Stephens[5], J.M. Gibson[5], B. Ollier[5], N. Pendleton[5], W. Mahoney[6], D. Meyre[7], J. Delplanque[7], P. Froguel[7], O. Luzzatto[8], B. Yakir[8], A. Darvasi[8]* 1) Oy Jurilab Ltd, Kuopio, Finland; 2) University of Kuopio, Kuopio, Finland; 3) Ernst Moritz Arndt University of Greifswald, Greifswald, Germany; 4) Center of Cardiology and Diabetes, Karlsburg, Germany; 5) University of Manchester, Salford and Manchester, UK; 6) Nanogen Inc, San Diego, CA; 7) Institut Pasteur de Lille, Lille, France; 8) The Hebrew University of Jerusalem, Jerusalem, Israel.

Type 2 diabetes (T2D) is a common, polygenic chronic heritable disease. DiaGen is a whole-genome association (WGA) study in 500 familial cases and 497 age- and gender-matched controls from two founder (East Finns, Ashkenazi Jews) and two heterogeneous (Germans, English) populations. The Illumina HumanHap300 tagging array was used with mean call rate of 99.5%. Statistical inferences for single SNPs were based on stratified analysis across populations using the Cochrane-Mantel-Haenszel statistic. Correction for multiple testing was based on 10,000 permutations. Only one SNP in the TCF7L2 gene reached the corrected statistical significance. Intragenic SNPs close to genome-wide significance were in AHI1 and LOC441171. The SNPs rs1535435 and rs9494266 are located within LD block of 178 kb with AHI1 gene and LOC441171 on 6q23.3. The association of these SNPs with T2D was retested and confirmed in 2573 cases and 2776 controls from France (odds ratio 2.52 for homozygote, 95% confidence interval 1.43 to 4.47, p=0.001 for rs1535435 and 2.25, 1.33 to 3.79, p=0.002 for rs9494266), confirming AHI1 as a novel T2D susceptibility gene. The replication of the TCF7L2 finding provides strong evidence for the robustness of the WGA study approach at least for the identification of genes with allelic odds ration greater than 1.7. The identification of genes affecting common diseases such as T2D may provide novel insights as to the biology of the diseases and hence serve as the basis for efficient treatments and better diagnostic tools such as disease predisposition, molecular subtyping and pharmacognenetic tests.

An On-line Database System for Knock-down Analysis of KAO-NASHI Genes. *A. Shimizu[1], S. Asakawa[1], T. Sasaki[1], N. Shimizu[2]* 1) Dept Molecular Biol, Keio Univ Sch Medicine, Tokyo, Japan; 2) GSP Center, The Leading Institute of Keio University, Tsukuba, Japan.

The human genome project has provided a computer-estimation of 23,000 protein-coding genes in the human genome. However, many of these protein-coding genes are not fully proven for their existence by experimental evidence. In general, proteins with known motifs are readily classified, but substantial numbers of protein have no obvious motifs in their sequences. We designated these genes/proteins without obvious motifs as KAO-NASHI (Face-less) and initiated a project to unveil their face (kao) by comparative genomics and knockdown analysis.

We extracted 1,000 KAO-NASHI genes from human genome sequence by step-wise data filtration with InterPro motif analysis, BLAST homology search and PubMed document search. A small fish medaka (Oryzias latipes) was chosen as an experimental system to knockdown medaka orthologs of human KAO-NASHI genes with morpholino-antisense oligos. As an initial study, we designed antisense oligos to target translation initiation sites of 100 medaka kao-nashi genes. When these antisense oligos were micro-injected into medaka fertilized eggs, their morphogenesis at early developmental stages was occasionally disturbed and morphological changes were observed. Thus, we obtained initial information how these medaka kao-nashi genes are involved in the developmental process of patterning and organ formation. About 60 genes were found to cause morphological defects and these were further classified in terms of developmental sub-stages and expression profiles. Especially, suppression of the three kao-nashi genes resulted in brain vesicle expansion. All these knockdown data were combined with the pictures of knockdown medaka embryo and stored in our original database.

Thus, our approach using medaka will eventually provide functional information on the human KAO-NASHI genes/proteins.

GENOTYPING OF PATIENTS WITH PYRIDOXIN-DEPENDENT EPILEPSY (PDE) BY RT-PCR IN cDNA OF LEUKOCYTES IS DISTURBED BY AN ANTIQUITIN PSEUDOGENE. *E. Paschke[1], K. Paul[1], W. Erwa[3], B. Plecko[1,2]* 1) Department of Pediatrics, Medical University of Graz, Graz, Austria; 2) British Columbia Childrens Hospital , Vancouver, BC, Canada; 3) Institute of Clinical and Chemical Laboratory Diagnosis, Medical Universtiy of Graz, Graz, Austria.

Patients with Pyridoxine Dependent Epilepsy (PDE, MIM# 266100) present with pyridoxine-responsive seizures and elevated concentrations of pipecolic acid as well as alpha-aminoadipinic semialdeyde in urine, plasma and cerebrospinal fluid. PDE is caused by a deficiency of alpha-aminoadipinic semialdehyd-dehydrogenase (Antiquitin; ALDH7A1, MIM#107323;), located on chromosome 5q31. At the gene level, a total of 17 pathogenic mutations in 29 patients have recently been described by Mills P al. (Nature Med (2006) 12: 307-309) and Plecko B et al. (Human Mutation (2007) 28:19-26). Among these, we recently detected four heterozygous patients with a new common transversion of G>T at a highly conserved acceptor splice site in intron 17 (c.1482-1G>T) and a novel A>G transition affecting the acceptor splice site in intron 7 (c.612-2A>G). Further characterization of these mutations by RT- PCR revealed homozygous cDNA products containing 39 mismatches to the ALDH7A1 sequence. We subsequently sequenced preparations of 6 RT-PCR products spanning the entire cDNA sequence in leukocytes of normal individuals. We found that only the first amino-terminal fragment of six replicons covering the ALDH7A1 cDNA was 100% identical to the ALDH7A1 gene, while the others contained the exact ALDH7A1 pseudogene (NG_001082) sequence. When, in contrast, analogous replicons were prepared from fibroblasts at an elevated annealing temperature of 64 C, all products were entirely free of pseudogene sequences. These findings are of special importance for the evaluation of presumptive disease-causing effects of novel splice site mutations in the ALDH7A1 gene considering m-RNA structure and protein expression.

The Importance of Genetic Counseling and Multidisciplinary Approach to Rare Disease Report a case of Johanson-Blizzard Syndrome and review of Literature. *B. Bozorgmehr[1], A. Kariminejad[1], M. Zenker[2], M.H. Karimi-Nejad[1]* 1) Clinical Genetics, Kariminejad-Najmabadi Pathology & Genetics Center, Tehran, Iran; 2) Institute of Human Genetics, Erlangen, Germany.

Proband is an eleven month old Iranian girl, third offspring of first cousin parents. Their first and second child died in the neonatal period without any diagnosis. The proband revealed growth and developmental delay, short statures, microcephaly, hypoplastic alae nasi, scar of repaired scalp defect, upsweeped hair, hypothyroidism, deafness and malabsorption, consistent with Johanson-Bilizzard syndrome. She was admitted to hospital several times without any conclusive diagnosis. DNA samples of the proband and parents were sent to institute of Human Genetics, Dr. Zenker for molecular analysis of the UBR1 gene. A homozygous sequence alteration in intron 26 was detected in proband. She was homozygous for some known SNPS dispersed over the UBR1 gene. Heterozygous carrier state was detected in her parents.

Relic Distribution of Y-Chromosome Haplogroup D Suggests Ancient Paleolithic Migration of Modern Humans in Eastern Asia. *H. Shi[1], H. Zhong[2], Y. Peng[1], Y.L. Dong[3], X.B. Qi[1], F. Zhang[4], L.F. Liu[5], S.J. Tan[3], R.L. Ma[2], C.J. Xiao[3], L. Jin[4], B. Su[1]* 1) Kunming Institute of Zoology and Kunming Primate Research Centre, Chinese Academy of Sciences, Kunming, PR China; 2) Institute of Genetics and Developmental Biology, Chinese Academy of Sciences, Beijing, PR China; 3) Human Genetics Centre, Yunnan University, Kunming, PR China; 4) State Key Laboratory of Genetic Engineering and Center for Anthropological Studies, School of Life Sciences, Fudan University, Shanghai, PR China; 5) Huaihua Medical College, Huaihua, Hunan, PR China.

The Y chromosome haplogroup D is East Asian specific and prevalent in Tibetan and Japanese populations (30%-40%), but rare in other East Asian populations (<5%). We analyzed 5,174 Y chromosomes from 74 East Asian populations by typing haplogroup D related SNPs and eight Y chromosome microsatellite loci. We identified six sublineages under haplogroup D, and their distribution across East Asia suggested an ancient Paleolithic south-to-north migration, which likely predates the previously proposed northward diaspora of modern humans (reflected by the dominant occurrence of O3-M122 in East Asians) resulting in current relic distribution of haplogroup D in East Asia.

***KCNJ11* 23E, not 23K, correlates with an increased risk of obesity and metabolic syndrome in Japanese.** *H. Morisaki[1], E. Mizuta[1], I. Yamanaka[1], Y. Miyamoto[2], Y. Kokubo[3], Y. Yoshimasa[2], T. Morisaki[1]* 1) Dept Bioscience, NCVC Research Inst, Suita, Osaka, Japan; 2) Dept Internal Med, NCVC Hosp, Suita, Osaka, Japan; 3) Div Cardiovascular Preventive Med, NCVC, Suita, Osaka, Japan.

KCNJ11 encodes an ATP-sensitive inward rectifier potassium channel 11 (Kir6.2), a major component of K_{ATP} channel which plays a critical role in regulation of glucose-induced insulin secretion in pancreatic beta cells. The E23K polymorphism (rs5219) in the *KCNJ11* was repeatedly shown to be associated with type 2 diabetes in Caucasians, suggesting individuals with 23K allele are prone to type 2 diabetes (T2D), while several studies in other populations including Japanese failed to reproduce the result. We examined the association of *KCNJ11* E23K with several clinical parameters, including body mass index (BMI), blood pressure, serum lipid levels, HbA1c, fasting blood glucose (FBS) and serum insulin levels in a large population-based Japanese cohort (the Suita Study, n=3637). We also evaluated the association of E23K with T2D and metabolic syndrome in Japanese. The 23E allele, but not 23K, showed a significant association with greater BMI as well as greater weight gain after age 20. We also confirmed this tendency in another group of Japanese healthy subjects. Also, 23E allele showed a significant association with metabolic syndrome, while no association was observed between E23K and T2D in our study. Interestingly, when stratified with FBS levels, 23K allele showed a significant association with decreased basal insulin secretion only with higher FBS groups, while fasting insulin levels or HOMA-beta showed no significant differences between genotypes as a whole. These results indicate that 23K allele is responsible for decreased insulin secretion in higher FBS circumstances that lead to susceptibility to T2D, while 23E alleles can maintain sufficient insulin secretion resulting in obesity and metabolic syndrome possibly through the anabolic effect of insulin. Our observations not only provide the possible explanation of discordances in previous reports, but also provide the caution that *KCNJ11* 23E allele has an increased risk of metabolic syndrome in Japanese.

Evidence that a high myopia locus maps to chromosome 12q. *C.P. Pang, C.Y. Lam, D.S.P. Fan, P.O.S. Tam, D.S.C. Lam* Ophthalmology & Visual Sci, Chinese Univ Hong Kong, Hong Kong, HKSAR, China.

High myopia is defined as refractive error -6.00 D. It affects more than 10% adult population in Hong Kong. Heredity is a major contributing factor of high myopia. While no myopia gene is known yet, 14 chromosomal loci were mapped and two candidate genes were suggested. The aim of this study was designed to evaluate the genetic component of Chinese high myopia pedigrees originating from Hong Kong. Whole genome scan was performed on 14 participants from a 3 generations autosomal dominant Hong Kong family by using the ABI MD-10 marker set with an average spacing of 10cM. Regions containing markers that yielded LOD scores > 1.0 were further analyzed by fine mapping in which additional microsatellite markers flanking the particular marker with the highest LOD score. Mutation screening of candidate gene was performed by direct sequencing of the gene. From whole genome scan, two point LOD score > 1 were observed on chromosomes 12. Region was further analyzed by additional microsatellite markers flanking the particular markers. A Maximum two point LOD score of 2.11 was obtained at marker D12S88 and suggested linkage region was narrowed at 12q22.2 by haplotype analysis in one pedigree. Lumican, which is located within this region, was screened and no segregation of polymorphism was observed within the pedigree. The mapped high myopia locus on chromosome 12 in this study overlapped with the reported MYP3 locus but with a smaller interval than the one reported. Lumican was excluded to be a candidate gene of high myopia. The results give evidence that unidentified genes will underlie high myopia in our Hong Kong Chinese pedigrees.

A novel Angiogenin gene mutation in a sporadic patient with Amyotrophic Lateral Sclerosis from Southern Italy.

T. Sprovieri, R. Mazzei, A. Patitucci, C. Ungaro, A. Magariello, L. Citrigno, F. Condino, A.L. Gabriele, M. Muglia, F.L. Conforti Institute of Neurological Sciences, National Research Council, Mangone, Cosenza, Italy.

Amyotrophic Lateral Sclerosis (ALS) is a devastating untreatable neurodegenerative disorder. It is characterized by progressive wasting and weakness of limb, bulbar and respiratory muscles due to degeneration of motoneurons in the spinal cord, brain stem and motor cortex. Disease onset is usually in the fifth or sixth decade of life and, in most affected individuals, progresses to death due to respiratory failure 3-5 years after onset. Genetic analysis of ALS patients has identified mutations in the Cu/Zn superoxide dismutase (SOD1) gene in approximately 33% of familial cases (FALS) and 2.5% of apparently sporadic cases (SALS). Mutations in the SOD1 gene account for such a small proportion of familial cases of ALS that a concerted effort has been made to identify other disease-causing genes. Mutations in the Angiogenin gene (ANG), linked to 14q11.2 have been recently discovered to be associated with Amyotrophic Lateral Sclerosis (ALS) in Irish and Scottish populations. In our study we investigated the role of ANG gene in ALS patients from Southern Italy. We found a novel mutation (M1I) of the ANG gene in a sporadic patient with ALS (SALS). The molecular analysis of the ANG gene also demonstrated an allelic association with the rs11701 single nucleotide polymorphism (SNP) in familial ALS (FALS) but not in SALS patients. Our finding supports the evidence that the ANG gene is involved in ALS.

Rapid detection of Down syndrome & Edward syndrome using FISH in amniocentesis. *K. Lee, S. Lee, D. Cha, J. Park* Ostetrics and gynecology, CHA general hospital, Kangnam-Gu, Seoul, Korea.

PURPOSE : The purpose of this study was to evaluate the clinical utility of rapid detection of down syndrome and Edward syndrome by Interphase Fluolescence in Situ Hybridization (FISH) analysis. METHODS : A retrospective study in 309 cases of amniotic fluid samples, analysed by interphase FISH with DNA probes specific to chromosome 18 and 21, was performed. All FISH results were compared with conventional cytogenetic karyotypings. RESULTS : The results were considered as informative and they were obtained within 48 hours. A case of Down syndrome and a case of Edward syndrome were diagnosed by FISH and confirmed by subsequent cytogenetic analysis. In 12 cases with normal FISH results, the cytogenetic analysis showed a case of partial trisomy 22, three cases of sex chromosomal aneuploidy, two cases of mosaicism, two cases of microdeletion, and four cases of structural rearrangement. CONCLUSION : FISH is a rapid and effective diagnostic method, which can be used as an adjunctive test to cytogenetic analysis, for prenatal idetification of chromosome aneuploidies. For the more genome-wide screening with variety of probes, the technique of FISH is both expensive and labour-intensive.

A Japanese infant with ARC syndrome and tracheobronchomalacia. *H. Yoshihashi[1], K. Takamura[2], T. Yokoyama[2], N. Furuya[1], K. Kurosawa[1], K. Izumi[3], K. Kosaki[3]* 1) Division of Medical Genetics, Kanagawa Childrens, Medical Center, Yokohama, Japan; 2) Division of Neonatology, Tokyo Metropolitan Kiyose Childrens Hospital, Tokyo, Japan; 3) Department of Pediatrics, Keio University School of Medicine, Tokyo, Japan.

Arthrogryposis, renal dysfunction and cholestasis (ARC) syndrome (MIM 208085)is an autosomal recessive multisystem disorder that may be associated with germline VPS33B mutations. Other features variably reported include ichthyosis, mild dysmorphic signs, absent corpus callosum and recurrent infections, worsening nephrogenic diabetes insipidus (Gissen 2006). We describe a Japanese ARC infant with tracheobronchomalacia, which has not been reported. The subject was a girl infant born at term to non-consanguineous parents, with a weight of 2666g (-0.8SD), a length of 46cm (-1.4SD). At birth, there was generalized hypotonia and flexion contractures of the fingers and knees. At 9 days of life, she was evaluated for jaundice (serum TB,12.0mg/dl; DB,8.2mg/dl) and had a persistent cholestasis in infancy. At 3 weeks, she developed renal tubular acidosis with glycosuria, generalized aminoaciduria, hyper-2-microglobulinuria and was diagnosed with Fanconis syndrome. A peripheral lymphocyte karyotype was 46,XX. These findings were highly suggestive of ARC syndrome. Direct sequencing for VPS33B documented heterozygous splice donor site mutation (c.403+2TA : maternal) within intron 6 and 143bp deletion (paternal) including whole sequences of exon12. Since 3 months of age, she has required mechanical ventilation because of progressive dyspnea and was diagnosed as having a tracheobronchomalacia, which had not observed as yet. In summary : As a common complications of ARC syndrome, the tracheobronchomalacia has not yet been reported. Recurrent infections described in most of previous reports may result from that by exclusion of other causes. For the early diagnosis, it would appear reasonable to repeat the urinary analysis if the neonate has arthrogryposis and persistent jaundice. There are only a few reports of ARC syndrome in Japan. Further cases may provide insight into the consideration of clinical information.

Association between high myopia and PAX6 promoter polymorphic region. *C.Y. Lam, P.O.S. Tam, D.S.P. Fan, S.W.Y. Chiang, D.Y. Wang, B.J. Fan, G.H.F. Yam, D.S.C. Lam, C.P. Pang* Ophthalmology & Visual Sci, Chinese University of Hong Kong, HKSAR.

Myopia is the most common eye disorder worldwide and the prevalence in Asia may exceed 65%. High myopia (HM) is defined as refractive error -6.00 D. There is a high and increasing prevalence of HM in Hong Kong. Apart from impaired vision, it is a common cause of severe complications of macular diseases and retina detachment. A myopia locus was reported on chromosome 11p13 and the PAX6 gene located at that region was postulated to be associated with myopia development. This study aims to investigate the association of the PAX6 gene with HM in a Hong Kong Chinese cohort. The promoter, coding sequences and adjacent splice-site regions of the PAX6 gene were screened in 191 unrelated HM patients with refractive error -6.00D or below and 161 unrelated control subjects by direct sequencing after PCR. Three sequence changes were identified. R81R (678A>G) was found in one HM patient and S412S (1617C>T) was found in one control subject. Another polymorphism in the non-coding region, IVS10-12C>T, occurred in both patients and control subjects with $P > 0.05$. Twenty polymorphisms were identified in the promoter region but none of them showed association with HM ($P>0.05$). Two dinucleotide repeats (AC)m and (AG)n in the promoter region were found to be highly polymorphic. Association was observed between these two repeats with HM in which HM patients had high repeat number in both (AC)m and (AG)n (p-value=0.0001317 and p-value=0.001). Our results indicated that the Chinese population does not show association between HM and polymorphisms in PAX6 coding region but the AC and AG dinucleotide repeats in the promoter region was significantly associated with HM. These two repeats in the promoter region may affect the transcription activity of PAX6 and therefore contribute to myopia. We are conducting functional analysis of the PAX6 promoter polymorphic variants to confirm investigate the effect of the length variations of these repeats in transcriptions.

First Evidence of a Pathogenic Insertion in the NOTCH3 Gene Causing CADASIL. *C. Ungaro[1], F.L. Conforti[1], D. Guidetti[2], M. Muglia[1], G. Cenacchi[3], P.L. Lanza[1], A. Patitucci[1], T. Sprovieri[1], A. Magariello[1], A.L. Gabriele[1], L. Citrigno[1], R. Mazzei[1]* 1) Institute of Neurological Sciences, National Research Council, Piano Lago di Mangone, Cosenza; 2) UOC di Neurologia, Ospedale Guglielmo da Saliceto di Piacenza; 3) Department of Radiological and Istocytopathological Sciences, Section of Pathology, University of Bologna.

CADASIL is an autosomal dominant disorder leading to cognitive decline and dementia. Mutations in the NOTCH3 gene are responsible. These highly stereotyped mutations are located within the 22 exons, encoding for the 34(EGF)-like repeats of the extracellular domain of the Notch3 receptor, all mutations resulting either in a gain or loss of a cysteine residue. Therefore it has been suggested that the unpaired cysteine residues, generated by these mutations may cause aberrant interaction of the Notch3 receptor with its ligands. In the present study we examined the NOTCH3 gene exons in a subject with clinical and radiological findings consistent with CADASIL having distinctive GOM deposits in her skin biopsy. The proband underwent MRI investigation of the brain that revealed a severe diffuse leukoencephalopathy and multiple lacunar lesions. The proband was analyzed for mutations in the NOTCH3 gene using the DHPLC analysis and direct sequence. The examination was extended to the probands family: an affected mother and an unaffected sister. DHPLC analysis revealed a variant profile in exon 3 of both proband and her mother. Sequencing of the exon 3 showed a 3bp insertion (nt 357ins TGC) in the second EGF-like repeat, resulting in an insertion of a cysteine residue. This mutation was not observed in 560 control chromosomes. Using both DHPLC analysis and direct sequence, in the subjects carrying the mutation in exon 3 no mutation was found in the other exons containing EGF-like repeats (exons 2-23). The insertion together with the neurological and clinical phenotype suggests it is the pathogenic mutation in our patient. This novel pathogenic mutation represented by the first insertion found in a CADASIL patient, suggests that the change towards an unpaired reactive cysteine residue is a very critical molecular event in CADASIL.

Genomic Investigation of AMD. *P.O.S. Tam[1], T.K. Ng[1], S.W.Y. Chiang[1], L.J. Chen[1,2], W.M. Chan[1], D.T.L. Liu[1], D.S.C. Lam[1], C.P. Pang[1,2]* 1) Department of Ophthalmology and Visual Sciences, The Chinese University of Hong Kong, Hong Kong; 2) SU/CUHK Joint Shantou International Eye Center, Shantou, China.

Purpose: To investigate the association of HTRA1 in the risk of exudative AMD and its interaction effect with smoking and CFH in the development of exudative AMD. Methods: The whole gene of HTRA1 was sequenced by direct sequencing to investigate the existence of genetic variants in HTRA1 contributing to the risk of exudative AMD. A total of 163 exudative AMD and 183 controls were screened in the study. Smoking and a SNP of CFH were used to investigate the gene-environment and gene-gene interaction on exudative AMD, respectively. Results: A total of 45 sequence variants were identified in HTRA1 promoter, exons and exon-intron boundaries. Among which 4 SNPs have violated HWE and were excluded for further association and haplotype analysis. For the remaining 41 SNPs, 15 variants were found only in one AMD case while 6 variants existed in only one control. This leaves 18 SNPs for further association analysis. After Bonferroni correction, four variants still remained significantly associated with exudative AMD. Carriers of two risk alleles were at substantially higher risk (about 4 times higher) to exudative AMD than are carriers with one risk allele. Three haplotype blocks were constructed with the first haplotype block that lies in the promoter and exon one region was significantly associated with exudative AMD (p= 6.68E-14). Results from logistic regression suggested that the joint effects of smoking and specific SNPs were best described by independent multiplicative effects, without significant dominance nor interacting effects. Estimates from this model demonstrated a 15.71 fold increased risk to exudative AMD in homozygote carriers of the HTRA1-risk allele who were ever-smokers. A joint disease odds ratio of 23.3 for individuals with homozygous risk alleles at both loci containing HTRA1 and CFH was observed when compared with the baseline wild-type (non-risk) genotype. Conclusions: The promoter and coding exons of HTRA1 possess SNPs significantly associated with exudative AMD. Smoking and variant at CFH exerted no interaction with HTRA1 to the development of exudative AMD.

Extended pedigree with multiple cases of XX sex reversal in the absence of SRY and of mutation at SOX9 and RSPO1 loci. *S.G. TEMEL[1], T. GULTEN[1], T. YAKUT[1], H. SAGLAM[2], N. KILIC[3], E. BAUSCH[4], W.J. JIN[4], M. LEIPOLDT[4], O. RADI[5], G. CAMERINO[5], G. SCHERER[4]* 1) Medical Genetics Department, Faculty of Medicine,Uludag University, BURSA, Turkey; 2) Pediatric Endocrinology Department, Faculty of Medicine, Uludag University, Bursa, Turkey; 3) Pediatric Surgery Department, Faculty of Medicine, Uludag University, Bursa, Turkey; 4) Institute of Human Genetics and Anthropology, University of Freiburg, Freiburg, Germany; 5) Istituto di Biologia Generale e Genetica Medica, Universita di Pavia, Pavia, Italy.

It is well established that testicular differentiation of the human embryonic gonad depends on the action of the Y-chromosomal gene SRY. However, exceptional cases such as SRY-negative cases of 46,XX testicular disorder of sexual development (DSD) and of 46,XX ovotesticular DSD document that testicular tissue can develop in the absence of the SRY gene. These SRY-negative XX sex reversal cases are very rare and usually sporadic, but a few familial cases have been reported. We present a large, consanguineous family with nine affected individuals with phenotypes ranging from 46,XX testicular DSD to 46,XX ovotesticular DSD, with predominance of male characteristics. Absence of SRY in peripheral blood was documented by fluoresence in situ hybridization (FISH) and PCR analysis in all nine affected individuals, and by FISH analysis on gonadal sections with testicular tissue in four affected individuals. By quantitative PCR, a duplication of the SOX9 gene was excluded. In addition, as linkage analysis showed that the nine affected members of the family do not share a common SOX9 haplotype, any mutation at the SOX9 locus could be ruled out. Also, no mutation was found within the RSPO1 gene, recently found to be mutated in familial XX sex reversal. Together, these findings implicate a mutation at a sex-determining locus other than SRY, SOX9 and RSPO1 as the cause for the XX sex reversal trait in this family.

***BRCA1* c.5074+3AG (IVS17+3AG) is a clinically relevant splice site mutation.** *A.H. van der Hout, I.M. Mulder, M.J. Berends, R.H. Sijmons, Y.J. Vos* Dept Genetics, University Medical Centre Groningen, Groningen, Netherlands.

During screening of the *BRCA1* and *BRCA2* genes in patients at risk for hereditary breast/ovarian cancer syndrome, numerous germline variants with unknown clinical relevance are encountered. Some of these are intronic variants, other than at the invariant GU at the 5 site of the intron or the AG at the 3 site, of which the effect on pre-mRNA splicing cannot be predicted from genomic sequence alone. We found a variant c.5074+3A>G (affecting the third nucleotide of intron 17) in *BRCA1* in index patients from three different Dutch families with several cases of breast- and ovarian cancer, that were seen in our family cancer clinic. Haplotype analysis showed that these families most likely share a common ancestor. To establish the clinical relevance of this variant we studied its effect on *BRCA1* pre-mRNA splicing. One of three on-line splice site prediction programmes predicted this mutation to abolish the splice donor of exon 17. We cultured fibroblasts from a skin biopsy from one of the carriers of the variant. Shortly before harvesting we added to half of the culture cycloheximide to inhibit Nonsense Mediated mRNA Decay. RNA was isolated and RT-PCR performed, using primers in exon 15 and exon 19. In the cycloheximide treated sample we detected an additional band, which was not present in the untreated sample or in controls. Sequence analysis showed skipping of exon 17. Analysis of a polymorphic site in exon 16 showed that one allele solely produces the wild type transcript, while the other allele solely produced the transcript without exon 17. We conclude that c.5074+3A>G disturbs the proper splicing of the *BRCA1* pre-mRNA, leading to skipping of exon 17, and therefore is a clinically relevant mutation.

Coinheritance of a novel deletion of the entire SPINK1 gene with a CFTR missense mutation (L997F) in a family with chronic pancreatitis. *E. Masson[1, 2], C. Le Maréchal[1, 2, 3, 4], P. Lévy[5], N. Chuzhanova[6], P. Ruszniewski[5], D. Cooper[7], J. Chen[1, 3], C. Férec[1, 2, 3, 4]* 1) INSERM U613, BREST, France; 2) Faculté de Médecine de Brest et des Sciences de la Santé, Université de Bretagne Occidentale,Brest, France; 3) Etablissement Français du Sang - Bretagne,Brest, France; 4) Laboratoire de Génétique Moléculaire et dHistocompatibilité, Centre Hospitalier Universitaire de Brest, Hôpital Morvan, Brest, France; 5) Pôle des Maladies de l'Appareil Digestif, Service de Gastroentérologie-Pancréatologie, AP-HP, Hôpital Beaujon, Clichy, France; 6) Department of Biological Sciences, University of Central Lancashire, Preston PR1 2HE, United Kingdom; 7) Institute of Medical Genetics, Cardiff University, Heath Park, Cardiff, CF14 4XN, United Kingdom.

Quantitative fluorescent multiplex PCR (QFM-PCR) was established in order to make possible the rapid and efficient analysis of the pancreatic secretory trypsin inhibitor (SPINK1) gene. Using QFM-PCR, a novel deletion encompassing the entire SPINK1 gene was identified in one of nine newly recruited French Caucasian families with chronic pancreatitis. The breakpoints were fully characterized and the ~30 kb deletion was termed c.1-15969_c.240+7702del30588bp. Whilst sequences with the potential to form non-B DNA structures were found to span both the 5 and 3 deletion breakpoints, the generation of this gross deletion is potentially explicable in terms of non-homologous end-joining facilitated by the presence of a 1-bp microhomology at the two ends. The SPINK1 gene deletion identified in the index patient was also detected in her affected father and paternal uncle but not in 50 healthy French Caucasians. Remarkably, in all three affected individuals, the SPINK1 deletion was found to occur in trans with a p.L997F missense mutation in the unlinked CFTR gene, a lesion which has been previously reported to be associated with a variety of cystic fibrosis-related diseases including idiopathic pancreatitis. Given that the SPINK1 deletion constitutes a clear-cut disease-causing factor, it may be that the CFTR missense mutation acts as a disease modifier in the context of this particular family.

A series of 60 rhombencephalosynapsis cases and CGH array results lead to new phenotype and genotype considerations. *L. Pasquier[1,2], C. Bendavid[2], P. Loget[3], C. Dubourg[2], S. Jaillard[2,4], C. Henry[4], J. Lucas[4], J. Lespinasse[5], C. de la Rochebrochard[1], P. Marcorelles[6], F. Pelluard[7], D. Carles[7], M. Ferry[8], C. Fallet-Bianco[9], S. Odent[1], A. Laquerrière[10], V. David[2]* 1) Dept Clinical Genetics, Rennes Univ Hosp, Rennes, France; 2) Molecular genetics unit and UMR 6061 CNRS, IFR 140 GFAS, Rennes Univ Hosp, France; 3) Pathology laboratory, Le Mans Hosp, France; 4) Cytogenetics unit, Rennes Univ Hosp, France; 5) Cytogenetics unit, Chambéry, France; 6) Pathology laboratory, Brest Univ Hosp, France; 7) Pathology laboratory, Bordeaux Univ Hosp, France; 8) Radiology unit, Rennes Univ Hosp, France; 9) Pathology laboratory, Saint-Anne Hosp, Paris, France; 10) Pathology laboratory, Rouen Univ Hosp, France.

Rhombencephalosynapsis (RES) is a rare cerebellar malformation described by vermian agenesis, fusion of the hemispheres and dentate nuclei. RES is usually described as an isolated malformation which developmental and cognitive impairment are fuzzy. Except for 2 cases with chromosomal anomalies, genetic background is currently unknown. We initiated a database of RES cases throughout France to review the phenotype carefully including familial, clinical, radiological and pathological patterns. To date, 55 foetuses and 5 children were included and recurrences lead us to suggest phenotypical entities: 1- isolated, 2- syndromic with VACTER association, 3- syndromic with other cerebral malformations as Neural Tube Defect (NTD) or Holoprosencephaly (HPE), 4- others syndromic conditions (Gomez-Lopez-Hernandez syndrome was suspected once only). All children have motor delay and cognitive impairment, one with hypopituitarism and another with cataracts and polysyndactyly. Pathological review of cases confirmed rhombencephalosynapsis, isolated or associated with other cerebral lesions responsible for hydrocephalus. When DNA samples were available, CGH array technology was carried out leading to the discovery of 3 de novo microrearrangments. 2 cases of familial recurrences and 2 cases of consanguinity support the idea of a great genetic heterogeneity.

Extended meta-analysis of genome-wide linkage studies in Schizophrenia. *M.Y.M. Ng[1], C.M. Lewis[1], D.F. Levison[2], Schizophrenia Meta - Analysis Consortium* 1) Medical and Molecular Genetics, King's College London, London, UK; 2) Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Palo Alto, CA, USA.

Introduction: We previously reported that a Genome Search Meta-Analysis (GSMA) of schizophrenia linkage scans provided evidence for linkage in 10 chromosomal regions. We performed an updated analysis to incorporate multiple new studies.

Method: Results (LOD, NPL scores or p-values) were obtained from investigators for 31 genome-wide linkage scans: 16 from the previous analysis (including 6 with new genotyping, some with expanded samples) and 15 new scans, totaling 3,215 pedigrees with 7,212 genotyped schizophrenia or schizoaffective cases, compared with 1,208 and 2,945 previously. GSMA is a non-parametric method which ranks the strongest evidence for linkage from chromosomal regions (bins) of equal width (Rutgers map), and sums ranks across studies to assess evidence for linkage. A primary analysis (all families and 30 cM bins) was compared with results for the subset of 22 scans of European-ancestry samples and for bin widths of 20 and 40 cM.

Results: Aggregate significance criteria identified the regions most likely to contain linked loci, including a region of chromosome 2q identified previously (but now extending across a broader region), and regions of chromosomes 8p (30-90 cM), 5q (150-210 cM), 1p (120-150 cM), 16p (30-60 cM) and 4q (120-150 cM). Much stronger evidence for linkage was identified in this analysis on chromosome 8p, particularly in European-ancestry samples. Further studies of empirical significance thresholds are in progress.

Discussions: Linkage regions supported by meta-analysis may contain schizophrenia susceptibility loci, which could include common SNPs, copy number variants and/or multiple rare variants. Intensive studies are warranted to identify these loci.

Multiplex SNP typing method: DigiTag2. *N. Nishida[1], T. Tanabe[2], M. Takasu[1], A. Suyama[3], K. Tokunaga[1]* 1) Dept Human Genetics, Univ Tokyo, Tokyo, Japan; 2) Bio Business Division, Olympus Corporation, Tokyo, Japan; 3) Dept Life Sciences, Univ Tokyo, Tokyo, Japan.

DigiTag2 assay performs multiplex SNP typing by encoding all of the SNP genotypes to the well-designed oligonucleotides, named DNA coded numbers (DCNs). The assignment of the DCNs to the target SNPs is unconstrained, therefore, the DNA chips prepared to read out the types of DCNs are universally available for any types of SNPs. And, the DigiTag2 assay uses non-labeled primers and probes, which lead to save the cost of the assay. We investigated the feasibility of the DigiTag2 assay by genotyping 96 SNPs, located in the 610 kb genomic region including IL-4 and IL-13 genes, using 936 individual genomic DNA samples. The conversion rate, which is defined by the proportion of successfully genotyped SNPs in the total number of SNPs examined, was revealed to be over 90%, and the typing result was 100% identical to the result from direct sequencing. To verify the applicability of DigiTag2 assay, we genotyped 19 SNPs that were miss-genotyped by the other SNP typing method. Sixteen of 19 SNPs were revealed to be successfully genotyped by the DigiTag2 assay. We estimated the running cost for the DigiTag2 assay (for oligonucleotides, reagents, DNA microarrays, etc.) is less than $0.06/genotype. The DigiTag2 assay can use the same set of DCNs for any set of target SNPs, thereby enabling 96-pelx genotyping with the same assay protocols and the same DNA chip having the same set of probes. We expect that the DigiTag2 assay will be used for high-resolution mapping of primary genes after genome-wide search for disease susceptibility regions.

Application of HR-CGH and Chromosomal Microarray Analysis (CMA) in the cohort of 117 patients with mental retardation. *B. Nowakowska[1,2], E. Bocian[1], P. Stankiewicz[1,2], M. Smyk[1], E. Obersztyn[1], Z. Ou[2], J. Li[2], K. Borg[1], S.W. Cheung[2], T. Mazurczak[1]* 1) Dept. of Medical Genetics, Institute of Mother and Child, Warsaw, Poland; 2) Dept. of Molecular & Human Genetics, Baylor College of Medicine, Houston TX, USA.

Advances in molecular cytogenetics enable detection of small chromosomal aberrations, undetectable by routine chromosome banding, in 5-20% of patients with mental retardation (MR). The aim of this study was to compare two genome-wide screening techniques, HR-CGH and targeted array CGH, termed Chromosomal Microarray Analysis (CMA). In contrast to conventional CGH, HR-CGH enables genome-wide screening for DNA copy-number changes with a 3-5 Mb resolution. CMA version 5.0 developed at Baylor College of Medicine (853 BAC/PAC clones) enables detection of DNA copy-number changes in more than 60 chromosomal regions of known diagnostic significance and in all subtelomeric regions in a single test. In this study, we analyzed 117 patients with unexplained MR and other features suggestive of chromosomal abnormality, with apparently normal or balanced karyotypes using HR-CGH (44 patients) and/or CMA (92 patients). HR-CGH detected seven interstitial deletions and one interstitial duplication (18,2%), among which two deletions, 16p11.2p12.2 and 8q21.11q21.2 were previously described in the literature only once and a 2q23 duplication is demonstrated herein for the first time. CMA revealed 20,7% (19/92) abnormalities, among which 11 (11.8%) were clinically relevant, 6 (6.5%) cases were interpreted as polymorphic variants and two (2.1%) were of uncertain significance. HR-CGH and CMA findings varied in size from 0.5 Mb to 12.9 Mb and were all validated by FISH. In summary, our results show that HR-CGH and array CGH techniques have high detection rates of genomic imbalances in the tested groups. Both methods have become important components in cytogenetic diagnostics, particularly for detecting cryptic constitutional chromosome imbalances in patients with MR, in whom the underlying genetic defect is unknown.

Analysis of WDR36 gene on Finnish glaucoma families. *S. Lemmela[1], E. Forsman[2], H. Nurmi[1], A. Eriksson[2], H. Forsius[2], I. Järvelä[1]* 1) Department of Medical Genetics, University of Helsinki, Helsinki, Finland; 2) Population Genetics Unit, Folkhälsan Institute of Genetics, Helsinki, Finland.

Primary open angle glaucoma (POAG) is a heterogeneous group of disorders that have in common a characteristic optic neuropathy with associated visual field loss. Despite many positive linkage studies only three predisposing genes for POAG have been identified. The most recently identified susceptibility gene, *WD40-repeat 36 gene* (WDR36), is located on 5q22.1 at locus GLC1G. In the original study overall 24 sequence variations were identified in WDR36; four *predicted disease causing mutations*, three *potential disease susceptibility mutations*, five amino acid polymorphisms and 12 intronic-polymorphisms. Since the original report controversial results have been reported concerning WDR36 as a susceptibility gene for POAG. The aim of the current study was to analyse the role of WDR36 in Finnish patients by sequencing all 23 exons and flanking splice sites of the WDR36-gene in 21 Finnish POAG and 8 XFG (exfoliation glaucoma) and one XFS (exfoliation syndrome) patients. Two non-synonymous (D658G, I264V), two synonymous (V714V, V727V) and one intronic (IVS530C>T) sequence alterations were identified. All of these variations have been reported previously. Heterozygous D658G alteration was found in 1/21 POAG patients. This variation, originally defined as a *predicted disease causing mutation*, was not present in 100 Finnish anonymous blood donors as controls. Neutral variant I264V was identified in 12/21 POAG and 3/8 XFG subjects. Heterozygous synonymous polymorphism V714V alteration was found in 5/21 POAG patients and 1/8 XFG subject. Sequence polymorphism V727V was detected in 12/21 POAG patients and 3/8 XFG subject and intronic change IVS530C>T was detected in 16/21 POAG patients and 6/8 XFG subjects. Non-synonymous common variant I264V, synonymous alterations and intronic variation has been reported as neutral polymorphisms, whereas contradictory results of D658G mutations role in pathogenesis of POAG have been represented. Our results do not support the crucial role of the WDR36 gene in POAG pathogenesis in Finnish patients but suggests genetic heterogeneity underlying POAG.

Population structure in Sweden - A Y-chromosomal and mitochondrial DNA analysis. *T. Lappalainen[1], U. Hannelius[2], E. Salmela[1,6], C.M. Lindgren[3], K. Huoponen[4], M.-L. Savontaus[4], J. Kere[2,5,6], P. Lahermo[1]* 1) Finnish Genome Center, Institute for Molecular Mecidine Finland, University of Helsinki, Helsinki, Finland; 2) Department of Biosciences and Nutrition, Karolinska Institutet, Huddinge, Sweden; 3) Wellcome Trust Centre for Human Genetics, Oxford University, Oxford, UK; 4) Department of Medical Genetics, University of Turku, Turku, Finland; 5) Clinical Research Centre, Karolinska University Hospital, Stockholm, Sweden; 6) Department of Medical Genetics, University of Helsinki, Helsinki, Finland.

A population sample representing the current Swedish population was analyzed for both maternally and paternally inherited markers with the aim of characterizing the genetic variation and structure of a modern North European population. We genotyped 12 Y-chromosomal and 27 mitochondrial DNA SNPs from DNA extracted and amplified from Guthrie cards of all the children born in Sweden during one week in 2003. The sample set consisted of 1914 samples (960 males) grouped according to place of birth. The ancient migration patterns are reflected in the clear north-south gradients in several palaeolithic and neolithic haplogroups in the mtDNA (U5, I, K, T, X) and the Y chromosome (R1b, N3). The haplogroup frequencies of the counties closest to Finland and Norway showed clear associations to the neighboring populations, resulting from the formation of the nations during the past millennium. Moreover, the recent immigration waves of the 20th century are visible both maternally and paternally, and have led to increased diversity and divergence from the main population in the major cities. Unfavorable population development in the ancient or recent past can be detected in several remote counties with low diversities and other signs of low population size and/or population crises. In conclusion, our study yielded valuable information about the various factors affecting the structure of the modern Swedish population that is vital for the use of the population in large population-based studies. Our sampling strategy, nonselective on the current population rather than stratified according to ancestry, represents the future of genetic studies in the increasingly panmictic populations of the world.

Mutation screening and asscoiation study of the *FMR1* gene in Thai boys with autism. *P. Limprasert[1], C. Maharat[1], N. Ruangdaraganon[2], T. Hansakunachai[3], R. Sothanayongkul[2], T. Somboontham[2], T. Sripo[1], W. Maisrikhaw[1], V. Praphanpol[4]* 1) Prince of Songkla University, Hat Yai, Songkhla, Thailand; 2) Ramathibodi Hospital, Bangkok, Thailand; 3) Thammasat University, Pathumthani, Thailand; 4) Rajanukul Institute, Bangkok, Thailand.

Autism is a common neurodevelopmental disorder characterized by impairments in communication and social interactions, and repetitive and stereotypic behaviors. The presence of a genetic contribution to autism has been indicated by sibling and twin studies. Fragile X syndrome (FXS) is one of the most common single gene defects associated with autism. Some patients diagnosed as having autism or PDD-NOS have had FXS with expanded CGG repeats in the *FMR1* gene. Normally, FXS patients show some autistic behaviors and may be difficult to distinguish at a young age from autistic children. In an attempt to elucidate these connections, we screened 108 unrelated boys with autism or PDD-NOS, age < 15 years, using FXS PCR screening and EcoRI/EagI southern blot with StB12.3 probe. One patient was confirmed to have FXS, giving a frequency of FXS in autism of ~1% in our study. We also analyzed SNP haplotypes (WEX5-ATL1-rs25702) of the *FMR1* gene using biallelic ARMS-PCR in 77 autistic and 30 PDD-NOS patients, comparing them to 126 normal control males. The three major haplotypes in the combined cases and controls respectively were G-G-A (55% vs 59%), C-A-G (22% vs 22%) and C-G-A (13% vs 12%). No statistically significant differences between cases and controls were found for these haplotypes using the chi-square test ($P > 0.05$). When we analyzed the autistic or PDD-NOS subgroups, the frequencies of major haplotypes were still similar in both groups and not significantly different compared to the controls. To summarize, we did not find any association between SNP-haplotypes of the *FMR1* gene and Thai males with autism and/or PDD-NOS.

Clinical and molecular-cytogenetic studies in a family with features of Jacobsen syndrome caused by an ~5 Mb deletion del(11)(q24.3). *J. Pietrzak[1], K. Szczaluba[1], E. Bocian[1], M.M. Sasiadek[2], I. Makowska[2], P. Stankiewicz[1], R. Smigiel[2]* 1) Dept of Medical Genetics , Institute of Mother and Child, Warsaw, Poland; 2) Dept of Genetics, Wroclaw Medical University , Wroclaw, Poland.

To date, over 100 cases with terminal deletion of 11q have been described and the resulting Jacobsen syndrome (JBS; MIM147791) has been well characterized. Clinical expression in JBS depends on the deletion size that varied between ~7-15 Mb. Typical features include developmental delay/mental retardation, short stature, congenital heart defects, thrombocytopenia, and a characteristic facial dysmorphism. In most JBS cases, *de novo* deletions have been found. In the remainder, the monosomy was the result of a product of a balanced chromosome translocation present in one of the parents. We present a family, in which a 4-year-old girl, her mother and mothers brother have features of JBS, including square asymmetric face, broad forehead, epicanthal folds, thick eyebrows, short nose with long philtrum, down-turned corners of the mouth and low-set posteriorly rotated ears. In addition, the proband has psychomotor and speech delay while her uncle is mentally retarded and has psychiatric disturbances such as dementia, oligophrenic symptoms, and psychoorganic delusions. Notably, neither thrombocytopenia nor congenital defects were detected in this family. The initial G-banding analyses in this family were normal. Using FISH, we have identified a deletion of the terminal part of chromosome 11q in all three family members. The breakpoint was subsequently mapped to 11q24.3 between BAC clones RP11-507F16 and RP11-678L3, thus defining the deletion size ~ 5 Mb. This is the smallest terminal deletion associated with features of JBS. Interestingly, the *ETS* (*v-ets erythroblastosis virus E26 oncogene*) and *FLI1* (*friend leukemia virus integration 1*) hematopoiesis factor genes located ~6.5 Mb from 11qter and usually deleted in patients with JBS, are intact. We propose that one of these genes can be responsible for thrombocytopenia in JBS.

Bioaminergic deficits in Rett syndrome : from pathophysiology to clinical trials. *L. Villard*[1], *E. Dura*[1], *J. Mancini*[2], *A. Moncla*[1,3], *J.C. Roux*[1] 1) Inserm U491, Faculte de Medecine de La Timone, Marseille, France; 2) Dpt of Pediatric Neurology, La Timone Children's Hospital, Marseille, France; 3) Dpt of Medical Genetics, La Timone Children's Hospital, Marseille, France.

Rett Syndrome (RS) is a severe neurological disorder with an incidence of about 1/10,000 female births. It is caused by mutations in the *MeCP2* (methyl-CpG binding protein 2) gene located on the X chromosome. The MeCP2 protein is believed to play a pivotal role in silencing other genes. RS girls exhibit a number of neurodevelopmental defects associated to autonomic dysfunctions. Because a significant proportion of deaths in RS may be caused by sudden respiratory arythmia, we have investigated breathing dysfunction in *Mecp2*-deficient mice. We have shown that adult *Mecp2*-deficient mice have erratic breathing with highly variable respiratory rhythm and frequent apneas probably due to reduced norepinephrine content and a drastic decrease in the number of tyrosine-hydroxylase (TH) expressing neurons in the medulla. We subsequently developed a pharmacological protocol to treat *Mecp2*-deficient animals when they start to manifest breathing problems. We have shown that treating these mice with a norepinephrine reuptake inhibitor (desipramine) significantly improves their respiratory rhythm during several weeks. This treatment significantly extends the lifespan of the treated animals up to twice the lifespan of untreated animals. We recently identified a cellular mechanism to explain this efficiency, mainly characterized by an increase of the number of TH-expressing neurons in the medulla. These results suggest that pharmacological stimulation of the noradrenergic system could be useful in RS. We are currently starting a phase II clinical trial with RS patients in France using desipramine.

Prediction of the linked regions and exclusion probabilitiesRequirement on family sizes in linkage analyses. *W.L. Yang[1], Z.Y. Wang[2], L.S. Wang[2], P. Huang[3], Y-L. Lau[1]* 1) Dept Paediatrics and Adol Med, LKS Faculty of Medicine, University of Hong Kong, Pokfulam, Hong Kong; 2) Dept Computer Sci, City University of Hong Kong, Hong Kong; 3) Dept Biostat, Bioinfor, and Epidemiol, Medical University of SC, Charleston, SC.

Transition of genotyping methods from the use of sparse microsatellite markers to the use of high-density SNPs in linkage analyses allows accurate determination of crossover points and allele sharing status among individuals in families. This facilitates extraction of full inheritance information and making full use of family members available. For well-defined inheritance models, linkage analyses based on single families of intermediate size is feasible because of the development in genotyping technology, and necessary since large families or multiple families with homogeneous genetic causes of unknown mutations become very rare. In this study, we developed an algorithm that can predict the fractions of genomic regions that can be excluded by linkage studies based on family structure and size. Software was also developed to allow evaluation of family sizes in linkage analyses based on crossover simulations and determination of allele sharing status among family members. The program can determine, given a certain family structure and size, inheritance model and penetrance: 1). the probability that a chromosome can be excluded from consideration and 2). size distribution of the regions not being excluded when the chromosome does not contain the mutation; 3). size distribution of the true region with the causal mutation that can be determined in that family based on a number of simulations. It provides a reliable prediction tool to help determine the sufficiency of a family for a linkage analysis, or portion of the genome that can be excluded from consideration when the size of a family is too small for a complete linkage analysis. The latter is important for identifying the mutation responsible for a given family for diseases of known causes but of enormous genetic heterogeneity, and also for mutation identification of a candidate gene approach, in narrowing the list of candidates need to be screened.

The Autochthonous Origin and a Tribal Link of Indian Brahmins: Evaluation Through Molecular Genetic Markers. *S. Sharma[1,2], E. Rai[1,2], S. Singh[1,2], P.R. Sharma[1,3], A.K. Bhat[1], K. Darvishi[1], A.J.S. Bhanwer[2], P.K. Tiwari[3], R.N.K. Bamezai[1]* 1) NCAHG, SLS, JNU, New delhi; 2) Department of Human Genetics, GNDU, Amritsar; 3) Centre for Genomics, SOS zoology, JU,Gwalior.

The co-existence and associated genetic evidences for the major rival models: i) recent Central Asian introduction of Indian caste system, ii) rank related west Eurasian admixture, iii) South Asian origin for Indian caste communities, and iv) late Pleistocene heritage of tribal and caste populations, leave the question of the origin of caste system in India hazy and obscure. To resolve the issue, we screened 621 Y-chromosomes (of Brahmins, occupying upper most caste position and Dalits and Tribals with the lower most positions in the Indian caste hierarchical system) with fifty-five Y-chromosomal binary markers and Y-microsatellite markers and compiled a data set of 2809 Y-chromosomes (681 Brahmins, 2128 Tribals and Dalits) for conclusions. Overall, no consistent difference was observed in Y-haplogroups distribution between Brahmins, Dalits and Tribals, except for some differences confined to a given geographical region. A peculiar observation of highest frequency (upto 72.22%) of Y-haplogroups R1a1* in Brahmins, hinted at its presence as a founder lineage for this caste group. The widespread distribution and high frequency across Eurasia and Central Asia of R1a1* as well as scanty representation of its ancestral (R*, R1* and R1a*) and derived lineages across the region has kept the origin of this haplogroup unresolved. The analyses of a pooled dataset of 530 Indians, 224 Pakistanis and 276 Central Asians and Eurasians, bearing R1a1* haplogroup resolved the controversy of origin of R1a1*. The conclusion was drawn on the basis of: i) presence of this haplogroup in many of the tribal populations such as, Saharia (present study) and Chenchu tribe in high frequency, ii) the highest ever reported presence of R1a* (ancestral haplogroup of R1a1*) in Kashmiri Pandits (Brahmins) and Saharia tribe, and iii) associated averaged phylogenetic ages of R1a* (~18,478 years) and R1a1* (~13,768 years) in India. The study supported the autochthonous origin of R1a1 lineage and a tribal link to Indian Brahmins.

Mitochondrial haplogroup H1 is protective for stroke. *A. Rosa[1], B.V. Fonseca[1], T. Krug[1], H. Manso[1,2], I. Albergaria[2], G. Gaspar[2], M. Correia[3], M.V. Baptista[4], R. Silva[5], J.R. Fontes[6], G. Lopes[3], J.P. Gabriel[7], I. Matos[8], R. Taipa[3], M.R. Silva[7], L. Gouveia[9], J.M. Ferro[9], A.M. Vicente[1,2], S.A. Oliveira[1]* 1) Instituto Gulbenkian de Ciência, Portugal; 2) Instituto Nacional de Saúde Dr. Ricardo Jorge, Portugal; 3) H. Geral de Santo António, Portugal; 4) H. Garcia de Orta, Portugal; 5) H. Fernando Fonseca, Portugal; 6) H. São Marcos, Portugal; 7) H. de São Pedro, Portugal; 8) H. Distrital de Mirandela, Portugal; 9) H. de Santa Maria, Portugal.

Several neurological disorders have been associated with mutations/polymorphisms in mitochondrial DNA (mtDNA), which alter gene expression and ultimately compromise mitochondrial function. The best-known example is that of MELAS syndrome, characterized by stroke-like episodes, where the A3243G transition causes a respiratory chain deficiency through a generalized effect on protein synthesis. In addition, the mtDNA phylogenetic background was also shown to influence the expression of particular diseases (e.g. Parkinsons disease, LHON disease, and occipital stroke in migraine). In order to evaluate the role of the mitochondrial genome in stroke susceptibility, we tested the allelic and haplogroup association of 27 polymorphisms (tagging SNPs or SNPs defining European haplogroups) in 515 stroke patients and 476 controls, all Caucasians and of Portuguese nationality and ancestry. Haplogroup H1 was found to be significantly less frequent in stroke patients than in controls (OR=0.56, 95% CI=0.41-0.77, p=0.001), when comparing each clade against all other haplogroups pooled together. Conversely, the pre-HV/HV and U mtDNA lineages emerge as potential genetic factors conferring risk for stroke (OR=2.74, 95% CI=1.21-6.16, p=0.013 and OR=3.22, 95% CI=1.18-8.79, p=0.018, respectively). SNPs G3010A and C7028T strongly influence the risk, their allelic state in haplogroup H1 corroborating for its protective effect. Although the functional dynamics are not yet clear, these mtDNA substitutions most likely interact with the predisposing allele(s), either mitochondrial or nuclear, increasing the expression of the primary variant or predisposing the origin and fixation of the pathogenic alleles.

Association study of neuroprotection genes erythropoietin, heme-oxigenase 2, and kallikrein 1 with stroke. *S. Violante[1], T. Krug[1], H. Manso[1,2], B.V. Fonseca[1], L. Gouveia[3], I. Albergaria[2], G. Gaspar[2], R. Taipa[4], M.R. Silva[5], M. Correia[4], M.V. Baptista[6], A. Pinto[7], R. Silva[7], G. Lopes[4], J.P. Gabriel[5], I. Matos[8], J.M. Ferro[3], A.M. Vicente[1,2], S.A. Oliveira[1]* 1) Instituto Gulbenkian de Ciência, Portugal; 2) Instituto Nacional de Saúde Dr. Ricardo Jorge, Portugal; 3) H. Santa Maria, Portugal; 4) H. Geral de Santo António, Portugal; 5) H. São Pedro, Portugal; 6) H. Garcia de Orta, Portugal; 7) H. Fernando Fonseca, Portugal; 8) H. Distrital de Mirandela, Portugal.

Recent animal studies of cerebral ischemia, hypoxia and oxidative stress allowed the identification of several neuroprotective molecules, but most of the genes encoding for these proteins or hormones have not been tested as risk markers for stroke. In this study, we tested the association of erythropoietin (EPO), heme-oxigenase2 (HO2), and kallikrein1 (KLK1) genes with stroke in a Portuguese population. EPO, a critical cytokine in hematopoiesis, has been localized in the CNS where its upregulation by the presence of hypoxia has been observed after ischemia, protecting neurons by inhibiting their apoptosis. HO2 is believed to be an important endogenous neuroprotective agent against oxidative stress in the brain. It is constitutively expressed, but its activity can be modulated by phosphorylation. The KLK1 gene encodes a serine protease that catalyzes the release of vasoactive peptides and may be involved in hypertension and cardiovascular diseases. KLK1 gene seems to provide neuroprotection against cerebral ischemia injury by enhancing glial cell survival and migration and inhibiting apoptosis through suppression of oxidative stress and activation of signaling pathways. We genotyped 3, 3, and 5 tagging SNPs in the genes and flanking regions in EPO (2.9 kb), HO2 (33.9 kb) and KLK1 (4.6 kb), respectively, on 533 stroke patients (82% ischemic strokes) and 507 unrelated controls. We found weak evidence of association (OR=0.82, 95% CI=0.67-0.99, p=0.04) with stroke risk for SNP rs7702, located 0.5 kb downstream of HO2. Other allele or haplotype association tests did not reveal any significant findings, suggesting that these neuroprotection genes are not important risk factors for stroke.

Williams-Beuren syndrome with cardiomyopathy and cerebellar hypoplasia; proposing a severe infantile form.

N. Okamoto[1], T. Yamagata[1], S. Nakamura[1], K. Ichihashi[1], Y. yada[1], N. Takahashi[1], H. Shiraishi[1], M.Y. Momoi[1], N. Matsumoto[2], T. Mizuguchi[2] 1) Pediatrics, Jichi Medical University, Shimotsuke, Tochigi, Japan; 2) Dept Hum Genet, Yokohama City Univ Grad Med, Yokohama, Japan.

Williams-Beuren syndrome (WBS) is caused by hemizygous deletion of chromosome 7q11.23. The phenotype of WBS consists of characteristic elfin face, cardiovascular anomaly, growth deficiency and mental retardation. Supravalvular aortic stenosis is specific to WBS and other cardiac anomalies are also reported. We report a patient with WS who had atypical and severe manifestations. Case report: A Japanese boy was born at 35 weeks of gestation by caesarean section. His facial appearance showed blepharophimosis, broad and depressed nasal bridge, anteverted nares, full cheeks, long philtrum, prominent lower lips and micrognathia. He also presented with typical features of WS such as redundant soft skin, hypoplastic right foot nails, contracture of hip and knee joints, right inguinal hernia and hoarse voice. As cardiac anomalies, he had aortic hypoplasia, localized narrowing of the descending aorta, small VSD, ASD and PDA. Additionally he showed hypertrophic cardiomyopathy that induced left ventricular outflow obstruction, and severe mitral insufficiency. As CNS abnormalities, he showed congenital hydrocephalus, cerebellar and brain stem hypoplasia and sensory deafness. He showed intractable tonic convulsions since three months of age. Hypothyroidism was also noted. He died at 1 year and 5 months of age for progressive cardiomyopathy. His serum transferrin isoelectric focusing pattern was normal and Congenital Disorder of Glycosylation syndrome was excluded. Microarray CGH containing 4200 BACs revealed a unique abnormality, approximate 1.0-Mb deletion in 7q11.23, ranging from RP11-614D7 (72,182,285-72,371,583) to RP11-137E8 (73,389,371-73,574,238). Discussion: The deletion detected in this patient was typical as WBS. However, some of his major marformations, such as central nervous system dysplasia, deafness, hypertrophic cardiomyopathy and hypothyroidism, were atypical as WBS. WBS should include such severe infantile form.

The DNA damage signalling kinase ATM is aberrantly reduced or lost in BRCA1/BRCA2-deficient and ER/PR/HER2-triple-negative breast cancer. *J. Tommiska[1], J. Bartkova[2], M. Heinonen[3], L. Hautala[1], O. Kilpivaara[1], H. Eerola[1,5], K. Aittomaki[4], J. Lukas[2], C. Blomqvist[5], A. Ristimaki[3], P. Heikkila[3], J. Bartek[2], H. Nevanlinna[1]* 1) Dept Obst & Gyn, Helsinki University Central Hospital (HUCH), Finland; 2) Inst Cancer Biology and Centre for Genotoxic Stress Research, Danish Cancer Society, Copenhagen, Denmark; 3) Dept Pathology, HUCH, Finland; 4) Dept Clinical Genetics, HUCH, Finland; 5) Dept Oncology, HUCH, Finland.

The ATM (Ataxia Telangiectasia-Mutated) kinase is a key transducer of DNA damage signals within the genome integrity network, and a tumor suppressor whose germline mutations predispose to familial breast cancer. Recently, the ATM-regulated signalling cascade was found constitutively activated in early stages of diverse types of human malignancies and cell culture models in response to oncogene-induced DNA damage, and proposed to provide a barrier against tumor progression. As BRCA1 and BRCA2 are also components of the genome maintenance network and their mutations predispose to breast cancer, we have examined the ATM expression in series of human breast carcinomas of BRCA1/2 mutation carriers, sporadic cases and familial nonBRCA1/2 patients. Our immunohistochemical results show that ATM protein expression is aberrantly reduced or lost more frequently among BRCA1 and BRCA2 tumors (in 33.3% and 30.0%, respectively) than in nonBRCA1/2 tumors (10.7%) ($p=0.0003$ and $p=0.0009$, respectively). Furthermore, the nonBRCA1/2 tumors with reduced ATM expression were more often estrogen receptor (ER) negative ($p=0.0002$), progesterone receptor (PR) negative ($p=0.004$), and of higher grade ($p=0.0004$). In our series of 1013 nonBRCA1/2 cases, ATM was more commonly deficient among the difficult-to-treat ER/PR/HER2-triple-negative subset of tumors compared with cases which expressed at least one of these markers ($p=0.0006$). Overall, our results support the participation of ATM, BRCA1 and BRCA2 in a DNA damage-induced anti-cancer barrier and suggest higher demand for the tumor suppressor function of ATM (and consequently higher rate of its inactivation) during development of the more genetically unstable BRCA1/2 and triple-negative breast carcinomas.

Elevated Serum LDH-3 Level in sputum positive TB patients of Sahariya tribe of Central, India: A possible diagnostic marker for TB. *P.R. Sharma[1], S. Jain[2], P.K. Tiwari[1]* 1) Centre for Genomics SOS ZOOLOGY, Jiwaji University, Gwalior, Madhya Pradesh, India; 2) RNTCP unit, Sheopur District Hospital, Sheopur, M. P., India.

Indian populations are culturally stratified as tribals and non-tribals. Madhya Pradesh (Central India) is a home to large numbers of tribal groups. Sahariya tribe is one of the major primitive tribal groups confined mainly to North Madhya Pradesh. Unfortunately, the incidence of tuberculosis is very high in this tribal group. Lactate Dehydrogenase (LDH) is a tetrameric enzyme of pathophysiological importance in disease diagnosis. It has five isoforms each representative of individual tissue type. The present investigation was to find out if sputum test, which is generally performed to assess mycobacterial infection status, is in anyway correlated with one or more of the LDH isoforms level to employ it for diagnostic purpose. We conducted a case control study in 200 cases (Pulmonary tuberculosis patients) and 180 controls from the tribe to estimate the levels of various Lactate dehydrogenase isoforms in serum. The sputum (twice) and blood sample were collected after well informed & written consent of donors. The Ziehl-Neelsens staining of sputum smear was carried out as per RNTCP (Revised National Tuberculosis Control Programme), WHO protocol. Each sputum slide was categorized into sputum one, two and three positive, according to the numbers of bacilli seen per oil immersion field. Total serum LDH level was estimated spectrophotometrically. The levels of individual isoforms were assessed on 6% native PAGE and quantitated using Uvitek gel-documentation system. The LDH content was found significantly ($p< 0.0001$) elevated in blood sera of sputum positive, especially in three positive individuals (444 270 IU) as compared to sputum negative samples (242 125 IU). Of the all LDH isoforms (LDH1, 2, 3, 4 and 5) LDH-3 was found to be highly elevated in sputum positive samples as compared to sputum negative samples. The statistical comparisons between sputum negative and sputum positive groups were made using Wilcoxon rank-sum test and Mann-Whitneys U test. $P < 0.01$ was considered statistically significant. Since, LDH-3 represents leakage from lung tissue in human body, its significant elevation in sera of sputum three positive TB patients suggests its possible use in diagnosing pulmonary tuberculosis along with standard sputum test. This combination of test is recommended because a pulmonary tuberculosis patient becomes sputum negative in one month after the start of TB chemotherapy, while serum LDH-3 levels are still found elevated (ongoing investgation) and may take more time to come down to its normal level in serum.

Testing for association between Alzheimer's disease with psychosis and variations in candidate genes for psychosis. *R. Sims[1], P. Hollingworth[1], A. Morgan[1], V. Moskvina[2], S. Lovestone[3], C. Brayne[4], D. Rubinsztein[4], M. O'Donovan[1], M. Owen[1], J. Williams[1,2], R. Abraham[1]* 1) Department of Psychological Medicine, Cardiff University, Wales College of Medicine, Cardiff, United Kingdom; 2) Biostatistics and Bioinformatics Unit, Cardiff University, Wales College of Medicine, Cardiff, United Kingdom; 3) Institute of Psychiatry, King's College, London, United Kingdom; 4) University of Cambridge, United Kingdom.

As Alzheimers disease (AD) progresses many sufferers experience additional behavioural and psychological symptoms such as psychosis. Psychotic symptoms are reported to affect 30-60% of individuals with AD and are associated with more rapid cognitive and functional decline, more severe cognitive impairment, premature institutionalization, and increased risks for agitated and aggressive behaviour. Evidence suggests that AD with psychosis shows greater familiality and evidence of linkage to specific chromosomal regions. As at least one of these overlaps with regions of linkage to psychotic disorders schizophrenia and bipolar affective disorder (BPAD), we set out to identify genes increasing risk of psychotic symptoms across diseases. Variants from nine genes (DAOA, GRM3, OLIG2, CNP, BDNF, DISC1, GRIK2, COMT, and DTNBP1) which show some evidence of influencing risk in psychotic disorders were individually genotyped in a sample of 1205 Caucasian cases of late onset AD (NINCDS-ADRDA criteria) and 1361 aged matched controls from the UK. Preliminary results show evidence for a psychosis susceptibility gene which modifies psychotic symptoms in Alzheimers disease (allelic p = 0.0061; OR = 1.37, 95% CI; 1.0895 OR 1.7276).

Association Study of Diacylglycerol Kinase Eta (DGKH) Gene with Bipolar Disorder Patients in Japanese Population and Biological Function Analysis of DGKH Isoform 2 Val1201Ala Polymorphism. *A. Takata, H. Kawasaki, H. Mitsuyasu, Y. Kobayashi, L. Gotoh, N. Oribe, S. Kanba* Dept Neuropsychiatry, Kyushu Univ, Fukuoka, Japan.

Bipolar disorder (BD) is a common, severe, chronic, and life-threatening illness where patients alternate between episodes of depression and mania. Detailed pathophysiology of BD is still unclear, but family, twin and adoption studies consistently indicate a strong genetic component. Therefore, a number of genetic studies of BD have been conducted and recent genome-wide association study of BD revealed several candidate genes those influence disease risk. Among such genes, diacylglycerol kinase eta (DGKH), a member of diacylglycerol kinase (DGK) gene family, showed strong association statistically. In addition, DGK plays an important role in the lithium-sensitive phosphatidyl inositol pathway and DGKH is located within the bipolar disorder linkage region on chromosome 13q14.Thus, in order to elucidate the pathophysiological mechanisms of BD, it should be a good approach to examine detailed function of DGKH. In this study, we carried out association study with several polymorphisms selected from exons and exon/intron boundaries of DGKH between BD patients matched to DSM-IV criteria and healthy controls in Japanese population. We focused on a single nucleotide polymorphism (SNP) in exon 30 of DGKH. DGKH has two splicing variants (DGKH1 and DGKH2) those manifest gene expressions and biochemical features in different manners respectively and above described SNP causes nonsynonymous amino acid substitution (valine to alanine) only in DGKH2. Therefore, cell biological experiments of this amino acid change of DGKH2 are now in progress. In this study, we show detailed results of genetic association study and cell-biological experiments. All subjects were given informed consent before blood collection strictly based on the ethical regulations of Kyushu University.

Association study between 5HTTLPR polymorphisms of the serotonin transporter *(SLC6A4)* gene and Thai patients with autism. *W. Suwannarat[1], N. Ruangdaraganon[2], T. Hansakunachai[3], R. Sothanayongkul[2], T. Somboontham[2], T. Sripo[1], W. Maisrikhaw[1], V. Praphanpoj[4], P. Limprasert[1]* 1) Department of Pathology, Faculty of Medicine, Prince of Songkla University, Hat Yai, Songkhla 90110, Thailand; 2) Department of Pediatrics, Ramathibodi Hospital, Faculty of Medicine, Mahidol University, Bangkok, 10400, Thailand; 3) Department of Pediatrics, Faculty of Medicine, Thammasat University, Pathumthani, 10120, Thailand; 4) Rajanukul Institute, Bangkok, 10400, Thailand.

Autism is a form of pervasive developmental disorder (PDD) manifested by qualitative impairment in social interactions, language and communication, and restricted interest and repetitive behaviors. Although a large genetic contribution is strongly suspected in autism, the specific underlying genetic variants remain unidentified. Hyperserotoninemia has been reported in some autistic patients, and several studies have demonstrated an association between 5HTTLPR polymorphisms in the serotonin transporter gene *(SLC6A4)* and autism, indicating a possible involvement of the serotonin system in the etiology of autism. To explore this situation further, we did a case-control association study between 5HTTLPR polymorphisms and Thai autistic patients. One-hundred-and-twenty patients fulfilling the DSM-IV criteria for autistic disorder (87 individuals) or PDD-NOS (33 individuals) were recruited from two university hospitals in Bangkok. One hundred and fifty-two normal controls were collected from the same ethnic backgrounds. 5HTTLPR polymorphisms were genotyped and named as long (L) or short (S) alleles. Genotypes were compared between patients and normal controls using chi-square statistics. The L/L genotype was more common in patients than in controls (13.3% vs 3.9%, P = 0.0188). When we analyzed either male patients alone (106 individuals) or only patients with autism (87 individuals), the associations were still statistically significant with P = 0.0076 and P = 0.0199, respectively. Our findings support previous reports suggesting an association between the 5HTTLPR polymorphism of *SLC6A4* and patients with autism.

Evidence and characterisation of a colorectal cancer susceptibility locus on chromosome 3q22 from a high-density SNP genome-wide linkage scan. *E. Papaemmanuil[1], Z. Kemp[2], E. Webb[1], L. Carvajal-Carmona[2], W. Wood[1], E. Barclay[2], M. Gorman[2], I. Tomlinson[2], R. Houlston[1]* 1) Molecular population genetics, The Institute of Cancer Research, Sutton, Surrey, United Kingdom; 2) Molecular and Population Genetics, London Research Institute, Cancer Research UK, London, United Kingdom.

Germline mutations in *APC*, DNA mis-match repair genes, *MutYH, SMAD4, ALK3* and *STK11* contribute to inherited susceptibility to colorectal cancer (CRC). Colorectal tumor families which show evidence against linkage to known loci and from kindreds who fulfil the clinical (Amsterdam) criteria for Hereditary non polyposis colorectal cancer (HNPCC) but whose CRCs do not show microsatellite instability (MSI), provide evidence for the existence of uncharacterized high/moderate-penetrance CRC genes. Such observations strongly support the continued search for novel CRC predisposition genes through genome-wide linkage searches.

To identify novel colorectal cancer susceptibility genes through linkage analyses we have been analyzing CRC families that segregate microsatellite stable (MSS) cancers in which involvement of known susceptibility genes has been excluded. Our analysis is being based on the use of high-density SNP arrays that provide maximal power to detect linkage and allow the incorporation of genotyping information from additional families when they become available. Based on the analysis of 69 families we have shown evidence for a new susceptibility locus on chromosome 3q22. To clarify the impact of this locus on CRC susceptibility we have analyzed an additional series of 32 families. Data on a combined analysis will be presented.

Genotype, clinical presentation, neuropsychological profile, and brain pathology in 5 families with primary microcephaly due to ASPM/MCPH5 mutations. *A. Verloes[1,8], L. Titomanlio[2], F. Guimiot[3], A. Afenjar[4], L. Burglen[4], T. Billette deVillemeur[5], J-F. Gadisseux[1], S. Odent[6], A. Megarbane[7], B. Gerard[1]* 1) Genetics dept; 2) Child neurology dept; 3) Fetal pathology dept, Robert Debre Hospital, Paris, France; 4) Genetics dept,; 5) Child neurology dept, Trousseau Hospital, Paris, France; 6) Genetics dept, Rennes University, Rennes, France; 7) Genetics dept, Saint Joseph University, Beirut, Lebanon; 8) INSERM U676, Robert DEBRE hospital, Paris.

Human recessive primary microcephalies (MCPH) count at least six loci (MCPH1-6). MCPH5, caused by the ASPM gene(1q31) gene mutations is the most commonly involved. We report new mutations in 5 families with MCPH5. In family 1, the proband was born with an OFC of 32 cm. At age 4, OFC is -5SD and height is at -1SD. The boy shows mild MR. A further pregnancy was terminated. Neuropathology showed a small brain (biometry of 27-28 GW for 33 GW) with a simplified gyral pattern for age, decreased neuronal population and premature depletion of the germinal zone. In family 2, 2 brothers were affected with different severity. The eldest one, aged 25, had an OFC < -8SD. His IQ was 55, with homogeneous scores and preserved memory functions. The youngest, aged 10, has an OFC at -5SD. His IQ was 70 with normal memory functioning but weaknesses in executive functions. In family 3, 2 brothers aged 17 and 19 had microcephaly (-4 SD) with simplified gyral pattern, and mild to moderate MR. One of the sibs had seizures at age 14. In family 4, the affected girl was born with an OFC of 30cm. At age 12, OFC was at -7SD and associated with hypotelorism. Clinical and neuropsy details on the last family (with several affected patients) are currently gathered, and will be presented. Systematic sequencing of the whole coding sequence of ASPM demonstrated compound heterozygocyty or homozygocyty for non-sense mutations in the 5 families. Our patients illustrate inter- and intrafamilial variability of ASPM mutants, confirm surprisingly good preservation of cognition despite major reduction in brain size in some of them, and confirm the absence of specific histological anomalies of brain in ASPM-related MCPH.

The possible role of UCP2 -866 G/A polymorphism in Type 2 Diabetes in two population groups of North India.

E. Rai[1,2], S. Sharma[1,2], A. Koul[1], A.K. Bhat[1], A.J.S. Bhanwer[2], R.N.K. Bamezai[1] 1) NCAHG, SLS, Jawaharlal Nehru University, New Delhi, India; 2) Department of Human Genetics, Guru Nanak Dev University, Amritsar, India.

A common UCP2 promoter -866G/A polymorphism (rs659366) is suggested as an important link between obesity, beta cell dysfunction and type 2 diabetes mellitus (T2DM). Indians show low BMI but higher central obesity and more insulin-resistance than Europeans.

We have explored the association of UCP2 -866G/A polymorphism with the development of T2DM in 868 T2DM patients and 930 healthy controls belonging to two diverse population groups of North India (Punjab and Kashmir) in a replicate study. Further, we explored mtDNA 10398 G/A polymorphism proposed to be involved in ROS modulation, independently as well as in interaction with UCP2 -866G/A polymorphism. The UCP2 -866G/A polymorphism showed a significant association with T2DM in Population 1 and 2. The population risk attributable (PAR) to the UCP2 -866 GG genotype was approximately 15% for Population 1 and 20% for Population 2. Interestingly, independently mtDNA 10398 A allele was observed to be significantly associated with increased risk of T2DM (Bhat et al. 2007) in Population 1 and Population 2. And, the PAR (population attributable risk) for UCP2 -866 GG genotype increased to approximately 23% in Population 1 and 34% in Population 2 in mtDNA 10398A background, which was higher than the risk provided independently by UCP2 -866 GG genotype. Further, in interaction analyses between mitochondrial 10398 A background and genotype status (XA versus GG) of UCP2 gene, subjects carrying UCP2 -866 XA genotype were at reduced risk to develop T2DM which was not the case in mtDNA 10398 G background. The effect of UCP2 -866 XA genotype towards a reduced risk for T2DM could be explained by its role in protection from mitochondrial ROS production and pancreatic beta cell apoptosis.

Reference: Hum Genet; 120(6): 821-6.

A complex insertion event produced a chimeric dystrophin-IL1RAPL1 transcript in the dystrophin gene. *Z. Zhang, Y. Takeshima, M. Yagi, A. Nishiyama, Y. Okizuka, H. Awano, M. Matsuo* Dept Pediatrics, Kobe Univ, Kobe, Japan.

Duplications of one or more exons in the dystrophin gene located at Xp21.3-p21.2 are the second common mutation in Duchenne and Becker muscular dystrophies (DMD and BMD) and have been considered as a simple insertion of genomic region. Here, we report a DMD case with a complex duplication in the dystrophin gene, creating a chimeric dystrophin-IL1RAPL1 transcript. Multiplex ligation dependent probe amplification (MLPA) analysis revealed the duplication of exons 56-62 of the dystrophin gene. However, the analysis of the dystrophin mRNA of the patient by RT-PCR resulted in the identification of an unexpected 621-nucleotide insertion between the repetition of duplicated exons. The inserted 621bp nucleotide sequence was found to be homologous to exons 3-5 of the IL1RAPL1 gene in Xp22.1-Xp21.3. Though duplication of these exons was confirmed in his genome, nomal IL1RAPL1 mRNA was also obtained. These results indicated double insertions of IL1RAPL1 exons and dystrophin exons between exons 62 and 63 of the dystrophin gene. This is the first report of the complicated duplication in the dystrophin gene and provides a clue to understand the mutational mechanism of insertion event.

A Review and Meta-analysis of Homozygosity Mapping Publications from 1987-2006. *T. Roscioli*[1,2], *C.G. Bell*[1], *M.F. Buckley*[1], *R. Lindeman*[1] 1) Department of Haematology and Genetics, Prince of Wales and Sydney Children's Hospitals, Sydney, NSW, Australia; 2) Sydney South West Integrated Genetics Service, Royal Prince Alfred Hospital.

Homozygosity mapping, the process by which pathogenic gene mutations are inferred based on the presence of excess homozygosity at linked marker loci, was suggested formally as a gene identification technique by Lander and Botstein in 1987. It has resulted in the identification of the genetic aetiology of many autosomal recessive disorders. There has however been no systematic review of the success of this technique. We report the results of a systematic review of 179 papers reporting 619 families published between 1987 and 2006 employing this technique. Based on this, we discuss the size of families reported, the most efficient mapping density, the properties of candidate regions and the success of gene identification in the published literature to guide future studies.

Identification of the G1363S mutation of the lactase gene (LCT) in two siblings of Turkish origin. *S. Torniainen[1], C. Gijsbers[2], M. Potter[3], I. Jarvela[1, 4]* 1) Department of Medical Genetics, University of Helsinki, Helsinki, Finland; 2) The Juliana Children's Hospital, The Hague, The Netherlands; 3) Department of Pathology and Molecular Medicine, McMaster University, Ontario, Canada; 4) Helsinki University Hospital, Laboratory Services, Helsinki, Finland.

Congenital lactase deficiency (CLD) is a rare, severe gastrointestinal disorder where the activity of lactase is very low or absent in the intestinal wall since birth. The main symptoms are watery diarrhoea and severe dehydration after ingestion of lactose. CLD is inherited as an autosomal recessive trait and it is enriched in the Finnish population. Five mutations in the lactase gene (LCT) have recently been identified to underlie CLD in the Finnish population. Of them, the founder mutation (Y1390X) is present in 90% of the disease alleles. The other four mutations S1666fsX1722, S218fsX224, G1363S, Q268H are family specific. We have obtained DNA from three foreign origin patients with clinical features compatible with CLD. Two of the patients are siblings from the Netherlands whose parents are second cousins. Their ethnic origin is Turkish. The third patient is from Canada with Portuguese origin. In order to characterize the spectrum of mutations in non-Finnish CLD patients we have sequenced the LCT gene in these patients. We have identified the previously know mutation G1363S in exon 9 in homozygous form in Turkish siblings. Both parents were carriers of the same mutation. No mutation has so far been identified in the third patient. In conclusion, we report here the first non-Finnish CLD patients whose mutations have been identified. Our results further confirm the role of LCT in CLD. We hypothesize that the G1363S mutation could have arrived Finland from Asia.

High-resolution analysis of Segmental DNA Changes in various cancer tissues. *Y. Murayama[1], S. Ozawa[2, 3], S. Asakawa[1], Y. Saikawa[2], H. Hasegawa[2], H. Jinno[2], K. Aiura[2], A. Takayanagi[1], M. Maekawa[4], Y. Kitagawa[2], M. Kitajima[2, 6], N. Shimizu[1, 5]* 1) Dept. of Molecular Biology, Keio University School of Medicine, Shinjyuku, Tokyo, Japan; 2) Dept. of Surgery, Keio University School of Medicine, Shinjyuku, Tokyo, Japan; 3) Department of Surgery, Banbuntane Houtokukai Hospital, Fujita Health University, Nagoya, Japan; 4) GSP Lab. Inc., Kawasaki, Kanagawa, Japan; 5) The Leading Institutes of Keio University, GSP Center, Tsukuba, Ibaraki, Japan; 6) Tokyo Mita Hospital, International University of Health and Welfare, Tokyo, Japan.

We have made original BAC-microarray using the Keio BAC-library that was used extensively for genomic DNA sequencing during the human genome project. The Keio BAC-microarray consisted of 7,718 DNA segments of average size 150 kb in triplicates and those DNA segments covered over 1/3 of the human genome in the interval of one BAC clone every 400 kb. The chromosomal position of each BAC DNA is located on the updated genome sequence data (Build36), and known genes present in the corresponding DNA region can be readily identified by using home-made computer software. We employed the Keio BAC-microarray to detect segmental DNA copy number changes in various cancer tissues. We have analyzed 80 among 200 cancer samples so far collected from esophagus, breast, colorectal and gastric origins. In fact, we detected copy number changes of particular DNA segments in those cancer tissues, in which some of known oncogenes and tumor suppressor genes are identified. We detected copy number changes at a locus of 9q33 in a colorectal cancer, where a cancer related gene was identified. Further studies on these 2,000 cancer samples would provide new information which should be inevitable to establish new marker genes for the diagnosis of each cancer type and discovery of therapeutic agents.

Clinical Variability and Mutation Frequency in *REEP1* (SPG31) Hereditary Spastic Paraplegia. *W.A.G. van Zelst-Stams[1,2], S.G.M. Frints[1,2], M. Gerards[1,2], R.G. Janssen[1,2], C.E.M. de Die-Smulders[1,2], C.T.R.M. Schrander-Stumpel[1,2], H.J. Smeets[1,2]* 1) Department of Clinical Genetics, Academic Hospital Maastricht, Maastricht, Limburg, Netherlands; 2) Research Institute GROW, Maastricht University, Maastricht, The Netherlands.

Hereditary spastic paraplegia (HSP) is a neurodegenerative disorder characterized by clinical and molecular heterogeneity. In autosomal dominant (AD) spastic paraplegia (SPG), *SPASTIN* (SPG4) and *ATLASTIN* (SPG3A) gene defects account for approximately 40% and 10%, respectively. We performed parametric linkage analysis, using the Affymetrix 10K SNP array, to identify the SPG locus in a nine-generation Dutch pedigree (1050 individuals). A maximum LOD score of 5.03 was obtained at the SPG31 locus (2p11-p12). Mutation analysis of the receptor expression-enhancing protein 1 gene (*REEP1*) was performed in 10 additional AD SPG families from the South-East part of the Netherlands. A truncating four basepair deletion in exon six (c.537_540delCGGC p.Ser179ArgfsX43) was identified which co-segregated with the disorder in the large linked family and in two other small unrelated families, suggesting a founder effect. The clinical features within these families ranged from normal to severe spasticity of legs and the age of onset was from birth till >75 years of age. The search for a founder haplotype is ongoing. Furthermore, we try to identify modifying loci or genes which can contribute to nonpenetrance in HSP. In conclusion, we identified a possible founder *REEP1* mutation in 27% (3/11) of the AD pure SPG families investigated in the South-East part of the Netherlands. Thus *REEP1* gene defects seem to be more common than earlier reported.

Genetic analysis of the human striatum-enriched CalDAG-GEFI gene with Japanese schizophrenia patients. *H. Mitsuyasu[1, 2], H. Kawasaki[1], L. Gotoh[1], Y. Kobayashi[1], N. Oribe[1], A. Takata[1], S. Kanba[1]* 1) Dept Neuropsychiatry, Kyushu Univ, Fukuoka, Japan; 2) Dept Psychiatry, Kyushu Kousei Nenkin Hospital, Kitakyushu, Japan.

We previously reported the isolation of striatum-enriched novel guanine nucleotide exchange factor (GEF) that has both calcium (EF-hand) and diacylglycerol (DAG) binding domains (CalDAG-GEFI) and the presence of its orthologue, CalDAG-GEFII. These genes are part of the novel second-messenger regulated GEF gene family whose GEF activities are regulated by the binding of second-messenger molecules such as cAMP, calcium and DAG (Kawasaki et al., 1998). Both CalDAG-GEFI and CalDAG-GEFII mRNAs are expressed almost exclusively in the brain and hematopoietic system (Kawasaki et al., 1998). It is shown that CalDAG-GEFI proteins are localized at the synaptic terminals of GABAergic output neurons in the striatum. Since the dysregulation of the striatal GABAergic output neurons are implicated in the pathophysiological mechanisms of schizophrenia, CalDAG-GEFI gene can be a good candidate for molecular studies of schizophrenia. In this study, we analyzed single nucleotide polymorphisms (SNPs) of the CalDAG-GEFI gene with Japanese schizophrenic patients (n=193) diagnosed based on DSM-IV criteria and control subjects (n=242). We amplified total 18 exons and their flanking regions of the CalDAG-GEFI gene. Out of 18, 16 fragments could be amplified and were screened by DHPLC. Three fragments showed heteroduplex elution pattern. Four SNPs were identified and were confirmed by direct sequencing method. All subjects were genotyped with four SNPs. Genotype and allele frequencies and linkage disequilibrium were calculated. We performed association study between the schizophrenia patients and the controls using single marker analysis and haplotype analysis with the four SNPs. There was no significant difference regarding the allele and genotype frequencies. There was no significant difference in haplotype frequencies. We could not find any significant differences between schizophrenia and controls in this study. All subjects were given informed consent based on the ethical regulations of Kyushu University.

Secondary cytogenetic changes accompanying the t(2;7)(p11-12;q21-22) of chronic lymphoproliferative disease: implications for mechanisms underlying disease progression. *S. Moore[1], N. Wickham[2], R. Fraser[1], J. Suttle[1], D. Kotasek[2], T. Hillier[1]* 1) Cancer Cytogenetics, I.M.V.S., Adelaide, SA, Australia; 2) Adelaide Cancer Centre, Ashford, SA.

Initially, translocations involving the CDK6 gene at 7q22 were considered to identify a specific subgroup of SLVL/SMZBL. It is now apparent that they also occur in CLL, with approximately equal frequency. These translocations result in over expression of CDK6,which is a gene involved in cell cycle progression through G1. The translocation breakpoints have been shown to cluster upstream of CDK6 and to involve the kappa immunoglobulin light chain locus at 2p12. 12 patients with CLD characterised by t(2;7) have been reported to date (1 B-PLL, 6 CLL and 5 SLVL/SMZBL). We now describe a 67 year old man who has low grade lymphoma characterised by 46,XY,t(2;7)(p12;q22),der(8)t(8;12)(p11;q13).

Over expression of CDK6 by translocation is likely to be insufficient, on its own, to cause aggressive disease since the cases reported so far have fairly indolent disease unless accompanied by additional cytogenetic changes.

Of the 13 patients now recognised with t(2;7), 8 showed additional cytogenetic changes. 6 patients showed changes in common: loss of 8p in 5, loss of 17p in 4 and trisomy 12 in 4. Interestingly, an unbalanced translocation involving 8p and 17p provides the mechanism for loss of these regions in 2 patients and unbalanced translocations between 8p and 12q resulted in loss of 8p and gain of 12q in 2 patients. The likely tumour suppressor gene on 17 is the p53 gene. Trisomy 12 is a common finding in CLL and has also been reported in the karyotypes of patients with various forms of lymphoma, although the gene(s) that contribute to oncogenesis have not yet been identified. The tumour suppressor(s) on 8p are unknown. Characterisation of the minimal regions of deletion on 8p and gain on 12q may help to identify patients who have a more aggressive disease and who may benefit from some of the newer therapies that are being developed to target cyclin-dependent kinases. To this end we are using BAC FISH to explore the breakpoints of the t(8;12) in our patient.

PRELIMINARY EVIDENCE OF A NOS2A PROTECTIVE EFFECT IN PATIENTS WITH RELAPSING-REMITTING MULTIPLE SCLEROSIS. *I. Manna[1], M. Liguori[1], P. Valentino[2], F. Condino[1], A. Clodomiro[2], R. Nisticò[2], G. Di Palma[1], A. Quattrone[1,2]* 1) Institute of Neurological Science (ISN) - CNR, Mangone, Cosenza, Italy; 2) Institute of Neurology, University Magna Græcia, Catanzaro, Italy.

Multiple sclerosis (MS) is the most common demyelinating disease of the central nervous system, characterised by a chronic inflammatory process. Nitric oxide,was implicated in the inflammatory process and its potential contribution to the development of MS has been extensively tested in humans and animal models. The human gene encoding inducible nitric oxide synthase (NOS2A) is located on chromosome 17q11.2-q12.In order to evaluate the possible implication of NOS2A in the pathogenesis of MS, we performed a case-control study in a selected RRMS population from Southern Italy and in an ethnically matched healthy subjects, by considering two distinct polymorphisms:(CCTTT)n and(AAAT)n. A group of patients with clinically definite MS (n=113) and ethnically matched healthy controls (n=237) were studied. Patients and controls were genotyped for the NOS2A polymorphic markers using a PCR methods. All PCR products were electrophoresed on ABI PRISM 377 and then sized by the GENESCAN TM software. Unpaired t-test was used to compare age at examination between patients and controls. This test was also applied to compare age at disease onset, disease duration and brain volumes (GM, WM). The distribution analysis of the markers frequencies showed that the (CCTTT)14 allele was found in 11.5%; of the RRMS patients and in 25.3%; of the healthy subjects, with a statistically significant difference (2= 8.843, p= 0.003). Considering the presence/absence of at least one (CCTTT)14 allele, the RRMS patients carrying one (CCTTT)14 allele showed a significant higher age at disease onset (p= 0.03) and a higher current disability score (p= 0.027) than the other patients, whereas no significant differences were observed for the other studied clinical or MRI features. In the our group of RRMS patients and healthy controls, we found a significant different distribution of the (CCTTT)n marker located in the NOS2A gene. Further studies in different populations are needed to better investigate the role of the NOS2A gene in MS.

Genome-wide association study of sporadic amyotrophic lateral sclerosis identifies ITPR2 as a susceptibility gene. *M.A. van Es[1], P.W. van Vught[1], H. Blauw[1], L. Franke[2], C.G.J. Saris[1], P.M. Anderson[3], L. Vandenbosch[4], A. Birve[3], V. de Jong[5], F. Baas[5], H.J. Schelhaas[6], K. Sleegers[7], C. van Broeckhoven[7], J.H.J. Wokke[1], C. Wijmenga[2], W. Robberecht[4], J.H. Veldink[1], R.A. Ophoff[2,8], L.H. van den Berg[1]* 1) Neurology, University Medical Centre Utrecht, Utrecht, Utrecht, Netherlands; 2) Complex Genetics Section, Department of Biomedical Genetics, University Medical Center Utrecht, The Netherlands; 3) Institute of Pharmacology and Clinical Neuroscience, Umeå University, Umeå, Sweden; 4) Department of Neurology, University Hospital Gasthuisberg, Leuven, Belgium; 5) Department of Neurology and Neurogenetics, Academic Medical Center, Amsterdam, The Netherlands; 6) Department of Neurology, Radboud University Medical Center, Nijmegen, The Netherlands; 7) Department of Molecular Genetics, University of Antwerp, Antwerpen, Belgium; 8) Department of Human Genetics and Neuropsychiatric Institute, University of California, Los Angeles, USA.

Amyotrophic lateral sclerosis (ALS) is a devastating disease characterized by progressive degeneration of motor neurons in the brain and spinal cord. We performed a genome-wide association study in 461 patients with sporadic ALS and 450 matched controls. After replication in two independent sample series we identified rs2306677 located in the Inositol 1,4,5-triphosphate receptor 2 (ITPR2) gene to be significantly associated with ALS. Combined analysis of all samples (total: 1,337 cases and 1,356 controls) gave an overall odds ratio (OR) of 1.58, with 95% confidence interval (CI) of 1.30-1.91. ITPR2 is an important regulator of intracellular Ca2+-levels and is involved in glutamate-mediated neurotransmission. We further observed significantly elevated gene expression levels of ITPR2 in peripheral blood of 126 ALS cases compared to 126 healthy controls (P = 0.00016). Elevated ITPR2 levels have been shown to play a major role in apoptosis. Since ITPR2 is involved with glutamate, Ca2+ and apoptosis, it is a strong biological candidate for a susceptibility gene in ALS.

Serotonin transporter polymorphism in Japanese patients with bipolar disorder. *N. Oribe, H. Kawasaki, H. Mitsuyasu, Y. Kobayashi, L. Gotoh, A. Takata, S. Kanba* Dept.Neuropsychiatry, Kyushu University, Fukuoka, Japan.

Since serotonin transporter (SERT) is one of the sites of action of antidepressants, this gene has been indicated to be related to the pathophysiological mechanisms of mood and anxiety disorders. Differences in SERT expression and function produced by gene polymorphisms are associated with several psychiatric diseases. Two polymorphic regions of SERT gene, a 44-base-pair (bp) insertion / deletion polymorphism in the promoter region (SERTPR) and variable number of tandem repeats (VNTR) in second intron (SERT-in2), have been characterized. SERT-in2 is reported to be associated with unipolar depression, bipolar depression, schizophrenia, and anxiety disorders. SERTPR is also shown to be associated with unipolar and bipolar depression. However, the results from various sources are inconsistent. In this study we investigated the frequency distribution of polymorphic variants of short (S, s) and long (L, l) alleles, genotypes and haplotypes of SERTPR, and SERTin2, in patients with bipolar disorder (BD) and compared them with those obtained from the Japanese healthy population. Twenty bipolar disorder patients diagnosed using the Structured Clinical Interview for DSM-IV (SCID) and nineteen healthy volunteers were included in this study. The SERTin2 and SERTPR are amplified by polymerase chain reaction (PCR). Allele sizes were determined by electrophoresis. Association analysis of each polymorphism was performed between bipolar disorder patients and normal individuals. SERTPR indicated statistically significant difference between two populations (chi square = 8.114, d.f. = 2, P = 0.0173) ,whereas SERTin2 shows no differences (chi square = 1.767, d.f. = 2, P = 0.4133). We are now carring out further analysis with more samples. All subjects were given informed consent before blood collection strictly based on the ethical regulations of Kyushu University.

Improving tag SNP portability in India using optimal mixtures of database samples. *T.J. Pemberton[1], M. Jakobsson[2], D.F. Conrad[3], G. Coop[3], J.D. Wall[4], J.K. Pritchard[3], P.I. Patel[1], N.A. Rosenberg[2]* 1) Institute for Genetic Medicine, University of Southern California, Los Angeles, CA; 2) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 3) Department of Human Genetics, University of Chicago, Chicago, IL; 4) Department of Epidemiology and Biostatistics, University of California, San Francisco, CA.

When performing tag SNP association studies in populations that have not been the focus of large-scale studies of haplotype variation, it is necessary to rely on genomic databases in other populations for the selection of suitable tag SNPs. Recent studies have found that among the populations for which such databases are least effective in tag SNP selection are populations of low or intermediate linkage disequilibrium that are genetically distant from populations in the databases. One important geographic region that has not been the focus of major SNP genotyping efforts is India. To improve the performance of tag SNPs in India - and in non-HapMap populations more generally - we study tag SNP portability using genotypes at 2,810 SNPs spanning 12 Mb of DNA sequence in a worldwide sample of 957 individuals, including 30 individuals from India. We show that a strategy that uses tag SNPs chosen based on mixtures of HapMap populations has the potential to produce improved tagging compared to a strategy that relies only on the most similar HapMap population. The difference in composition between optimal mixtures in different populations from across Asia is compatible with the differing geographic positions of the groups. These results are important both for association studies in India and more generally for improving tag SNP portability in non-HapMap populations.

ACDC protective haplotype in a black South African cohort: Perspectives on the phenotypic context. *A. Olckers[1, 2], G.W. Towers[1], A. van der Merwe[2], A.E. Schutte[3], P. Rheeder[4], P.E.H. Schwarz[5]* 1) Centre for Genome Research, North-West University (Potchefstroom Campus), Pretoria, South Africa; 2) DNAbiotec (Pty) Ltd, Persequor Park, Pretoria, South Africa; 3) School for Physiology, Nutrition and Consumer Sciences, North-West University (Potchefstroom Campus), Potchefstroom, South Africa; 4) Division of Clinical Epidemiology, University of Pretoria, Pretoria, South Africa; 5) Department of Endocrinopathies and Metabolic Diseases, Medical Faculty Carl Gustav Carus, Technical University Dresden, Dresden, Germany.

Consisting of an array of clinically heterogeneous disorders, type 2 diabetes mellitus (T2D) is one of the fastest growing non-communicable diseases in the world, with the developing regions such as sub-Saharan Africa being at greatest risk. T2D affects circa 4% of the general population and is caused by the pathogenic interaction between insulin resistance and secretion.

During this investigation a diabetic (n=227) and control cohort (n=226) of adult black South African individuals were screened for the reported single nucleotide polymorphisms (SNPs) termed C-11377G and G-11391A, within the promoter of the adiponectin (ACDC) gene. Genotyping was achieved via a real time PCR method.

In a previous investigation it was determined that the 12 (haplotype structure = C-11377G; G-11391A) haplotype was significantly associated with a protective effect against T2D (OR = 0.16, 95% CI 0.03-0.72, $p<0.01$). In this investigation, individuals harbouring the 12 haplotype were compared to individuals that did not contain this haplotype for certain clinical parameters. This investigation was undertaken to elucidate the biological origin of the change in the risk phenotype.

The study strengthens the conclusions drawn previously that the genetic risk towards T2D is population dependent. Furthermore it highlights the fact that therapeutic regimens should be developed in a population dependent manner in order for these treatments to be effective on a global scale.

The Einstein/Montefiore Spina Bifida Clinic at Blythedale: A 20 Year Perspective. *R. Marion[1,2], L. Schendel[2], L. Seimon[1,2], J. Goodrich[1,2], S. Kogan[1,2], R. Borkow[2]* 1) Dept Pediatrics, Childrens' Hosp Montefiore, Bronx, NY; 2) Blythedale Children's Hospital, Valhalla, NY.

In February 1987, the Einstein/Montefiore Spina Bifida Clinic moved from the Bronx to Blythedale Children's Hospital in Valhalla, NY. Since that time, the clinic has provided care for 238 patients (pts)with myelomeningocele and related congenital anomalies of the spine. Recently, after 20 years of continuous service, we analyzed data from our population, evaluating: (1) number of pts entering the clinic each year; (2) frequency and causes of mortality; (3) frequency of allergy to Latex; (4) incidence of secondary medical complications, as well as other paramenters. Analysis of these data revealed that (1) since 1998, when enriched of food with Folic Acid began, the number of pts entering the clinic dropped from an average of 9.3/yr to 2.4/yr; (2) over 20 years, 12 pts. died (5.0 percent), significantly below national figures published in the 1980s; although the majority of deaths were due to complications related directly to the underlying disease, pts died from other causes, including child abuse, anaphylaxis due to Latex exposure and unrelated infections; (3) incidence of Latex allergy rose from less than 10 percent in 1987 to virtually 100 percent in 2007; and (4) as our population ages, the 3 most common secondary complications include obesity, chronic decubitus ulcers, and depression.

Over the 20 years that our clinic has functioned at Blythedale, management of pts with Spina Bifida has changed. Folic acid fortication has decreased the number of infants entering our clinic by 75 percent; coupled with the reduction in mortality, this has led to an increase in the average age of pts, making us a center that cares for older pts; universal allergy to Latex has altered the way we approach and counsel pts., as well as the way we provide equipment; and the presence of secondary complications noted above requires that some members of the multidisciplinary team, specifically nutritionist and psychiatrist, must play more of an active role in the care of older pts.

Translational re-initiation of DNp63 protein causes Rapp-Hodgkin syndrome. *T. Rinne[1], K. Krahn[2], E. Lamme[3], J.C. Murray[4], B. van den Heuvel[5], J. Schalkwijk[3], H.G. Brunner[1], J. Zhou[1], H. van Bokhoven[1]* 1) Department of Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands; 2) Department of Genetics Research Laboratory, University of Iowa, Iowa City, USA; 3) Laboratory of Skin Biology and Experimental Dermatology, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands; 4) Department of Paediatrics, University of Iowa College of Medicine, Iowa City, USA; 5) Laboratory of Paediatrics and Neurology, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands.

A group of human developmental disorders is characterized by combinations of ectodermal dysplasia, orofacial clefting and limb malformations. So far, seven different entities have been reported to be caused by dominant mutations in the transcription factor gene p63. 5% of p63-linked patients have Rapp-Hodgkin syndrome (RHS), which is characterized by generalized ectodermal dysplasia and orofacial clefting. We have recently identified a RHS family with an a-typical stop mutation (Q11X). Intriguingly, the N-terminal position of this nonsense mutation appears to be incompatible with the postulated dominant-negative/gain-of-function mechanism of other p63 mutations. Initial RNA analysis in patient cells revealed normal expression of both alleles. Protein analysis revealed an additional protein of reduced size. Through extensive proteomic analyses we could demonstrate that the smaller p63 protein was produced by translation re-initiation at the next methionine, causing N-terminal truncation of 25 amino acids for the DNp63 isoforms. This N-terminal truncation abrogates a non-canonical transactivation domain in the DN-specific isoforms, which was functionally shown by testing a natural target of p63, Keratin-14 promoter. These data establish that the Q11X mutation does not represent a null-allele, but gives rise to an abnormal DNp63 protein with dominant effects. Since other RHS mutations as well as mutations in the related Hay-Wells syndrome are invariably located in p63 the C-terminal a-tail, we conclude that the specific disruption of DNp63a is key to phenotypes of these syndromes, which comprise severe ectodermal dysplasia and abnormal orofacial development but not limb defects.

Characterization of a complex karyotype in a patient with primary plasma cell leukemia using multicolour spectral karyotyping. *E. Van Assche[1], Z. Berneman[2], A. van de Velde[2], M. van der Plancken[2], K. Vermeulen[2], H. De Raeve[2], R. Van Luijck[1], S. Scheers[1], B. Blaumeiser[1], J. Wauters[1]* 1) Dept Medical Genetics, Univ Hospital Antwerp, Edegem, Belgium; 2) Dept Hematology and Hemostasis, Univ Hospital Antwerp, Edegem, Belgium.

Primary plasma cell leukemia (PCL) is a rare neoplastic disorder that usually carries an aggressive course with a rapidly fatal outcome. We report on a 51-year-old patient who developed primary PCL. In agreement of previous reports (Saccaro et al., 2005; Avet-Loiseau et al., 2001) chromosomal analysis of bone marrow of this PCL case showed a complex chromosomal abnormalities. As GTG-banding was not able to resolve all karyotypic changes multicolour spectral karyotyping (SKY) was done. Using this molecular cytogenetic approach the karyotype can be described as: 48,XX,t(1;10)(p11;q26),+der(1)t(1;10)(p11;q26),del(6)(q?),+7,t(13;16)(q22;q?),t(14;16)(q32;q?). Only few cytogenetic analyses of patients with primary PCL have been published, especially the translocations involving the immunoglobulin heavy chain locus at 14q32, specifically t(11;14) and t(14;16) have been reported in 80% of patients with PCL. In our patient the t(14;16) could not be observed by conventional cytogenetics, only by using SKY the abnormality became visible. As mentioned by other authors (Saccaro et al., 2005; Avet-Loiseau et al., 2001; Hayman et al., 2001; Mateo et al., 2005), the karyotype of our PCL patient showed also abnormalities of chromosome 13, and abnormalities of chromosome 1. An overview of literature of other PCL cases will be given. Flow immunophenotypic studies were also performed but were not typical for PCL.

The Morphogenesis of Wormian Bones: A Study of Craniosynostosis and Purposeful Cranial Deformation. *P.A. Sanchez-Lara[1,2], J.M. Graham, Jr.[2], J. Lee[2], A.V. Hing[3], M. Cunningham[3]* 1) Dept of Medical Genetics, Children's Hospital Los Angeles, Los Angeles, CA; 2) Medical Genetics Institute, Cedars-Sinai Medical Center, David Geffen School of Medicine at UCLA, Los Angeles CA; 3) Division of Craniofacial Medicine, Dept. Pediatrics, University of Washington School of Medicine, Seattle WA.

Wormian bones (WBs) are accessory bones that occur within cranial suture lines. WBs occur more frequently in genetic disorders that reduce cranial ossification, possibly resulting from a more brachycephalic skull. The frequency and location of WBs are also known to vary with the type and severity of cranial deformation practiced by primitive cultures. We considered the hypothesis that the pathogenesis of WBs may be due to environmental variations in dural strain within open sutures and fontanelles, as well as with genetic variations in calvarial mineralization. In our study, we measured the cephalic index in 20 purposefully deformed pre-Columbian skulls and compared them to 20 anatomically-normal skulls used for medical school anatomy classes. There was no direct correlation between the cephalic index (CI) and the number of WBs in skulls. When the CI was grouped into three categories Normal (CI<81), brachycephalic (CI 81-93) and severely brachycephalic (CI >93), there was a trend in the number of WBs as the skull became more brachycephalic (p=0.039). We also tabulated the frequency and location of large WBs (> 1cm) in 3D-CT scans from 207 cases of craniosynostosis and compared these data with published data on 485 normal dry skulls from Parker (1905). There was a very significant difference between the two groups. Among cases of craniosynostosis, large WBs were more frequent (117 out of 207 3D CT scans) than in dry skulls (131 out of 485) (p<0001). We also found that midline synostosis, specifically metopic or sagittal synostosis has more WBs in the midline, whereas unilateral lambdoidal or coronal synostosis more often had WBs on the contralateral side. Taken together, these data suggest that WBs may arise as a consequence of mechanical factors that affect dural strain within sutures and fontanelles.

Missense and non-sense mutations in the alternatively spliced exon 2 of COL2A1 cause the ocular variant of Stickler Syndrome. *M. Mannikko[1], A. McAlinden[2], M. Majava[1], P.N. Bishop[3, 4], R. Perveen[4], G.C.M. Black[4], M.E. Pierpont[5], L. Ala-Kokko[1, 6]* 1) Collagen Research Unit, Biocenter and Department of Medical Biochemistry and Molecular Biology, University of Oulu, Finland; 2) Department of Orthopaedic Surgery, Washington University School of Medicine, St Louis, Missouri, USA; 3) Wellcome Trust Centre for Cell-Matrix Research, Faculty of Life Sciences,University of Manchester, UK; 4) Medical Genetics Research Group, School of Medicine, University of Manchester, UK; 5) Childrens Hospital of Minnesota, Department of Pediatrics and Ophthalmology, University of Minnesota, Minneapolis, Minnesota, USA; 6) Connective Tissue Gene Tests, Allentown, PA, USA.

Stickler syndrome type I (STL1) is a phenotypically heterogeneous disorder characterized by ocular and extraocular features. It is caused by null-allele mutations in the COL2A1 gene which codes for procollagen II. COL2A1 precursor mRNA undergoes alternative splicing, resulting in two isoforms, a long form including exon 2 (IIA) and a short form excluding exon 2 (IIB). The short form is predominantly expressed in adult cartilage, and the long form during early development and in the vitreous, the only adult tissue containing procollagen IIA. Recent evidence indicates that due to the tissue-specific expression of these two isoforms, premature termination codon mutations in exon 2 cause Stickler syndrome with minimal or no extraocular manifestations. We describe here two mutations in exon 2 of COL2A1 in three patients with predominantly ocular Stickler syndrome: Cys64Stop in two patients, and a novel structural mutation, Cys57Tyr, in one. RT-PCR of total lymphoblast RNA from one patient with the Cys64Stop mutation revealed that only the normal IIA allele was present, indicating that the mutation resulted either in complete loss of the allele by non-sense-mediated mRNA decay or by skipping of exon 2 via non-sense-mediated altered splicing, resulting in production of the type IIB isoform. The results of COL2A1 mini-gene expression studies suggest that both Cys64Stop and Cys57Tyr alter positive cis regulatory elements for splicing, resulting in a lower IIA:IIB ratio.

Clinical Outcomes in Menkes Disease Patients with a Potentially Treatment-Responsive ATP7A Mutation, G727R. *J.R. Tang, A. Donsante, S.G. Kaler* Unit Pediatric Genetics, LCG, NICHD/NIH, Bethesda, MD.

Menkes disease is a fatal neurodegenerative disorder caused by diverse mutations in an X-linked copper transport gene, ATP7A. Emerging evidence from a long-term clinical trial indicates that favorable response to early copper treatment in this disorder requires a mutation that allows partial copper transport. We identified and characterized such a mutation, G727R, in two infants treated beginning at 25 and 228 days of life, respectively. G727R occurs in exon 10 of ATP7A and affects the second transmembrane segment of the copper-transporting ATPase encoded. Western analysis showed equivalently reduced quantities of the full length protein in both G727R patients fibroblasts compared to wild type, indicating post-translational degradation or possibly aberrant splicing, mechanisms we are formally investigating. Importantly, the mutant allele complemented the *S. cerevisiae* copper transport mutant, ccc2, a finding consistent with partial functional activity. Patient A was diagnosed at 22 days of age, based on a positive family history, and entered the clinical trial of daily copper injections at 25 days of age. After two years, his neurodevelopment was normal in fine motor, personal-social, and language spheres, and delayed in gross motor (13 months). Brain MRI at 15 months of age revealed slightly delayed myelination. Serial electroencephalographs showed no abnormalities. Patient B had no family history of the disorder and was diagnosed at 6 months of age based on clinical phenotype, biochemical findings (low serum copper), and molecular testing that revealed G727R. Based on the relatively favorable response to copper treatment in patient A, we enrolled patient B, beginning at 228 days (7.6 mos) of age. After 6 months, however, there were no major improvements in his clinical status. Neurodevelopmental levels ranged from 1 to 2 months. The EEG was markedly abnormal and his seizures persisted. The outcomes in these two patients, each with the same missense mutation associated with residual copper transport function, confirm the importance of early medical intervention and highlight the potential benefit of newborn screening for Menkes disease.

Moving towards a combined framework for association with extensions to meta-analysis. *B.M. Neale[1,2,3], P.C. Sham[4], P.I.W. deBakker[2,3], S. Purcell[2,3], M.J. Daly[2,3,5]* 1) SGDP Centre, King's College London, United Kingdom; 2) Broad Institute, Boston, MA; 3) CHGR, Massachusetts General Hospital, Boston, MA; 4) Psychiatry and Genome Research Depts, University of Hong Kong; 5) School of Medicine, Harvard, Boston, MA.

We extend the TDT to incorporate information from singletons and suggest a correction for the analysis of SNPs imputed from the linkage disequilibrium (LD) structure from HapMap. Both of these developments are useful for meta-analysis and improving power of association studies. Using probands in a case/control design positively correlates with the TDT evidence under the null. Identifying a source of association signal independent of the transmission information will improve the power. We propose modelling parents as *half-cases* as half the genetic material is shared with a case. From simulation, parental genotypes do not correlate with the TDT under the null and deviate from control frequencies under the alternative. Based on Mitchell (2000), case/control and TDT association information can be combined and tested using a single degree of freedom. This parental association information is subject to other population-based difficulties such as stratification, and so due diligence is necessary. We apply this to genome-wide association studies (GWAS) of ADHD and autism.

Imputing untyped variation in samples based on LD is viable for GWAS. These untyped variants are known imprecisely because of the uncertainty inherent in LD and the sampling variance associated with the HapMap. We explore the two approaches to the generation of the SNP data for analysis: *best guess* and *dosage*. *Best guess* imputes the most likely allele, and *dosage* generates a probabilistic counts of alleles. Our simulation and empirical results show that the *dosage* approach is preferable. However, *dosage* is conservative under the null. To resolve this, we propose a correction to the variance of the association test statistic. By doing so, we can now utilize imputation to combine evidence across non-overlapping SNP sets using Z-score combination. We apply this GWAS of Crohns disease for meta-analysis.

FUNCTIONAL ANALYSIS OF HNPCC RELATED MISSENSE MUTATIONS IN MSH6. *J. ou[1], R. Niessen[1], K. Kooi[1], J.H. Kleibeuker[2], R.H. Sijmons[1], R.M.W. Hofstra[1]* 1) Dept. of Genetics, University Medical Center of Groningen, groningen, groningen, Netherlands; 2) Gastroenterology, University Medical Center Groningen, University of Groningen, Groningen, The Netherlands.

Inherited pathogenic mutations in the mismatch repair (MMR) genes MLH1, MSH2 and MSH6 predispose to HNPCC. A major challenge in HNPCC diagnostics are the DNA variants with an unclear pathogenic nature (unclassified variants, UVs) such as single amino acid substitutions and small or large in-frame deletions. In particular MSH6 UVs account for a substantial proportion of these UVs. This study was to evaluate the pathogenicity of 5 of such inherited MSH6 UVs found in patients suspected of HNPCC. The mutated MSH6 proteins (all single amino acid substitutions) were tested for expression and stability in a MSH2/MSH6 deficient cells (LOVO cells), MSH2/(mutant)MSH6 interaction by yeast two-hybrid and for the sub cellular localization of the mutatnt proteins. Protein expression of 4 of the 5 MSH6 mutants (S144I, A1021D, A326V and T1219I) was significantly decreased after transfection when compared with WT. Possibly this is due to mutant protein instability or to lower mRNA levels. No effects was seen on protein-protein interaction (with MSH2) In our yeats two hybrid screen and the subcellular localization was normal for all 5. Conclusion Our data shows that 4 of the 5 tested MSH6 UVs influence protein abundancy. These UVs might therefore be pathogenic. In vitro assays are currently being performed to further evaluate the pathogenicity of thes UVs. Our data does however suggest that missense variants in MSH6 do play a role in HNPCC development.

A spectrum of molecular variation in a cohort of Italian patients affected by Pagets Disease of Bone. *I. Marino[1], F. Gianfrancesco[1], T. Esposito[1], D. Rendina[2], G. De Filippo[3], R. Nuti[4], D. Merlotti[4], A. Ciccodicola[1], L. Gennari[4], P. Strazzullo[2], G. Mossetti[2]* 1) Institute of Genetics and Biophysics, Italian National Research Council, Naples, Italy; 2) Department of Clinical and Experimental Medicine, Federico II University, Naples, Italy; 3) Unit of Pediatric Endocrinology, Gaetano Rummo Hospital, Benevento, Italy; 4) Department of Internal Medicine, Endocrine-Metabolic Sciences and Biochemistry, University of Siena, Italy.

Paget disease of bone (PDB) is a chronic disease of the skeleton that affects up to 2-3% of the population aged 50 years. The disorder is characterized by focal areas of increased osteoclastic bone resorption and a coupled, but disorganized, increase in osteoblastic bone formation. The PDB geographic distribution is not uniform, with a higher prevalence of the disease in North America, Australia, and New Zealand. In Europe, the PDB prevalence shows a north-south gradient, with highest prevalence in England and a lower prevalence in Italy and Greece. Mutations in the ubiquitin protein-binding domain (UBA), of the sequestosome 1 (SQSTM1) gene, which is a scaffold protein in the NF-B signalling pathway were identified as a common cause of PDB. To examine the prevalence of mutations of SQSTM1 in Italian families, and to assess potential genotype-phenotype associations, we performed mutational analysis in 150 sporadic and familial Italian Pagets cases, recruited in the Campania Region. An increased PDB clinical severity was observed in the PDB cohort from Campania in comparison with patients from other Italian regions. Moreover, neoplastic degeneration of pagetic bones (osteosarcoma and giant cell tumor) was exclusively observed in Campania patients with polyostotic PDB. In 15% of these patients with PDB disease, heterozygous mutations in the SQSTM1 gene were identified. These were the previously described P392L mutation, and four new mutations. All mutations were located in the ubiquitin-associated domain of the gene, representing a mutational hot spot area. Our findings confirm the hypothesis of an involvement of the SQSTM1 gene in the pathogenesis of Italian Pagets cases.

Preimplantation diagnosis for mitochondrial DNA disorders: contribution to understanding mitochondrial DNA segregation during early human embryonic development. *J. Steffann[1], N. Gigarel[1], N. Frydman[2], P. Burlet[1], V. Kerbrat[3], G. Tachdjian[2], J.P. Bonnefont[1], R. Frydman[3], A. Munnich[1]* 1) Genetics Department, Necker Hospital, Paris, France; 2) Reproductive Medecine, Beclere Hospital, Clamart, France; 3) Obstetrics and Gynecology, Beclere Hospital, Clamart, France.

Mitochondrial DNA (mtDNA) mutations cause a wide range of serious genetic diseases with maternal inheritance. Due to the high transmission risk and the absence of efficient therapy in these disorders, at risk couples often ask for prenatal and/or preimplantation diagnosis (PGD). However, little is known about the factors that might determine the mutant loads (heteroplasmy) in a child of a carrier mother. Studies in animals and humans of pathogenic mtDNA mutations have suggested that a genetic bottleneck during oogenesis can affect the segregation of mtDNA sequence variants. We recently performed the first PGD for the NARP (Neurogenic weakness, Ataxia, Retinitis Pigmentosa) mtDNA mutation and an extremely skewed mtDNA segregation was observed supporting the hypothesis of a tight bottleneck during oogenesis. We performed 2 PGD for 2 women at risk of transmitting the MELAS m.3243A>G mutation, responsible for Mitochondrial myopathy, Encephalopathy, Lactic Acidosis and Stroke-like episodes, and the ND3 m.10197G>A mutation responsible for Leigh syndrome, respectively. Mutant loads were assessed in two oocytes and six embryos at risk of carrying either MELAS or ND3 mutations, by using PCR tests enabling single-cell quantification of heteroplasmy. Unlike NARP embryos, the majority of these oocytes and embryos were heteroplasmic (only one embryo was homoplasmic for the ND3 mutation). At this stage, comparative analysis of heteroplasmy in different blastomeres from non-transferable embryos (5 affected or arrested embryos) did not show any variation of the mutant DNA rate between cells from a given embryo. Only one embryo, carrying less than 10% of ND3 mutation was transferred but no pregnancy ensued. These results emphasize the wide variation of the bottleneck size, arguing that the nature of the mtDNA variant and/or individual factors might influence these variations.

Mutational analysis of Japanese families with childhood-onset dominantly inherited diabetes mellitus. *T. Yorifuji, S. Nagai, M. Kawai, T. Momoi, T. Nakahata* Pediatrics, Kyoto University Hospital, Kyoto, Japan.

(Background) Dominantly-inherited diabetes mellitus (DM) comprises approximately 5% of all type 2 DM. Typical forms with adolescence-onset have been called MODY. So far 6 causative genes have been identified and termed MODY1-6. Mutational analyses of Caucasian families have shown that most MODY cases could be explained by MODY1-6. However, in east Asian populations, mutations in these genes can be identified in only 10-20%. (Aims) To understand the mutational spectrum of Japanese patients with dominantly inherited DM.(Methods) Twenty-five Japanese families with dominantly inherited DM were analyzed. At least one member of each family had the onset of DM during childhood. Then, all exons, exon-intron boundaries, and the promoter region of the known MODY genes, KCNJ11, and ABCC8 were amplified from genomic DNA and directly sequenced.(Results) Mutations were identified in 11 out of 25 families (Table), much more frequently than previously reported for Japanese patients. GCK mutations were identified more frequently than TCF1 mutations. Notably, KCNJ11 mutations were identified in two families, more frequently than other MODY genes.

Gene	Mutation
GCK	P59S, E40K, G299R, P417Q
TCF1	R131W, L348P, p291fsdelC
KCNJ11	C42R, D323G
TCF2	S148W
HNF4A	-82G>C (exon 1D)

.

***Chd7* loss of function phenotypes in mice resemble those in human CHARGE syndrome and include variable and highly penetrant inner ear defects and postnatal growth delays.** *D. Martin[1,2], E. Hurd[1], M. Adams[3], K. Cheng[1], W. Layman[2], D. Swiderski[3], L. Beyer[3], Y. Raphael[3]* 1) Pediatrics, The University of Michigan, Ann Arbor, MI; 2) Human Genetics, The University of Michigan, Ann Arbor, MI; 3) Otolaryngology, The University of Michigan, Ann Arbor, MI.

CHARGE syndrome is a multiple anomaly condition characterized by ocular Coloboma, Heart defects, Atresia of the choanae, Retarded growth and development, Genital hypoplasia, and Ear defects including deafness and semicircular canal dysgenesis. Heterozygous loss of function *CHD7* mutations are present in 60-80% of CHARGE individuals, yet little is known about the pathogenesis of tissue specific defects associated with *CHD7* deficiency. To explore developmental roles of CHD7, we have generated a *Chd7* gene trapped *lacZ* reporter allele, $Chd7^{Gt}$. Homozygous $Chd7^{Gt/Gt}$ mice are embryonic lethal, whereas heterozygous $Chd7^{Gt/+}$ mice exhibit circling behaviors and postnatal growth delays reminiscent of human CHARGE syndrome. Here we show that $Chd7^{Gt/+}$ mice have variable and highly penetrant defects of the lateral and posterior semicircular canals, with severe defects in innervation of vestibular sensory epithelia despite the presence of intact sensory hair cells. Using a newly available anti-CHD7 antibody, we observed absence of CHD7 protein in homozygous $Chd7^{Gt/Gt}$ embryos, confirming that $Chd7^{Gt}$ is a null allele. Tissue specific expression of anti-CHD7 and -galactosidase in $Chd7^{Gt/+}$ mice show the utility of $Chd7^{Gt}$ for tracking the fates of CHD7-expressing cells. CHD7 is expressed in dividing cells of the embryonic brain and ear, and in mouse embryonic fibroblasts (MEFs), validating the use of MEFs for *in vitro* studies of CHD7 function. These results improve our understanding of developmental CHARGE phenotypes. Inner ear malformations are one of the most highly penetrant clinical features in CHARGE and in $Chd7^{Gt/+}$ mice, suggesting the mammalian inner ear has a unique requirement for *Chd7* function. Ongoing studies in our laboratory are aimed at exploring the downstream target genes and molecular mechanisms of *Chd7* loss of function in the developing inner ear and craniofacial structures.

Molecular characterization of a new Ewing sarcoma cell line: *EWS-ERG* fusion gene hidden within a complex three chromosomes rearrangement, associated with *RB1* loss and polyploidyzation. *G. Maire[1], J. Bayani[1], C. Pereira[2], C. Brown[3,4], D.H. Gravel[5], J.C. Bell[3,6], J.A. Squire[1,7], M. Zielenska[2,7,8]* 1) Ontario Cancer Institute, toronto, Ontario, Canada; 2) Pediatric Laboratory Medecine and Pathology, The Hospital for Sick Children, Toronto, Canada; 3) Ottawa Health Research Institute, Center for Cancer Therapeutics, Canada; 4) Microbiology and Immunology, University of Ottawa and Orthopaediatric Surgery, Ottawa Hospital and the University of Ottawa, Canada; 5) Pathology and Laboratory Medecine, Ottawa Hospital and University of Ottawa, Canada; 6) Biochemistry, Microbiology and Immunology, University of Ottawa, Canada; 7) Laboratory Medecine and Pathology, University of Toronto, Canada; 8) Genetics and Genome Biology, Hospital for Sick Children, Toronto, Canada.

A 25 yo male presented with a very aggressive and metastatic Ewing Sarcoma (ES). Cells cultured from the biopsy transformed into a cell line. The objective was to characterize at the molecular level what were the original abnormalities of this new cell line derived from an unusually aggressive ES tumor. Cultured cells were analyzed by molecular cytogenetics techniques: SKY, FISH, aCGH and by RT-PCR. SKY analysis showed a simple pseudo tetraploid karyotype, with an apparent balanced and reciprocal t(19;22) as the sole structural rearrangement. The breakpoint on chromosome 22 mapped the *EWS* gene, and the RT-PCR for the *EWS-ERG* fusion gene was positive. Further FISH characterization using a collection of 30 BAC, identified a cryptic insertion and inversion between chromosome 21 and 22, resulting in the formation of an in frame fusion of the *EWS* 5end with the *ERG* 3end. In addition, aCGH identified a 16Mb deletion which included the *RB1* gene. An analysis of the biopsy prior to the cell line being established confirmed the presence of the rearrangements involving chromosomes 19, 21 and 22, but both *RB1* deletion and tetraploidization were not detected; suggesting acquisition of these aberrations was most likely an *in-vitro* effect. This study allowed us to propose a sequence of molecular evens that may account for the clinically aggressive behavior of this particular ES case.

Comprehensive Genetic Analysis of the Platelet Activating Factor Acetylhydrolase Gene and Cardiovascular Disease in Case/Control and Family Datasets. *B. Sutton[1], D. Crosslin[1], S. Shah[1, 2], S. Nelson[1], A. Bassil[1], A. Hale[1], C. Haynes[1], P. Goldschmidt-Clermont[3], J. Vance[3], W. Kraus[2], S. Gregory[1], E. Hauser[1].* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) Division of Cardiovascular Medicine, Duke University Medical Center, Durham, NC; 3) Department of Medicine, University of Miami, Miami, FL.

Platelet Activating Factor Acetylhydrolase (PAFAH) is a potent pro- and anti-inflammatory molecule that has been implicated in multiple inflammatory diseases, including cardiovascular disease. The goal of this study was to investigate the genetic effects of PAFAH in two large, independent coronary artery disease (CAD) datasets to better elucidate its genetic role in CAD. Using a haplotype tagging (ht) approach, 19 htSNPs were genotyped in CATHGEN case/control samples (cases = 807 and controls = 267) and in the GENECARD Family Study (1,101 families, 2,954 individuals). Single SNP analysis using logistic regression was performed on all CATHGEN subjects, resulting in nine SNPs showing significant association (P-values 0.0004-0.02). CATHGEN cases were further stratified into subgroups based on age of CAD onset (AOO) and severity of disease; 600 young affecteds (YA, AOO<56) and 207 old affected (OA, AOO >56) to provide a consistent validation set for the early onset CAD GENECARD Family study. After AOO stratification, the OA subgroup remained the most associated, with 14 SNPs significantly associated (P-value 0.0001-0.02). Similar association to that seen in the YA subgroup was detected in the GENECARD probands (P-values 0.002-0.05). Three SNPs, I198T, A379V, and R92H, were nonsynonymous coding changes. Interestingly, A379V and R92H constituted the most significantly associated SNPs, even after Bonferroni correction and appear to represent independent associations. Haplotype analysis was performed on all 19 SNPs using a two-SNP sliding window approach, with significant association identified in 161 of the 171 haplotypic combinations. In summary, PAFAH represents an important, potentially functional candidate in the pathophysiology of CAD based on numerous associations using two independent data sets and multiple statistical approaches.

Leptin resistance and neuroendocrine defects in mouse models of Bardet-Biedl Syndrome. *S. Seo[1,2], K. Rahmouni[3], V.C. Sheffield[1,2]* 1) Dept. of Pediatrics, Univ. of Iowa, Iowa city, IA; 2) Howard Hughes Medical Institute, IA; 3) Dept. of Internal Medicine, Univ. of Iowa, Iowa City, IA.

Bardet-Biedl syndrome (BBS) is a pleiotrophic genetic disorder with cardinal features of obesity, polydactyly, and retinal degeneration. We have previously developed mouse BBS models for BBS2 (Bbs2-/-), BBS4 (Bbs4-/-), and BBS6 (Bbs6-/-). These mice recapitulate most of the phenotypes observed in humans. We have used these models to dissect the mechanisms involved in the metabolic disorders associated with BBS. We found that the development of obesity in BBS null mice is associated with hyperphagia, decreased activity and increased circulating level of the adipocyte-derived hormone leptin. Intraperitoneal administration of leptin failed to reduce appetite or body weight in Bbs2-/-, Bbs4-/-, and Bbs6-/- mice suggesting leptin resistance. Increased leptin levels in the cerebrospinal fluid and resistance to intracerebroventricular injected leptin in all BBS mice indicate that a defect in leptin transport across the blood brain barrier is not the cause of leptin resistance in BBS mice. To gain further insight into the etiology of obesity and leptin resistance in BBS mutants, we examined expression of key regulators of energy homeostasis in the hypothalamus. We found that expression of leptin receptor and melanocortin receptor 3 and 4 were unaffected. In contrast, all BBS KO models showed a slight reduction in the expression of key hypothalamic neuropeptides regulating appetite and energy homeostasis: AgRP, NPY, and POMC. Together, our results suggest that BBS proteins may be required for the normal function of the hypothalamic neuroendocrine circuit that controls appetite and energy balance.

REVERSE PHENOTYPING USING MULTIVARIATE DISTANCE-BASED ANALYSIS. *T.G. Schulze[1], O. Libiger[2], A.E. Baum[3], L. Kassem[3], A. Georgi[1], J. Strohmaier[1], F. Schirmbeck[1], A. Karpushova[4], R. Abou Jamra[5], J. Schumacher[5], S. Hoefels[6], M.M. Noethen[4], S. Cichon[4], M. Rietschel[1], F.J. McMahon[3], N.J. Schork[2], NIMH Genetics Initiative Bipolar Disorder Consortium* 1) DivGen Epidemiology Psychiatry, Centr Inst Mental Health, Mannheim, Germany; 2) Scripps Res Inst, San Diego, CA; 3) GBMAP, NIMH, Bethesda, MD; 4) Genomics, Life & Brain Cntr, Univ of Bonn, Germany; 5) Inst of Hum Genet, Univ of Bonn, Germany; 6) Dept of Psychiatry, Univ of Bonn, Germany.

We recently introduced the concept of reverse phenotyping in complex genetic traits in order to identify genotype-phenotype correlations contributing most to linkage or association findings: genetic marker data is used to drive, or form the basis of, new phenotype definitions. With the advent of whole genome association, there is a need to perform reverse phenotyping for a multitude of phenotypic and genotypic data in order to understand the biological and clinical significance of associated genetic variations. We outline an approach combining the idea of reverse phenotyping with recently developed multivariate analysis methods that consider variation in measures of genomic and phenotypic distance (or similarity) among a set of individuals. We study the utility of different measures of genomic similarity, e.g. IBS allele sharing weighting by allele frequency ancestry. The methodology is illustrated using data from our recently published whole genome association study on bipolar disorder (Baum et al. 2007; initial US study set: 461 cases and 563 controls; German replication set: 772 cases and 876 controls) identifying and replicating 88 SNPs in 80 genes. Our method exhibits great power while maintaining appropriate type I error rates. Varying degrees of missing genotype or phenotype data can be accommodated. Compared to a reverse phenotyping approach based on consecutive single marker or haplotype analyses, our more holistic multivariate approaches provide insights traditional univariate methods cannot. The joint of effect of variations within a gene or across different genes can be flexibly modelled and related to single or cluster of phenotypes.

Gene expression profiling of rheumatoid arthritis patients treated with anti-tumour necrosis factor. *E.J.M. Toonen[1], P. Barrera[2], H. Scheffer[1], T.R.D.J. Radstake[2], P.L.C.M. van Riel[2], B. Franke[1], M.J.H. Coenen[1]* 1) Department of Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, Gelderland, Netherlands; 2) Department of Rheumatology, Radboud University Nijmegen Medical Centre, Nijmegen, Gelderland, Netherlands.

Rheumatoid arthritis (RA) is a severe inflammatory disease and genetic factors are known to play an important role in disease susceptibility, prognosis as well as therapy response. Treatment strategies blocking TNF have proven very successful showing beneficial effects in at least 60% of the patients with RA. The reason why a subset of patients does not respond is unknown. In this study we test the hypothesis whether gene expression profiles can be used to predict anti-TNF response as well as the effect of therapy on these profiles. Expression profiles of white blood cells of 50 patients before therapy (baseline) and 14 weeks after therapy start were analyzed using the Affymetrix GeneChip Human Exon 1.0 ST Array. The search was focused on the differences between treatment responders and non-responders at baseline and on differences in effect (before and after therapy) between these groups. Treatment responses were assessed using European League Against Rheumatism (EULAR) response criteria. Genes that showed at least a two-fold lower expression in non-responders compared to responders at baseline in the pilot to this project included the inflammatory genes IL1B, TLR10 and CD274. These genes might be candidates predicting anti-TNF treatment outcome before therapy start. Genes that were two-fold or more downregulated in responders (but not non-responders) after three months of therapy included IL1R1, IL1R2 and CXCL11. This analysis might give new leads concerning the mechanism underlying the mode of action of anti-TNF. HLA-DQA2 showed a three-fold upregulation in non-responders compared to responders at baseline, which might indicate that the HLA system is involved in determining the responsivity to anti-TNF treatment. Confirmation of the results to verify the validity of the identified markers predicting anti-TNF outcome in the larger sample is needed to elucidate the role of the identified genes in anti-TNF response.

THE FIRST LATINO WHOLE GENOME ADMIXTURE SCAN, FOCUSING ON COLOMBIANS WITH TYPE 2 DIABETES. *F. Yu[1, 2], A. Price[1, 2], N. Patterson[1, 2], A. Waliszewska[1, 2], C. Schirmer[1, 2], J. Neubauer[1, 2], G. Bedoya[3], C. Duque[3], A. Villegas[3], A. Ruiz-Linares[3, 4], D. Reich[1, 2]* 1) Dept Genetics, Harvard Med Sch, Boston, MA; 2) Broad Inst. of MIT & Harvard; 3) Laboratorio de Genética Molecular, Universidad de Antioquia, Medellín, Colombia; 4) The Galton Laboratory, Dept. of Biology, Univ. College London.

The prevalence of type 2 diabetes (T2D) in Latino populations is much higher compared with populations of European ancestry. The history of recently admixed ancestries from different continents in Latinos makes admixture mapping a potentially powerful technology for finding T2D susceptibility loci in this population. With the recent success of admixture scans in African Americans for multiple sclerosis, prostate cancer, and markers of inflammation, the likelihood of success of whole-genome admixture scans in Latinos is all the greater. However, the application of admixture mapping to find genes in Latinos was not feasible until recently, when three groups including our own simultaneously published genome-wide admixture mapping SNP panels for Latinos (Mao et al. 2007, Price et al. 2007, and Tian et al. 2007). We took advantage of this opportunity and embarked on, to our knowledge, the first Latino whole genome admixture scan. Based on the three independent mapping panels, we selected a panel of 1536 SNP markers across the genome. Here, we will report the results of genotyping these SNPs in >1,000 Colombian T2D cases to screen for T2D disease genes. We will report the results of analyses, using our ANCESTRYMAP software, to search for genomic segments with increased ancestry from one of the ancestral populations, which can indicate the position of a disease locus. If there is a positive signal, a second stage fine mapping will be used for follow-up analysis.

Association of SLC34A2 and Sodium-Lithium Countertransport. *X. Zheng[1], C.M. Kammerer[1], L.A. Cox[2], A. Morrison[3], R.E. Ferrell[1]* 1) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 2) Department of Genetics, Southwest Foundation for Biomedical Research, San Antonio, TX; 3) Human Genetics Center, School of Public Health , University of Texas Health Science Center at Houston, Houston, TX.

Sodium Lithium Countertransport (SLC), which is a premorbid marker of essential hypertension, has been linked to a region of baboon chromosome 5, homologous to the region of human chromosome 4. The specific aim of our study is to examine the relationship between a positional candidate gene SLC34A2 (Type II Na/Pi-cotransporters IIb) and SLC by sequence analysis of SLC34A2 in baboons of known phenotype and of its human homolog, and to conduct association analysis between variation in SLC34A2 and SLC phenotype. We sequenced the SLC34A2 gene, including coding exons, splice junctions and predicted promoter sequences in 24 baboon founders and 94 human samples. Strong homology was established in exonic organization and sequence between the human and baboon SLC34A2 genes and extensive variation in both species was identified. A total of 17 exonic single nucleotide polymorphisms (SNP) were observed in the baboon compared to five in the human, no SNP were shared between the two species. Association studies between SLC and SLC34A2 were carried out in 1856 RFHS phase II samples and 634 baboons. Significant association of SLC with human SNP rs3775909 ($p=0.03$) in SLC34A2 and haplotype block 2 ($p<0.005$) were observed. Strong evidence for association of SLC34A2 with SLC were from baboon SNP Asn136Asn ($p=0.0001$) in SLC34A2. This single SNP explained about 5% of variance in SLC. Consistent findings in two different species implied that SLC34A2 may be one of the genes involved in SLC. However, linkage analyses conditional on genotypes of baboon Asn136Asn suggest that Asn136Asn is not the primarily functional site responsible for SLC, there might be other variants with larger effect in or near SLC34A2 accounting for the linkage signal in baboon. We conclude that SLC34A2 is associated with the phenotypic variation of SLC, though it may not be the major effect gene.

Assessing Knowledge of Genetics by the United States Medical Licensing Examination (USMLE). *D.J. Waggoner[1], M.G. Blitzer[2], G. Feldman[3], M.S. Watson[4], R.E. Pyeritz[5]* 1) Univ Chicago; 2) Univ Maryland; 3) Wayne State Univ; 4) Am Coll Med Genetics; 5) Univ Pennsylvania.

American medical students and recent graduates take 3 Steps of the USMLE. Step 1 assesses understanding and application of sciences basic to the practice of medicine; Step 2 assesses patient care under supervision; and Step 3 assesses unsupervised medical practice. Four times in the past 12 years, most recently in May, 2007, representatives of the APHMG, ACMG & ASHG worked with the National Board of Medical Examiners (NBME), which creates and administers the USMLE, to assess the focus on genetics in each Step. Exams in 1995 had few questions that assessed knowledge of genetics, and most (2/3) were in Step 1. Genetics societies counseled the NBME, and medical geneticists volunteered and were selected for item-writing committees. Subsequent audits documented gradual progress in incorporating genetics questions. Currently, questions that address basic genetic principles or knowledge of hereditary disorders and congenital malformations were more frequent on all Steps, with the greatest increases on Steps 2 and 3. Importantly, even when a genetic term or disease was the incorrect answer (a distractor, which did not qualify the question as genetic), it was much more relevant to the sense of the question compared to previous audits. NBME identifies in Step 1 genetic questions to report an average genetic score for students at each medical schools. We independently confirmed the validity of all questions NBME classed as genetic, but also identified additional questions that could have been so classified. Assisting the NBME in classifying questions will improve the reliability and utility of the genetics performance report. When the content of the genetic questions was evaluated in reference to 2001 APHMG & ASHG curricular criteria for medical schools, certain areas were overrepresented (e.g., specific facts about diseases), and other areas were not assessed. We also identified needed revisions to the existing curricular guidelines. The NBME remains committed to working with genetics societies to improve the assessment of genetics education for medical students and interns.

qPCR quality assessment of whole genome amplified FFPE DNA samples and comparison of their use on BAC and oligo array platforms. *C. Williams[1], S. Michalik[2]* 1) PerkinElmer Life and Analytical Sciences, Waltham, MA; 2) Sigma-Aldrich, St. Louis, MO.

Archival, formalin-fixed, paraffin-embedded (FFPE) tissues are an invaluable source of material for molecular genetic studies linked to patient history. Unfortunately FFPE samples are regarded to be poor resources for such applications since they tend to contain small amounts of highly fragmented and damaged nucleic acids. Array-based comparative genomic hybridization (aCGH) is a relatively new technology used to assess chromosomal aberrations, particularly in evaluation of cancer samples. A limitation of aCGH to FFPE applications is that it typically requires microgram quantities of high quality input DNA. Typically the DNA yields of FFPE samples are less than the microgram range, so aCGH application to FFPE tissues has yet to be reliably established. Recent reports suggest that FFPE DNA can be directly labeled for oligo-based aCGH, however the high DNA input requirement (5 g) is unreasonable for most situations. A number of studies have shown the successful use of whole genome amplified (WGA) FFPE DNA in aCGH applications, but none have directly compared the performance of WGA product on an oligo-array and BAC array platforms. Here we show that as little as 10ng FFPE genomic DNA or ~1mg FFPE tissue can be amplified directly with GenomePlex WGA and analyzed via PerkinElmer SpectralChip 2600 BAC arrays to generate high quality aCGH data from archival samples. We surmise that BAC aCGH is more reliable than oligo aCGH platforms for determining chromosomal gains or losses when using GenomePlex WGA FFPE DNA due to lower signal-to-noise that likely arises due to oligo aCGH probe length (~25 - 70 mer) as opposed to BAC aCGH probe length (~100Kb).

In addition, we show that the assessment of DNA quality is a crucial step in acquiring meaningful data from FFPE tissues, and other sources of damaged DNA. Determining the quality of FFPE DNA via PCR strategies prior to downstream applications is key for successful analysis of chromosomal aberrations (e.g. aCGH, SNP analysis, LOH, etc.).

Infantile spasms and seizure disorder associated with deletion of a 2.5 Mb interval of 7q11.23-7q21.11. *L.R. Osborne[1], J. Skaug[2], P. Kaplan[3], E.J. Young[1], M.L. Freckmann[4], M. Morimoto[5], S.W. Scherer[2]* 1) Medicine, University of Toronto, Toronto, Ontario, Canada; 2) Genetics & Genomic Biology, SickKids, Toronto, Canada; 3) Pediatrics, The Children's Hospital of Philadelphia, Philadelphia, PA; 4) Clinical Genetics, Sydney Children's Hospital, Randwick, NSW, Australia; 5) Pediatrics, Kyoto Prefectural University of Medicine, Kyoto, Japan.

Deletion of a 1.55 Mb region of chromosome 7q11.23 results in Williams-Beuren syndrome (WBS), a disorder associated with cardiovascular symptoms, mild to moderate mental retardation and a variety of cognitive and behavioral deficits. Seizures are rare in the WBS population, but several individuals with larger deletions that extend toward the telomere have been reported to exhibit seizures in addition to WBS. As part of our ongoing study to relate genotype to phenotype at the WBS locus, we have used copy number variant analysis to define deletion breakpoints in subjects with deletions of the 7q11.23 region, distal to the WBS interval. We have mapped the extent of deletion in eleven new subjects with deletions of 7q11.23, identified through our study of WBS and through the continuous curation of our Chromosome 7 Annotation Project. DNA samples were genotyped with the Affymetrix GeneChip Human Mapping NspI Array, the scans were analyzed using dChip 2006 software and comparative intensity analysis performed. Eight of the subjects were hemizygous for the WBS region, and three had deletions that did not include the common WBS deletion region. Together with information from ten previously published subjects with deletions of 7q11.23, we have defined an approximately 2.5 Mb interval of 7q11.23-7q21.11 that is commonly disrupted in subjects with infantile spasms or seizure disorders, but is intact in subjects with no seizure symptoms. This common interval spans only four known genes, all of which are expressed in the brain and are therefore candidates for causing seizure symptoms. The identification of additional subjects with 7q11.23 deletions should allow further narrowing of the critical interval, with eventual identification of the causative gene.

MEP1A is a susceptibility gene for inflammatory bowel disease. *B. Oneda[1], L. Min Yap[2], F. Seibold[3], D. Jewell[2], E.E. Sterchi[1], D. Lottaz[1]* 1) Institute of Biochemistry and Molecular Medicine, University of Bern, Switzerland; 2) Gastroenterology Unit, Radcliffe Infirmary, University of Oxford, United Kingdom; 3) Department of Gastroenterology, University of Bern, Switzerland.

Crohns disease (CD) and ulcerative colitis (UC), the two most common forms of inflammatory bowel disease (IBD), are idiopathic, chronic, relapsing, inflammatory conditions, which are characterized by overreactive immune response. Genetic and environmental factors are known to influence the development and course of the disease, although the exact cause is still not known. Several IBD-susceptibility regions (IBD1-IBD9) across different chromosomes are known from linkage studies. The IBD3 susceptibility region on chromosome 6 harbors the MEP1A gene that encodes for the metalloprotease meprin-, which is abundantly expressed in intestinal epithelial cells and is secreted into the gut lumen. In a previous genetic association study, we have found a significant association of MEP1A in a cohort of 379 UC and 380 CD patients, compared to 372 healthy controls. One non-synonymous and three synonymous SNPs in the coding region were significantly associated with UC, but not CD, whereas one 3UTR SNP (C2417A) was particularly strongly associated with both UC and CD ($p=2.10^{-7}$ and 3.10^{-3}, respectively). We hypothesized that the IBD-associated meprin-? 3UTR alleles show quantitative differences. Indeed, quantitative RT-PCR showed a marked reduction of meprin-? mRNA in inflamed mucosa, as well as a trend for lower expression in non-inflamed mucosa in IBD patients. These data indicate that MEP1A is a susceptibility gene that contributes to the pathogenesis of IBD and that a reduction in expression of meprin- can be associated with intestinal inflammation. Because the 3UTR is a region frequently recognized by miRNAs, we did an in silico analysis to compare the effect of the observed C2417A transversion on putative miRNA bindings sites. Two miRNAs targeting this site were identified, both of which highly expressed in human colon. Ongoing studies using cell culture models and reporter gene assays are now aimed to reveal the function of this 3UTR polymorphism in meprin-? mRNA and protein expression.

A novel mutation of the NDUFS7 gene leads to activation of a cryptic exon and impaired assembly of mitochondrial complex I in a patient with Leigh syndrome. *S. Lebon[2], L. Minai[1], D. Chretien[1], J. Corcos[2], V. Serre[1], N. Kadhom[2], J. Steffann[2], JY. Pauchard[3], A. Munnich[2], JP. Bonenfont[2], A. Rotig[1]* 1) INSERM U781, hopital Necker, Paris, France; 2) Service de Génétique, Hôpital Necker Enfants Malades, Paris, France; 3) Service de Pédiatrie, Hôpital de Pontarlier, Pontarlier, France.

Complex I deficiency is a frequent cause of mitochondrial disease as it accounts for one third of these disorders. By genotyping several putative disease loci using microsatellite markers we were able to describe a new NDUFS7 mutation in a consanguineous family with Leigh syndrome and isolated complex I deficiency. This mutation lies in the first intron of the NDUFS7 gene (c.17-1167 C to G) and creates a strong donor splice site resulting in the generation of a cryptic exon. This mutation is predicted to result in a shortened mutant protein of 41 instead of 213 amino acids containing only the first five amino acids of the normal protein. Analysis of the assembly state of the respiratory chain complexes under native condition revealed a marked decrease of fully-assembled complex I while the quantity of the other complexes was not altered. These results report the first intronic NDUFS7 gene mutation and demonstrate the crucial role of NDUFS7 in the biogenesis of complex I.

Gene expression profiling of peripheral blood of patients with SCA1 and SCA3 identifies potential disease progression markers. *M. Walter[1], S. Poths[1], T. Schmitz-Hübsch[2], O. Riess[1], M. Bonin[1], The Eurosca Consortium* 1) Microarray Facility Tübingen, Institute of Human Genetics, Department of Medical Genetics, Eberhard-Karls-University, Tübingen, Germany; 2) Dept. of Neurology, University of Bonn, Germany.

Spinocerebellar ataxias (SCAs) are dominant, late onset hereditary disorders characterized by a progressive ataxia that is variably associated with other neurological symptoms. The clinical hallmarks result from a progressive degenerative process that mostly affects the cerebellum, brainstem and spinal cord. To date at least 28 different loci are associated with SCAs and related diseases. Therefore, we used whole genome expression profiling of peripheral blood to search for easily accessible markers, which should i) differentiate between patients with different SCA types and ii) be able to monitor disease progression. Whole blood of 12 patients with SCA1 and 15 patients with SCA3 were analyzed on Affymetrix U133plus 2.0 Gene Chips. However, using Support Vector Machines (SVM) and Prediction Analysis for Microarrays (PAM) no predictor could be defined that clearly distinguish between the two disease types. This is most likely due to the large heterogeneity of the patients which had disease durations between two and over 20 years. To identify progression specific markers, the patient collective was subdivided in early, intermediate and late stage of disease according to their SARA value (Scale for the Assessment and Scaling of Ataxias). Transcripts, that showed differential expression between early and late stage patients, were identified and subsequently used to define a gene predictor set of 18 genes, which is able to correctly predict the disease stage of all patients of all three disease stages. Neither of these transcripts showed significant changes in age matched healthy control samples. Taken together, grouping of the patient samples according to their stage of disease progression enabled us to identify markers that did not change with age but with severeness of disease and could classify the patients into early, intermediate or late stage.

Prenyldiphosphate synthase (PDSS1) and OH-benzoate prenyltransferase (COQ2) mutations in ubiquinone deficiency and oxidative phosphorylation disorders. *J. Mollet[1], I. Giurgea[1], D. Schlemmer[1], G. Dallner[2], D. Chretien[1], A. Delahodde[3], D. Bacq[4], P. de Lonlay[1], A. Munnich[1], A. Rötig[1]* 1) INSERM U781 and Department of Genetics, Hôpital Necker-Enfants Malades, 149 rue de Sèvres, 75015 Paris, France; 2) Department of Molecular Medicine and Surgery, Karolinska Hospital, Karolinska Institute, Stockholm, Sweden; 3) Institut de Génétique et Microbiologie, UMR 8621 CNRS, Université Paris-Sud, Orsay, France; 4) Centre National de Génotypage, 2 rue Gaston Crémieux, 91057 Evry, France.

Coenzyme Q10 (CoQ10) plays a pivotal role in oxidative phosphorylation (OXPHOS), as it distributes electrons between the various dehydrogenases and the cytochrome segments of the respiratory chain. We have identified two novel inborn errors of CoQ10 biosynthesis in two distinct families. In both cases, enzymologic studies showed that quinone-dependent OXPHOS activities were in the range of lowest control values, while OXPHOS enzyme activities were normal. CoQ10 deficiency was confirmed by restoration of normal OXPHOS activities after addition of quinone. A genome-wide search for homozygosity in family 1 identified a region of chromosome 10 encompassing the prenyldiphosphate synthase gene (PDSS1) which encodes the human ortholog of the yeast COQ1 gene, a key enzyme of CoQ10 synthesis. Sequencing PDSS1 identified a homozygous nucleotide substitution modifying a conserved amino acid of the protein (D308E). In the second family, direct sequencing of the OH-benzoate prenyltransferase gene, the human ortholog of the yeast COQ2 gene, identified a single base pair frameshift deletion resulting in a premature stop codon (c.1198delT, N401fsX415). Transformation of yeast coq1 and coq2 strains by mutant yeast COQ1 and mutant human COQ2 genes, respectively, resulted in defective growth on respiratory medium showing that these mutations are indeed the cause of OXPHOS deficiency.

Frequent inactivation of NDRG2 by promoter hypermethylation in human colon cancers. *A. Piepoli[1], R. Cotugno[1], G. Merla[2], A. Gentile[1], B. Augello[2], M. Quitadamo[1], A. Merla[1], M. Carella[2], R. Maglietta[3], N. Ancona[3], A. Andriulli[1], F. Perri[1]* 1) Unit and Research Laboratory of Gastroenterology, Casa Sollievo della Sofferenza, Hospital, IRCCS, San Giovanni Rotondo, Italy; 2) Medical Genetics Service, Casa Sollievo della Sofferenza, Hospital, IRCCS, San Giovanni Rotondo, Italy; 3) Istituto di Studi sui Sistemi Intelligenti per lAutomazione - CNR, Bari, Italy.

BACKGROUND & AIM: Epigenetic aberrations have been shown to play an important role in the pathogenesis of most human cancers. In the present study, promoter hypermethylation status in colorectal tumor were investigated to identify and validate novel target genes. METHODS: Using qRT-PCR assay, the gene expression profiles of colon cancer cell lines before and after treatment with the demethylating agent 5-aza-2'-deoxycytidine were evaluated and compared. The expression levels of seven responding genes were compared with the microarray expression data obtained on primary colorectal carcinomas. These down-regulated genes were subjected to bi-sulfite sequencing and methylation-specific polymerase chain reaction (MSP) using colon cancer cell line (n= 3), tumor and normal tissue (n= 30) of patients with colorectal cancer (CRC). RESULTS: In colon cancer cell lines, hypermethylation was subsequently identified in four of seven genes analyzed, HPDG (67%), PRDX6 (34%), STX12 (34%) and NDRG2 (100%). For the latter three genes, absence or reduced gene expression was not associated with promoter hypermethylation. The methylation status of NDRG2 was moreover investigated in primary colon tumor and in normal colon tissue of 30 CRC patients using both bi-sulfite sequencing and MSP. Twenty-two of 30 (73%) carcinomas were hypermethylated for this gene. Finally, analysis of normal colorectal mucosa demonstrated that the observed promoter hypermethylation was cancer-specific. CONCLUSION: These findings highlight the utility of combining microarray, expression, and epigenetic data to identify clinically significant tumor biomarkers, and suggest that NDRG2 expression will be a useful and functionally relevant biomarkers to predict patients with colorectal cancer.

QMPSF : A novel method for detection of 1p19q deletions in gliomas. *V. Paquis-Flucklinger[1, 2], S. Monnot[2], D. Fontaine[1, 3], F. Vandenbos[1, 4], P. Paquis[1, 3], J.F. Michiels[1, 4]* 1) UMR CNRS 6543, Medicine School, NICE cedex 2; 2) Department of Medical Genetics, CHU Nice; 3) Department of Neurosurgery, CHU Nice; 4) Department of Anatomopathology, CHU Nice.

Gliomas are the most common primary cerebral malignancies. Deletions of 1p and 19q chromosomes have shown to be predictors of chemotherapeutic response and better survival in oligodendrogliomas. Different techniques are available for the detection of these alterations including LOH, FISH and CGH. Despite good concordance exists in terms of sensitivity and specificity between these methods, all have specific limitations. The aim of our study was to describe a reliable novel technique for the detection of 1p/19q deletions in gliomas. For each chromosome arm (1p and 19q), we devised a multiplex PCR assay of fluorescent fragments corresponding to exons, which belong to genes located in the minimal deleted region. A control gene, located on chromosome 1q or 19p, is simultaneously amplified in each assay. PCR products are analysed on an automated sequencer and electropherograms generated from control and tumor samples are superimposed. We have searched for 1p/19q deletions by LOH and QMPSF (Quantitative Multiplex PCR of Short Fluorescent fragments) in a series of 50 patients with a glioma. We found that QMPSF, which does not require constitutional DNA, is a simple, rapid and reliable method to detect 1p/19q deletions. There was a good concordance with LOH data in (88% for 1p deletion and in 83% for 19q deletion). Furthermore, we show that QMPSF has a higher sensitivity than LOH and allows the detection of 1p/19q duplications. In conclusion, QMPSF can be routinely used in diagnosis laboratories for the detection of 1p/19q rearrangements in glial tumors.

LCR22-B - mediated chromosome translocation t(4;22)(q11.2;q21.22): A search for the AT-rich cruciform structures. *M. Smyk[1], J. Pietrzak[1], M. Lisik[2], E. Obersztyn[1], E. Bocian[1], P. Stankiewicz[1,3]* 1) Department of Medical Genetics, Institute of Mother and Child, Warsaw, Poland; 2) Department of Medical Genetics, Silesian University School of Medicine, Katowice, Poland; 3) Dept. of Molecular & Human Genetics, Baylor College of Medicine, Houston TX.

Chromosome 22q11.2 is an unstable genomic region associated with a number of common genomic disorders such as DiGeorge/Velocardiofacial syndrome (deletion 22q11.2), microduplication dup(22)(q11.2q11.2), cat-eye syndrome and der(22) syndrome. The increased instability of this region is related to the presence of several highly homologous low-copy repeats. The der(22) syndrome results from an unbalanced product of the most frequent non-Robertsonian recurrent translocation in humans, t(11;22)(q11.2;q23.3). The breakpoints of this translocation have been mapped within the center of the AT-rich cruciform structures also known as the Palindromic AT-Rich Repeat or PATRR. The chromosome 22q11.2 palindrome is located within the LCR22-B copy, is 595 bp in size and has been found to harbor the breakpoints of a few other non-recurrent translocations: t(17;22)(q11.2;q11.2) (two cases), t(1;22)(p21.2;q11.2), t(4;22)(q35.1;q11.2), and t(8;22)(q24.13;q11.21). Interestingly, the partner chromosome breakpoints have been mapped also within palindromic sequences, most of which are AT-rich. We present an apparently balanced translocation t(4;22)(q11.2;q21.22) identified in a phenotypically normal girl and her mother, who had several miscarriages. Using FISH with BAC clones, we have mapped the chromosome 22q breakpoint within the LCR22-B copy and the chromosome 4q21.22 breakpoint within an ~50 kb fragment of a BAC clone RP11-51G24. Using computer analyses of the DNA sequence of this DNA segment, we have identified three AT-rich palindromes. We hypothesize that one of them, together with the 595 bp palindrome in LCR22-B, might have mediated the formation of the described translocation t(4;22)(q11.2;q21.22). Our data identify a novel potentially unstable region in the human genome.

New light on the changing epidemiology of cystic fibrosis: the 15-year experience of Brittany (western France). *V. Scotet[1], I. Duguépéroux[1], MP. Audrézet[1,2], M. Blayau[3], P. Parent[4], H. Journel[5], P. Boisseau[6], C. Férec[1,2]* 1) Inserm U613, Brest, France; 2) Dept of Genetics, Brest, France; 3) Dept of Genetics, Rennes, France; 4) Unit of Medical Genetics, Brest, France; 5) Unit of Medical Genetics, Vannes, France; 6) Dept of Genetics, Nantes, France.

This study aimed to describe 15-year experience in the field of prenatal diagnosis (PD) for cystic fibrosis (CF) of Brittany, a region where CF is frequent and where the uptake of PD is common. For this, we registered, by the genetic laboratories of our region, all the PDs performed in women living in Brittany over the period 1991-2005. First, we described the number of PDs made for each reason (way by which the one-in-four risk was identified: previous affected child, family testing, echogenic bowel, etc). We then reported the proportion of CF fetuses and of consecutive terminations, and assessed the incidence modification due to PD. Over the 15-year period, a total of 253 PDs were performed in couples living in Brittany. Most of them were done in couples already having CF child(ren) (n=167, 66.0%). Extended testing in families led to the identification of 18 new one-in-four risk couples among the relatives of CF patients who opted for PD 38 times over the study period (15.0%). The 48 other PDs were made in couples without previous history of CF. The one-in-four risk was mainly identified following the detection of an echogenic bowel during pregnancy ultrasound examination (n=40 - 15.8%). The other PDs were consecutive to the detection of an heterozygote through newborn screening (n=6, 2.4%) or for an other reasons (n=2, 0.8%). Overall, a total of 88 CF fetuses were identified, among whom 77 were terminated (87.5%). The inclusion in the incidence calculation of these 77 pregnancy terminations led that to an incidence modification of 28.8% over the study period. This study reports the long experience of a region in the field of PD for CF. It shows that this test is commonly used in Brittany and highlights the impact of family testing and of routine ultrasound examination of pregnancies in that region. Supported by the French CF association « Vaincre La Mucoviscidose ».

Mitochondrial respiratory chain assembly and function during human fetal development. *L. Minai[1], D. Chretien[1], F. Razavi[2], A. Munnich[1], A. Rotig[1]* 1) INSERM U781, Hopital Necker, Paris, France; 2) Service Histologie Embryologie Cytogenetique, Hopital Necker, Paris, France.

Although a number of metabolic diseases undergo a symptom-free period, respiratory chain deficiency may have an early antenatal expression, presumably related to the time course of the disease gene expression in the embryofoetal period. We present the investigation of the assembly and function of the mitochondrial respiratory chain during human foetal development. The study was carried out on human foetuses aged from 4 to17 weeks of gestation and aborted for genetic diseases unrelated to mitochondrial function. For each foetus, several different tissues (brain, heart, liver, kidney and muscle) were examined. The assembly of the various respiratory chain complexes studied by blue native gel electrophoresis showed a similar size and amount of these complexes whatever the stage of development in the various tissues tested. Moreover, this pattern was the same as observed for post-natal tissues. SDS-PAGE followed by Western blot revealed that all complexes were fully assembled. However, a slightly faster migrating -ATPase subunit of CV was detected in fetal brain compared to other pre- and post-natal tissues. Finally, enzyme measurement of respiratory chain complexes showed a similar repartition of the five complexes in pre- and postnatal tissues. Nevertheless, prenatal values were constantly lower than pos-natal values. Our results showed that the subunits of the respiratory chain are fully assembled and functional in the very early steps of fetal development. Therefore, the time dependent expression of respiratory chain deficiency should be related to different spatiotemporal variations of genes involved in regulation and maturation of these multienzymatic complexes.

Long QT syndrome patients with double heterozygous and compound heterozygous mutations. *J. Thistleton[1], K. Livesey[1], K. Thomson[1], H. Lord[1], E. Blair[2], A. Seller[1]* 1) Oxford Molecular Genetics Lab., Churchill Hospital, Oxford, United Kingdom; 2) Dept. of Clinical Genetics, Churchill Hospital, Oxford, United Kingdom.

To date we have screened over 250 probands, with either a suspected or definite diagnosis of Long QT syndrome, for mutations in the 4 cardiac K+ channels genes: KCNQ1, KCNH2, KCNE1 and KCNH2 and in the cardiac Na+ channel gene, SCN5A, using WAVE dHPLC technology and direct sequencing. Pathogenic variants have been identified in over 50% of our probands, thus enabling cascade screening and better clinical management of at risk relatives.

However, approximately 10% of our patient positive cohort show a complex molecular pattern, with a second mutation identified in either the same gene (compound heterozygosity) or in a different gene (double heterozygosity), which is much higher than has been described previously in the literature. This has raised issues for the interpretation of the clinical significance of each variant and for the provision of predictive testing to family members.

We present 2 cases of double heterozygosity for KCNQ1 and KCNH2, as well as KCNH2 and KCNE1, and a further 2 cases of compound heterozygosity for KCNQ1 and KCNH2. We describe the implications of these findings on molecular screening strategies and patient care, this data emphasising the importance of screening all relevant genes even when a pathogenic mutation is identified in one gene. We will also demonstrate the need for good liaison between clinical genetics and laboratory departments.

Congenital hip dislocation : the report of a genome-wide linkage scan in Brittany (Western France). *K. Rouault[1], V. Scotet[1], S. Autret[1], F. Dubrana[2], B. Fenoll[3], F. Gaucher[4], D. Tanguy[5], C. Yaacoub[6], C. Férec[1]* 1) Inserm U613, CHU Morvan, University, Brest, France; 2) Department of orthopaedic surgery, CHU La Cavale Blanche, Brest, France; 3) Department of paediatric surgery, CHU Morvan, Brest, France; 4) Department of orthopaedic surgery, Hotel Dieu, Pont LAbbé, France; 5) Department of physical medicine, Centre de Perharidy, Roscoff, France; 6) Department of orthopaedic surgery, CH Cornouaille, Quimper, France.

Congenital dislocation of the hip (CDH) is a public health matter because of its high frequency, the severe functional handicap induced if it is not treated early and its natural evolution towards hip osteoarthritis. This disease presents a mechanical component linked to the pregnancy and delivery conditions but the ethnical predispositions and the familial aggregation observed is also in favour of a genetic component. Clusters of CDH have been observed among Lapps and Navajo Indians, but this condition is also very frequent in the area of Finistère (Brittany - France). In order to identify the gene(s) responsible for CDH, we set up the first genome-wide linkage scan on this disease. To date, 38 family structures including affected sib-pairs (n=29) or at least four cases of CDH (n=9) could have been recruited. The whole scanning of the genome is carried out by typing 400 markers microsatellites (STRs) at 10 cM intervals (kit Linkage Mapping Set MD10 v2.5). The linkage analysis between the loci markers and the locus of gene responsible for pathology is carried out, in a first step, by a non-parametric method (npl) using the Merlin software. To date, the genotyping of all the markers is completed for the nine most informative family structures. The interpretation of the data is currently in process but non-parametric analyses could not yet bringing to light any area of interest. If this genome-wide linkage analysis enable to locate the area(s) of interest on the genome, it will enable to better understand the physiological basis of the CDH and should lead to earlier detection and treatment of subjects at risk to develop CDH. This work was supported by a grant from Projet Hospitalier de Recherche Clinique and from Programme de Recherche dInitiative Régionale.

Follow-up of italian families who received a prenatal diagnosis of triple X. *V. Viassolo[1], F. Forzano[1], S. Gattone[1], F. Faravelli[1], E. Grosso[2], U. Cavallari[3], E. Folliero[4], D. Quagliarini[4], F. Lalatta[3]* 1) Clinical Genetics Unit, Galliera Hospital, Genova, GE, Italy; 2) Genetica Medica, ASO S.Giovanni Battista, Torino, Italy; 3) Medical Genetics Unit, Department D.B.N. Fondazione Ospedale Maggiore Policlinico Mangiagalli e Regina Elena, Milan, Italy; 4) Prenatal Diagnosis Unit, Department D.B.N. Fondazione Ospedale Maggiore Policlinico Mangiagalli e Regina Elena, Milan, Italy.

Sex chromosome abnormalities (SCA) are the most frequently occurring chromosomal abnormalities both at prenatal diagnosis and at birth. Approximately 1/400 newborns has SCA and incidence at prenatal diagnosis is even greater (1/250-1/300). Among SCA, 47,XXX, which is expected to have few clinical consequences to the affected individual, requires complex and challenging genetic counselling and outcome is often not fully documented. We have identified 61 couples who required genetic counselling after prenatal diagnosis of 47,XXX in the first or second trimester of pregnancy (period 1998-2005). Among these, 32 accepted to be included in our study. Average maternal age was 38 years. Eight couples performed fetal karyotype for reasons other than maternal age. The protocol included clinical genetic evaluation of the carrier girls comprehensive of auxological measurements and detailed personal history. A questionnaire including an assessment of motor, language, behavioural and cognitive skills was then administered. Preliminary results did not show any serious clinical consequence, with the exception of one individual with global developmental delay and microcephaly. Anthropometric parameters evaluated at birth and at the follow-up age were within the normal range. In six cases we identified a congenital anomaly (club foot, flat foot, lymphangioma, preauricular tag, thyroid agenesis, hip dysplasia). In three cases language delay was identified. The present study might contribute to better understanding the 47,XXX phenotype and to provide a better counselling in prenatal diagnosis settings.

Clinical Benefit Of Treatment with Alglucosidase Alfa in Infants and Children with Advanced Pompe Disease. *M. Nicolino[1], B. Byrne[2], C. Spencer[2], J. Levine[3], N. Leslie[4], E. Wraith[5], P. Kishnani[6]* 1) University Hopital Debrousse, Lyon France; 2) Shands Hospital at the University of Florida, Gainsville, FL; 3) Children's Hospital, Boston, MA; 4) Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 5) Royal Manchester Hospital, Manchester, UK; 6) Duke University Medical Center, Durham NC.

Introduction. Pompe disease is caused by a deficiency of acid alpha glucosidase (GAA). Severe GAA deficiency manifests during infancy with muscle weakness/hypotonia, cardiomyopathy and severe motor delay. Most patients die from cardio-respiratory failure by 2 years of age. **Methods.** An open-label, multinational, multicenter study in patients with cardiomyopathy, minimal residual GAA (<1%) and age >6 to 36 months. Human recombinant GAA (alglucosidase alfa) was administered IV at 20 mg/kg/qow. **Results.** Twenty one patients (10M:11F) were enrolled; 7 were already ventilated. Median age at treatment was 13 months (range: 3.7-46.1); median duration of treatment was 124 weeks (range: 1-172). Treatment with alglucosidase alfa reduced the risk of death by 79% (p=0.0009) and the risk of death or invasive ventilation by 58% (p=0.02) when compared to an untreated historical cohort (n=86). LVMI improved in 17 patients (81%). Motor gains occurred in 13 patients (62%). Over 80% of patients maintained normal growth parameters. Six deaths occurred, none related to alglucosidase alfa. Eleven patients (52%) had infusion-associated reactions (IARs), all managed successfully. Anti-rhGAA antibodies developed in 95% of patients (non inhibitory by in vitro testing). A trend towards decreasing titers was observed with continued treatment for >52 weeks. **Conclusions.** In spite of the late age at initiation of treatment and the advanced stage of disease progression at baseline, results of this study indicate that alglucosidase alfa significantly prolongs survival and invasive ventilation-free survival in patients with Pompe disease when compared to a similar untreated historical cohort. A previous study (Kishnani et al. Neurol 2007) established that treatment at an early age, prior to irreversible muscle tissue damage, may optimize the clinical response.

Up-regulation of ARH1 in Galactose-stressed, Isogenic Human Fibroblasts deficient in Galactose-1-phosphate Uridyltransferase. *K. Lai[1,2], M. Tang[2,3], X. Yin[2], H. Klapper[2], K. Wierenga[1,2], L.J. Elsas[1,2,3]* 1) Dept Pediatrics, U. Miami, Miami, FL; 2) The Dr. John T. Macdonald Foundation Center for Medical Genetics, U. Miami, Miami, FL; 3) Dept. Biochemistry & Mol. Biology, U. Miami, Miami, FL.

The cause and mechanisms for premature ovarian failure (POF) and cerebellar impairment commonly manifested among patients with inherited deficiency of galactose-1-phosphate uridyltransferase (GALT) remain unsolved. GALT-knockout mouse models do not manifest either ovarian failure or ataxia. Here we studied primary fibroblasts derived from patients homozygous for a 5kb deletion or the Q188R missense mutation in their GALT genes. Using gene expression microarrays, we found that the human tumor suppressor gene aplysia ras homolog I (ARHI) was up-regulated six-fold in cells treated with 0.5mM galactose for two hours, and the level of up-regulation rose to 11-fold at the end of a 24-hour incubation. Up-regulation of ARHI was not observed in normal cells similarly challenged. The microarray data were confirmed by quantitative real-time PCR. It is noteworthy that the murine ARHI gene was lost as a consequence of evolutionary chromosome rearrangement (Fitzgerald and Bateman, 2004). Over-expression of the human ARHI gene in transgenic mouse models produced failure of folliculogenesis and loss of neurons in the celebellar cortex (Xu et al., 2000). We conclude that increased expression of ARHI is a novel result of galactose toxicity in GALT-deficient cells, and may explain both the lack of a phenotype in the GALT-knockout mice, and the organ-specific effects of GALT-deficiency in humans.

Association between the p53 codon 72 polymorphism and primary open angle glaucoma in the Japanese population. *F. Mabuchi[1], K. Kashiwagi[1], Z. Yamagata[2], H. Iijima[1], S. Tsukahara[1]* 1) Dept Ophthalmology, Univ Yamanashi, Chuo, Yamanashi, Japan; 2) Dept Health Sciences, Univ Yamanashi, Chuo, Yamanashi, Japan.

Purpose Previous studies looking at the association of the p53 gene polymorphism and primary open angle glaucoma (POAG) revealed conflicting results. Additionally, there have been no studies in the Japanese population. We thus assessed whether genetic polymorphism of p53 was associated with POAG in the Japanese population.

Methods Genomic DNA was examined in a cohort of 426 Japanese patients with POAG, including 213 patients with normal tension glaucoma (NTG) and 213 patients with high tension glaucoma (HTG), and 188 control subjects. The average age was 63.7 13.6 years (mean SD) for the NTG patients, 62.9 14.8 years for the HTG patients, and 65.9 11.2 years for the control subjects. The p53 genotype (a G to C substitution at codon 72 which changes an arginine to a proline residue) was determined using allele specific primer PCR analysis, and compared between POAG patients and control subjects.

Results No significant difference (NTG vs. control, P = 0.98, and HTG vs. control, P = 0.69, Chi-square test) was observed regarding the frequencies of the p53 genotype between the NTG (GG: 43.2%, GC: 44.6%, CC: 12.2%) or HTG (GG: 40.4%, GC: 47.9%, CC: 11.7%) patients and the control subjects (GG: 44.1%, GC: 43.6%, CC: 12.3%). Additionally, there was no significant difference (NTG vs. control, P = 0.94; and HTG vs. control, P = 0.66, Fishers exact test) in the frequencies of the p53 alleles between the NTG (G allele: 65.5%, C allele: 34.5%) or HTG (G allele: 64.3%, C allele: 35.7%) patients and the control subjects (G allele: 66.0%, C allele: 34.0%).

Conclusion The p53 codon 72 polymorphism was not found to be associated with POAG in the Japanese population. Further studies in the other ethnic populations should be performed to elucidate the relationship between the p53 gene and POAG.

Differential gene expression in peripheral blood of ALS patients associated with genetical variation. *C.G.J. Saris[1], S. Horvath[2], P.W.J. Vught[1], M.A. van Es[1], H.M. Blauw[1], T. Fuller[2], J. Veldink[1], L.H. van den Berg[1], R.A. Ophoff[3,4]* 1) Department of Neurology, University Medical Center Utrecht, The Netherlands; 2) Department of Human Genetics en Biostatistics, University of California Los Angeles, CA; 3) Semel Institute of Neuroscience and Human Behavioral, University of California Los Angeles, CA; 4) Department of Medical Genetics, University Medical Center Utrecht, The Netherlands.

Objective: The genetics of the sporadic form of **Amyotrophic Lateral Sclerosis** is still largely unknown. Combining the genetical variation with genome wide gene expression profiles of complete blood (genetical genomics) within one individual will give insight in genes associated with the disease.
Method: Of 116 ALS patients and 110 matched healthy controls whole blood gene expression profiling using Illumina HumanRef-8 Expression BeadChip was combined with genome wide genotyping using 300K Illumina Infinium BeadChip.
Using weighted gene co-expression network analysis (WGCNA) genes can be grouped into modules with similar expression patterns. In the first half of the dataset two out of the seven identified modules were differentially expressed in ALS patients and validated in the second part. Mean expression per module (principal component) was mapped on the genome treating it as a quantitative trait. SNPs associated with the differential expressed modules are significantly associated with ALS status.

Conclusion: we find differentially expressed genes in peripheral blood that can be validated. These genes can be used as a biomarker for ALS. Using genome-wide genetic marker data we provide evidence that at least one of these modules is causal for ALS.

Association and Copy Number Variation analysis of *SHANK3* as a candidate gene for autism. *N.H. Sykes[1], I. Sousa[1], C. Allan[1], A. Jefferson[1], N. Alsamhouri[1], A. Morris[1], A. Pagnamenta[1], J. Lamb[2], A.J. Bailey[3], A.P. Monaco[1], IMGSAC[4]* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Centre for Integrated Genomic Medical Research, The University of Manchester, Manchester, UK; 3) University Department of Psychiatry, Park Hospital for Children, Oxford, UK; 4) http://www.well.ox.ac.uk/~maestrin/iat.html.

Autism is a severe neurodevelopmental disorder that usually occurs due to a complex genetic predisposition. It is characterized by impairments in reciprocal social interaction and communication, and restricted and stereotyped patterns of interests and activities. *SHANK3* is a scaffolding protein present on 22q13 that is found in excitatory synapses opposite to the pre-synaptic active zone. It is a binding partner of the neuroligin proteins, some of whose genes have been found to contain mutations in a small subset of individuals with autism. A number of recent studies have found *SHANK3* to be disrupted by deletions ranging from hundreds of kilobases to megabases in several individuals with autism. To further analyse this gene's involvement in autism, 12 haplotype tagging SNPs were chosen across *SHANK3* using Tagger in Haploview v4.0beta12 ($r^2 > 0.8$, MAF > 0.05) and data from the HapMap phase II (release 21). These SNPs were then genotyped in 338 affected sibling pairs from the IMGSAC sample. The extent of homozygosity across these SNPs was examined as a potential indicator of hemizygosity. 54 individuals out of the 1603 typed were found to be homozygous across all 12 SNPs, 23 of which were affected probands. 6 FOSMID clones are currently being used as FISH probes across a region of ~ 150kb covering the *SHANK3* gene to look for deletions in these samples. Association analysis was carried out using the Transmission Disequilibrium Test (TDT), but no significant association was found. Further association results and FISH analysis will be presented.

Generalized Arterial Calcification of Infancy (GACI): Clinical Course and Prevalence of *ENPP1* mutations. *F. Rutsch[1], P. Böyer[1], Y. Nitschke[1], N. Ruf[2], G. Weissen-Plenz[3], P. Nürnberg[4], R. Terkeltaub[5]* 1) University Children's Hospital, Münster, Germany; 2) Max-Delbrück Center, Berlin, Germany; 3) Medicine, University Hospital, Münster, Germany; 4) Cologne Center for Genomics, Cologne, Germany; 5) Medicine, VAMC, UCSD, La Jolla, USA.

GACI is often associated with autosomal recessively inherited defects in Ecto-nucleotide pyrophosphatase 1 (ENPP1). The resulting deficiency in extracellular inorganic pyrophosphate leads to calcification of arteries and intima proliferation, and, occasionally, periarticular calcifications. Clinical data available from 52 clinically diagnosed GACI patients were analyzed retrospectively. Mutation analysis of *ENPP1* was performed by direct sequencing in all patients. 27 of the 52 patients were delivered prematurely. 12 of these presented signs of fetal distress. 35 patients demonstrated signs of heart failure soon after birth, 21 patients developed arterial hypertension. 26 patients presented with pulmonary symptoms, 20 needed ventilatory support. Arterial calcifications were demonstrated predominantly in the aorta and coronary arteries by imaging studies. Additionally, autopsy confirmed calcification of pulmonary and renal arteries in 16 deceased patients. 10 patients showed periarticular calcifications. 21 patients were surviving at the time of data collection, 31 had died, 15 by heart failure. 9 of 14 patients treated with bisphosphonates survived, and calcifcations resolved in 8 of them. Of the 38 patients not treated with bisphosphonates, 12 patients were surviving. In 4 of these, spontaneous resolution of calcifications was demonstrated. Homozygous or compound heterozygous mutations in *ENPP1* were found in 40 of the 52 patients. 26 of these patients died in infancy. Also, 5 of the 12 patients without *ENPP1* mutations died in infancy. *ENPP1* mutations account for 77% of clinically diagnosed GACI cases. 40% of all patients studied survived the critical period of infancy. There is no significant difference in disease manifestations and clinical course in patients with and without *ENPP1* mutations. Bisphosphonate treatment in GACI seems to be reasonable, although a standardized treatment regimen does not exist.

Investigation of 300 patients with delayed psicomotor development, obesity, hyperphagia, learning disabilities and behavioral problems. *M.C. Varela[1], C.S. D'Angelo[1], I. Kohl[1], C.I.E. Castro[1], F. Kok[1,2], C.A. Kim[3], C.P. Koiffmann[1]* 1) CEGH, Dept Gen & Evol Biol, Univ São Paulo; 2) Child Neurol Service, Dept Neurol, Univ São Paulo School of Medicine; 3) Children's Institute, Hospital das Clínicas, School of Medicine, Univ São Paulo, São Paulo, Brazil. E-mail: mcvarela@ib.usp.br.

Obesity in association with phenotypic abnormalities and mental retardation characterizes syndromic obesity. Herein we present molecular studies in 300 patients with syndromic obesity. On an ongoing research we diagnosed 142 patients with Prader-Willi syndrome (PWS), the most common form of syndromic obesity: 86 cases had a paternal deletion of 15q11-q13, 54 maternal uniparental disomy of chr15, and 2 had a defect in the imprinting center. These patients were diagnosed by methylation pattern analysis of the SNRPN-SNURF gene and by microsatellite profiling of loci within and outside the 15q11-q13 region. Two patients with unbalanced translocations were detected. Amongst the remaining 158 patients one had 6q16.2 deletion (including SIM gene) diagnosed by GTG-banding. Multiplex ligation-dependent probe amplification (MLPA) studies (SALSA P147, P036/B, P064) were performed on the remaing patients. These analyses disclosed 4 patients with <3Mb 1p36 terminal deletion, 1 patient with an atypical 17p11.2 deletion (including RAI1 gene) and 1 patient with an inherited atypical 22q11.2 deletion further characterized by SALSA P023; P204, FISH and microsatellites analyses. Besides, subtelomeric MLPA detected a deletion of chromosome 3p probe in 1 patient, subsequentely confirmed with SALSA P208 which revealed a <2.5Mb terminal deletion. The clinical features of patients with 1p36, 17p11.2 and 22q11.2 deletions were either not typical or specific enough to allow diagnosis before MLPA analyses. Human disorders such as PWS and other syndromes associated with obesity and hyperphagia as those described here could play an important role in the understanding of feeding behavior. Investigation of patients with syndromic obesity in spite of the overlap of their phenotypes can lead to the recognition of new syndromes. Supported by: FAPESP, CEPID/FAPESP, CNPq.

Translocations and inversions in Finland. *T. Varilo[1, 2], M. Pöyhönen[2, 3], R. Salonen[4], L. Peltonen[1, 2, 5]* 1) Dept of Mol Med, NPHI, Helsinki, Finland; 2) Dept of Med Genet, U of Helsinki; 3) Dept of Clinical Genet, Helsinki U Central Hospital; 4) Dept of Med Genet, Väestöliitto, Helsinki; 5) The Broad Institute at MIT and Harvard, Boston, MA.

Finland is known of its high standard of clinical medicine and unique founder populations exploited in the hunt of disease genes. What is perhaps not so well recognized is that Finland is probably the country with most comprehensive health registers and records. Information from all the hospitalizations, surgeries, chronic diseases, and prescriptions among many other health related information of the population has been filed for decades.

Relying this infrastructure we are collecting all some 3000 known reciprocal balanced translocations and inversions to a national database (www.fintransloc.org). By analyses of all the medical records and by searches of national medical registers, we are obtaining novel information of not only monogenic diseases with unidentified mutations, but also of multifactorial traits associated with any given chromosomal abnormality. Importantly, such a database will greatly assist genetic counseling efforts.

To date, we have gathered 494 carriers of translocations and inversions and linked them to 195 families. We are currently performing more detailed analyses if these families with the expectation that they could provide shortcuts in the identification of disease genes.

Examples: Fam 5, t(1;12), Specific delay in development, 6 carriers, 2 with specific delay, 1 with dyslexia, 2 with school difficulty. Fam 29, t(2;18), Dyspractic developmental speech disorder, 7 carriers, 3 with speech difficulty, 1 with dyslexia. Fam 45, t(2;22), Learning difficulty, 3 carriers, 1 with multiform learning difficulty. Fam 82, t(5;12), Fibroma molle in palate, 3 carriers, 3 with fibroma molle (plus 1 patient with chr. status unknown). Fam 107, inv 8, Borderline mental retardation, 16 carriers, 11 with borderline mental retardation. Fam 128, t(10;11), Aorta dilatation, 2 carriers, 1 aorta dilation (plus 3 patients with chr. status unknown).

Genome-wide aCGH analysis in patients with sporadic birth defects. *D. Scott[1], J.F. Felix[4], A.M. Holder[1,6], M. Klaassens[3,4], L. de Jong[4], K.P. Lally[5], C. Fernandes[2], D. Tibboel[4], A. de Klein[3], B. Lee[1,6]* 1) Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX; 2) Dept Peds, Baylor Col Med, Houston, TX; 3) Dept of Clin Genet, Erasmus M C, Rotterdam, the Netherlands; 4) Dept of Paed Surg, Erasmus M C, Rotterdam, the Netherlands; 5) Dept of Ped Surg, Univ of Texas Med School, Houston, TX; 6) Howard Hughes Medical Institute.

Congenital diaphragmatic hernia (CDH) and esophageal atresia/tracheoesophageal fistula (EA/TEF) are relatively common sporadic birth defects. Both defects are life threatening and require surgical correction in the newborn period. Although CDH and EA/TEF can occur in isolation, approximately 50% of cases occur with additional anomalies. In the case of EA/TEF, VACTERL (Vertebral, Anal, Cardiac, Tracheo-Esophageal Fistula, Renal, Limb) association is found in approximately 10% of cases. The sporadic nature of these defects makes linkage-based approaches to gene identification impractical. We are using a positional candidate approach based on chromosomal data to localize and identify these genes that cause or predispose to the development of these defects. By reviewing published case reports we have identified 19 recurrently deleted/duplicated chromosomal regions in CDH and 10 recurrently deleted/duplicated chromosomal regions in EA/TEF. We hypothesize that each of these regions harbors a gene(s) related to these birth defects. To identify new regions, and refine those previously reported, we are screening for deletions/duplication in affected individuals using high density genome-wide array comparative genome hybridization (aCGH). With the Agilent 244K platform we typically identify between 20 and 40 copy number variants between subjects and sex match controls. Greater than 90% of these variants have been reported previously in healthy individuals making them less likely to be the cause of these birth defects. We are using qPCR to confirm the novel variants identified in 25 previously unreported patients and to determine their inheritance pattern with families. De novo changes identified in this approach are likely to be disease related and to affect the expression of one or more CDH- or EA/TEF-related genes.

Methylation-Specific Multiplex Ligation-Dependent Probe Amplification (MLPA) Analysis of Subjects with Chromosome 15 Abnormalities. *M.F. Theodoro, D.C. Bittel, N. Kibiryeva, M.G. Butler* Section of Medical Genetics, Children's Mercy Hospital and Clinics and University of Missouri-Kansas City, MO.

Prader-Willi syndrome (PWS) and Angelman syndrome (AS) are neurodevelopmental disorders caused by loss of expression of imprinted genes from the 15q11-q13 region. They arise from similar defects in the 15q11-q13 region but originate on the paternal or maternal chromosome 15, respectively. There are two recognized typical 15q11-q13 deletions depending on size identified in the majority of PWS and AS subjects. Several diagnostic assays are available for identifying genetic subtypes in PWS and AS. However, each has limitations due to cost, time or reliability which make them less than ideal. We evaluated the usefulness of methylation specific multiplex ligation-dependent probe amplification (MLPA) in 95 subjects with chromosome 15 abnormalities (62 PWS, 10 AS, 10 individuals with other chromosome 15 abnormalities [e.g., markers, rings, duplications, translocations, distal deletions] and 13 cytogenetically normal individuals). A commercially available MLPA kit (MRC-Holland; Amsterdam) was used to detect copy number changes as well as to analyze CpG island methylation in the 15q11-q13 region. It contains 25 probes specific for sequences in or near the PWS /AS critical region. Five of these probes contain a HhaI recognition site and are specific for imprinted sequences. Eighteen probes for genes located outside the PWS/AS region are used as controls for copy number changes. Three of these probes contain a HhaI site and unmethylated in control DNA samples used to check for completeness of digestion. We developed an algorithm for MLPA probe analysis which correctly identified methylation abnormalities associated with PWS and AS and accurately determined copy number to correctly assign genetic subtype status including microdeletions of the imprinting center. Furthermore, MLPA analysis identified copy number changes in those with distal 15q deletions and ring 15s. MLPA is a relatively simple, reliable and cost-effective technique which is useful and accurate for analysis of methylation status, copy number and genetic subtype in PWS and AS as well as other chromosome 15 abnormalities.

A fast-throughput service for Familial Hypertrophic and Dilated Cardiomyopathy using High resolution melt curve analysis on the Lightscanner. *M. Wilson[1], J. Thistleton[1], K. Thomson[1], J. Livesey[1], J. McKinney[2], E. Blair[3], H. Watkins[4], A. Seller[1]* 1) Oxford Molecular Genetics Lab., Churchill Hospital, Oxford, United Kingdom; 2) Idaho Technology Inc., 390 Wakara Way, Salt Lake City, Utah 84108, USA; 3) Dept. of Clinical Genetics, Churchill Hospital, Oxford, United Kingdom; 4) Dept. of Cardiovascular Medicine, John Radcliffe Hospital, Oxford, United Kingdom.

High resolution melt curve analysis using the Lightscanner is a newly available technology that provides fast throughput mutation screening, with the capacity to produce results for a 96-well plate in less than 15 minutes. Using this technology there is the potential to reduce reporting times and decrease costs while maintaining the same high sensitivity and specificity as other screening technologies such as dHPLC and CSCE. Our service for Hypertrophic Cardiomyopathy (HCM) and Dilated Cardiomyopathy (DCM) provided an opportunity to test the utility of the Lightscanner in the diagnostic laboratory.

Mutations in the sarcomeric genes; -myosin heavy chain gene (MYH7), myosin binding protein C gene (MYBPC3) and troponin T gene (TNNT2), are thought to account for up to 60% of familial HCM and approx. 10% of familial DCM. Since 2004 a service for HCM and DCM has been available in the Oxford Molecular Genetics Laboratory in conjunction with the Oxford Genetics Knowledge Park. In January 2007, analysis of the 84 amplicons of the sarcomeric genes was transferred from dHPLC to the Lightscanner, including additional analysis of the MYH7 rod domain and TNNI3.

Here we describe the validation carried out prior to the transfer of all service work and demonstrate both efficiency and cost savings as a result of introducing this technology into our diagnostic service.

Pur Alpha Gene Mutations Are Not a Major Cause of Unexplained Spinocerebellar Ataxia. *T.A. Maher[1], G. Zhao[1], J.M. Milunsky[1,2,3]* 1) Center for Human Genetics, Boston University School of Medicine, Boston, MA; 2) Department of Pediatrics, Boston University School of Medicine, Boston, MA; 3) Department of Genetics and Genomics, Boston University School of Medicine, Boston, MA.

The inherited Spinocerebellar ataxias (SCAs) are a group of progressive neurologic disorders that have significant genetic heterogenecity and clinical variability. Clinical molecular testing is available for a growing number of these SCAs, but a significant group of symptomatic patients remain without a known etiology following genetic testing. We evaluated the Pur alpha gene (MIM 600473) as a candidate for causing SCA given its interaction with the FMR1 protein. Our laboratory, retrospectively, bidirectionally sequenced 200 samples for mutations in the Pur alpha gene. The cohort of samples were previously submitted for SCA testing with negative results for SCA1, 2, 3, 6, 7, 8, 10, 12, 17 and DRPLA. This cohort of samples was also screened for the $(CGG)_n$ repeat in the Fragile X mental retardation syndrome gene (FMR1). The FMR1 repeat has been associated with Fragile-X Tremor/Ataxia Syndrome (FXTAS) in patients with repeat sizes in the premutation range of Fragile X. Pur alpha is a ubiquitously expressed sequence-specific DNA- and RNA- binding protein. It has been implicated in the transcripitional control of neuronal genes such as myelin basic protein (MBP), gata2 (mouse), and the nicotinic acetylcholine receptor gene (nAch). Pur alpha also binds triplet $(CAG)_n$ and $(CGG)_n$ repeat domains and interacts with the FMR1 protein. None of our cohort harbor mutations in the Pur alpha gene. Hence, Pur alpha gene mutations appear not to be a major cause of unexplained SCA.

A functional common polymorphism in the Vitamin D-Responsive Element (VDRE) of the GH1 promoter contributes to Isolated Growth Hormone Deficiency (IGHD) susceptibility. *P. Momigliano-Richiardi, M. Godi, S. Mellone, L. Tiradani, Y. Carlomagno, A. Petri, G. Corneli, D. Vivenza, S. Bellone, C. Santoro, G. Bona, M. Giordano*
Department of Medical Sciences, University of Eastern Piedmont, Novara, Italy.

High penetrance mutations in the growth hormone gene (GH1) have been found in the severe growth hormone (GH) deficiency and in the familial forms of IGHD. However most of the IGHD subjects present with a low but detectable serum GH, no family history and no deleterious mutations. The involvement of (GH1) polymorphisms in sporadic isolated growth hormone deficiency (IGHD) was investigated by a case-control study. Seven SNPs in the GH1 promoter (at positions -308,-278,-75,-57,-31,-6,-1), one intronic (IVS4+90) and two SNPs in the LCR region, 14.5 Kb upstream, were analysed in 118 IGHD patients and in two control groups, namely normal stature (N=200) and short stature individuals with normal GH secretion (N=113). The variation -57T within a VDRE showed a positive significant association when comparing patients both with normal (p=0.006) or with short stature (p= 0.0011) controls. The genotype -57TT showed an OR of 2.93 (1.44-5.99) and 2.99 (1.42-6.31) respectively. The functional relevance of the -57T variation was demonstrated by a reporter gene (luciferase) assay, performed in the presence of vitamin D. The addition of vitamin D induced a repressive effect on in vitro GH1 gene transcription. This inhibition was significantly (p=0.012) stronger for the promoter haplotype carrying the associated variation -57T (hp#1) with respect to hp#2, bearing -57G. When replacing the T with a G at -57 on hp#1 the transcriptional activity became comparable to that of the same haplotype in the absence of vitamin D, suggesting that the T at position -57 is necessary to determine the greater vitamin D induced inhibitory effect of hp#1. The functional role of the -57 SNP was confirmed by EMSA experiments showing a different band shift pattern of the T and G sequences. In conclusion, the common -57T/G polymorphism contributes to IGHD susceptibility indicating that in the majority of the patients IGHD is a multifactorial disease.

Acetyl CoA carboxylase and malonyl CoA decarboxylase gene promoter SNPs are associated with body weight in a large female cohort. *S.D. O'Dell[1], A.K. Lee[1], T. Kyriakou[1], D. Ge[2], G. Liu[3], H. Snieder[3,4], T.D. Spector[4]* 1) Nutritional Sciences Division, King's College London, UK; 2) Center for Population Genomics and Pharmacogenetics, Duke University, Durham, NC; 3) Department of Epidemiology, University of Groningen, The Netherlands; 4) Twin Research and Genetic Epidemiology Unit, Kings College London, London, UK.

Malonyl-CoA is a potent inhibitor of carnitine palmitoyltransferase (CPT1), which transfers LCFA to the mitochondria for -oxidation. The formation of malonyl CoA is catalysed by acetyl-CoA carboxylase (ACC) and its degradation by malonyl CoA decarboxylase (MCD). The dual action of ACC and MCD therefore modulates malonyl CoA levels and in turn the cytoplasmic accumulation of esterified FA resulting from CPT1 inhibition. Elevated LCFA in the hypothalamus signals energy surfeit and leads to inhibition of feeding. We proposed that genetic variation influencing the level of expression of ACC gene *ACACB* and MCD gene *MLYCD* could modulate signalling of energy surfeit and thereby influence feeding behaviour and body weight. We investigated whether potential functional SNPs in the promoters of *ACACB* and *MLYCD* were associated with anthropometry, body fat and serum leptin in 2614 healthy Caucasian females from the Twins UK cohort (mean age 47.312.6 years). For *ACACB* rs16939972, we found significant associations with weight, total body fat, fasting glucose and HOMA (Ps=0.002-0.021). For *MLYCD* rs880088 we found significant associations with leptin, BMI, weight, waist circumference, total and central body fat, fasting insulin and HOMA (Ps=0.005-0.03). We then tested the effect of rs16939972 alleles on activity of a luciferase reporter gene in transiently transfected HepG2 cells. The constructs contained a 902bp region (from position -865bp to +37bp relative to the transcriptional start site) carrying either allele. There was no significant difference in luciferase reporter gene activity with respect to the *ACACB* rs16939972 allele. In conclusion, both gene promoter SNPs are associated with anthropometry, body fat and insulin sensitivity, but as yet we have no evidence to suggest that either SNP affects gene expression.

SPASTIN GENE MUTATIONS IN ITALIAN PATIENTS WITH PURE AND COMPLICATED FORMS OF SPASTIC PARAPLEGIA. *A. Magariello[1], A. Patitucci[1], RL. Mazzei[1], F.L. Conforti[1], A.L. Gabriele[1], T. Sprovieri[1], C. Ungaro[1], L. Citrigno[1], A. Gambardella[2], F. Bono[2], T. Piccoli[3], F. Patti[4], M. Zappia[4], M. Muglia[1]* 1) Inst Neurological Sci, National Research Council, Mangone, Cosenza, Italy; 2) Institute of Neurology, University Magna Graecia, Catanzaro, Italy,; 3) Department of Clinical Neurosciences, University of Palermo, Palermo, Italy; 4) Department of Neurosciences, University of Catania, Catania, Italy.

Mutations in the spastin gene are the commonest cause of spastic paraplegia accounting for up to 40% of autosomal dominant (ADHSP) and 12% of sporadic cases. The phenotype associated with disease due to mutations in the spastin gene (SPG4) tends to be pure. However, there is increasing evidence of patients with complicated forms of spastic paraplegia in which spastin mutations have been identified. To characterize in more detail the genetic and phenotypic characteristic of SPG4, we examined twenty unrelated Italian patients. The mutational screening of the spastin gene was performed by Denaturing High Performance Liquid Chromatography (DHPLC) and sequence analysis. Sixteen patients showed a pure form of spastic paraplegia (11-ADHSP and 5-sporadic) and four patients had a complicated phenotype of whom 2-ADHSP resulted with ataxia and 2-sporadic with cerebellar signs. We detected 8 different mutations, 4 of which were novel (Glu143fsX, c.1687-3C>G, Asp548Asn, Gln568X). One possible pathogenic variant (2*G>T) was also identified in the 3UTR of the gene after two nucleotides from the stop codon. The overall rate of mutation in the spastin gene in our sample was 40% (8/20). Two out of 8 mutations were detected in sporadic patients affected by a complicated phenotype with cerebellar signs, whereas six mutations were found in patients with a pure ADHSP. The obtained results confirm that the spastin screening has be performed in complicated cases of HSP. The identification of mutations in the spastin gene in patient with complicated forms is important in order to characterize in more detail the genetic and phenotypic characteristic of SPG4.

Mutation and functional analysis of the *IRAK-M* gene in Sardinian asthmatic patients. *S. Naitza[1], L. Balaci[1], M.C. Spada[1], N. Olla[1], G. Sole[1], F. Anedda[1], M.A. Zuncheddu[1], A. Maschio[1], C. Caria[1], S. Sanna[1], S. Pilia[1], S. Sanna[1], L. Crisponi[1], G. Malerba[2], P.F. Pignatti[2], D. Schlessinger[3], A. Cao[1], M. Uda[1]* 1) Istituto di Neurogenetica e Neurofarmacologia (INN), CNR, Monserrato , Cagliari, Italy; 2) Dipartimento Materno Infantile e Biologia-Genetica, Sezione di Biologia e Genetica, Università di Verona, Verona, Italy; 3) Laboratory of Genetics, National Institute on Aging, Baltimore, MD, USA.

Asthma is a multifactorial disease influenced by genetic and environmental factors. Its prevalence in industrialized countries is now 5% and growing, with increasing associated mortality. Interest in finding etiologic factors has correspondingly intensified. To understand the genetic basis of asthma, we are conducting linkage and association analyses in the Sardinian founder population, where limited heterogeneity of pathogenetic alleles for monogenic and complex disorders as well as of environmental conditions facilitates the study of multifactorial traits. Analysing a cohort of affected Sardinian subjects, we have recently identified *IRAK-M* as a new asthma susceptibility gene in the candidate region 12q13-24. This gene, which we found associated with early-onset persistent asthma, is a negative regulator of the Toll-like receptor/ IL-1 receptor pathways and a master regulator of NF-B and inflammation. We showed that IRAK-M is highly expressed in lung epithelial cells, suggesting a mechanistic link between hyperactivation of the innate immune system and chronic airway inflammation, and indicating IRAK-M as a potential target for therapeutic intervention against asthma. To better understand the pathogenetic mechanisms of *IRAK-M* variants in asthma, we sequenced all the coding as well as the non-coding regulatory regions of this gene in the entire cohort of affected asthmatic subjects. We detected non-sense, missense and splicing mutations in conserved domains and tested functional significance of some *in vitro*. Furthermore, we studied *IRAK-M* gene expression in monocytes derived from individuals carrying the risk vs the protective *IRAK-M* haplotype.

Genetic analysis of the GAA gene for 47 newborn screening samples. *P. Labrousse[1], L.M. Hire[1], Y.H. Chien[2], S.C. Chiang[2], W.L. Hwu[2], J. Keutzer[1], R. Pomponio[1], T. Scholl[1]* 1) Genzyme Corp. Cambridge, MA; 2) National Taiwan University Hospital, Taipei, Taiwan.

Genzyme Genetics has launched a sequencing assay for genotyping the entire coding region and intron/exon boundaries of the acid -glucosidase (GAA) gene. This clinically validated assay identifies sequence variants in DNA isolated from various specimen types. Extensive use of quantitative metrics enabled the development of this sensitive, specific, and robust assay. In addition, a workflow implementing assay-ready frozen reagent plates for PCR and sequencing enhanced quality assurance and turn-around time. Pompe disease is an autosomal recessive lysosomal storage disorder caused by a deficiency of lysosomal GAA. One application of the assay described above was in support of a Taiwanese newborn screening (NBS) pilot program. To aid clinicians in better delineating the enzyme ranges between normal and those defining infantile or late-onset Pompe disease, we sequenced 47 samples from the NBS program that had enzyme activity just above the range indicating Pompe disease. The majority of the samples were carriers of either a known deleterious mutation or contained sequence variants of unknown significance (78%). It is known that some variants (e.g. p.G576S and p.E689K) have been shown to contribute to reduced enzyme activity in phenotypically normal individuals. Overall, 13 novel variants and 6 distinct haplotypes were identified in this population. Two haplotypes have not been previously reported. In this study we were able to characterize the molecular defects that most likely were the contributing factor to the observed low GAA activity in these infants. By combining genotyping with the practice of analyzing enzyme activity and other clinical parameters, clinicians will have comprehensive information when decisions for intervention and treatment are required in symptomatic individuals or those identified by NBS. Likewise, genotype determination may offer some predictive value as to the patient status as it relates to Pompe disease. Genotyping also provides individuals with a family history a means of assessing carrier status which aids in genetic counseling of these patients.

Mutation in a C2 domain-containing gene cause autosomal recessive non-syndromic mental retardation. *A. Noor[1], C. Windpassinger[1,2], M. Azam[3], M. Ayub[4], J.B. Vincent[1]* 1) Neurogenetics, Centre For Addiction & Mental Health, Toronto, Ontario, Canada; 2) Institute of Medical Biology and Human Genetics, University of Graz, Graz, Austria; 3) Pakistan Institute of Medical Sciences, Islamabad, Pakistan; 4) St. Luke's Hospital,Middlesbrough, United Kingdom.

Mental retardation (MR) is defined by an intelligence quotient (IQ) of less than 70 associated with functional deficits in adaptive behaviour and it has a prevalence of 1-3%. Although, autosomal recessive forms of MR (ARMR) are believed to be more common, yet only three genes, the PRSS12, CC2D1A and CRBN have been reported so far to cause this. In this study, we ascertained a consanguineous family from Pakistan affected with non-syndromic autosomal recessive mental retardation. The phenotype was present in 5 individuals from three branches of the family. We used the Affymetrix ~260K NspI chip to perform homozygosity mapping and identified a homozygous and haploidentical region of 11.2-Mb on chromosome 4p15.33-p15.2, but only in four out of five affected individuals. Further analysis of the SNP microarray data for copy number variants (CNVs) revealed the duplication of entire chromosome X in the fifth affected individual who did not share the 4p15 homozygous region. Subsequent cytogenetic analysis has indicated the karyotype 48,XXXX in this individual. We also performed genotyping using 11 microsatellite markers across the 4p region; Analysis confirmed a common haplotype spanning 11.2 Mb in four affected individuals. Linkage analysis was also performed and a maximum two-point logarithm of odds (LOD) score of 3.59 at theta=0.0 was obtained at markers D4S419. The 11.2 Mb critical region, containing approximately 39 known genes was fine mapped by genotyping and sequencing of flanking SNPs rs6814906 and rs7664104. Furthermore, we sequenced genes in the critical region and identified a splice site mutation segregating with the phenotype in a C2 domain-containing gene. This splice site mutation is predicted to result in truncated protein lacking the C2 domain. This sequence variant was not found in 230 healthy controls. Further studies are required to understand the role of this gene in development.

BBS7 is involved in BBSome formation and loss of BBS7 in mice results in Bardet Biedl Syndrome phenotypes.

Q. Zhang[1], M. Nachury[2], A. Loktev[2], P. Jackson[2], E. Stone[3], V. Sheffield[1] 1) Department of Pediatrics, HHMI, University of Iowa, Iowa City, IA; 2) Department of Tumor Biology and Angiogenesis, Genentech, CA; 3) Department of Ophthalmology, HHMI, University of Iowa, Iowa City, IA.

Bardet Biedl Syndrome (BBS) is a phenotypically pleiotrophic and genetically heterozygous disorder. Through linkage analysis, homozygotic mapping, positional cloning, and mutation analysis of candidate genes, twelve BBS genes have been identified. These twelve BBS genes account for approximately 70% of the patients. Recently, seven highly conserved BBS proteins have been shown to form a complex known as the BBSome. The BBSome is involved in ciliary membrane biogenesis. In order to learn more about interactions between BBSome components, we performed pairwise co-immunoprecipitation assays in cultured cells. BBS9 was shown to strongly interact with BBS2 and BBS8, BBS9 was also shown to interact with BBS1 and BBS5. These data indicate that BBS9 is a central component of the BBSome. BBS7 was shown to be part of the BBSome through interaction with BBS2. Neither the N-terminus nor the C-terminus of BBS7 is required for the interaction. The interaction domain localizes to the center of the protein, which has homology to BBS2. To further study BBS7, we generated Bbs7 knockout mice. Bbs7-/- mice show similar phenotypes to other BBS gene knockout mice, including retinal degeneration, hyperphagia, obesity, hydrocephalus, and male infertility. Using tissues from Bbs7-/- mice, we showed that BBS7 and BBS2 depend on each other for stability. Using BBS6 knockout mice, we also demonstrate that BBS2 and BBS7 protein stability requires BBS6. Together our results suggest that BBS7 protein plays a role in BBSome formation and that BBS6 plays a role in BBSome formation by affecting BBS2 and BBS7 stability.

Micronuclei in human lymphocytes exposed to sodium pertechnetate, in vitro: Preliminary results. *M.B. Santana[1], C.M. dos Santos[2], I.P. Aranha[3]* 1) Fac. Ciências Médicas, Univ. do Estado do Rio de Janeiro, Rio de Janeiro, Brazil; 2) Inst. de Ciências Biológicas e Ambientais, Univ. Santa Úrsula, Rio de Janeiro, Brazil; 3) Inst. de Biologia, Univ. do Estado do Rio de Janeiro, Rio de Janeiro, Brazil.

Since its humble beginning in 1958, technetium-99m (^{99m}Tc)has become the most widely used radioisotope in the detection of inflamatory sites as well as in the diagnosis of transplanted tissues. The goal of the present work is to study the effect of sodium pertechnetate on human lymphocytes *in vitro*, using the micronucleus assay. Peripheral whole blood cells collected from healthy donors, 18 to 30 years old, were incubated at 37^{o}C for 48 hours in the presence of ^{99m}Tc (3.7 MBq/100l). Cells not exposed to the radionuclide served as control for the experiment. Cytochalasin B (4g/ml) was added to the cultures 20 h postinitiation. After fixation, cells were stained with Gurr's Giemsa (2%) and were observed under optical microscope. In the test group, 3573 binucleated cells were studied and 143 micronuclei were found. In the control group, 4845 cells were observed and 3 micronuclei were seen. The chi-square test with Yates correction indicated that the results were extremely significant (p0.0001) suggesting that sodium pertechnetate was responsible for the micronuclei observed.

Familial Interstitial Pneumonia (FIP) is linked to Chromosomes 10, 11 and 12. *M.C. Speer[1], L.H. Burch[2], M.P. Steele[1,2], A. Herron[1], J.E. Loyd[3], K.K. Brown[4], J.A. Phillips III[3], A. Wise[2], S.H. Slifer[1], C.F. Potocky[1], M.I. Schwarz[4], D.A. Schwartz[1,2]* 1) Duke Univ Medical Ctr, Durham, NC; 2) National Institute of Environmental Health Sciences, Research Triangle Park, NC; 3) Vanderbilt University School of Medicine, Nashville, TN; 4) National Jewish Medical and Research Center and University of Colorado Health Science Center, Denver, CO.

The idiopathic interstitial pneumonias (IIP) are a clinically heterogeneous group of fibrosing interstitial lung diseases that lead to hypoxemic respiratory insufficiency with both genetic and environmental contributions to etiology. The most common IIP is usual interstitial pneumonia (UIP), the underlying histology of idiopathic pulmonary fibrosis(IPF). Typically, IPF (OMIM178500) presents in late life and is lethal within 4-5 years of diagnosis. Treatment options, apart from lung transplantation, are limited and do not appear to prolong survival. Identifying the genetic basis for this condition will lead to earlier identification and enhanced interventions. We performed a genomic screen using 890 microsatellite repeat markers spaced at an average 4.1 cM including 82 families with 2 members with probable/definite IIP. We identified a maximum multipoint lod score of 3.03 at D11S1318, incorporating a 16.4 cM region bounded by D11S4046 and D11S4149. A second linkage peak spans 15 cM and is bounded by D10S1751 and D10S1664 (maximum multipoint LOD score of 2.27 at D10S1649). Families with fewer than 67% smokers among affected individuals contributed significantly to evidence for linkage at 11pter (p=0.01; maximum lod = 4.58). The 82 families were subdivided into those with only IPF-type disease [homogeneous familial interstitial pneumonia - FIP] and families with 1 case of IPF and one other type of IIP [heterogenous FIP]. When considered alone, the homogeneous families identified a region of interest at D12S368 (maximum multipoint lod score 1.89). In summary, we identified regions on chromosomes 10, 11, and 12 that likely contain genes contributing to FIP. Moreover, our findings indicate that linkage on chromosome 11 is influenced by cigarette smoking and that linkage on chromosome 12 is influenced by disease phenotype.

Mutation screening of 7 candidate genes within the MYP12 high grade myopia locus. *KN. Tran Viet[1], R. Metlapally PhD[1,2], TR. White[1], D. Kao[1], A. Bulusu[1], YJ. Li PhD[1], TL. Young, MD[1,2]* 1) Duke Center for Human Genetics, Durham, NC; 2) Duke Eye Center, Durham, NC.

Purpose: Myopia, or near-sightedness, is an ocular refractive error of unfocussed image quality in front of the retinal plane. An initial linkage study of a large autosomal dominant high myopia kindred identified a 9.1 cM interval (MYP12) at chromosome 2q37.1. This was contracted by haplotype analysis to a 2.22 cM interval. All genes within the refined interval (5 known and 2 hypothetical genes) were screened for sequence variants associated with the high grade myopia phenotype.

Methods: Utilizing public databases, a compilation of genes in the 2.22 cM region was obtained. All known and hypothetical genes (INPP5D, ATG16L1, NR_003006, NR_003008, SAG, DGKD, and USP40) were screened by direct sequencing. Primers for PCR and sequencing were designed to cover coding and untranslated gene regions, including intron-exon boundaries. Genomic DNA samples of two affected family members with myopic refractive errors of greater than -15 diopters were tested, along with 2 unaffected internal control samples.

Results: In all, 73 polymorphisms were detected by sequencing; 5 were missense, 7 were silent, 34 were intronic, 18 were located in untranslated regions, 8 were deletions, and 1 was an insertion. Fourteen were novel polymorphisms, and will be submitted to appropriate public online databases. No polymorphisms segregated with the myopic affection status in the family.

Conclusion: Within the 2.22 cM region of the MYP12 locus, the screened candidate genes did not exhibit sequence variants associated with the phenotype. Additional studies are currently underway to screen flanking region candidate genes at this locus.

The MMP-2 gene contributes to functional outcome after stroke but not to stroke susceptibility. *H. Manso[1,2], T. Krug[1], B. Nunes[2], I. Albergaria[2], G. Gaspar[2], L. Gouveia[3], I. Matos[4], M.V. Baptista[5], G. Lopes[6], R. Taipa[6], J.P. Gabriel[7], M.R. Silva[8], C. Dias[2], F. Gonçalves[9], M. Correia[6], J.M. Ferro[3], S. Oliveira[1], A.M. Vicente[1,2]* 1) Instituto Gulbenkian de Ciência, Portugal; 2) Instituto Nacional Saúde Dr. Ricardo Jorge, Portugal; 3) H. Sta. Maria, Portugal; 4) H. Distrital Mirandela; 5) H. Garcia de Orta; 6) H. Geral Sto. António, Portugal; 7) H. S. Pedro; 8) H. Fernando Fonseca; 9) H. Universidade Coimbra, Portugal.

Given the increased life expectancy of populations, finding ways of preventing stroke and adequate treatment is a priority, requiring the characterization of risk factors for disease and functional outcome. In this study we analyzed the role of two specific matrix metalloproteinase (MMP) genes, MMP-2 and MMP-9, in stroke susceptibility and recovery. MMPs are zinc-endopeptidases that contribute to brain damage in stroke, promoting edema and hemorrhage and triggering cell death. Recent studies in rats, however, suggest that MMPs may mediate repair in later stages after stroke, through their role as regulators of neurogenesis, axon regeneration and processing of biologically active growth factors. 11 tag SNPs in the MMP-2 gene and 3 tag SNPs in the MMP-9 gene were tested in a population sample of 533 stroke patients and 507 controls in the same age range. No association with stroke risk was found for single markers or haplotypes at either gene, indicating that these do not significantly contribute to disease susceptibility. We further analyzed the role of these genes in functional outcome after stroke in 403 patients under 65, assessed three months after a stroke episode using the modified Rankin Scale (mRS). Using the Kruskal-Wallis non-parametric test, we found a significant association of one MMP-2 SNP with mRS scores (rs2241145: ^{2}=6.729, df=2, P=0.035), with several specific haplotypes including this SNP associated (0.0032P0.0046) with favorable (mRS1) or bad (mRS2) recovery. None of the markers at MMP-9 were associated with stroke susceptibility or recovery. The results suggest that genetic variation in MMP-2 may be an important mediator of functional outcome after stroke.

A Genome Wide Study to Identify a Disease Specific Expression Profile and Downstream Targets of Cohesin Regulation in Cornelia de Lange Syndrome. *J. Liu[1], Z. Zhang[2], E. Rappaport[1], S. Tandy[1], I.D. Krantz[1]* 1) Division of Human Genetics, Abramson Research Institute; 2) Bioinformatics Core, Center for Biomedical Informatics, The Childrens Hospital of Philadelphia, PA 19104.

Cornelia de Lange Syndrome (CdLS) (OMIM 122470) is a dominant disorder of multiple congenital anomalies including characteristic facial, physical, and developmental features. Our laboratory has identified mutations in the *Nipped B-like* (*NIPBL*) gene, a regulator of the cohesin complex, as a cause of CdLS. Gene screening has identified *NIPBL* mutations in approximately 50% of probands who met clinical criteria for CdLS. Recently mutations in the genes that encode the two structural arms of the cohesin complex, *SMC1A* and *SMC3*, were found to contribute to approximately 5% of CdLS cases. This finding confirms genetic heterogeneity in CdLS and emphasizes the possibility that there may yet be additional genes that contribute, either individually or in combination, to the CdLS phenotype. We hypothesized that genome-wide expression array analysis in CdLS would provide insights into the underlying molecular mechanisms contributing to the phenotype as well as identifying a specific profile of the differentially expressed genes. We performed array based expression profiling from lymphoblastoid cell lines (LCLs) from 16 severely affected CdLS patients (with confirmed mutations in *NIPBL*) as controlled by 17 matched healthy subjects and further validated with 6 additional samples with various diagnoses. The unsupervised Principle Component Analysis (PCA) clearly separated CdLS samples from the controls, and leave-one-out cross validation successfully categorized the testing samples, suggesting a distinctive molecular profile for CdLS. We then identified a unique list of 420 probe sets, with *NIPBL* ranked as the most significantly changed gene, that are differentially expressed in CdLS. We further defined a 7-gene CdLS-specific expression signature. Further work is in process to delineate the identified genes with altered expression to investigate their relevance to the phenotypic differences in CdLS as well as to see if expression profiling can be used as a diagnostic tool for other developmental disorders.

Candidate single nucleotide polymorphisms associated with age of onset from a genome-wide association study of Alzheimers disease. *S. Wetten[1], L. Li[1], P. St. Jean[1], R. Upmanyu[1], J. Williams[2], GenADA. Investigators[3], M. Plumpton[1], A.D. Roses[1], R.A. Gibson[1], M.C. Irizarry[1]* 1) GlaxoSmithKline, NFSP and RTP, USA and United Kingdom; 2) Cardiff University School of Medicine, Cardiff, UK; 3) Multi-site centre across Canada.

Twin and family studies support a strong genetic component to late-onset Alzheimers disease (AD), for which the APOE 4 allele is the major identified risk factor. Case-control association analyses have reported multiple genetic polymorphisms as potential risk factors for AD. Our objective was to identify candidate SNPs associated with age of onset in a primary population and replicate in a secondary population. We performed an association analysis with Cox proportional-hazards regression using the Affymetrix 500K Array stratified by education and adjusting for gender, French-Canadian ancestry, number of APOE 4 alleles and study site. Our primary population consisted for 753 cases in Canada and 736 ethnically-matched controls. Our replication population consisted of 418 cases and 249 controls from the UK. 469,438 SNPs passed initial quality controls with >70% genotyping efficiency and HWE p>10-7. For SNPs with minor allele frequency (MAF) 0.10, dominant, additive, and recessive effects were examined in the multivariable adjusted Cox model; the Wald p-value for the optimal model adjusted for the 3 genetic tests is reported. For SNPs with 0.10 > MAF .005, only the dominant model was tested. One SNP was significant in the primary dataset after study-wide Bonferroni correction. The top 100 SNPs from the primary analysis were examined in the secondary dataset under the same genetic model. Two of these SNPs were nominally significant in the second dataset with the same risk genotypes. APOE 4 was the main risk factor for AD, with HR 2.0-2.5 for 1 4 allele and 3.9-6.4 for 2 4 alleles relative to no 4 alleles. These associations, from the first genome-wide assessment of AD age of onset, will be reported. Once published, results will be released into the public domain to aid the evaluation and discovery of further susceptibility loci which may have definitive but modest effects on AD.

Candidate single nucleotide polymorphisms associated with case-control status from a genome-wide association study of Alzheimers disease. *H. Li[1], S. Wetten[1], L. Li[1], P. StJean[1], R. Upmanyu[1], J. Williams[2], GenADA. Investigators[3], M. Plumpton[1], A.D. Roses[1], R.A. Gibson[1], M.C. Irizarry[1]* 1) GlaxoSmithKline, RTP and NFSP, USA and UK; 2) Cardiff University School of Medicine, Cardiff, UK; 3) Multi-Site Centres across Canada.

Identification of genes associated with more common forms of AD provides an opportunity to develop novel therapeutic targets, and to identify potential genetic factors influencing phenotypic expression of disease or responses to treatment. We performed a whole genome scan analysis in a case-control study of 753 AD patients and 736 non-demented control individuals from Canada as a hypothesis generating dataset. 100 SNPs with the strongest genetic association with AD were evaluated in a second dataset of 418 AD cases and 249 non-demented controls from Cardiff, UK, to assess generalizability and to reduce false negative associations. Association of each SNP genotype with AD was examined by multivariable logistic regression adjusting for age, sex, education, French Canadian ancestry (in Canada dataset), study site, and number of APOE 4 alleles (The results from an age of onset analysis are presented in a separate abstract). In both datasets, the APOE 4 allele was strongly associated with AD. In the multivariable adjusted logistic models, one 4 allele had an OR for AD of 4.6 and two 4 alleles an OR of 21.1-21.4 relative to 0 4 alleles ($p < 3.9 \times 10-24$). Among the 100 most significant genes in the Canada dataset, there were four that replicated in the Cardiff dataset according to the following criteria: (1) allele frequencies sufficient to allow analysis; (2) nominal significance at $p < 0.05$; and (3) a risk genotype consistent with the Canada results. In conclusion, screening of the entire genome confirms that the APOE 4 allele is the strongest risk factor for AD. There is evidence for additional SNPs associated with AD by replication in a second dataset, although these effects appear weak, and merit further evaluation.

Role of dyneins in genetic asthenozoospermia. *D. Zuccarello, A. Ferlin, C. Vinanzi, C. Cazzadore, C. Foresta*
Department of Histology, Microbiology and Medical Biotechnologies, Centre for Male Gamete Cryopreservation, University of Padua, Italy.

The asthenozoospermia (AZS) is a common cause of male infertility characterized by a reduced (progressive motility <50%) or absent sperm motility in fresh ejaculate. The genetic type is a very rare heterogeneous condition. To clarify the role of genetic factors in isolated AZS we analyzed 3 candidate genes for non syndromic AZS, DNAI1 (9p21-p13), DNAH5 (5p15) e DNAH11 (7p21), codifying for 3 proteins belonging to axonemal dyneins cluster, particularly expressed in testis and trachea. In detail, we analyzed 20 exons from DNAI1, 9 out of 79 exons from DNAH5 and 2 out of 82 from DNAH11 in 70 patients affected by isolated AZS. By direct sequencing and DHPLC analysis we have identified 4 heterozygote sequence changes never described: R663C in DNAI1, E1756K and E2666D in DNAH5, and I3040V in DNAH11. Moreover, other 3 known sequence changes were detected: A8S and V335I in DNAI1 and R3004Q in DNAH11. We tested 200 controls (normospermic men) and we found the E1756K with a frequency of 1%; the R3004Q with 2%; the A8S with 9,5%; the V335I with 6%. We never found mutations R663C, E2666D and I3040V in the control subjects. The presence of E1756K, R3004Q, A8S and V335I in control subjects, suggests they are common polymorphisms. Mutations E2666D, located in the exon 48 and codifying for AAA-3 domain, and I3040V, located in the exon 55 downstream to AAA-4 domain, are extremely conserved during the evolution, indicating the crucial role of these aminoacids in the function of core. Also the mutation R663C, located in WD5-repeat, which is critical for propeller-structure assembly, is conserved in the superior species. By electronic microscopy of ejaculated spermatozoas tails from patients carrying the mutations R663C (1 patient), I3040V (in 2 unrelated patients) and E2666D (1 patient), we discovered an altered axonemal structure with severe disorganization of microtubules, abnormal dynein outer arm and central pair. The obtained results are very prominent cause of these patients are involved in assisted reproductive programs with probable chance of diseases transmission to the offspring.

COPY-NUMBER VARIATIONS IN A CASE-CONTROL STUDY OF SCHIZOPHRENIA. *F. Martinelli Boneschi[1,2], F. Torri[1], S. Lupoli[1,2], A. Orro[3], C. Dal Fiume[1], G. Comi[2], D. Keator[4], J. Turner[4], J. Fallon[4], S. Potkin[4], C. Barlassina[1], F. Macciardi[1]* 1) University of Milan, Milan, Italy; 2) INSPE, Scientific Institute San Raffaele, Milan, Mi, Italy; 3) CILEA Consortium, Segrate Milan, Italy; 4) University of California, Irvine,Usa.

Recent studies have highlighted DNA copy-number variations (CNVs) as a largely under-explored source of human genetic variation, which could be responsible for the development of complex disorders. According to this hypothesis, evaluation of DNA copy number in schizophrenia may yield insights into the discovery of genetic risk factors for this disease, since CNVs can also be transmitted as mendelian traits(1). We have assayed 317.511 SNPs in 173 DNA samples from a case-control study of schizophrenia, including 91 controls and 82 schizophrenics, representing the first wave of a much larger sample, using the Illumina HumanHap300 Genotyping BeadChip. In an effort to examine individual chromosomes for structural mutation, we used Homozygosity Detector and ChromoZone algorithms within BeadStudio v3.0.22 to detect respectively extended tracts of homozigosity and chromosomal aberrations in the single sample mode. Using the ChromoZone algorithm, we performed analyses at a genome-wide level, and found that some of the areas of CNV fall into regions previously known to be associated with schizophrenia. We also looked at the distribution of LOH regions larger than 2 Mb across the genome, and found that they seem to be equally distributed in cases and in controls. We selected CNV regions smaller than 4 Mbs and present in at least 1% of the screened sample, and tested if they were differentially distributed in cases and in controls. About 250 regions have been identified, and few of them are more frequent in cases than in controls. In our preliminary analyses, CNVs tend to be sparse in the genome, and they seem to be equally distributed between cases and controls. In the next step of our investigation, we will focus on the 250 already identified regions to get a prioritized list of those CNVs potentially associated to the disease. REFERENCES: 1. Sebat J. et al., Science 316, 445-49, 2007.

The clinical significance of Y chromosome loss in hematologic disease. *D.L. Van Dyke, A.E. Wiktor, J.M. Hodnefield, C.A. Hanson* Dept Lab Medicine & Pathology, Mayo Clinic, Rochester, MN.

In 1972, Pierre & Hoagland (Cancer 30:889) wrote that Y chromosome loss is a common event, correlated with advancing age, and should not be considered evidence of a specific disease state. Loss of the Y chromosome as the sole cytogenetic change is more common in older men, and the size of the 45,X,-Y cell population probably increases gradually with age. This natural phenomenon challenges our ability to distinguish between a normal and a potentially disease-associated 45,X,-Y clone. Wiktor et al (Genes Chrom Ca 27:11, 2000) observed a difference between the disease and control populations only when the percentage of -Y was greater than 75%. To examine this finding further, we identified 129 Mayo Clinic patients seen from March 1995 to May 2006 whose bone marrow karyotype revealed >75% of cells with Y loss as the sole cytogenetic change. Of these 129, three were under age 50 years and 61 were age 75 years or older. There was a similar age distribution for the 51 cases with 100% -Y metaphases as compared to the entire group. A hematopathology review of the bone marrow was done in each case. There were 43 samples (33%) with no evidence of hematologic disease, including 9 of the 51 cases (18%) with 100% Y loss. For 23 of 30 patients (77%) with lymphoproliferative disease or lymphoma, the proportion of malignant cells in the bone marrow aspirate was negligible and cannot account for the high proportion of -Y cells. The clear lack of association between Y loss and the disease clone in 66 of the 129 patients (51%) makes an association between -Y and disease seem unlikely for the remaining 56 patients with myeloid disease. It is possible that the association is merely coincidental because loss of the Y and risk of hematologic disease both increase with age. A hematologic disease may just as easily arise in a normal cell or in a cell that happens to be -Y. This is consistent with the typically similar risk categorization of normal and -Y karyotypes in AML (Slovak et al., Blood 96:4075, 2000). In exceptional cases where Y loss waxes and wanes with recurrence and remission of disease, the disease-causing mutation(s) are likely to be submicroscopic.

Population-based and case-control whole genome association studies confirms known genes and identifies novel transcription factors associated with atherogenic dyslipidemia. *D. Waterworth[1], K.S. Song[1], X. Yuan[1], Y.A. Kesaniemi[2], R. McPherson[3], R. Mahley[4], T. Bersot[4], P. Barter[5], D.K. Burns[1], E.H. Lai[1], P. Vollenweider[6], L.T. Middleton[1], A.D. Roses[1], S.M. Grundy[7], G. Waeber[6], V.E. Mooser[1]* 1) GlaxoSmithKline, King of Prussia, PA, RTP, NC; 2) Dept of Internal Medicine and Biocenter Oulu, University of Oulu, Oulu, Finland; 3) University of Ottawa Heart Institute, Ottawa, Canada; 4) Gladstone Institute of CVD, UCSF, CA and American Hospital, Istanbul, Turkey; 5) The Heart Research Institute, Sydney, Australia; 6) CHUV University Hospital, Lausanne, Switzerland; 7) Center for Human Nutrition, University of Texas Southwestern Medical Center, Dallas, TX.

Atherogenic Dyslipidemia, operationally defined here as low HDL (< 25%ile for HDL adjusted for gender, age and population) and high triglyceride (> 75% triglycerides), is an important risk factor for CVD and has a genetic component. We performed a WGAS using the Affymetrix 500k chip on 923 cases and 924 controls (> 50%ile for HDL and < 50%ile for triglycerides) from the GEMS study and 633 cases and 678 controls selected from the CoLaus Lausanne population-based study. Single point analysis was performed in each sample separately using logistic regression and the Armitage trend test, as implemented in PLINK. A total of 581 SNPs were nominally significant with an allelic effect in the same direction in both studies; many of these SNPs were not independent of each other. A meta-p was also generated using Fishers method. Multilocus methods, BEAGLE and the Bayesian Graphic Model were also applied to the data and replicated regions were retained for further evaluation. Several genes known to be involved in lipid metabolism were found to be highly significant, e.g. LPL, APOAV, GCKR and APOC1. The pool of novel genes was enriched with transcription factors, particularly those with zinc finger motifs. Testing for association against lipid levels as continuous variables in the population, contextualization of these results, replication with other datasets and pathway analyses are now underway and the results of this analysis will be described.

Use of targeted array-based CGH for the diagnosis of chromosomal imbalance in polymalformed syndrome patients with apparently balanced karyotype. *A.C. Tabet[1], E. Pipiras[2], A. Delahaye[2], S. Kanafani[2], A. Aboura[1], C. Dupont[1,2], M. Uzan[4], J.F. Oury[3], B. Benzacken[1,2]* 1) UF de Cytogenetique, Hopital Robert Debre , Paris, France; 2) UF de Cytogenetique, Hopital Jean Verdier , Bondy, France; 3) Service d'Obstetrique, Hopital Robert Debre , Paris, France; 4) Service d'Obstetrique, Hopital Jean Verdier , Bondy, France.

In prenatal diagnosis as in pediatrics, some polymalformed patients with suspicion of chromosomal abnormalities have normal standard karyotype. High-resolution comparative genomic hybridization (CGH) based microarrays (array CGH) were developed to increase the resolution of chromosomal studies and to provide a comprehensive assay by using large-insert clones as the target for analysis.We propose to use this technology to better understand the pathology in few patients and fetuses with polymalformed syndrome and normal karyotype.We used a DNA microarrays (Integragen) with 3172 clones providing an average of 1 Mb resolution.

In 3 cases, this technology allowed us to correlate the abnormal phenotype with an imbalance chromosomal abnormality.In the first case, a newborn was referred for facial dysmorphy, cardiopathy and short arm segments. Her lymphocytes karyotype was normal since cultured fibroblasts failed. We performed CGH array on DNA extracted from a post-mortem pulmonary biopsy and identified a tetrasomy 12p corresponding to a Pallister Killian syndrome. In the second case, the fetus presented a complex cardiopathy with cerebral malformations. By CGH array, we report an unexpected additional deletion of 7qter in an inherited apparently balanced reciprocal translocation t(7;10)(q11.23;p14)mat. In the third case, the prenatal karyotype of a fetus with holoprosencephaly showed a *de novo* apparently balanced reciprocal translocation t(7;8)(q31.3;q12) and the CGH array identified an additional deletion in the region of the Sonic Hedgehog gene .

As a conclusion, we confirmed the feasibility and the usefulness of CGH array in constitutional cytogenetic. Use of array CGH should increase the detection of chromosomal abnormalities in polymalformed fetuses with apparently balanced chromosomal anomalies.

AKT2 gene variants associate with muscle phenotypes in young men and women. *F. E. Orkunoglu-Suer, H. Gordish-Dressman, EP. Hoffman, JM. Devaney* Research Center for Genetic Medicine,Children's National Medical Center,Washington,DC.

PURPOSE:AKT2 is a key signaling intermediate for insulin-stimulated glucose uptake and glycogen synthesis in skeletal muscle and is activated by exercise and muscle contraction in both rodents and humans.This makes AKT2 an attractive candidate gene for examining human skeletal muscle size and function following resistance training. We hypothesized that variants in AKT2(rs2304186,rs969531,rs892118)would be associated with muscle strength and size phenotypes.METHODS:524 European Americans(235y)were enrolled by eight different exercise physiology sites.Phenotype measures included muscle volume/strength,bone and fat volume and exercise induced changes. SNP/phenotype associations were tested using a general linear model with Sidak post-hoc tests and logistic regression;covariates included baseline body weight and age.RESULTS:AKT2 rs2304186 was significantly associated with muscle strength,whole muscle volume and baseline bone volume in males($p<0.05$).In males TT homozygotes had higher baseline one repetition max(1RM) values($p=0.0009$,4.1%) but did not show any training effect.For rs2304186, females homozygous for the T allele had lower baseline subcutaneous fat volume($p=0.04$).For rs96953,females with two copies of the A allele had higher change in isometric strength after exercise($p=0.014$).For rs892118, males with a copy of the T allele showed a gain in muscle volume with exercise that explained 3.6% of population variance.CONCLUSIONS:These data suggest a sex-specific effect of AKT2 genotypes on exercise training induced strength changes in young white adults.AKT2 SNP rs969531 is associated with responses to resistance training in females.In addition, rs2304186 genotype associated with higher baseline muscle strength values but did not show any training effect in males.Additionally, males with two copies of the T allele for rs892118 gained muscle volume with resistance training.The genetic variation in AKT2 may affect the phosporylation and its regulation of creatine kinase in muscle cells, thus skeletal muscle differentiation and predisposition to rehabilitation medicine and metabolic syndrome.ACKNOWLEDGEMENT: This study was supported by NINDS-1R01NS040606.

Persistent Hyperplastic Primary Vitreous and Tuberous Sclerosis. *J.G. Pappas[1], K. Daley[1], M.A. Steele[2]* 1) Pediatrics, Human Genetics, NYU, School of Medicine, New York, NY; 2) Ophthalmology, NYU, School of Medicine, New York, NY.

We describe a 5 month old boy that presented at birth with left leukocoria and left microphthalmia. Ophthalmology evaluations including slit lamp, ultrasound and visual evoked response. The right eye was normal for age. The examination of the left eye revealed persistent fetal vasculature from the optic disc to the posterior lens capsule, severe cornea opacification with reduced corneal diameter and disorganized anterior chamber and the diagnosis of persistent hyperplastic primary vitreous (PHPV) was made. The patient was referred to us because of seizures at age 3 months and Woods lamp examination of the skin reveled hypopigmented spots. The brain MRI revealed scattered patchy areas of abnormal signal within both cerebral hemispheres, predominantly involving the gray and subcortical white matter consistent with tubers as well as nodular contour of the bodies of the lateral ventricles consistent with subependymal nodules. It also reported left sided phthisis bulbi. The findings were typical of tuberous sclerosis (TS). DNA sequencing of the TSC1 and TSC2 genes revealed no mutations in TSC1 and a deletion of T at position 3218 of the exon 10 of the TSC2 gene. Renal sonogram revealed multiple renal cysts and angiomyolipomata in both kidneys consistent with TSC2 associated TS. One case of PHPV in a child with retinal tumor and TS has been reported in the medical literature (Milot J et al 1999). The etiology of unilateral PHPV is unknown and it is not hereditary. PHPV usually occurs together with other ocular abnormalities and it has been described in the autosomal recessive oculopalatocerebral syndrome. Our case is the second reported case of PHPV in tuberous sclerosis. PHPV is readily recognizable in the newborn and we suggest examination of newborns with PHPV for ocular, cutaneous and other signs of TS.

A CLINICAL AND MOLECULAR STUDY IN TWO MEXICANS FAMILIES WITH X-LINKED SPINAL AND BULBAR MUSCULAR ATROPHY. *M.A. LOPEZ, A. MONARRES, J.J. MORALES, B. CACHO, G. RAMOS, O.M. MUTCHINICK* GENETIC AND NEUROLOGY DEPARTMENTS, INCMNSZ.MEXICO,D.F.

X-linked Spinal and Bulbar Muscular Atrophy (SBMA; Kennedy disease) is a hereditary neurodegenerative disease characterized by slow progressive muscle weakness and atrophy of bulbar, facial and limb muscles, accompanied by signs of androgen insensitivity such as gynecomastia and reduced infertility. The cause of SBMA is a expansion of trinucleotide CAG repeat, wich encode the polyglutamine tract, in the first exon of the androgen receptor (AR) gene. SBMA mainly occurs in adult males, whereas neurological symptoms are rarely detected in females having mutant AR gene. The aim of this work is to report the detailed phenotypic study and the molecular analysis in a serie of 34 individuals evaluated in two mexicans kindreds. Males with suspected of SBMA phenotypic and females carriers probably were examined. DNA was isolated from peripheral blood leukocytes and used for further PCR amplification of the segment of AR gene containing CAG repeats. The number of these repeats was determinated by electrophoresis on a 3.5 percent of agarose gel and confirmed by sequencing. The molecular genetic diagnosis showed an abnormal number of CAG repeats in nine males SBMA patients and seven females carriers, the first one family with 52 repeats and the last one with 51 repeats. The healthy individulas of both families showed of normal size (18-26 repeats). The two kindreds showed a wide spectrum of different clinical characteristics. All males with SBMA had gynecomastia and neurological manifestations. This is the first report in mexicans families with SBMA confirmed. Although an early diagnosis may not be crucial for the treatment, given the lack of effective therapy, the molecular testing can be of great relevance for carrier detection, disease prognosis and genetic counseling.

Integrating representation of variation at NCBI: RefSeqGene, OMIM, GeneReviews, dbGaP and dbSNP. *D. Maglott, J. Paschall, L. Phan, G. Yu, Y. Shao, L. Forman, K. Pruitt, M. Feolo, S. Sherry* Natl Ctr Biotechnology Info, NIH/NLM, Bethesda, MD.

Integrating and reporting information about molecular variation is a critically important task advancing understanding of biomedical data for researchers, clinicians and patients. As the number of research and clinical tests expands, so too does the need to make it easy to determine (1) whether information about a specific variant has been reported previously, (2) how often a variant has been identified, (3) in what populations or genetic backgrounds a variant has been observed, (4) where public information can be found about a variant, (5) laboratories known to test for a variant, and (6) current understanding of a variant's clinical significance. One step to facilitate this process is the generation of stable, gene-specific genomic reference sequences, termed RefSeqGene. Having a single, well-defined genomic coordinate system as a reference standard, independent of chromosome re-assemblies, provides a common currency for inter-group communication about the sequences being tested, especially when a gene has multiple splice variants or frequent mutations in non-transcribed regions. RefSeqGene accessions (format NG_000000.0) are being established in collaboration with gene-specific authorities to complement the existing RefSeq mRNAs so often used to report mutations. These sequences are being used within NCBI to increase explicit connections among multiple resources including dbGaP, dbSNP, Entrez Gene, GeneReviews, OMIM, and PubMed.

This presentation will summarize current progress in improving access to gene-specific variation data at NCBI. New tools to facilitate data submission, new viewers, and new mutation reports will be reviewed.

Loss of necdin in the mouse impairs the migration of neurons in the developing nervous system. *A.A. Tennese, J.R. Bush, R. Wevrick* Medical Genetics, University of Alberta, Edmonton, Alberta, Canada.

Prader-Willi syndrome (PWS) is a rare neurodevelopmental disorder characterized by failure to thrive, neonatal hypotonia, hyperphagia, childhood-onset obesity, and global developmental delay. PWS is caused by the inactivation of a subset of genes on chromosome 15. Necdin is one of the genes inactivated in individuals with PWS and is located in a syntenic region on chromosome 7C in the mouse. The expression of necdin in the mouse is highest in tissues relevant to PWS, including the central and peripheral nervous systems, and muscle. We previously determined that loss of necdin in mice causes axonal extension, bundling, and branching defects in cultured sympathetic chain ganglia neurons. Therefore, we examined the sympathetic nervous system during prenatal development in necdin-null mouse embryos using immunohistochemistry. We identified a defect in the size and location of the superior cervical ganglia (SCG), the most rostral ganglia in the sympathetic chain, in necdin-null embryos. The SCG appears normal at midgestation, but does not migrate towards the head at later stages in development as is normally observed in control embryos. In later stage necdin-null embryos, a decrease in innervation of SCG target tissues and an increase in cell death are also observed. As the survival of neurons requires nerve growth factors produced by target tissues, the reduction in axonal outgrowth likely causes the increased apoptosis in the maturing SCG neurons. To address the molecular mechanisms by which necdin might promote proper migration, we cultured fibroblasts from necdin-null embryos and control littermates. Necdin-null fibroblasts show reduced migration in cell culture wound-healing assays, suggesting that loss of necdin may affect the ability of the cytoskeleton to reorganize itself in response to environmental cues. We propose a novel role for necdin in the migration of neurons and other cell types in which it is expressed. Understanding the function of necdin in cytoskeletal reorganization and cellular migration may identify a cause for many characteristics of the PWS phenotype.

Chromosome 22q11 deletion syndrome: is MTHFR a modifier of the cardiovascular phenotype? *G.M. Repetto[1], J.F. Calderon[1], M.L. Guzman[1], A. Puga[1], C.P. Astete[2], M. Aracena[2], C. Mellado[3], T. Aravena[4], M. Arriaza[5], P. Sanz[6]*

Chromosome 22q11 microdeletion syndrome (del22q11) affects 1:4000 live borns. Its main clinical features include congenital heart defects (CHD), cleft palate and learning disabilities. Most patients share a common deletion, but clinical variability is marked. CHD is a significant cause of morbidity and mortality, and is present in 50-75% of cases reported in large series. MTHFR polymorphism 677CT is associated with an increased risk of non-syndromic CHD, but its effect on CHD in del22q11 patients has not been studied. We evaluated the association of 2 common polymorphisms in the MTHFR gene, 677 CT and 1298 AC, with the presence or absence of CHD in patients with 22q11 deletion. Seventy-one unrelated patients were included in the study. CHD disease was present in 52% of them. We found a significant difference in allelic and genotypic frequencies at position 1298. Variant A had a frequency of 0.84 in patients with and 0.69 in those without CHD (p=0.04). Genotypic frequencies were AA=0.7, AC=0.27 and CC=0.03 in patients with CHD and 0.38, 0.62 and 0.0 in patients without CHD, respectively (p=0.02). No significant difference was observed in allelic or genotypic frequencies of 677C>T between patients with or without CHD or with healthy population controls. We report a significantly higher frequency of MTHFR allele 1298C in patients with 22q11 deletion and no CHD compared to those with CHD. The cause of this association remains to be explored. Funded by Fondecyt-Chile, Grant # 1061051.

Prader-Willi syndrome is caused by paternal deficiency for the HBII-85 C/D box snoRNA cluster. *T. Sahoo[1], D. del Gaudio[1], J.R. German[1], M. Shinawi[1], S.U. Peters[1], R. Person[1], A. Garnica[2], S.W. Cheung[1], A.L. Beaudet[1]* 1) Dept Human & Molec Gen, Baylor Col Medicine, Houston, TX; 2) St. Francis Hospital, Tulsa, OK.

Prader-Willi syndrome (PWS) is a neurobehavioral disorder manifested by infantile hypotonia, feeding difficulties in infancy, followed by morbid obesity secondary to hyperphagia. It is caused by lack of paternally expressed genes within the human chromosome region 15q11-q13. The small nuclear ribonucleoprotein polypeptide N (*SNRPN*) and necdin (*NDN*) genes have been considered as PWS candidate genes. PWS patients harboring balanced chromosomal translocations with breakpoints within *SNRPN* have provided significant evidence that the snoRNA HBII-85 cluster is likely to play a major role in the PWS- phenotype. Here we report the identification and characterization of a de novo microdeletion within 15q11.2 in a child expressing a typical PWS phenotype. The patient exhibits all the 8 major diagnostic criteria including neonatal and infantile central hypotonia, feeding problems in infancy, excessive or rapid weight gain after 12 months, characteristic facial features, hypogonadism, hyperphagia/food foraging, and deletion 15q11-q13. He also exhibits mild mental retardation and meets criteria for a diagnosis of autism. A combination of high-resolution deletion analysis, breakpoint mapping and expression studies identified a loss of ~174 kb leading to the complete loss of the HBII-85 snoRNA cluster and partial loss of the HBII-52 cluster. Based on expression analysis in lymphoblasts for *SNRPN* (Exon1-3), HBII-13, AK094315, AB061718, and *UBE3A*, this interstitial deletion does not negatively impact the physical integrity or expression of other imprinted genes in its vicinity. Combined with previously reported data, this case provides strong evidence that paternal deficiency of the snoRNA HBII-85 cluster causes most or all of the phenotypic features of PWS. This interpretation would represent the first well documented example of a human phenotype caused by deficiency of a snoRNA, a subclass of regulatory noncoding RNAs.

An interstitial duplication of Xp22.31 defines a new candidate region for lissencephaly loci. *J.A. Martinez-Agosto*
Division of Medical Genetics, Department of Pediatrics, David Geffen School of Medicine at UCLA, Los Angeles, CA.

We report on a 3 year old female with a history of lissencephaly, dysmorphic features, seizure disorder, microcephaly, central hypoventilation syndrome, poor swallow and suck coordination, ventricular septal defect, cardiomyopathy, gastroesophageal reflux, vesicoureteral reflux with hydronephrosis, multiple pneumonias, and sensorineural hearing loss. This patient also developed bilateral cataracts. Skull series was negative for craniosynostosis. At birth she was noted to be hypotonic and was diagnosed with central hypoventilation. An EEG showed epileptiform activity. Additional testing included very low chain fatty acids, mitochondrial and metabolic testing that were all normal, a karyotype that showed 46,XX, and fluorescent in-situ hybridization for subtelomeric deletions that were negative. On further testing, microarray analysis identified a duplication of Xp22.31. The duplicated region is proximal to, but does not include the STS locus and it is distal to, but does not include the KAL1 locus. The duplication does not include the XLAG/Arx locus, and it is distal to the Aicardi syndrome region. Microdeletions that include this region have been previously associated with variable phenotypes including mental retardation and dysmorphic features. In particular, two previous reports of large deletions including this region presented with a wide spectrum of physical features. This is the first report of a duplication of this region. Genes within this region include VCX-C/VCX3A, which is expressed in the fetus, brain, liver, skin, stomach and testis germ cells, and a new gene enriched in embryonic stem cells, CN268333. We suggest that these may represent candidate genes for lissencephaly and/or some of the additional congenital anomalies present in this patient.

The European Cytogenetic Initiative: Molecular karyotyping of 120 patients with unexplained mental retardation by Mapping 500K SNP arrays. *J.A. Veltman[1], A. Dufke[2], D.J. McMullan[3], B.B.A. de Vries[1], E.C. Rattenberry[3], M. Bonin[2], S. Jacobs[4], M. Steehouwer[1], R. Pfundt[1], N. de Leeuw[1], A. Riess[2], O. Altug-Teber[2], H. Enders[2], E.V. Davison[3], O. Riess[2], L. Brueton[3]* 1) Dept. Human Genetics, UMC Nijmegen, Nijmegen, The Netherlands; 2) Dept. Medical Genetics, University of Tuebingen, Tübingen, Germany; 3) West Midlands Regional Genetics Laboratory & Clinical Genetics Unit, Birmingham Womens Hospital, Birmingham, United Kingdom; 4) Affymetrix, Inc, Santa Clara, USA.

The underlying genetic defect remains difficult to diagnose in the majority of patients suffering from mental retardation. Recent developments in genomic microarray technology now allow for the genomewide detection of subtle chromosomal alterations, and this has been demonstrated to significantly improve the diagnostic yield in this patient group. This technology has rapidly matured and now appears ready for widespread introduction in routine diagnostics. We hypothesize that it is best to use commercially available microarrays as these provide the highest genome coverage, they can be produced according to industrial quality standards, are available to all diagnostic laboratories, and their widespread use will generate large reference datasets. In this study three European diagnostic centres assessed the use of Mapping 500k SNP arrays for molecular karyotyping in patients with mental retardation. Each centre tested DNA from 40 patient-parent trios. In addition, 40 known submicroscopic copy number variations (CNVs) were run for validation purposes and for optimizing data-analysis. All known CNVs were unequivocally detected on the Mapping 500K arrays. In the cohort of 120 patients with unexplained MR a total of 17 de novo CNVs were identified, varying in size from 700 kb to 12 Mb. In addition numerous inherited CNVs were detected, including a large maternally transmitted deletion on 16p13.11-p12.3. In conclusion, we show that Mapping 500K SNP arrays can be used to reliable detect and characterize subtelomeric and interstitial CNVs. The diagnostic yield of this approach is significant and warrants a rapid diagnostic implementation of these microarrays in mental retardation.

***Cirh1a*, mutated in North American Indian Childhood Cirrhosis, plays important roles in the genesis of multiple organs during mouse embryonic development.** *B. Yu, G. Mitchell, A. Richter* Medical Genetics, Hopital Sainte-Justine, Montreal, PQ, Canada.

Missense mutation R565W in human *CIRH1A* causes North American Indian childhood cirrhosis (NAIC), a hereditary cholestasis frequent in native children from Western Quebec. The gene product, cirhin is a nucleolar protein of unknown function that interacts with HIVEP1, a component of the Dpp/MBP/TGF signalling pathway. To elucidate gene function, we generated a *cirh1a* knockout mouse using exon targeted XH230 ES cells that have a -gal-NEO insertion in intron 9 of the gene. Expression of the -gal reporter is driven by the *cirh1a* promoter. Heterozygotes are fertile and show no physiologic or histological signs of liver dysfunction. In contrast, we obtained no liveborn *cirh1a* (-/-) animals. To determine the timing of embryonic lethality, we performed X-Gal staining of whole mount embryos and cryostat sections. Our results show that the homozygous knockout state is embryonic lethal before mid-gestation: as early as E8.5 we found no (-/-) embryos. To understand this embryonic lethality, we examined gene expression patterns in (+/-) embryos. No expression was detected in early (E5.5)or late (E12.5) embryos. Between E6.0 and E12.0, we observed changes in spatial and temporal expression patterns: initial expression of *cirh1a* in liver coincides with the appearance of the hepatic diverticulum (E9.5), followed by expression in the liver buds and the cystic (gall bladder) primordium. Between E10.0 and E12.0 *cirh1a* expression becomes progressively restricted. By E12.0, only liver and stomach show high level expression.

The expression pattern of cirhin during embryogenesis is similar to that of proteins in the Dpp/MBP/TGF signalling pathway. We hypothesize that *cirh1a* may have a role in early embryonic patterning, morphogenesis, and in the genesis of multiple organs. This is compatible with a role for cirhin in development, although a physiological function can not be excluded. Study of its direct role in liver and biliary tract development will be undertaken in R565W *cirh1a* knock-in animals. Supported by the CIHR.

Molecular Characterization of BRCA1 and BRCA2 genes in breast cancer mexican mestizo patients. *S. Vidal, L. Taja-Chayeb, V. Rosas, O. Gutierrez, A. Dueñas* Dept Basic Research, Inst Nal de Cancerologia, Mexico City.

Breast and ovarian cancer are the most frequent causes of death in women, generating an important public health problem. A small proportion of these tumors results from alterations in cancer susceptibility genes. Two of these genes are BRCA1 and BRCA2, which are described as hereditary breast and ovarian cancer genes. To date, over 500 sequence variants have been reported for BRCA genes. Specific mutations to particular ethnic groups have been described. There are no known mutations for the Mexican mestizo population. The purposes of this work were to determine the mutation frequency of BRCA1 and BRCA2 genes in breast cancer patients under 40 years old or patients with familiar breast and/or ovarian cancer history, through DHPLC analysis and, to establish genotype-phenotype correlations. Those families with mutations will be follow up for early detection, and wiil receive genetic counseling. 40 breast and/or ovarian cancer patients were included. DNA was obtained from peripheral leukocytes, and was amplified for the 24 exons of BRCA1 using 31 pairs of oligonucleotides, and for the 26 exons of BRCA2 with 39 pairs of primers. The primers were designed to include each exon flanked by a small portion of the corresponding introns. The amplifications were analyzed by DHPLC (Transgenomics). The alterations found were corroborated by direct sequencing. We have analyzed the entire BRCA1 and BRCA2 genes for 40 patients, we found in BRCA1 gene 1 polymorphism at exon 13 in 5 patients, 1 intronic deletion in exon 7 in 5 patients, the same deletion plus 3 base-changes in 9 patients, 1 missence mutation without clinical significance in 7 patients at exon 11 and 2 small deletions in exon 11 in 2 patients. In BRCA2 we found 1 polymorphism at exon 4 in 4 patients, 4 different polymorphism at exon 11 in 24 patients, 1 patient with a missence mutation in exon 11 and 1 patient with a deleterius mutation in exon 11. We have found an elevated percentage of patients with polymorphisms (up to 30%). However, until now we have found only 2 mutations with clinical significance in BRCA1 and 1 for BRCA2. It seems that mutations in BRCA genes are not frequent in our population.

Zebrafish dax1 Has Novel Functions in Enamel-Forming Ameloblasts and Primary Tooth Development. *J. Powers[1], Y. Zhao[2,3], E.R.B. McCabe[1,2,4]* 1) Pediatrics, UCLA, Los Angeles, CA, USA; 2) Human Genetics, UCLA, Los Angeles, CA, USA; 3) Cell and Developmental Bio, UCLA, Los Angeles, CA, USA; 4) Bioengineering, Henry Samueli School of Eng and App Sci, UCLA, Los Angeles, CA, USA.

Dax1 is a nuclear receptor encoded by NROB1 in the human Xp21 chromosome region. Mutations in DAX1 cause X-linked Adrenal Hypoplasia Congenita (AHC) and Hypogonadotropic Hypogonadism (HH). Zebrafish dax1 is the mammalian Dax1 ortholog and the gene structures are absolutely conserved across species. In situ hybridization (ISH) of dax1 in zebrafish revealed an unrecognized dax1-expressing structure. Double ISH studies with appropriate markers showed that this structure is not the ears, pronephric tubule, or fin buds, but does localize to the fifth branchial arch, where pharyngeal tooth development is known to occur. Tooth markers, dlx2a, dlx2b, and pitx2a appearing around 48 hpf do not co-localize with dax1, and dax1 MO had no effect on the expression of these markers. Double ISH with dax1 and eve1, a gene known to be involved in differentiation of the enamel-forming ameloblasts and initiation of the first pharyngeal tooth, showed co-localization of their signals. Mismatch control and MO studies revealed that zebrafish dax1 reduced expression of eve1. We conclude that zebrafish dax1 has novel functions outside the Hypothalamic-Pituitary-Adrenal-Gonadal axis, specifically in influencing amelogenesis and primary pharyngeal tooth development, and therefore is the earliest tooth marker for zebrafish tooth development. DAX1 has been reported to be upregulated in sarcomas and to have a role in osteoblast development. We speculate that dax1 may involve similar NR partners to those involved in its roles in bone, and that DAX1 may be involved in abnormalities in primary tooth development and enamelogenesis.

Synergistic heterozygosity for functional TGF1 SNPs and BMPR2 mutations modulate age of diagnosis and penetrance of Familial Pulmonary Arterial Hypertension (FPAH). *J.A. Phillips III[1], J.S. Poling[1], C.A. Phillips[1], K.C. Stanton[1], E.D. Austin[2], J.D. Cogan[1], L.A. Wheeler[2], J.E. Loyd[2]* 1) Division of Medical Genetics; 2) Division of Pulmonary Medicine, Vanderbilt University School of Medicine, Nashville, TN.

Intro: FPAH is a progressive, autosomal dominant disease with pulmonary artery occlusion, heart failure and early death. FPAH is caused by mutations in the BMPR2 gene, which encodes a receptor in the TGF Superfamily. Two TGF1 SNPs (-509 C/T and codon 10 T/C) both increase levels of TGF1. The TGF and BMP pathways acting through SMADs 2/3 and 1/5/8, respectively can have opposing effects on apoptosis, differentiation and proliferation. Hypothesis: Synergistic Heterozygosity for functional TGF1 SNPs increases TGF/BMP signaling imbalance in BMPR2 mutation heterozygotes to modulate the age at diagnosis and penetrance of FPAH. Methods: TGF1 SNPs were genotyped by sequencing genomic DNAs of BMPR2 mutation heterozygotes and correlating TGF1 SNP haplotypes and FPAH phenotype. Results: BMPR2 mutation heterozygotes having least (CC) or more active (CT or TT) -509 TGF1 SNP genotypes had mean ages at diagnosis (AAD) of FPAH of 40.2 and 33.5 yrs, respectively (p=0.046 Mann Whitney). Those with least (TT) or more active (CT or CC) codon 10 TGF1 SNP genotypes had mean AAD of 42.3 and 34.1 yrs, respectively (p=0.022 Mann Whitney). Kaplan Meier analysis of BMPR2 heterozygotes having no active versus 1-4 active TGF1 SNP alleles had mean AAD of 44.4 and 33.4 yrs, respectively (p=0.004 log rank). Heterozygotes for all BMPR2 mutations that did not elicit nonsense mediated decay who had 0, 1 or 2 active -509 or 0-1, 2 or 3-4 active -509/codon 10 alleles had 27, 70 and 80% or 28, 70 and 75% penetrance of FPAH (p=0.002 and 0.003 ANOVA), respectively. Conclusions: 1) TGF1 SNP genotypes associate with AAD and penetrance of FPAH in BMPR2 mutation heterozygotes, 2) more active TGF1 SNP alleles may increase the TGF/BMP signaling imbalance to lower the AAD and increase the penetrance of FPAH, and 3) modulation of rare BMPR2 mutations by common TGF SNPs is an example of Synergistic Heterozygosity in reciprocal, interactive pathways.

Identification by array-CGH of new candidate regions for utero-vaginal defects. *C. Rosenberg, C. Cheroki, A.C. Krepischi-Santos, P.A. Otto* Dept Genet. Evol Biology, Univ Sao Paulo, Sao Paulo, Brazil.

Failure in fusion of müllerian ducts has an incidence of about 1/5000 newborn females and results in defects of the genital tract ranging from upper vaginal atresia to total absence of fallopian tubes, uterus and upper vagina. It might occur in otherwise phenotypically normal females (Mayer-Rokitansky-Küster-Hauser anomaly - MRKH [OMIM 277000]), but it is often associated with other malformations involving kidneys, skeleton, extremities and hearing defects (known as the MURCS association), suggesting the involvement of major developmental genes. Although a mutation in the WNT4 gene has been identified in one atypical patient and chromosomal alterations have been sporadically reported, the etiology of mullerian anomalies remain poorly understood. Array-based comparative genomic hybridization (array-CGH) allows ascertaining cryptic chromosomal imbalances that escape detection by routine chromosome analysis. It provides a genome-wide screening by hybridizing differentially labeled test and reference DNAs to arrays consisting of thousands of genomic clones. This approach has proved useful in determining the etiology of 15-20% of mental retardation of previously unknown cause, and lead to the identification of novel genes involved in malformation syndromes. We investigated by array-CGH fifteen syndromic females with uterus-vaginal defects, but normal G-banded. Cryptic imbalances were detected in five patients (33%). Relatives carrying the imbalances showed variable penetrance and expressivity, including renal defect in a probands son. The results point to 1q21.1, 17q12, 22q11.21-q11.22 and Xq21.31 as relevant regions for urogenital tract development.

Epitope-tagging of endogenous proteins in somatic cells for ChIP-chip. *P.C. Scacheri, X. Zhang, Z. Wang*
Department of Genetics, Case Western Reserve University, Cleveland, OH.

Chromatin immunoprecipitation coupled with DNA microarray (ChIP-chip) technology offers enormous potential for genome-wide identification of transcription factor binding sites. The success of ChIP-chip relies heavily on antibodies with high affinity and specificity, yet such antibodies are not available for most proteins. In principle, this problem can be circumvented by constructing epitope-tagged proteins recognizable by well characterized antibodies. However, expression of tagged proteins at non-physiological levels can reduce the efficiency of ChIP and produce a genomic distribution of the tagged protein that differs from that of the endogenous proteins. To surmount this problem, we developed a strategy whereby recombinant adeno-associated virus (rAAV) is used to epitope tag endogenous loci by homologous recombination-mediated "knock-in". The tagging approach is fast, can be applied to numerous loci and multiple somatic cell lines, and facilitates western, immunofluorescence, and immunoprecipitation analyses of targeted proteins. As proof of principle for use in ChIP-chip, we introduced a triple FLAG tag into the C-terminus of STAT3, a transcription factor that is constitutively activated in a multitude of tumors. ChIP-chip analysis of FLAG-tagged STAT3 in colon cancer cells enabled discovery of hundreds of STAT3 binding sites, and ChIP-chip analysis of untagged STAT3 indicated that the locations of the STAT3 sites were not affected by the presence of the tag. The majority of STAT3 binding sites are located far from promoters, suggesting that the regulatory role of STAT3 in colon cancer is highly complex. This knock-in approach can be used to target virtually any locus, obviates the need for cloning tagged full-length cDNAs, insures normal expression profiles, and provides a general solution for the study of proteins for which antibodies are substandard or not available.

Genotype-phenotype relationships in desminopathy. *H. Lee[1], A. Shatunov[1], M. Olivé[2], P. Vicart[3], A. Kaminska[4], K. Bushby[5], F. Muntoni[6], M. Dalakas[1], H. Goebel[7], L. Goldfarb[1]* 1) National Institute of Neurological Disorders and Stroke, National Institutes of Health, Bethesda, MD; 2) Hospitalet de Llobregat, Barcelona, Spain; 3) Univ. Paris, Paris 7 Denis Diderot, France; 4) Medical Univ. of Warsaw, Warsaw, Poland; 5) Inst. of Human Genetics, Newcastle upon Tyne, UK; 6) Imperial College, London, UK; 7) Mainz Univ. Med. Ctr, Mainz, Germany.

Desminopathy is one of the most common neuromuscular disorders, which is associated with mutations in desmin and alphaB-crystalline. These proteins are in close interactions in striated muscle Z-disc structure. Desminopathy patients may suffer from smooth muscle myopathy, neuropathy, respiratory dysfunction, facial paralysis, or cataracts. However skeletal myopathy and cardiomyopathy are two major clinical features, of which patients may suffer either one of the two, or both. With few exceptions, such phenotypic manifestations in members of the same family are concordant with respect to developing either skeletal or cardiac myopathy, which suggests a diverse underlying genetic cause of different desminopathy phenotypes. This gave us the impetus to investigate the possibility of genotype (type and location of forty-two reported desminopathy-causing mutations in the desmin gene) and phenotype (cardiac, respiratory and/or skeletal involvement) relationship among desminopathy patients. Our study includes clinically and pathologically characterized 91 desminopathy patients, all of whom have mutations in various domains of desmin. These patients were grouped into two-way contingency table according to: 1) the location of mutation in the desmin gene domain, and 2) the degree of cardiac and skeletal muscle involvement. Armitage trend test revealed that mutations in the 1B domain tend to cause predominantly cardiac myopathy when compared to mutations in 2B domain. Tail domain mutations also showed more cardiac involvement than skeletal myopathy when compared against 2B domain. We conclude that the location of desmin mutation exerts a significant influence on desminopathy phenotypes, with cardiomyopathy occurring more frequently with mutations in 1B and tail domains, while mutations in 2B domain are linked to the skeletal myopathy phenotype.

Identification of a genomic locus associated with early onset familial Essential tremor. *A. Shatunov[1], Z. Mari[1], E. Peckham[1], R. Elble[2], J. Clarimon[1], N. Sambuughin[1], H.S. Lee[1], A.B. Singleton[1], D. Vojcic[1], M. Hallett[1], L.G. Goldfarb[1]*
1) National Institutes of Health, NINDS/NIA, Bethesda, MD; 2) Southern Illinois University School of Medicine, Springfield, IL.

Essential tremor (ET) is the most prevalent movement disorder showing evidence of non-random accumulation in some families. Late onset ET has previously been mapped to genetic loci on chromosomes 2p, 3q, and 6p, but no causative genes identified. We conducted a genomewide linkage screening of two North American and one Spanish family comprising a total of 52 genotyped individuals that included 19 patients diagnosed as definite ET. The average age of disease onset in each family was before 21 years. Genotyping was performed with Affymetrix GeneChip10K assay with 10,000 SNPs, and the region of interest additionally genotyped with 7 polymorphic microsatellite markers covering the area of 13 cM on chromosome 11p15. Linkage analysis was based on methodology implemented in Genehunter2 programs. The results indicate linkage to the 11p15 region with maximum cumulative LOD score 2.85 at marker D11S1984. The multipoint LOD score in the 13 cM region is 3.6. The multiple NPL score is 7.7 with p= 0.000038. Our findings provide evidence for linkage of ET to a novel susceptibility locus on chromosome 11p15.

Bayesian approaches for detecting association in case-control studies. *D. Vukcevic, P. Donnelly* Department of Statistics, University of Oxford, Oxford, United Kingdom.

Following recent marked successes, it seems likely that genome-wide association studies will become a method of choice for understanding the genetics of common human diseases. Questions of how best to analyse such studies remain unresolved. A typical initial approach would be to apply classical frequentist statistical tests based on contingency tables or regression models, such as the Cochran-Armitage, or Trend, test. The strength of evidence at each SNP is then summarised by the p-value of the test. This approach suffers from at least two disadvantages. (1) Interpretation of the p-value is difficult without also knowing the power of the test. Since power depends on allele frequency, a p-value of a given magnitude represents much weaker evidence of association at a rare SNP than at a more common SNP (assuming similar effect sizes in each case). (2) There is confusion about how to handle multiple testing. Several studies have shown that Bayesian approaches can have advantages in terms of power and efficiency, and the Bayesian analogue of a p-value, called the Bayes Factor, is often easier to interpret. Here we use data from recently published large association studies and simulations to compare and contrast the use and interpretation of p-values and Bayes Factors as measures of evidence in genome-wide association studies.

Global gene-expression analysis of eczema skin; a focus on skin barrier function. *A. Sääf, A. Liedén, E. Ekelund, M. Nordenskjöld, M. Bradley* Center for Molecular Medicine, Karolinska University Hospital, S-171 76 Stockholm, Sweden.

Atopic eczema (AE) is a common skin disorder currently affecting up to 20% of children in some countries (1). AE usually begins in infancy or early childhood with a significant proportion of children having continued problems into adult life. Patients with AE suffer from itchy, dry and inflamed skin, often in combination with other atopic manifestations such as allergic asthma and allergic rhinoconjunctivitis (hay fever). Twin studies indicate a strong genetic contribution in the development of AE (2,3) and genetic linkage analyses have identified several chromosomal regions linked to AE (4-7). However, very little is known about specific genes involved in this complex skin disease and the underlying molecular mechanism is not yet identified. We used human cDNA microarrays to identify a molecular picture of the programmed responses of the human genome to the pathological condition of AE. Among the genes consistently over-expressed in AE skin as compared to skin from healthy control individuals were members of the transglutaminase family (TGM1 and TGM3) and corneodesmosin (CDSN) that play a central role in forming the outermost layer of the skin, the cornified envelope. These genes are localized to known susceptibility chromosomal regions for eczema (TGM1; 14q11, TGM3; 20p13, CDSN; 6p21.3). It is not known, however, if genetic polymorphisms in these genes contribute to skin barrier dysfunction in eczema patients. To answer this question, we investigated the role of genetic variation at these loci in the development of eczema. In summary, we here present a global gene signature of eczema skin, and furthermore genetic polymorphisms are described in candidate AE susceptibility genes identified by the microarrays. In conclusion, our data supports the hypothesis that barrier dysfunction is an important factor in eczema pathogenesis. 1. Morar 2006, J Allergy and Clin Immun 118(1):24-34 2. Intrafamilial correlation of age at breast cancer onset in *BRCA1* and *BRCA2* carriers. *S. Panchal[1, 2], M. Ennis[3], S. Canon[1], L.J. Bordeleau[1, 2]* 1) Familial Breast Cancer Clinic, Mount Sinai Hospital, Toronto, ON, Canada; 2) The University of Toronto, Toronto, ON, Canada; 3) Applied Statistician, Markham, ON, Canada.

BRCA1 and *BRCA2* mutations account for the majority of known hereditary breast cancer. For female carriers, lifetime breast cancer (BC) risks range from 56-87%. Although general data are available on cancer risk estimates by age and mutation type, personalized BC onset risk estimates are not available for individual carriers. This study attempts to determine if there is a correlation between the age at BC onset among family members in any given *BRCA* mutation positive family. Data were collected from a chart review of patients followed in the Familial Breast Cancer Clinic at Mount Sinai Hospital, Toronto, Canada. Detailed 3-generation pedigrees were constructed and analyzed and ethics approval was obtained to review and record chart information. Carrier families with 2 or more cases of BC were included. Age at diagnosis and age at onset are used interchangeably. The intraclass correlation (ICC), representing the correlation in BC diagnosis age between two randomly drawn family members from the same family, was calculated using the ANOVA method. Variability in diagnosis age was explored using multilevel (mixed model) methods. A total of 48 *BRCA1* and 42 *BRCA2* families were included in the study. The average number of family members diagnosed with BC was 2.8 (range:2-5). The average age at BC diagnosis is significantly younger (p=0.009) in *BRCA1* carriers (42.92 years) compared to *BRCA2* carriers (46.82 years). The ICC for *BRCA1* (0.08) and *BRCA2* (0.04) were not significantly different from zero. Data from our population are consistent with previous studies showing that the average age at BC diagnosis in *BRCA1* carriers is lower than in *BRCA2* carriers. ICC results suggest that there is no correlation between the age at BC diagnosis among *BRCA* carriers from the same family. This study demonstrates that the age at BC diagnosis for affected *BRCA* carriers cannot be used clinically to predict the age at which an unaffected carrier from the same family will develop BC.

Association of Polymorphisms in Cyclooxygenase (COX)-2 with Coronary and Carotid Calcium in the Diabetes Heart Study. *M.E. Rudock[1], J. Ziegler[2], S.G. Allen[3], A.B. Lehtinen[1,5], J.J. Carr[4], C.D. Langefeld[2], D.W. Bowden[1,5], Y. Liu[2,3]* 1) Center for Human Genomics; 2) Departments of Public Health Sciences; 3) Internal Medicine; 4) Radiology; 5) Biochemistry, Wake Forest University, Winston Salem, NC.

BACKGROUND: Cardiovascular Disease is the leading cause of death among Americans. Inflammation is a hallmark feature in the development of atherosclerosis and is mediated by prostaglandins, catalyzed by cyclooxygenase (COX)-2. We sought to determine if variants in the COX-2 gene were associated with measures of cardiovascular disease in a primarily type 2 diabetic population. METHODS: Eight polymorphisms in COX-2 were genotyped and vascular calcified plaque measured in the coronary, carotid, and aortic arterial beds in 978 Caucasian siblings (83% with T2DM) from 369 Diabetes Heart Study families. Tests for single SNP and haplotypic association were performed using SOLAR and QPDT, respectively (results adjusted for age, gender, diabetes affection status, smoking, and use of lipid altering medications). RESULTS: All eight SNPs genotyped were found to be in strong pairwise linkage disequilibrium (D=1.0). Three SNPs (rs689466, rs2066826 and rs20417) are associated with either coronary or carotid calcified plaque. Subjects homozygous for the G allele of rs689466 (n=31) or the A allele of rs2066826 (n=16) had a 32% (p=0.02) and 47% (p=0.04) increase in coronary calcified plaque, respectively. Similarly, subjects homozygous for the C allele of rs20417 (n=22) or the A allele of rs2066826 (n=16) had increased carotid calcified plaque (p=0.011, p=0.014). Furthermore, the overtransmission of the rs20417 + rs689466 GA haplotype was correlated with increased coronary calcified plaque (p=0.002), while the GG haplotype was correlated with decreased coronary calcified plaque (p=0.004). CONCLUSIONS: Polymorphisms in COX2 were associated with increased coronary or carotid calcium. Individuals with these variants may be at higher risk for developing cardiovascular disease.

Development of a Clinical Biomarker Assay for the t(4;14) Translocation Associated with Multiple Myeloma.

M.R. Reed[1], J.A. Roseberry Baker[2], G. Zhao[3], C. Lopez-Correa[1] 1) Integrative Biology, Eli Lilly and Company, Greenfield, IN; 2) Drug Disposition, Eli Lilly and Company, Indianapolis, IN; 3) Angiogenesis-Tumor Microenvironment Biology, Eli Lilly and Company, Indianapolis, IN.

Fifteen percent of Multiple Myeloma cases are associated with a translocation between chromosomes 4 and 14, and the patients carrying this genetic aberration typically have a poor prognosis. The t(4;14) translocation moves the FGFR3 gene from chromosome 4 to the vicinity of the IgH locus on chromosome 14 resulting in ectopic expression of FGFR3. It is thought that the transcriptional activation of FGFR3 resulting from its juxtaposition to the strong enhancers of the IgH locus may be one of the oncogenic events leading to the development of Multiple Myeloma. Since only fifteen percent of Multiple Myeloma patients bear the t(4;14) translocation, a clinical assay for this genetic biomarker is needed to identify which individuals have the translocation and will, therefore, benefit from FGFR3 treatment. We have assessed two techniques for their suitability to be translated into the clinic as biomarker assays for the t(4;14) translocation, RT-PCR and FISH. We tested five Multiple Myeloma cell lines, three with the t(4:14) translocation and two without, in each assay. Both assays were able to clearly distinguish Multiple Myeloma cell lines carrying the t(4;14) translocation from those without this translocation. However, variability in the RT-PCR assay caused by the fact that the translocation breakpoints span a 60 kb region lead us to the conclusion that it is not suitable for a clinical setting, while the FISH assay, which lacks this variability, could be more reliably translated into the clinic.

Skewed X-Inactivation in Women with Karyotyped Spontaneous Abortiions. *D. Warburton[1], J. Kline[1], S. Brown[2], A. Kinney[1], C-Y. Yu[1], B. Levy[1], V. Jobanputra[1], B. Levin[1]* 1) Columbia Univ, New York; 2) Univ. Vermont.

Several previous reports suggest that highly skewed X inactivation (HSXI) is associated with recurrent spontaneous abortion. A possible explanation is that HSXI is associated with trisomy. X-chromosome genetic changes could lead both to HSXI and to increased oocyte atresia, with a resulting increase in trisomic conception. Alternatively, an anomalous X chromosome could cause embryonic death in male conceptions. To test these hypotheses we measured XCI skewing in women ascertained through a karyotyped spontaneous abortion and in age-matched controls with births at the same hospital. We used the HUMARA assay with control Rsa1 and MIC2 digestion. Because ratios >=90% were infrequent (~2%), we defined HSXI as >=85%. A ratio >=85% occurred in 5.4% of controls (n=427), 5.5% of women with trisomic losses (n=163) and 2.2% of women with normal male losses (n=46). In comparison with controls, the age-adjusted odds ratio for XCI >=85% vs. XCI 50-<60% was 1.2 (95% CI 0.5-2.8) for trisomic losses and 0.3 (95% CI 0.04-2.4) for chromosomally normal male losses. Thus, our study does not support an association between HSXI and either trisomic or normal male loss. In secondary analyses, the skewing distribution was significantly different for non-trisomic abnormal losses (p=0.02), due mostly to increased HSXI (21.1%) among monosomy X losses (n=19). When trisomies were classified by type, the skewing distribution was significantly different for non-acrocentric trisomies other than 16 (n=38; p=0.03); 13.2% had HSXI. Because of small samples and the multiple tests performed, the latter results require confirmation. HSXI was unrelated to recurrent loss in our sample. All 45 women with HSXI had normal X chromosomes by G-banding; high-resolution oligonucleotide microarray analysis on 15 revealed no additional changes. Among 90 women for whom we measured skewing in left and right buccal smears, the correlation between the average ratio in buccal smears and blood was 0.53. Only 3 women showed skewing >=85% in all samples. This low correlation indicates that the XCI skewing ratio in a blood sample is not a good indicator of X-chromosome anomalies leading to skewing in all tissues.

Comparison of Hexosaminidase A enzyme assay and mutation testing: Is enzyme assay still necessary in Tay-Sachs population screening? *A. Schneider[1], R. Keep[1], D. Dorsainville[1], T. Bardakjian[1], D. Finegold[3], W. Sun[2], A. M. Roe[2], J. Lebow[1], S. Nakagawa[2], J. Zhan[2], S. Gross[2]* 1) Dept Genetics, Albert Einstein Med Ctr, Philadelphia, PA; 2) Albert Einstein College of Medicine, Bronx, NY; 3) Univ Pittsburgh,Childrens Hosp Dept Pediatrics, Pittsburgh, PA.

Background: The Victor Center for Jewish Genetic Diseases was established with the mission of education, screening and counseling for the disorders that occur more frequently in the Ashkenazi Jewish(AJ)population. The program provides free screenings on college campuses and for newlywed couples. While Tay-Sachs(TS)carrier screening historically has relied on biochemical enzymatic assays, molecular analyses for the common founder mutations is now also commonly performed. Aim: The goal of this present study was to clarify actual detection rates for these two methodologies in a community-based, non-selected Jewish population and thereby determine whether there is additional benefit to the continued use of the TS enzyme assay for carrier detection. Methods: During the period from March 2006 to March 2007, 632 people were screened for Tay-Sachs disease(college students and newlyweds). A single laboratory was used for all assays. All samples were tested for the common founder mutations, as well as the 2 pseudodeficiency alleles. Serum Hexosaminidase A(Hex A)assay was performed on all samples. Platelet assays were performed on inconclusive samples(68). Results: All of the carriers were detected by enzyme assay. Two of the 24 carriers(8%)were negative for the common AJ mutations by DNA testing. One of these individuals was adopted and the other reported mixed ancestry. Conclusion: As the AJ population diversifies with intermarriage and adoption, DNA testing for the common AJ mutations will invariably miss Tay-Sachs carriers. While molecular testing may be appropriate for cascade screening of family members of known carriers and for individuals with well delineated Ashkenazi Jewish background, these preliminary results strongly suggest the continued use of biochemical methodologies in the more genetically diverse, self-identified young adult Jewish population. **Background:Aim:Methods:Results:Conclusion:**.

A high resolution expression atlas of Retinitis Pigmentosa genes in the human and mouse retinas. *D. Trifunovic[1], M. Karali[1], D. Camposampiero[2], D. Ponzin[2], V. Marigo[3], S. Banfi[1]* 1) Tigem, Telethon Institute of Genetics and Medicine, Naples, Italy; 2) Fondazione Banca degli Occhi del Veneto, Venice; 3) Department of Biomedical Sciences, University of Modena and Reggio Emilia, Modena, Italy.

Retinitis Pigmentosa (RP) is one of the leading causes of visual handicap in the world population and is characterized by high genetic heterogeneity. The study of the disease mechanisms and the development of efficient therapeutic approaches so far have mostly relied on the availability of animal models for this condition. Nevertheless, little information is available about the RNA expression profiles of the RP genes in the human retina. To overcome this lack of information, we generated an expression atlas of 34 known RP genes in human and murine retinas by RNA *in situ* hybridization. The vast majority of the genes analyzed displayed similar patterns between human and mouse retina. Interestingly, four genes belonging to the visual cycle cascade, namely RGR, RPE65, RLBP1 and LRAT, were differently distributed in human and murine retina. We show that these four genes are expressed by cones in the human retina, suggesting that visual cycle processing occurs also in cones in a mechanism alternative to the one that takes place in the RPE. The generation of this atlas may shed new light on the function of RP genes and their putative role in disease pathogenesis.

ARSACS in the Dutch population: A frequent cause of recessive cerebellar ataxia? *S. Vermeer[1], H.P.H. Kremer[2], R.P.P. Meijer[1], B.J. Pijl[3], J.R.M. Cruysberg[3], J. Timmermans[4], M.M. Bos[2], H.J. Schelhaas[2], B.P.C. van de Warrenburg[2], N.V. Knoers[1], H. Scheffer[1]* 1) Departments of Human Genetics; 2) Neurology; 3) Ophthalmology; 4) and Cardiology, Radboud University Nijmegen Medical Centre, The Netherlands.

Introduction: Autosomal recessive spastic ataxia of Charlevoix-Saguenay (ARSACS:MIM 270550) is a neurodegenerative disorder characterized by a core phenotype of progressive early-onset cerebellar ataxia with evolving spasticity of the lower limbs and peripheral neuropathy. The disorder was first described among French Canadians in the isolated Charlevoix-Saguenay region of Quebec, but by now the disease has been recognized to occur worldwide. Therefore we initiated a systematic mutation analysis by direct automated sequencing of the coding regions of the huge SACS gene in Dutch ataxia patients.

Methods: Mutation analysis was performed in 31 index patients. Patients were classified into 3 different groups (A to C) based on clinical characteristics. All patients in group A (n=11) showed the ARSACS core phenotype. Group B (n=6) consisted of patients whom did not have all three features of the core phenotype. Group C (n=14) consisted of patients for whom routine SACS mutation analysis was requested, without the phenotype being precisely defined. All 5 coding exons of the SACS gene were PCR amplified and subsequently sequenced.

Results: We identified mutations in the SACS gene in 13 (42%) adult patients out of 31 index patients. All mutations are novel and most likely are loss of function mutations. Most ARSACS patients were identified in group A (9 out of 11). All the identified ARSACS patients of whom we were able to collect detailed clinical information (11) displayed the core phenotype.

Conclusion: Apparently, in Dutch patients the prevalence of ARSACS seems substantially higher than previously estimated. The phenotype of ARSACS patients seems rather uniform and recognizable as supported by the high mutation detection rate in group A (82%).

Mitochondrial *ADCK3*, an ancestral prokaryotic kinase involved in Coenzyme Q biosynthesis, is mutant in a new form of recessive ataxia. *C. Lagier-Tourenne[1], M. Tazir[2], C. Quinzii[3], L. López[3], C. Busso[4], N. Drouot[1], M. Assoum[1], S. Makri[2], L. Pacha[2], T. Benhassine[2], M. Anheim[5], S. Schmucker[1], D. Lynch[6], F. Plewniak[1], C. Tranchant[5], O. Poch[1], J.L. Mandel[1], M. Barros[4], M. Hirano[3], M. Koenig[1]* 1) IGBMC, CNRS/INSERM/ULP, Illkirch, France; 2) Service de Neurologie, Centre Hospitalier Universitaire Mustapha, Alger, Algeria; 3) Department of Neurology, Columbia University College of Physicians and Surgeons, New York, NY, United States; 4) Departamento de Microbiologia, Universidade de São Paulo, São Paulo, SP, Brasil; 5) Department of Neurology, Hospital of Strasbourg, Strasbourg, France; 6) Children's Hospital, Philadelphia, PA, United States.

A SNP-based genome-wide scan in a large consanguineous family allowed us to identify a new locus for autosomal recessive ataxia at chromosome 1q41. We found deleterious mutations in *ADCK3* gene in 7 patients from 4 families. All patients have childhood-onset cerebellar ataxia with slow progression and few additional signs. The yeast homologue of *ADCK3* encodes for a mitochondrial protein and is mutated in the ubiquinone (or Coenzyme Q) deficient S. cerevisiae strain *coq8*. Two mutations identified in patients result in protein truncation. Three non-truncating mutations were introduced into the yeast *COQ8* gene and resulted in growth failure on selective respiratory medium, confirming the deleterious nature of these mutations. Likewise, we found low Coenzyme Q in muscle of one patient and impaired ubiquinone synthesis in fibroblasts of 2 out of 3 patients. Although its biochemical function in ubiquinone biosynthesis is unknown, COQ8 most likely has an indirect role, because COQ8/ADCK3 belongs to a small family of ancestral prokaryotic kinases. Coenzyme Q10 deficiency was previously identified in severe encephalopathy-nephrotic syndromes with defects in the biosynthetic pathway and, surprisingly, in ataxia-oculomotor apraxia 1 which is caused by a defective nuclear DNA repair protein. The identification of *ADCK3* mutations emphasizes the role of Coenzyme Q10 in the physiopathology of degenerative ataxias and raises the possibility of supplementation therapy.

Genome-wide Scan for Coronary Artery Disease Genes using 500,668 markers. *A.F.R. Stewart, R. McPherson, L. Chen, K. Williams, N. Kavaslar, J. Rutberg, H. Doelle, G. Ewart, G.A. Wells, R. Roberts* Univ Ottawa Heart Inst, Ottawa, ON, Canada.

Coronary artery disease (CAD) is the leading cause of death in the western world. Genetics account for approximately 50% of CAD risk, but CAD is polygenic, meaning that any single gene variant is neither necessary nor sufficient to fully account for CAD risk. With the exception of rare genetic variants with major effects on LDL cholesterol concentrations such as the LDLR or PCSK9 genes, candidate gene studies have provided little information on variability in CAD risk. Genome wide association studies using high density single nucleotide polymorphism (SNP) genotyping are providing a more fruitful approach to the study of complex diseases. Here, we report on the Ottawa Heart Genomics Study, the first genome-wide association study using 500,668 SNPs to identify novel risk and protective loci for CAD in 997 cases with early onset disease and 1054 elderly asymptomatic controls sampled from the Caucasian population in the Ottawa region. We have identified 1,411 risk SNPs (minor allele associated with CAD) and 810 protective SNPs (minor allele associated with controls). Clusters of SNPs within genes identified DIAPH3, GPC6 and ACTN4 as risk loci and NBEA, ABO, and GNG12 as protective loci, among others. Large intergenic clusters were detected at 2q22.1, 5q33.2 and one previously reported by us at 9p21.3. Since there is sufficient power to detect the presence of causative polymorphisms of moderate effect when 1000 individuals are sampled, 500 cases and 500 controls were selected at random for analysis. Of the significant SNPs identified, 21% were also significant in the independent sample of the remaining 497 cases and 554 controls. Nearly all of these loci were novel and had not been previously associated with CAD. The entire dataset is made public so that further investigations in larger case/control cohorts can validate or reject these novel loci.

Evaluation of CXorf2 as a Candidate Gene for X-Linked High Myopia. *R. Metlapally[1,2], A. Bulusu[2], M. Schwartz[3], T. Rosenberg[3], C.C. Kroner[2], S. Zuchner[2], Y.J. Li[2], T.L. Young[1,2]* 1) Duke Eye Center, Durham, NC; 2) Duke Center for Human Genetics, Durham, NC; 3) National Eye Clinic for the Visually Impaired, Denmark.

Purpose: X-linked high myopia with mild cone dysfunction has been mapped to chromosome Xq28. CXorf2 is a nested gene within the red and green opsin cone pigment gene tandem array on Xq28. We investigated whether CXorf2 gene alterations are associated with the X-linked myopia phenotype. Two pedigrees (with protanopia and deuteranopia respectively) that mapped to Xq28 were screened for genomic DNA mutations and copy number variations. **Methods:** All exons of the CXorf2 gene including intron/exon boundaries were amplified and sequenced using standard techniques. To examine the copy number variation, ultra-high resolution array-comparative genomic hybridization (aCGH, NimbleGen Inc) assays were performed comparing the patient genomic DNA with control samples (2 pairs from each pedigree). Quantitative real-time (ABI7900HT) gene expression assays (Assays-by-Design) targeted on opsin and CXorf2 genes were used to validate the aCGH findings. Data were analyzed using Comparative CT method to calculate the copy number present in each individual. **Results:** A 5 UTR SNP in CXorf2 was observed in all five affected males but not in unaffected males in the protanopic pedigree. Of the 183 external controls screened, 6.5% possessed the SNP. Logistic regression analysis, which takes into account family strata, revealed significant association ($p<0.05$) between the SNP and disease status. The aCGH findings in both pedigrees revealed predicted duplications in affected patients in the opsin array region. While only 3 copies of CXorf2 have been reported within the opsin array, quantitative real-time analysis of the CXorf2 gene targeted assay on affected individuals in both these pedigrees revealed 4 to 5 copies. **Conclusions:** The 5UTR is thought to influence mRNA stability and translation efficiency, and 5 UTR SNPs have been associated with disease. Copy number variations play a role in disease inheritance and susceptibility as they affect gene dosage. These CXorf2 gene alterations may be responsible for this phenotype.

Bayesian methods for quantitative traits. *J.S. Pereira-Gale, J. Marchini, P. Donnelly* Department of Statistics, University of Oxford, Oxford, Oxfordshire, United Kingdom.

Genetic association studies focus on finding regions of the genome associated with particular diseases. While most genetic association studies focus on binary traits, the presence or absence of disease, there is potentially more information to be gained by studying continuous/quantitative traits. We have developed a Bayesian method for the analysis of single-SNP association for quantitative traits. We use a model formulated in terms of the trait population mean, additive and dominance effects and a within genotype variance parameter and show how these parameters are related to measures of trait heritability. We have found that this relationship is a useful guide when choosing priors for the parameters of our model. On simulated data we find that the Bayesian approach can be more powerful than a standard Frequentist association test (F-test) for quantitative traits. This work has been extended in two directions (a) we have developed a multi-point method for association testing that combines information from multiple SNPs to carry out tests at untyped variants, and (b) we have developed a model for multiple phenotypes. We illustrate both of these methods using simulated data.

Rate of mutation accumulation in coding and noncoding elements during mammalian evolution. *L. Parand[1], S. Nikolaev[1], J. Montoya-Burgos[2], K. Popadin[3], E.H. Margulies[4], NISC Comparative Sequencing Program[4,5], S.E. Antonarakis[1]* 1) Department of Genetics & Dev., University of Geneva Medical School; Geneva, Switzerland; 2) Department of Animal Biology, University of Geneva; Geneva, Switzerland; 3) Department of Genetics, Moscow State University; Russia; 4) Genome Technology Branch, NHGRI, NIH; Bethesda, Maryland 20892, USA; 5) NIH Intramural Sequencing Center, NHGRI, NIH; Bethesda, Maryland 20892, USA.

A comprehensive phylogenetic framework is indispensable for investigating the evolution of constrained genomic features in mammals as a whole and particularly in humans. Using the ENCODE sequence data from 1% of each of 18 mammalian genomes, we reconstructed evolutionary rates for three genomic matrices: silent (dS) substitutions, non-synonymous (dN) substitutions and Conserved Non Coding (CNC) elements. We show that synonymous substitutions (approximating neutral evolutionary rates) evolve according to the Generation Time (GT) hypothesis. Consistent with the longer generation time within mammals, primates and especially humans display a slowdown of neutral evolutionary rates. Constrained elements, however, evolve under different mechanisms. We show that dN substitutions, regarded to be slightly deleterious, are fixed as effectively neutral substitutions in species with small populations (human, chimp) and counter selected in those with large populations (mouse). We found that CNCs are more conserved than dNs in the majority of stem branches, but despite it the average rate of evolution of CNCs is 1.7 times higher than the average dN substitution evolutionary rate. This observation suggests that the selective pressure acting on a fraction of CNCs has been relaxed in a lineage specific manner not predicted by the population size or generation time hypothesis. Using the ENCODE data we detected three cases (Chimpanzee, Shrew and Eutheria) with significant relaxation among the 20 longest CNCs. Thus only a fraction of the CNCs detectable over the entire mammalian tree undergo purifying selection, while another fraction is suggested to be gradually replaced by lineage specific CNCs or those sequences become temporally unconstrained.

Detecting Loss-of-Heterogeneity and Amplification events from Illumina SNP genotyping data in the presence of stromal contamination and intra-tumor heterogeneity. *C. Yau[1], S. Colella[2], D. Peiffer[3], J. Ragoussis[2], C.C. Holmes[1,4]* 1) Department of Statistics, University of Oxford, Oxford, UK; 2) Genomics Laboratory, Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK; 3) Illumina, Inc. San Diego, CA, USA; 4) MRC Mammalian Genetics Unit, Medical Research Council, Harwell, Oxford, UK.

Existing approaches for the detection of copy number alterations from SNP genotyping data do not take into consideration the effect of tissue heterogeneity which is common within tumor samples. Normal tissue contamination and intra-tumor heterogeneity cause severe problems for copy number calling algorithms as the data, in the form of probe intensities, is derived from a population of cells that typically have differing copy number alterations. This produces unusual artefacts in the data and leads to regions of loss-of-heterozygosity (LOH) or amplification being missed. We have developed a novel Hidden Markov model-based approach for analyzing Illumina SNP genotyping data that allows for the identification of regions of LOH and amplification in tumors - even in the presence of tissue heterogeneity. Central to our approach is a generative probability model of genotyping data under copy number alterations and tissue heterogeneity. The model incorporates special "mixture" states (such as mixtures of LOH or amplifications with normal copies) and, using Bayesian inference, we show we are able to detect heterogeneous chromosomal regions and de-convolve these to identify the alterations in the constituent sub-populations. We demonstrate our method using data from samples containing known mixtures of normal and tumor cell line DNA and paired tumor samples from the Illumina Hap300 and Hap550 Genotyping BeadChips. We show that our method can detect LOH and duplication events under normal tissue contamination and heterogeneous conditions. For example, 32/34 LOH events in a pure tumor sample were detectable in 50:50 mixtures of normal and tumor DNA that are all missed using a conventional approach. Our method leads to the improved genomic profiling of tumor samples using Illumina SNP genotyping BeadArray data.

A new multipoint method for genome-wide association studies via imputation of genotypes. *J. Marchini, B. Howie, S. Myers, G. McVean, P. Donnelly* Dept Statistics, Oxford Univ, Oxford, United Kingdom.

Genome-wide association studies are set to become the method of choice for uncovering the genetic basis of human diseases. A central challenge in this area is the development of powerful multipoint methods that can detect causal variants that have not been directly genotyped. We propose a coherent analysis framework that treats the problem as one involving missing or uncertain genotypes. Central to our approach is a model-based imputation method for inferring genotypes at observed or unobserved SNPs, leading to improved power over existing methods for multipoint association mapping. Using real genome-wide association study data from the Wellcome Trust Case-Control Consortium, we show that our approach is accurate and well calibrated, provides detailed views of associated regions that facilitate follow-up studies, and can be used to validate and correct data at genotyped markers. An important future use of our method will be to boost power by combining data from genome-wide scans that use different SNP sets.

Positional candidate gene screening within the high grade Myopia-2 locus (MYP2). *T.R. White[1], R. Metlapally[1,2], K.N. Tran-Viet[1], D. Kao[1], J. Ellis[1], A.E. Shay[1], A. Bulusu[1], Y.J. Li[1], S. Zuchner[1], T.L. Young[1,2]* 1) Duke Center for Human Genetics, Durham, NC; 2) Duke Eye Center, Durham, NC.

Purpose: Myopia, or nearsightedness, is a common complex eye disorder that predisposes individuals to ocular morbidities such as retinal detachment, central chorioretinal degeneration, premature cataracts, and glaucoma. Seven families with autosomal dominant high myopia mapped to a 7.6cM genomic interval (MYP2) at chromosome 18p11.31. Previous base pair screening of 9 interval candidate genes revealed no sequence associations with the myopia phenotype. Sequence mutation screening of the remaining known positional candidate genes within the 7.6cM region was performed.
Methods: A physical map of the MYP2 locus was compiled using public databases. Gene expression studies in ocular tissues helped prioritize gene selection for screening. Of the 21 genes screened, 12 genes (CLUL1, TYMS, ENOSF1, YES1, ADCYAP1, C18orf2, METTL4, NDC80, BC006008, KIAA0650, MRCL3, and MRLC2) fall within and 9 genes (USP14, THOC1, COLEC12, CETN1, C18orf18, ZFP161, EPB41L3, TTMA, and L3MBTL4) flank the 7.6cM interval. Coding regions, intron-exon boundaries, and untranslated exons of the genes screened were sequenced by standard techniques using genomic DNA samples from selected affected and unaffected individuals from representative families. Gene sequences were obtained for the 21 genes and compared to known reference sequences from public genomic databases.
Results: In total, 151 polymorphisms were found with sequence analysis; 11 were missense, 12 were silent, 31 were untranslated, 83 were intronic, 1 insertion, and 13 deletions. Twenty polymorphisms were novel. No sequence alterations segregated with the disease phenotype.
Conclusions: Mutation analysis of the 21 positional candidate known genes did not identify sequence variants associated with the MYP2 high myopia phenotype. Efforts are now in place to interrogate several hypothetical genes that fall within and flank the interval.

Familial Hypochondroplasia and Epilepsy due to a FGFR3 mutation (C1620A) in a father and two children. *P.A. Levy[1,2], K. Cherian[3], Q. Pan[2]* 1) Department of Pediatrics, Children's Hospital at Montefiore, Bronx, NY; 2) Department of Pathology, Montefiore Medical Center, Bronx, NY; 3) Department of Neurology, Montefiore Medical Center, Bronx, NY.

Hypochondroplasia is an autosomal dominant skeletal dysplasia with short stature, disproportionate shortening of the limbs (micromelia), small hands and feet and macrocephaly. It is similar to but milder than achondroplasia. Hypochondroplasia, achondroplasia, thanatophoric dwarfism, and Muenke syndrome are all caused by mutations in FGFR3. Most patients with hypochondroplasia are heterozygous for one of two mutations in FGFR3, (either C1620A or C1620G). This falls within the tyrosine kinase domain and together, these mutations are present in 70 percent of the hypochondroplasia patients studied. FGFR3 is expressed in brain as well as bone and plays a role in brain development. Medial temporal lobe dysgenesis has been reported in three patients with hypochondroplasia and a C1620A mutation. We present a family with hypochondroplasia, seizures, as well as temporal lobe abnormalities. Our patients had seizures associated with apneic episodes in the newborn nursery. The older sibling, a male had seizures soon after birth and had MRI findings suggestive of a temporal lobe abnormality. EEG findings of both children found a focus for the seizures in the temporal lobe. Our patients had unilateral foci, the boy in the left temporal lobe and his younger sister in the right temporal lobe. DNA sequencing was done on the mother, father and their two affected children, looking for the C1620A mutation in exon 11 of the FGFR3 gene on chromosome 4 p16.3. The father and his two children were positive for this mutation. The mother and a control were normal. There is a lack of agreement on a definitive set of diagnostic criteria for hypochondroplasia, and it is difficult to diagnose radiologically. Testing for the two known mutations is warranted to help confirm the diagnosis. The association of temporal lobe dysgenesis and seizures with the C1620A mutation is probably underdiagnosed. DNA testing would identify patients at risk for seizures and help to better define the clinical picture of hypochondroplasia.

Genome-Wide Autozygosity Mapping in Human Populations. *S. Wang[1], C. Haynes[2], F. Barany[3], J. Ott[2]* 1) Dept Biostatistics, Columbia Univ, New York, NY; 2) Laboratory of Statistical Genetics, Rockefeller Univ, New York, NY; 3) Department of Microbiology, Weill Medical College of Cornell Univ, New York, NY.

Individuals are frequently observed to have long segments of uninterrupted sequences of homozygous markers. One of the major mechanisms that gives rise to such long homozygous segments is consanguineous marriages, where parents pass shared chromosomal segments to their child. Such chromosomal segments are also known as autozygous segments. The clinical evidence that progeny from inbred individuals may have reduced health and fitness because of homozygosity of recessive alleles is well-known. As the length of such homozygous segments depends on the degree of parental consanguinity, it would be logical to observe shorter homozygous segments in more outbred populations. However, a recent study identified long homozygous regions, thus likely to be autozygous segments in the HapMap populations. While an abundance of homozygous segments may significantly reduce the ability to fine map disease genes using association studies, detecting tracts of extended homozygosity related to disease status seems the natural next step in genome-wide association studies beyond allele, genotype and haplotype association analyses. In this study, we propose a new algorithm to map disease-related segments based on autozygosity using case-control data. The underlying rationale for the proposed method is that shared homozygous regions that differ between diseased and healthy individuals may harbor mutations underlying diseases. Specifically, our algorithm uses a sliding-window framework and employs a LOD score measure of autozygosity coupled with permutation-based methods to identify disease related regions. We illustrate the advantage of the algorithm with its application to a genome-wide association study on Parkinsons disease.

Sequence variants of insulin-secreting pathway genes contributing to type 2 diabetes risk in the Yakut population of Eastern Siberia. *Z. Odgerel[1], H.S. Lee[1], F.A. Platonov[2], N. Sambuughin[1], P. M. Ignatiev[2], L.L. Alekseeva[2], V.L. Osakovskiy[2], T.M. Sivtseva[2], V.G. Krivoshapkin[2], L.G. Goldfarb[1]* 1) NINDS, NIH, Bethesda, MD; 2) Institute of Health, Yakutsk, Russian Federation.

Yakut (Sakha) population originated from a nomadic Central Asian tribe that migrated about 900 years ago to the Siberian plains, the coldest area in the Northern hemisphere with average January temperatures of -41C and a world record of -72.2C. Basic metabolic rate in Yakut people is elevated, the level of blood glucose increased, and the amount of circulating insulin decreased as a result of adaptation to chronic and severe cold stress. A recent change in lifestyles and food composition from traditional to predominantly carbohydrate diets led to a 10-fold increase in the prevalence of type 2 diabetes, with an alarming tendency of further growth. We investigated whether adjustment to colder environment led to adaptive selection of functional polymorphisms in genes involved in the insulin-signaling pathway. The frequency of alleles previously shown to be associated with T2D was determined in the Yakut T2D patients and compared to the baseline population in the format of a case-control association analysis. The study population consisted of 178 subjects diagnosed with T2D and 125 individuals in which diabetes was excluded. Fifteen sequence variants in nine genes were selected on the basis of their association with T2D replicated in at least two previously studied populations. After computing odds ratio based on presence/absence of risk allele (allelic positivity test), we identified three variants showing significant association with T2D. Two were identified in the ABCC8 gene: a C>T change in the third nucleotide of codon 562 leaving His as the encoded amino acid (P=0.018) and an A>G substitution at codon 1273 with Arg residue remaining unchanged (P=0.041). The C variant at the minus 1031 position of the regulatory region in TNFalpha gene also shows association (P=0.006). The prevalence of risk alleles ABCC 562T and TNFalpha -1031C in non-diabetic Yakuts were 51% and 30% vs. 30 to 32% and 16 to 18%, respectively, in Southern Asian populations, from which Yakuts originated a millennium ago.

HapMap-based analysis of the schizophrenia candidate gene *NRG1* in the German population. *T.W. Mühleisen[1], M. Mattheisen[1], S. Herms[1], R. Fürst[1], A. Georgi[3], I. Nenadic[4], R. Abou Jamra[2], J. Schumacher[2], P. Propping[2], T.G. Schulze[3], M. Rietschel[3], M.M. Nöthen[1], S. Cichon[1]* 1) Dept Genomics, Life and Brain Ctr, Univ Bonn, Bonn, Germany; 2) Inst Hum Genet, Univ Bonn, Bonn, Germany; 3) CIMH, Mannheim, Germany; 4) Dept Psychiatry, Univ Jena, Jena, Germany.

Schizophrenia (SCZ) is a genetically complex psychiatric disorder. *Neuregulin 1 (NRG1)* is a strong positional candidate, and several independent studies have recently reported association between SCZ and this locus. In the present study, we systematically tested *NRG1* for association with SCZ in the German population. We selected 348 haplotype tagging SNPs from HapMap covering the entire *NRG1* and flanking sequences and capturing all haplotypes with a frequency 1% in the European population. The study sample consisted of 2,304 individuals comprising a sample of 210 trios and an independent sample of 820 cases and 854 population-based controls, all of German origin. In the trios, we found a cluster of haplotypes spanning a 40 kbp region associated with SCZ. Interestingly, this region overlaps with the previously reported risk-haplotype HapICE. In the case/control sample, two regions showed association with SCZ. The 20 kbp region, located 120 kbp upstream of HapICE, represents a cluster of associated haplotypes with P=0.00331 as the most significant P value. The 37 kbp region is located in intron 1 of the *GGF2* isoform. In addtition to the analysis of the total sample, we separately analyzed 8 phenotypic subgroups that possibly represent a more homogeneous etiology of SCZ. The greatest effect was seen in the gender-specific groups. In the female group (338 cases, 368 controls), signals concentrated in a 260 kbp region, covering the previously reported risk-haplotypes HapIRE, HapD and parts of HapICE. In contrast, the male subgroup (482 cases, 486 controls), did not show any significant association in that region but in a region farther downstream. Our study provides supportive evidence that *NRG1* is involved in the etiology of SCZ, and that different risk-variants contribute to disease susceptibility in females and males.

Identification of a novel mutation in the ARG1 gene, and prenatal diagnosis for hyperargininemia. *H. Laivuori[1], T. Linnankivi[2], P.J. Miettinen[3], J. Häberle[4]* 1) HUSLAB Department of Clinical Genetics, Helsinki, Finland; 2) Department of Pediatric Neurology, Helsinki University Central Hospital, Helsinki, Finland; 3) Department of Pediatrics, Helsinki University Central Hospital, Helsinki, Finland; 4) Universitätsklinikum Münster, Klinik und Poliklinik für Kinderheilkunde, Münster, Germany.

Hyperargininemia (OMIM 207800) is a rare (estimated incidence 1:2 000 000 births) autosomal recessive urea cycle disorder caused by a defect in the arginase I enzyme. It is characterized by predominantly neurological symptoms which usually appear between 2 and 4 years of age (slowly progressive spastic paraparesis and cognitive decline). Limitation of protein intake, supplementation with essential amino acids and sodium benzoate ameliorate the symptoms, although the spastic paraparesis may progress as patients become older. The enzyme activity can be measured in erythrocytes, but not in chorionic villous sample (CVS) or in cultured amniotic fluid cells. Prenatal diagnosis has been reported using enzyme measurement from fetal cord blood (Kamoun et al. 1995, Hewson et al. 2003) and DNA derived from CVS (Häberle & Koch 2004). Here we report a novel mutation in the ARG1 gene (Chr. 6q23) identified from the child affected with hyperargininemia (arginase enzyme activity in erythrocytes profoundly deficient: 5 IE/g Hb, normal: 35 IE/g Hb) born to consanguineous Kurdish parents (first cousins). The parents asked for the prenatal diagnosis in a subsequent pregnancy. All coding exons including the flanking intronic regions of the ARG1 gene of the index patient were sequenced. The mutation in the exon 3: c.282CG (S94R) was found in a homozygous state with both parents being heterozygous for this mutation. The prenatal diagnosis was performed from the CVS, and the fetus was unaffected. Direct mutation analysis from CVS can be regarded as the method of choice for prenatal diagnosis in hyperargininemia.

High-resolution oligonucleotide array-CGH applied to large rearrangements in BRCA1, BRCA2, MLH1 and MSH2 genes. *E. Rouleau, C. Lefol, S. Tozlu, C. Andrieu, C. Guy, F. Copigny, C. Nogues, I. Bieche, R. Lidereau*
Oncogenetic laboratory, Centre René Huguenin, St Cloud , France.

Genetic pre-disposition to breast, ovarian, colorectal cancers results mainly from alterations in BRCA1, BRCA2, and MLH1, MSH2 genes. However, the identification of large rearrangements represented a major advance in our understanding of familial forms. Indeed, 10 to 15 percent of deleterious mutations in the BRCA1, MLH1 or MSH2 genes correspond to a large rearrangements. In a less extent, some has been reported for BRCA2 gene. Nowadays, large rearrangements are starting to be included in routine genetic screening. Many techniques are available, but few give a panoramic view of the gene of interest and none explores promoting regions. We have developed a new method for detecting and characterizing large rearrangements in the BRCA1, BRCA2, MLH1 and MSH2 genes, based on high-resolution oligonucleotide array-CGH technology. We designed specific CGH arrays for the four genes and their flanking regions. Prior to use this approach in routine, we analyzed thirteen DNA samples known to contain a large deletion or a large duplication in one of the four genes, previously detected with QMPSF, MLPA or real-time quantitative PCR. All the large rearrangements from single small exon to large region were detected by the array-CGH method. Their size was estimated to within 1-2 kb. When possible, the deleted or duplicated region was sequenced to identify the break point. The characterization of the break point enabled us to develop a simple PCR screening test for other family members, and to explore the founder effect in families with the same deleted or duplicated exons. The high probe density in the microarray method described here gives the opportunity to rapidly screen a group of genes involved in a specific cancer, for instance, breast and colorectal cancer. Despite its cost, this method can assist with the development of simple PCR-based genetic test for family members. It should help to detect large rearrangements affecting long exon or promoting regions missed by other current methods. Additional studies are needed to define the role of this technique in routine genetic testing.

Log-multiplicative models of haplotype-haplotype interaction in case-only studies. *T.S. Price* ITMAT, University of Pennsylvania School of Medicine, Philadelphia, PA.

Case-only designs provide a powerful means to detect departures from multiplicative risk deriving from independent genetic or environmental factors. The results of case-only studies, however, are typically interpreted in terms of odds ratios for binary risk factors even when the measured risk factors have more than 2 categories. In particular, methods for detecting interactive effects between multilocus genotypes have not yet been implemented. I present a simple method using log-multiplicative models to assess the nonindependence of nominal or ordered risk factors. Log-multiplicative models have greater power than standard likelihood ratio or goodness of fit chi-square tests of independence when the contingency data approximate a latent class model with two classes, as is the case for unlinked haplotypes indexing a true epistatic interaction. Simulations are presented that attest to the power of the method across a range of parameters. The method generalizes to stratified analyses and cross-classifications of dimension greater than 2.

The impact of Alu insertions on local recombination rates. *J. Xing, D.J. Witherspoon, L.B. Jorde* Eccles Institute of Human Genetics, Univ. of Utah, Salt Lake City, UT.

Alu elements are the most successful primate Short Interspersed Elements (SINEs) and currently more than one million Alu elements are present in the human genome. Many young Alu elements are still polymorphic for presence and absence among human populations. This heterozygosity may pose a problem during the pairing of homologous chromosome pairs and influence the probability of recombination. On the other hand, fixed Alu elements have high GC content and may promote local recombination. Using single nucleotide polymorphism (SNP) data from the HapMap project, we examined recombination rates around all Alu elements belonging to the AluY subfamily (the youngest major Alu subfamily). Our recombination rate (Rho) estimates based on ~140,000 AluY loci indicate that on average the recombination rate in intervals containing AluYs is only 80% of the rate of other intervals within 50kb of the AluY locus. However, we found that SNP pairs directly adjacent to AluY elements are separated by larger physical distances compared with the average inter-SNP distance in the 50kb flanking regions. This probably reflects difficulties in ascertaining and typing SNPs very close to these repeat elements. Estimates of rho are in turn affected by the size of inter-SNP intervals. To determine to what extent a SNP ascertainment bias can account for local recombination rate variation, we resampled the 50kb AluY flanking genomic regions to match the Alu-containing SNP-pair interval sizes. We show that after taking into account the SNP interval size difference, recombination rates in AluY insertion loci are not different from their proximate regions. We conclude that the initial reduced recombination rate estimates around AluY insertions appears to be due to the strong association of AluYs with longer intervals, which are in turn correlated with biased upward estimates of rho. Researchers using the HapMap data for whole genome analysis should be aware of this type of systematic ascertainment bias and take it into account during their analyses. Supported by NIH Grant GM-59290 and NSF Grant BCS-0218370.

Genome-wide scan in a large French-Canadian Restless Legs Syndrome kindred: fine-mapping towards a novel candidate locus for linkage. *A. Levchenko[1], S. Provost[4], L. Xiong[1], M.P. Dubé[4, 5], J. St-Onge[1], P. Thibodeau[1], A. Desautels[2, 3], G. Turecki[2], J. Montplaisir[3], G.A. Rouleau[1, 5]* 1) CHUM Research Center, Notre Dame Hospital, Montreal, Quebec, Canada; 2) Research Center, Douglas Hospital, McGill University, Québec, Canada; 3) Centre d'étude du sommeil, Hôpital du Sacré-Cœur de Montréal and Centre de recherche en sciences neurologiques, Université de Montréal, Québec, Canada; 4) Montreal Heart Institute Research Center, Montreal, Quebec, Canada; 5) Department of Medicine, University of Montreal, Montreal, Quebec, Canada.

Restless Legs Syndrome (RLS) is a sensory-motor disorder affecting approximately 10% of the general population, with reported tendency to be more prevalent in populations of European origin. More than 60% of cases show segregation in families. We analyzed a large RLS kindred of French-Canadian (FC) origin using microsatellite 10 centi-Morgan genome-wide scan. Preliminary genome-wide two-point and multipoint linkage analysis, using MLINK and SIMWALK2 software, allowed to pinpoint several genomic regions harboring multipoint LOD scores greater than 1, 2 and 3, under a dominant model. The regions are on chromosomes 1p, 1q, 2q, 4p, 11q, 16p, 18q, and 22q. The fine-mapping, in order to establish a region significantly linked to RLS in this family, which will allow undertaking RLS gene cloning, is ongoing. To estimate the power of the family, single point power analysis was carried out using SLINK, UNKNOWN and MSIM, in which five alleles with frequencies set to 0.1, 0.1, 0.2, 0.2 and 0.4 were simulated. The disease was set at a distance of 1.25 cM which is the average distance between a gene and a marker in a 5 cM genome scan, showing that the family is able to reach LOD scores of 3.9. Previously, linkage analysis and large FC pedigrees allowed our team to report novel RLS loci on chromosomes 12q and 20p13.

Racial differences in genetic association of cytokine concentrations in the presence and absence of bacterial vaginosis. *K.K. Ryckman[1,2], M.A. Krohn[3], H.N. Simhan[3], S.M. Williams[1,2]* 1) Center of Human Genetics , Vanderbilt Univ, Nashville, TN; 2) Department of Medicine, Vanderbilt Univ, Nashville, TN; 3) Department of OBGYN, Magee-Womens Research Institute, Pittsburgh, PA.

Bacterial vaginosis (BV) is one of the most prevalent vaginal disorders in adult women and is characterized by alterations in the normal vaginal flora. BV is associated with pelvic inflammatory disease (PID) and spontaneous preterm delivery (sPTD). BV-related changes in the vaginal flora are accompanied by changes in cervical cytokine levels. To assess the role that genetic variation plays in changes in cytokines that occurs in relationship to BV during the first trimester of pregnancy we examined 52 African-Americans (AA); 20 with normal flora and 32 with BV and 64 Caucasians (CA); 44 with normal flora and 20 with BV. Analyses were stratified by race. BV by genotype analysis of variance (ANOVA) was performed for 15 cytokines and 376 single nucleotide polymorphisms (SNPs) in 28 cytokine-related genes. The two-way ANOVA with BV and each SNP revealed many significant overall model associations and several of these showed dramatic differences between AA and CA. In particular, there were 102 out of 119 SNPs that had significant full model associations for IL-1 in AA, whereas only 16 SNPs had significant full model associations in CA. The opposite was true for IL-1; there were 45 out of 123 SNPs that had significant full model associations in CA and only 13 full model associations in AA. The most significant BV by SNP interaction for IL-1 in African-Americans was rs1469007 (p-value=0.012) in the interleukin receptor 1 accessory protein. The recessive model for this SNP explained 24.7% of the variation in IL-1 concentration. In CA, the most significant BV by SNP interaction for IL-1 was rs7628250 (p-value=0.007). This dominant model included a significant BV by SNP interaction and explained 18.1% of the variation in IL-1 concentration. In conclusion, we found significant interactions between BV status and single SNPs for several cytokine concentrations. The patterns of associations between genotype and cytokine concentration differed by race.

Dosage changes in alpha-synuclein are rare in familial PD, yet promoter variation is associated with disease. *N. Pankratz[1], W.C. Nichols[2,3], V.E. Elsaesser[2], M.W. Pauciulo[2], D.K. Marek[2], C.A. Halter[1], A. Rudolph[4], T. Foroud[1], Parkinson Study Group - PROGENI Investigators* 1) Medical & Molec Genetics, Indiana Univ Sch Medicine, Indianapolis, IN; 2) Cincinnati Childrens Hospital Medical Center, Cincinnati, OH; 3) University of Cincinnati College of Medicine, Cincinnati, OH; 4) University of Rochester, Rochester, NY.

Mutations in five genes result in both autosomal dominant and autosomal recessive forms of Parkinson disease (PD). These mutations, however, are responsible for PD in fewer than 5% of patients with disease. One of these genes, alpha-synuclein (SNCA) has been reported to act as both a causative and a susceptibility gene for PD. Missense mutations, as well as whole gene duplications and triplications, have been found to segregate with disease. Variation in the promoter region has been shown to alter protein expression in vitro, providing biological plausibility that such variation can increase susceptibility. We performed a detailed study of SNCA in a sample of 517 families consisting of 873 individuals meeting strict diagnostic criteria for PD. Using data from a previous genome screen, one affected individual from each of the 92 families showing the greatest evidence of linkage to the region of chromosome 4 near SNCA was screened for dosage alterations in this gene using MLPA; none were found. The full sample was then genotyped for the Rep1 polymorphism in the promoter region of SNCA that was previously reported to be associated with PD susceptibility. Disease models were evaluated using logistic regression employing only one individual per family. Similar to a recent meta-analysis, cases had a 3% higher frequency of the 263 allele compared to controls (OR=1.44; p=0.04). Unlike the meta-analysis, there was an inverse linear relationship between the number of 263 alleles and age of onset (p=0.04). While this replication is modest, it further strengthens the evidence that the Rep1 polymorphism in the SNCA promoter conveys a moderate increase in the risk for PD.

Warfarin Pharmacogenetics: VKORC1 Allele and CYP2C9/VKORC1 Genotype Frequencies in the Ashkenazi and Sephardi Jewish Populations. *S.A. Scott, L. Edelmann, R. Kornreich, R.J. Desnick* Department of Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York, New York, 10029.

Warfarin is a widely used anticoagulant with a narrow therapeutic range due to both environmental (e.g., vitamin K intake, co-medications, body surface area, etc.) and genetic factors. CYP2C9*2 (p.R144C) and *3 (p.I359L) and the VKORC1 promoter polymorphism (g.-1639G>A) frequently occur in patients who require a lower average warfarin dose, while patients with VKORC1 missense mutations require higher warfarin doses. To determine and compare the CYP2C9 and VKORC1 allele and genotype frequencies among Ashkenazi (AJ) and Sephardi Jewish (SJ) individuals, genotyping was performed on 260 AJ and 80 SJ individuals from the greater New York metropolitan area. Genotyping of 14 different CYP2C9 and VKORC1 alleles was performed using the Tag-It Mutation Detection Kit (Luminex Molecular Diagnostics); the recently identified VKORC1 p.D36Y mutation associated with warfarin resistance was analyzed using a PCR-RFLP assay. The AJ CYP2C9*1, *2, *3, and *5 (p.D360E) allele frequencies were 0.790, 0.127, 0.081 and 0.001, and the SJ frequencies were 0.663, 0.194, 0.144 and 0.000, respectively. Of note, the SJ CYP2C9 frequencies were determined for the first time and were significantly different from those observed in the AJ (p0.025). The VKORC1 g.-1639A allele was found at a high frequency in both AJ (0.467) and SJ (0.500) individuals whereas the warfarin resistant p.D36Y mutation had significantly different (p0.025) allele frequencies in the AJ (0.043) and SJ (0.006). All the CYP2C9 and VKORC1 allele frequencies were in Hardy-Weinberg equilibrium and CYP2C9*4 and *6, and the remaining VKORC1 coding region mutations analyzed by the Tag-It system were not detected in the AJ and SJ cohorts. Based on the recently described warfarin dosing algorithms that incorporate CYP2C9*2, *3 and VKORC1 g.-1639A, and given that in our cohorts 220 AJ and 72 SJ had a deficient CYP2C9 and/or VKORC1 allele, our results indicate that 84.6% of AJ and 90.0% of SJ individuals would benefit from genotyping prior to warfarin administration.

Molecular etiopathophysiology of Diabetic Nephropathy (DN): Possible Role of SPARC and IGF2 signaling pathway. *S. Movva[1], S. Venkatasubramanian[1], K.K. Vattam[2], Y.R. Ahuja[3], Q. Hasan[1,2]* 1) Department of Genetics, Bhagwan Mahavir Hospital and Research Centre, Hyderabad-500004, Andhra Pradesh, India; 2) Department of Genetics & Molecular Medicine, Kamineni Hospitals. L.B.Nagar, Hyderabad- 500068, Andhra Pradesh,India; 3) Department of Genetics, Vasavi Hospital and Research Centre, Khairtabad, Hyderabad-500004, Andhra Pradesh, India.

Diabetic Nephropathy (DN) is a devastating complication of diabetes, which affects approximately 30- 40 percent of diabetics. However, the exact molecular pathophysiology of DN is not established. It is believed that elevated glucose damages the kidney, which is constantly repaired by modulators like Secreted protein acidic and rich in cysteine (SPARC). Hyperglycemia also increases insulin like growth factors (IGF)especially IGF2, which acts via the IGF receptors present on renal cells. Hence, it was hypothesized that SPARC and IGF2 may be playing an important role in the etiology of DN. Human renal biopsies categorized as controls, early DN and established DN by histopathology were analyzed by immunohistochemistry and real time RT PCR for the localization and expression of SPARC, IGF2, as well as it's downstream signalling protein, Akt and it's negative regulator phospahtase and tensin homolog on chromosome 10 (PTEN) using specific antibodies and primers. This is the first study, to the best of our knowledge, which has evaluated the role of these molecules in DN studying human renal biopsies . From the results obtained the following molecular etiopathophysiology of DN can be proposed: (i) Lowered expression of the repair modulator, SPARC results in development of DN (ii) Suppression of Akt in the presence of elevated IGF2 suggests that the alternative MAPK pathway may be the relevant signaling pathway in the etiology of DN (iii) Increased PTEN is responsible for down-regulating Akt (iv) Loss of negative IGF2-PTEN feedback loop may be pivotal in developing the renal changes characteristic of DN. Targetting the relevant molecular modulators like SPARC, IGF2 or it's downstream regulators may be important in the management of DN in the future.

Molecular Studies of three SNPs in the regulatory region of *DYX1C1*, a candidate dyslexia gene. *I. Tapia-Páez*[1], *K. Tammimies*[1], *S. Massinen*[2], *J. Kere*[1] 1) Department of Biosciences , Karolinska Institute, Stockholm, Sweden; 2) Department of Medical genetics, University of Finland, Helsinki, Finland.

Dyslexia is a complex disorder characterized by reading disability despite normal intelligence, senses and proper education; it affects 5-10% of the population. Genetic studies have pointed out loci linked to dyslexia on several chromosomes including 1, 2, 3, 6, 11, 15, 18 and X. Until today, six genes have been associated with dyslexia: *DYX1C1, DCDC2, KIAA0319, ROBO1* and two genes on chromosome 2, *MRPL19* and *C2ORF3*. Four of these genes are involved in neuronal migration or brain development and their functional role in dyslexia remains to be elucidated. The *DYX1C1* gene on chromosome 15 (Taipale et al. PNAS 2003) is the first gene implicated in dyslexia, it was cloned based on a translocation t(2;15)(q11;q21) that cosegregated with dyslexia in a Finnish family. Two sequence changes in *DYX1C1* showed association with dyslexia, one introduced a stop codon truncating the protein by four amino acids, and the second in 5UTR, close to the translation initiation site. Several groups with sample sets from different populations have attempted to replicate these results but the results have been ambiguous, prompting us to look for new SNPs in the promoter of the *DYX1C1* gene. Two new SNPs in the promoter region were found, and when combined with additional results from German samples, they showed supportive evidence for *DYX1C1* as a candidate dyslexia gene (Dahdouh F et al. manuscript). To further understand the functional consequences of these polymorphisms, we prepared constructs for the three SNPs to study in electrophoretic mobility shift assays. Allele-specific differential retardation of mobility was observed with the promoter and 5UTR SNPs, suggesting a functional effect of these variations in the regulation of *DYX1C1 gene*. We also prepared constructs for reporter assays in pGL3 basic and promoter vectors using these polymorphisms. We could detect very significant differences in luciferase expression with all three SNPs. Further association studies are motivated to confirm the role of these SNPs in the regulation of *DYX1C1*.

Development of a MLPA assay for Norrie disease gene (NDP) deletion testing. *Y. Shen[1,3], H. Zhu[3], W. Xin[1,3], S. Smith[2], J. Gusella[3], K. Sims[1,3]* 1) Neurogenetics DNA Diagnostic Laboratory, Massachusetts General Hospital, Boston, MA; 2) Division of Genetics at Childrens Hospital Boston and HPCGG at BWH and MGH, Harvard medical School, Boston, USA; 3) Center for Human Genetic Research,Massachusetts General Hospital, Boston, MA.

Norrie disease (OMIM #310600) is a rare X-linked recessive neurologic disorder. It is characterized by congenital bilateral blindness, and variable clinical features. In our clinical molecular DNA diagnostic lab, PCR-based exon sequencing technique is able to effectively detect small mutations in the Norrie disease gene (NDP). Large deletions including one or more exons were suspected when one or more exons failed to amplify after using a second set of primers. Carrier status of female family members in whom deletion is presumed could not be tested by direct sequencing. To improve female analysis in these deletion families for counseling purpose, we developed an easy, fast and reliable method using MLPA (multiple ligation-dependent probe amplification) technique. This method allows detection of deletion involving any or all three exons of the NDP gene in Norrie male patients and their female relatives. The MLPA based assay, using synthetic NDP exon specific probes, confirmed all suspected deletion cases (affected males) and confirmed the same deletion patterns in their respective carrier female family members. Patients with large deletion account for 23.4% (30/128) of all ND patients in whom we have identified pathogenic mutations in our lab. The deletion mutations were further confirmed by mapping of the deletion breakpoint. Furthermore,this assay confirmed the deletion carrier status in all available mother samples (n=14), suggesting that de novo deletion in NDP gene is not a frequent event in Norrie disease patients. Thus, we have demonstrated that the MLPA method is highly sensitive, specific and reliable. The MLPA assay is now a routine NDP mutation detection procedure in our clinical molecular testing lab and it is a valuable tool for diagnosis of male detection cases, genotype-phenotype correlation analysis of NDP deletion patients and female carrier status assessment.

METHYLATION ANALYSIS OF CANDIDATE GENES IN AUTISM. *M. Shinawi[1], R. Zascavage[1], P. Fang[1], A. Porter[2], D. Treadwell-Deering[2], A.L. Beaudet[1]* 1) Dept Molec & Human Genetics, Baylor Col Medicine, Houston, TX; 2) Dep Psychiatry & Behav Science, Baylor Col Medicine, Houston, TX.

The genetic predisposition to autism is thought to be substantial with an estimated heritability of more than 90%. However, genome-wide linkage studies have not shown strong evidence for major autism-related loci. While mutations in few genes have been found in a small number of families with autism, studies of larger series of patients indicate these are very rare causes of autism. The high male-to-female sex ratio in autism has been replicated and confirmed in several epidemiologic studies. We are testing the hypothesis that de novo or inherited epimutations of sex chromosome-linked genes are responsible for the disease in a subset of autistic individuals and contribute to male susceptibility to autism. Our focus is on sex chromosome-linked candidate genes that are: 1) expressed mainly in the brain or involved in neuronal function; 2) not subject to X-inactivation with or without a homologue on the Y chromosome; and/or 3) subject to sexual dimorphism. The methylation status is being analyzed by using gel-based radioactive bisulfite sequencing or Southern blot analysis in the CpG islands of the following genes: *NLGN4X*, *NLGN4Y* , *PCDH11X*, *PCDH11Y*, *MAOA*, and *MAOB*. Blood samples from 15 affected females, 30 affected males and 30 controls and brain samples from 9 autistic individuals and 5 controls are being examined and compared. The preliminary data on all brain samples and on blood samples from 15 affected females and 12 affected males did not show significant differences between patients and controls. In all samples from males, the DNA was completely unmethylated. The data for the pairs *NLGN4X*/*NLGN4Y* and *PCDH11X*/*PCDH11Y* in females were consistent with the interpretation that the inactive and active X chromosomes are unmethylated. For the *MAOA* and *MAOB* the data were consistent with the interpretation that the inactive X chromosome was fully or partially methylated and the active X unmethylated. Very high desity custom Agilent arrays of the X and Y chromosome are now being used to analyze copy number, DNA methylation and chromatin modification.

Genotype-phenotype correlation in a group of cystic fibrosis mexican patients. *E. Yokoyama[1], M. Chávez[1], C. Villarroel[1], F. Cuevas[2], A. Carnevale[3], J.L. Lezana[4], S. Frías[1], B. Molina[1], L. Orozco[5]* 1) Departamento de Investigación en Genética Humana, Instituto Nacional de Pediatría; 2) Servicio de Neumología, Instituto Nacional de Pediatría; 3) Coordinación Nacional de Medicina Genómica, ISSSTE; 4) Departamento de Neumología, Hospital Infantil de México; 5) Laboratorio de Genómica de Enfermedades Multifactoriales, INMEGEN.

INTRODUCTION: Cystic fibrosis (CF) is the most common autosomal recessive disorder. More than 1,400 mutations have been described in the cystic fibrosis transmembrane conductance regulator (*CFTR*) and the most common in Caucasian population is the F508 mutation. The classification of these mutations, as severe and mild, is according to their effect on the protein. There is a strong genotype-phenotype correlation for the pancreatic sufficiency; however this correlation is not clear for the other clinical manifestations as pulmonary disease. **OBJECTIVE**: This study aimed to correlate *CFTR* genotype with the clinical manifestations in a group of Mexican patients with CF. **MATERIAL AND METHODS**: Sixty Mexican patients with CF were included. They were divided in three groups; GROUP 1: homozygous for F508; GROUP 2: both alleles with severe mutations non F508; GROUP 3: at least one allele with mild mutation. Statistical analysis were done with the SPSS 11.0 version and an alpha level of 0.05 was considered to indicate statistical significance. **RESULTS AND DISCUSION**: Groups 1 and 2 had pancreatic insufficiency. In these groups the age of CF diagnosis and the first infection by *Pseudomona aeruginosa* were earlier than in group 3, making the phenotype more severe in patients with pancreatic insufficiency. At the same time, patients of the groups with severe mutations showed high levels of sweat chloride test. The presence of meconium ileus as well as the pulmonary phenotype measured by spirometry and expressed as a percentage of the predicted value for sex, age and height, did not correlate with *CFTR* genotype, probably because of the sample size or because there are other modifier genes involved.

Two approaches to Family Based Association Analysis. *Y. Song, R. Sinha, S. Won, C. Xing, C. Thompson, R. Goodloe, Y. Wang, C. Gray-McGuire* Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH.

The study of complex diseases via genome-wide association analysis has gained increased attention with the availability of densely spaced SNPs. However, most methods developed and evaluated for these designs have been based on case-control data, leaving family data unused. We evaluate type I error and power of two family based association methods, one that conditions on parental genotype (FBAT) and one that does not (ASSOC). FBAT models the offsprings transmitted allele as the dependent variable. ASSOC uses a regression model to obtain residuals that approximate normality, while at the same time allowing for the non-independence of family data. In addition, since ASSOC can utilize the unrelated control data, we evaluated the impact of including controls into the unconditional analysis. Analyses were done using densely spaced SNP data simulated as a part of the 15th Genetic Analysis Workshop. We chose 250 families and, additionally, in ASSOC, 125 controls. Significance of each of 17820 SNPs (average spacing of 9.6 kb) were evaluated after adjusting for covariates. Type I error was assessed using SNPs most telomeric to the two simulated disease genes, and power using each of 200 SNPs nearest the two disease loci. The distribution of the unconditional results is exactly as would be expected for an association test, with significance narrowing the region to about 0.5 cM from the disease locus and only to SNPs in LD with the disease at a $D > 0.6$. The FBAT results are just as would be expected for a test of linkage in the presence of association, with significance sustaining to > 1.5 cM from the disease locus and to SNPs in LD with the disease at a D as small as 0.2 . Combining family data and as few as 250 controls into the unconditional analysis did not change the type I error rate and resulted in a 5-11% increase in power. We note that these results highlight the differences between FBAT, a test for both linkage and association, and therefore best suited as a coarse filter of the genome, and ASSOC, a test for allelic association only, and best suited for more fine scale identification of disease loci.

Comparative genomic hybridization in clinical evaluation of stillbirth. *G. Raca[1,2], J.S. Lafin[1], P. Modaff[3], K.D. Montgomery[1,2], R.M. Pauli[3]* 1) UW Cytogenetics Service, State Laboratory of Hygiene, Madison, WI; 2) Department of Pathology, University of Wisconsin, Madison; 3) Wisconsin Stillbirth Service Program (WiSSP), Clinical Genetics Center, UW, Madison.

Even after careful clinical evaluation and autopsy, the etiology of late gestation pregnancy loss (stillbirth) remains unexplained in up to 60% of cases. Stillborn fetuses represent a diagnostic challenge, since dysmorphic features and even major anomalies can be concealed by maceration. Additionally, cytogenetic results are not obtained in more than 50% of cases due to failure of in vitro tissue growth. To ascertain the feasibility of using array based comparative genomic hybridization (aCGH) in diagnostic evaluation of stillbirth, we tested five frozen tissue samples from cytogenetically characterized stillborn infants, obtained through the Wisconsin Stillbirth Service Program (WiSSP). Samples were tested in a blinded fashion using commercially available Constitutional Chip 3.0 BAC Arrays (PerkinElmer). In four cases findings were completely consistent with chromosome analysis and included 2 normal cases, trisomy 13 and trisomy 21. In the fifth case aCGH provided greater precision in defining the cytogenetic aberration by showing gain of ~20Mb region from 10p and loss of ~6Mb region from 18p. While initial cytogenetic evaluation detected presence of the derivative chromosome 18 with 10p material translocated to 18p, loss of 18p material was not identified by karyotyping. Clinical features in this infant, miscarried at 19 week gestation, included intrauterine growth retardation, microcephaly, encephalocele and cleft palate, which are consistent with but more severe than what might be anticipated from the combination of the two cytogenetic aberrations. We suggest that aCGH analysis should be considered instead of or in addition to karyotyping for routine diagnostic evaluation of intrauterine death. aCGH could also be a valuable research tool to examine the role of subtle, submicroscopic deletions and duplications in the etiology of intrauterine death, and to identify candidate chromosomal regions that are critically involved in survival through late gestation.

Significant Reductions of SMN and Gemin3 in X-linked SMA: Implications for Common Disease Pathways. *K.O. Yariz, L. Baumbach* Miller School of Medicine, University of Miami, Miami, FL.

Our group has described an X-linked form of lethal infantile spinal muscular atrophy (MIM 301830), which is very similar clinically to Type I SMA, but with additional features of early onset/congenital contractures and/or fractures. Due to this phenotypic overlap, whether the SMN-Gemin complex (altered in autosomal recessive) is perturbed in XL-SMA is an important fundamental biological question. We have quantitatively measured SMN, Gemin-2 and Gemin-3 levels in lymphoblastoid cell lines from XL-SMA patients, SMA Type I patients, and controls. Preliminary results based on two unrelated XL-SMA patients suggest that XL-SMA patients have a significant reduction in steady-state levels of SMN and Gemin3 proteins as compared to a healthy control (40% less for SMN; 50% less for Gemin3), but they still have more of these proteins than a SMA (Type I) patient. The two unrelated XL-SMA patients display almost identical SMN and Gemin3 protein levels. Gemin2 protein levels were not altered in the XL-SMA cell lines. RNA expression studies were performed for SMN1 and Gemin3 in the same cell lines used above. These results indicate no significant difference in gene expression of SMN and Gemin3 in XL-SMA and SMA cell lines compared to the healthy control. This implies that these genes are expressed normally in XL-SMA, but protein levels are altered. Unexplained post-transcriptional, translational, or a post-translational events may likely account for this observation. It is intriguing that autosomal recessive SMA and XL-SMA share many clinical similarities; therefore, one could hypothesize common disease mechanisms. Our results suggest that SMN protein and at least one other component of the SMN complex is substantially reduced in XL-SMA patients, thus accounting in part, for the phenotypic overlap of these genetically distinct disorders. These observations also suggest new insights into therapeutic targets for XL-SMA.

Genetic interaction of Bardet-Biedl syndrome genes and implication for polydactyly utilizing zebrafish model system. *M. Tayeh[1,2,3], H-S. Yen[1,2,3], J. Beck[1,3], C. Searby[1,3], H. Griesbach[4], E. Stone[3, 5], D. Slusarski[4], V. Sheffield[1,3]*
1) Dept Pediatrics, Univ Iowa, Iowa City, IA; 2) Genetics Program, Univ Iowa, Iowa City, IA; 3) Howard Hughes Medical institute; 4) Dept Biology, Univ Iowa, Iowa City, IA; 5) Dept Ophthalmology, Univ Iowa, Iowa City, IA.

Bardet-Biedl syndrome (BBS) is a genetically heterogeneous autosomal recessive disorder, characterized by obesity, retinal degeneration, postaxial polydactyly, cognitive impairment, hypogenitalism, renal and cardiovascular anomalies. Multiple BBS genes have been identified and mutations in each of these genes result in a similar phenotype. In zebrafish, we previously demonstrated that knockdown of any of the zebrafish bbs orthologues (bbs1-11) using antisense morpholinos (MO) display similar phenotypes including disruption of Kupffers vesicle (KV), premature loss of KV cilia, organ laterality defects and delayed intracellular retrograde transport. We identified genetic interactions between a subset of BBS genes, using a pair-wise co-injection of low-dose bbs MOs. Low-dose knockdown of two genetically interacting bbs genes alters KV and retrograde transport. Since MO-induced phenotypes can be rescued by its wild-type RNA, we evaluated functional redundancy between bbs genes by testing if knockdown of one bbs gene can be rescued by RNA of a different bbs gene. As none of the RNAs was able to rescue different bbs MO-induced phenotypes, our data argue against functional redundancy but rather suggest a required stoichiometry within a multi-subunit complex. Of note, human polydactyly is a cardinal feature of BBS not reproduced in Bbs-mouse models. Since several bbs genes are expressed in the zebrafish fin bud, we evaluated Sonic hedgehog (SHH) expression due to its conserved role in the tetrapod limb patterning. Manipulation of SHH expression alters digit identity and in bbs morphant fin buds, we observe altered shh expression domains as well as subsequent changes in the fin skeletal elements. Consistent with the genetic interactions data, low-dose knockdown of two genetically interacting bbs genes alters shh expression and skeletal elements. Thus, SHH expression and skeletal patterning provide a model for BBS polydactyly. .

Whole-genome association studies have substantially increased power in admixed populations. *A.L. Price[1,2], S.R. Myers[2], N. Patterson[2], D. Reich[1,2]* 1) Harvard Medical School, Boston, MA; 2) The Broad Institute, Cambridge, MA.

Whole-genome association studies (WGAS) are a powerful way to identify common variants conferring disease risk. WGAS have been carried out almost exclusively in populations of European ancestry, with little or no representation of underserved populations such as Latinos and African Americans. This may be due in part to the technical challenges posed by admixed populations, but we and others have now developed methods that enable fully powered WGAS in these populations (see Myers et al. abstract). We set out to investigate the power of WGAS in admixed populations, and found that there is a major gain in power and efficiency. These populations offer more power on average because (a) multiple ancestral populations provide increased genetic variation, and (b) there is no noise introduced from controls in the admixture association component of the overall signal.

Using the empirical distribution of ancestry proportions in Latino Americans and the empirical joint distribution of European and Native American allele frequencies, we calculated how many Latino samples would be required to achieve power comparable to genotyping 1,000 European cases and 1,000 European controls in a whole-genome scan. We found that 10% fewer samples, or 900 cases and 900 controls, were required for random markers. For markers in the top 10% of frequency differentiation between Europeans and Native Americans, which might drive differences in prevalence of diseases such as type 2 diabetes, only 660 cases and 660 controls were required. (These calculations assume that the causal variant has been genotyped, and do not account for the advantage of increased linkage disequilibrium within chromosomal segments of Native American ancestry.) Sample for sample, our results indicate that admixed populations are substantially more powerful for identifying disease variants, even for variants with only average differences in frequency across populations. For these reasons we suggest that researchers should specifically choose to study admixed populations - in preference to unadmixed populations - for any WGAS for which samples from both admixed and unadmixed populations are available.

Retrotransposition rates of L1 elements in human germline DNA. *C.M. Macfarlane, P. Collier, A.J. Jeffreys, R.M. Badge* Department of Genetics, University of Leicester, Leicester, LE1 7RH, United Kingdom.

The Long Interspersed Nuclear Element-1 (LINE-1 or L1) family are non-LTR retrotransposons which are acknowledged to be the most prolific class of mobile or transposable elements within mammalian genomes. Within the human genome, the efficiency of autonomous L1 retrotransposition has led to 17% of the genome sequence being composed of L1 with a further 10% being comprised of transposable elements which utilise the L1 machinery in order to replicate (Alu and SVA). Although the contribution of L1 to genome plasticity is recognised, very little is known about the evolutionary dynamics of their mobilisation within the germline, for example their rate of de novo insertion. Current estimates are that between 1 in 8 and 1 in 100 humans carry a novel retrotransposon insertion somewhere in their genome. However, these estimates are subject to acquisition bias as they are based upon retrotransposon insertions that manifest a disease phenotype. In order to directly monitor endogenous L1 retrotransposition we have been using a genome-wide molecular approach to try to capture de novo retrotransposition events in human germline DNA (derived from ejaculated sperm). The technique is based upon ATLAS, a genomic display technique that selectively displays full-length L1 terminus/genomic DNA junctions from the most active L1 subfamilies. We have modified ATLAS to operate at the single molecule level. This has been confirmed through limiting dilution and poisson analysis of specific L1 insertions that are known to be recent evolutionary acquisitions within the human genome. In addition, by performing limiting dilution of display inputs we are able to estimate the amount of DNA scanned per reaction, thus placing an upper limit on the rate of de novo insertion. Finally, the technique has been developed to the point of high throughput (1000 sperm genome/experiment) screening of human sperm DNA and can also detect low levels of genomic DNA mosaicism.

Genetic Polymorphism of Aldehyde Dehydrogenase (*ALDH2*) in Chinese Populations. *G.S. Wu[1, 2], H.R. Luo[1, 2], Y.P. Zhang[1, 2]* 1) Lab of Cellular & Molecular Evol, Kunming Inst Zoology, CAS, Kunming, China; 2) Lab for Conservation & Utilization of Bio-resource, Yunnan University, Kunming, China.

Atypical aldehyde dehydrogenase (*ALDH2**487Lys*), the defect form of ALDH2, caused by the G to A substitution (*Glu487Lys*, *ALDH2**487Lys*) on the exon 12 of *ALDH2*, is known to influence the drinking behavior because of higher accumulation of acetaldehyde in liver after alcohol intake. *ALDH2**487Lys* is highly prevalent in Asian. In this study, we examined the *ALDH2**487Lys*, four non-coding SNPs within *ALDH2*, and one downstream microsatellite locus, in total of 1,072 unrelated healthy individuals from 14 Chinese populations. Our results showed that the frequency for the atypical *ALDH2**487Lys* in the total samples was 15.11%. Coupled with the data reported previously, our analysis indicated that the frequency of the atypical *ALDH2**487Lys* allele of Guangdong Han population was significantly higher than other geographic populations ($P < 0.05$). The frequency of *ALDH2**487Lys*was decreased gradually from the highest in South China as center to other areas. Based on five SNPs across 40kb, five common haplotypes (with frequency higher than 5%) were found in all East Asian populations. The frequency of the ancestral haplotype (2211G) and the East Asian special haplotype (2211A) was 44.8% and 14.9%, respectively. Linkage disequilibrium extends at least 120kb in almost all populations, indicating a very low level of recombination. The F_{ST} values of the promoter region SNP and the functional SNP were at least two times higher than the other three SNPs. These high F_{ST} values may indicate selection has operated at these tightly linked sites, besides the effect from ancestral population, random genetic drift and genetic differentiation in subpopulation.

Genome-Wide Germline Variation and Treatment Response in Acute Lymphoblastic Leukemia (ALL). *J. Yang[1], C. Cheng[1], W. Yang[1], L. Trevino[1], Y. Fan[1], S. Pounds[1], D. French[1], N. Shimasaki[1], D. Campana[1], J. Downing[1], W. Evans[1], C. Pui[1], M. Devidas[2], W. Bowman[3], B. Camitta[4], C. Willman[5], M. Borowitz[6], W. Carroll[7], S. Hunger[2], M. Relling[1]* 1) St Jude Children's Res Hosp, Memphis, TN; 2) Univ. of Florida, Gainesville, FL; 3) Cook Childrens Med. Ctr, Ft. Worth, TX; 4) Med. College of Wisconsin, Milwaukee, WI; 5) Univ. of New Mexico, Albuquerque, NM; 6) Johns Hopkins Med. Inst, Baltimore, MD; 7) NYU Med. Ctr, NY, NY.

Although cure rates for pediatric ALL exceed 80%, the contribution of germline genetic variability to therapy response remains largely unknown. We performed a genome-wide study to identify single nucleotide polymorphisms (SNPs) that predict minimal residual disease (MRD) after remission chemotherapy in 2 independent cohorts. Using Affymetrix platforms, we genotyped ~588,000 SNPs in germline DNA from 318 children on St. Jude (SJ) trials Total XIIIB & XV and 185 patients on the Childrens Oncology Group (COG) P9906 trial. MRD status was categorized as <0.01%, 0.01-1%, or >1% residual leukemic lymphoblasts. Associations (P<0.01) by Spearman rank correlation of genotypes with MRD were noted for 6995 SNPs in SJ and 6433 SNPs in COG cohorts. The number of significant associations exceeded that expected: 115 (SJ) and 90 (COG) SNPs with P<1e-4 (45 expected), and 12 (SJ) and 22 SNPs (COG) with P<1e-5 (~5 expected). Among SNPs with P<0.01, 69 predicted MRD in both SJ and COG. We explored mechanisms by which these 69 SNPs may affect therapy outcome. Of the 69 SNPs, 17 were associated with anticancer drug pharmacokinetics (6 with methotrexate (MTX) clearance, 4 with MTX accumulation in lymphoblasts, and 7 with etoposide clearance), all plausibly linked to MRD eradication corresponding to greater drug exposure. Moreover, 43 of the 69 SNPs predicted levels of 38 genes whose expression in the leukemic blasts differentiated MRD+ from MRD- patients. We conclude that host genetic variability affects treatment response for childhood ALL, and that germline variants may exert their effects on MRD by affecting host metabolism of anticancer drugs and by affecting gene expression in target leukemic blasts.

Genetic Testing and Genetic Counseling for Severe Male Factor Infertility Prior to Intracytoplasmic Sperm Injection (ICSI). *M. Wick[1], D. Morbeck[2]* 1) Dept of OB/GYN, Mayo Clinic and Foundation, Rochester, MN; 2) Dept of OB/GYN, Division of Reproductive Endocrinology, Mayo Clinic and Foundation, Rochester, MN.

Infertility affects 10-15% of couples. Twenty percent of cases are due solely to male factor. Genetic alterations including CF,chromosomal abnormalities and Y microdeletion account for 15-30% of severe male factor, i.e., azoospermia and severe oligospermia. Intracytoplasmic sperm injection(ICSI)enables couples with severe male factor to achieve pregnancy. However, ICSI offspring have a higher incidence of sex chromosome abnormalities than the general IVF population. Additionally,genetic causes of infertility in the male will be passed on to male offspring. Thus,the American Society for Reproductive Medicine and the American Urological Society have provided recommendations regarding counseling and genetic screening for male factor infertility(Fertil Steril 2006;86:S202-9). The guidelines recommend that couples planning ICSI for male factor infertility(<5-10 million sperm/ml;non-obstructive azoospermia)should be counseled about potential genetic risks. To establish a baseline for these recommendations at our institution,we reviewed records of all couples needing ICSI for male factory infertility from 1998-2006. Only histories of those consented for research studies were reviewed. Complete records were available for 469 couples. 126(27%)males had significant male factor infertility warranting informed risk and genetic testing under the new recommendations. Of the 126 reviewed, 7(5.5%) were informed of risk and offered genetic testing, 16 (12.7%) were offered testing but declined, 27(21%) were referred to Urology/Endocrinology, 20(15.9%) received testing and referred to Urol/Endo, 21(17%) were referred to Genetics, 2(1.6%) were referred to genetics for another genetic disease, and 33(26%) received no testing/counseling. These results indicate that at least a quarter of couples with severe male factor infertility were not fully aware of possible genetic risks associated with ICSI. Increased communication between Genetics and REI and adoption of the new guidelines should facilitate appropriate testing and counseling of these couples.

Utilization of Model Systems to Characterize Mutant BBS3/ARL6 Function. *P.P. Pretorius[1,2,3], R.F. Mullins[4], C.C. Searby[1,3], E.M. Berg[1,3], D.Y. Nishimura[1], M.P. Andrews[1,3], E.M. Stone[3,4], D.C. Slusarski[5], V.C. Sheffield[1,3]* 1) Dept Pediatrics, Univ Iowa, Iowa City, IA; 2) Genetics Ph.D. program, Univ Iowa, Iowa City, IA; 3) Howard Hughes Medical Institute; 4) Dept Ophthalmology, Univ Iowa, Iowa City, IA; 5) Dept of Biology, Univ Iowa, Iowa City, IA.

Bardet-Biedl Syndrome (BBS) is a pleiotropic disorder characterized by obesity, retinitis pigmentosa, polydactyly, renal abnormalities, hypogenitalism and cognitive impairment. To date, twelve BBS genes have been identified. BBS3 accounts for approximately 1% of all BBS cases. A member of the Ras family of small GTP-binding proteins, *BBS3* contains a GTP-binding site motif and is postulated to play a role in vesicular transport. In order to characterize known human *BBS3* mutations, a variety of model systems were utilized. Immunohistochemical analysis of human and mouse retina reveals BBS3 expression in both the ganglion and photoreceptor cell layers. Subcellular localization in 293T cells indicates that BBS3 is localized to the plasma membrane in the GTP-bound state. BBS3 mutations that have been identified in patients appear to impair BBS3 protein expression as well as diminish localization to the plasma membrane in 293T cells. To further evaluate the effects of *BBS3* deficiency, a morpholino antisense oligonucleotide approach was utilized to transiently knock down *bbs3* gene expression in zebrafish. Morphant embryos show defects to the ciliated Kupffers Vesicle as well as a delay in retrograde transport. Both defects exhibited a dose dependent response to knock down and are typical of BBS phenotypes in zebrafish. Additional studies are underway to examine the BBS3 mutations in zebrafish. These studies establish an initial functional characterization of wild type and mutant BBS3 proteins.

Genetic studies of familial autoimmune myasthenia gravis. *G. Landoure[1], M. Knight[1], H. Stanescu[2,3], A. Taye[1], R. Kleta[2,3], K.H. Fischbeck[1]* 1) NINDS, NIH, Bethesda, MD; 2) NHGRI, NIH, Bethesda, MD; 3) UCL, London, UK.

About 4% of patients with myasthenia gravis have a positive family history. We studied an Italian-American kindred with parental consanguinity and 5 out of 10 siblings affected by autoimmune myasthenia. The age of onset was 50 to 79 years. A genome-wide scan with 2000 microsatellite markers was performed in 7 family members. The consanguinity indicates autosomal recessive inheritance in this family. Based on this, we performed homozygosity mapping and found linkage to a region of shared homozygosity on chromosome 13 with a LOD score of 3.28. After taking unaffecteds into account the LOD score dropped to 1.57. Haplotype reconstruction showed homozygosity in the affecteds and also one unaffected individual. The region is 7.4 Mb and contains 57 genes, 37 of which are protein coding genes, with 33 expressed in muscle, nervous system, or immune system. A parametric analysis also showed linkage to a region of chromosome 2 with a LOD score of 2.18. Haplotype reconstruction indicated that the affected individuals are compound heterozygotes. This region is 6.6 Mb and contains 69 genes. 57 are protein-coding genes, with 48 expressed in appropriate tissues. Microarray expression analysis was done and showed one upregulated gene in the region of interest on chromosome 13 and two in the region on chromosome 2. These genes were sequenced and no change was found. Seventeen genes were sequenced in the chromosome 2 region, including AchR subunits gamma and delta, and no change was found. The region on chromosome 13 was considered, with the possibility of incomplete penetrance or late onset of the disease in the unaffected individual. Nearly all the genes in this region have been sequenced, and homozygous single nucleotide variants were found in two. One of these changes is located in a 3UTR, in a region that is not well conserved but contains a miRNA binding site. We have sequenced over 60 controls, and none had the variant. The second change is in a coding region but does not alter the corresponding amino acid. We are now sequencing additional controls and doing quantitative RT-PCR to determine whether these variants affect splicing or gene expression.

A common pathogenetic role for vitamin K-dependent inhibitors of calcification in PXE and the PXE-like syndrome: novel insights in ectopic mineralization. *O.M. Vanakker[1], L. Martin[2], D. Gheduzzi[3], B.P. Leroy[1], B. Loeys[1], P.J. Coucke[1], L. Schurgers[4], C. Vermeer[4], I. Pasquali-Ronchetti[3], A. De Paepe[1]* 1) Ctr Medical Genetics, Ghent Univ Hosp, Belgium; 2) Dpt of Dermatology, Porte-Madeleine Hosp, Orléans, France; 3) Biomedical Sciences Dpt, Univ of Modena and Reggio Emilia, Italy; 4) VitaK & CARIM, Dpt of Biochemistry, Univ of Maastricht, The Netherlands.

INTRODUCTION: Pseudoxanthoma elasticum (PXE) is an autosomal recessive disorder, characterized by oculocutaneous and cardiovascular manifestations, due to mineralization and degradation of elastic fibers. The causal ABCC6 gene encodes an ATP-dependent transmembrane transporter; however, the pathogenetic link with the elastic fiber abnormalities remains unknown. We recently identified a novel PXE-like syndrome, resembling PXE and associated with a deficiency of vitamin K (VK)-dependent clotting factors. We have shown it to be caused by mutations in GGCX, encoding a -carboxylase, important for activation of VK-dependent proteins, several of which are calcification inhibitors. As such, this disease provides novel possibilities to unravel further the pathogenetic events causing PXE and the PXE-like syndrome and to expand our knowledge on elastic fiber homeostasis. METHODS AND RESULTS: ELISA experiments revealed imbalanced ratios of active and inactive osteocalcin (OC) and matrix gla protein (MGP) in 3 PXE-like patients, with an increase of inactive protein. Immunohistochemistry revealed increased staining of inactive and active MGP, OC and fetuin in 3 PXE-like skin biopsies compared to controls. In 9 PXE patients, but not in 3 patients with elastofibroma/elastosis (elastic fiber dystrophy), identical results were obtained. CONCLUSION: We have shown that dysfunction of (VK-dependent) regulators of calcium metabolism may form a common final pathway in the PXE-like syndrome and PXE. Our findings, appearing specific for ectopic mineralization, represent a major advance in our understanding of this important pathophysiological process, of elastic fibre homeostasis and hence of the pathogenesis of PXE, opening potential avenues for therapeutic agents, such as vitamin K.

Genetic Substructure in New Hampshire. *C. Sloan, A. Andrew, E. Duell, M. Karagas, J.H. Moore* Dartmouth Medical School, Lebanon, NH.

The impact of geography and ecology on the genetic architecture of common human diseases is largely unknown. Understanding the geographic distribution of genetic background is likely to improve our ability to identify both genetic and environmental risk factors. The goal of the present study was to characterize genetic structure in the population of New Hampshire as a first step toward ecogeographic genetic epidemiology of spatially distributed common diseases in the United States. We sampled 865 control subjects for an epidemiologic study of cancer from across the state of New Hampshire. We measured 1474 SNPs from approximately 500 cancer susceptibility genes and used Bayesian clustering implemented in the Structure program to identify genetic substructure in this spatially extended sample of subjects. Clusters were evaluated using fixation index (Fst) and admixture statistics along with a novel Hamming distance metric. The Bayesian clustering results suggest four distinct genetic subgroups within New Hampshire (FSTs= 0.0699, 0.0798, 0.0466, 0.0204). The observed genetic structure may arise from the states unique ethnic composition and history that includes a large proportion of Caucasian individuals with French and French Canadian descent as well as Caucasian individuals of English-Irish descent. The identification of genetic substructure among a largely Caucasian population of European descent in the state of New Hampshire is consistent with recent genetic structure results from studies in Europe including countries such as Iceland. These results, in combination with spatial information about environmental exposure, will play an important role in helping to explain regional differences in incidence of common human diseases.

Polymorphisms in the genes of interleukin 12 and its receptors in association with protection against severe malarial anemia in children residing in western Kenya. *L. Zhang[1], D. Prather[1], E. Jodi Vanden[1], S. Crawford[1], S. Kariuki[2], F. O. ter Kuile[3], B. Nahlen[1], A. A. Lal[1], V. Udhayakumar[1], Y.P. Shi[1]* 1) National Center for Zoonotic, Vector-Borne & Enteric Diseases, Centers for Disease Control and Prevention, Atlanta, GA; 2) Kenya Medical Research Institute, Kisumu, Kenya; 3) Liverpool School of Tropical Medicine, Liverpool, UK.

Of the more than 1 million Africans who die from Plasmodium infection each year, most are under the age of 5 and die from severe malarial anemia (SMA). Plasmodium falciparum has been shown to drive selection of human genetic variants for conferring protection against severe forms of malaria such as SMA, which is characterized by the destruction of red blood cells infected by malaria and suppression of erythropoiesis. Interleukin 12 (IL12) significantly boosts erythropoietic responses in murine models and its production is suppressed in African children with SMA. For these reasons the genes encoding the two IL12 subunits, IL12A and IL12B, and its receptors, IL12RB1 and IL12RB2, are attractive candidate genes for studying SMA. In this study, a total of 75 tagging single nucleotide polymorphisms (tagSNPs) covering these four genes were examined. Genotyping was performed with the iPlex MassARRAY technology in a cohort of 940 children from the Asembo Bay region of western Kenya, an area with intense malaria transmission. Individuals possessing two copies of IL12A common allele (rs2243140) at 3UTR showed increased susceptibility to SMA (Hb < 6g/dl and the presence of P. falciparum > 10,000/uL) (p = 0.006, RR 3.63, 95%CI 1.27-10.38). Individuals possessing two copies of a rare variant in IL12RB1 (rs429774) appeared to be strongly protected against SMA (p = 0.00005, RR 0.18, 95%CI 0.05-0.69). Identification of genetic polymorphisms that influence human host susceptibility to malaria infection and severe disease outcomes may help us to better understand the immune response to malaria and design novel treatments against severe malarial anemia.

Characterization by microarray CGH of a de novo partial monosomy 10q26.3 and trisomy 17q25.3 in a patient with dysmorphic features and developmental delay. *Y. Wang, J. E. Martinez, J. Chaplin, C. M. Tuck-Muller, W. Wertelecki, T. J. Chen* Dept Medical Genetics, Univ South Alabama, Mobile, AL.

Patients with terminal deletion of 10q or partial duplication of terminal 17q have been suggested to have a characteristic phenotype (Irving, 2003; Brisset, 2006) and previously reported cases of partial trisomy 17q were associated with partial monosomies of other chromosomes (e.g. 5p15, 12p13.3, 9p21 and 12q24). We report a patient with dysmorphic features and global developmental delay with a de novo monosomy 10q26.3 and trisomy 17q25.3, karoytype that has not been previously reported. The patient is a 7 year old white male with history of early FTT and global developmental delay. He is the product of the only pregnancy to young, non-consanguineous parents. The child was born at term with a birth weight of 2.8 kg from a pregnancy that was uneventful and at 16 months of age, his measurements were: OFC 46 cm (5th%); Height 74 cm (<5th%) and Weight 9.6 kg (10th). He was short and disproportioned with a short arm span, craniofacial dysmorphism including prominent forehead, high nasal bridge, hypertelorism, long palpebral fissures, dysplastic ears, joint laxity, broad distal phalanges and brittle finger nails. Cytogenetic studies revealed 46, XY, add (10) (q26.3). Parental chromosomes were normal and analysis of subtelomeric regions by multiple ligation-dependent probe amplification (MLPA) revealed a deletion in 10q26.3 and duplication of 17q25.3. To precisely determine the deleted and duplicated regions, we performed microarray analysis using high resolution oligo CGH array. The deletion in 10q26.3 was about 1.7 Mb in size (from 133.6 MB to 135.3 MB of chromosome 10). The duplication in 17q25.3 was about 5.4 Mb in size (from 73.4 MB to 78.8 MB of chromosome 17). Both 10q26.3 and 17q25.3 are gene rich regions. Monosomy 10q and trisomy 17q are both characterized by postnatal growth retardation, hypertelorism, and microcephaly. Our patient also had severe, universal and progressive hypotonia, which has not been delineated in previous reports on either monosomy 10q or trisomy 17q .

Association of the PREX1 gene in 20q13 with type 2 diabetes in European Americans. *J.P. Lewis, N.D. Palmer, J. Bento, B.I. Freedman, D.W. Bowden* Wake Forest University School of Medicine, Winston-Salem, NC 27157.

We carried out a dense SNP map analysis of the 20q12-13.13 type 2 diabetes mellitus (T2DM)-linked region on chromosome 20 in a European American (EA) diabetic cohort enriched for end-stage renal disease (ESRD). In the initial survey three genes nuclear receptor coactivator 5 (*NCOA5*), cadherin-like 22 (*CDH22*), and phosphatidylinositol 3,4,5-triphosphate-dependent RAC exchanger 1 (*PREX1*) showed evidence of association with diabetes. Suggestive evidence of association in *PREX1* was observed within and 3 to the gene. To more thoroughly understand this 316 kb region, 31 additional SNPs were genotyped in the same cohort consisting of 300 Caucasian T2DM patients and 310 controls for a total of 59 markers genotyped across *PREX1*. Twelve of these SNPs were significantly associated with T2DM with P-values ranging from 0.002-0.033. In an effort to confirm these associations a subset of SNPs were genotyped in a replicate cohort recruited with the exclusion of ESRD consisting of 469 diabetic cases and 442 controls. In this replication population 6 SNPs located approximately 150 kb 3 of *PREX1* were associated with T2DM with P-values ranging from 0.021-0.042. Three of these SNPs showed significant association in the first cohort (rs7263053, rs1321006, and rs926692). In total, 769 cases and 752 controls were genotyped. The combined analysis resulted in 10 SNPs associated with T2DM and led to generally stronger evidence of association (P= 0.001-0.049) with odds ratios in the 1.17-1.30 range. Haplotype analysis was performed to assess whether a combination of alleles of these SNPs led to an enhanced risk or protective effect. Within the region of replicated association this analysis identified statistically significant differences in haplotype frequencies between cases and controls in multiple 2 and 3 marker haplotypes (P=0.001-0.030). These results suggest that the *PREX1* gene may contribute to diabetes susceptibility in European Americans.

Impact of an Undergraduate Genetics Education Workshop on Faculty Participants and Their Students. *C.L. Moskalik, C.A. Huether* Biological Sciences, University of Cincinnati, Cincinnati, OH.
