The purpose of this presentation is to enhance appreciation of the substantial risk for glioblastoma multiforme (GBM) among NF1 patients and to reconsider the utility and efficacy of cranial MRI screening of NF1 patients. The data derive from two sources: 1. the long-term follow-up of NF1 patients accrued through the Baylor NF Program (1978-1990) and Neurofibromatosis Institute (1990-2009); 2. the accumulation of inquiries of the NF Support Group of Western Michigan (1990-2009). In all instances there was special emphasis on particularly compromising manifestations of NF1. In contrast with data from surveys dealing with the frequency and nature of intracranial gliomas in NF1 and published from 1951 through 1990 (including those from the Baylor NF Program), there appears to be a clear excess of GBM in recent years. Moreover, NF1 GBM appears to develop in all four possible predisposition scenarios: 1. no neuroimaging screen; 2. no suspicious lesion on screening cranial neuroimaging (no documented mass); 3. a suspicious or asymptomatic static lesion; or 4. a progressive lesion, with or without therapeutic intervention. Given recent documentation of the NF1 locus undergoing somatic mutation in a significant proportion (15%) of non-NF1 GBM, we might expect a larger number/percentage of patients with NF1 to manifest this tumor, compared to what has been the published experience up through the early 21st Century. With the apparent increase indicated here, there is then the question of whether, on the one hand, the GBM frequency in NF1 was simply underappreciated early on or, on the other hand, there has been a recent increase in the risk among NF1 patients. The latter possibility is important given the increasing frequency of GBM in the adult population as a whole. In conclusion, we suggest, first, that the present data indicate a special need for alerting NF1 patients and families to the significant risk of GBM as part of the natural history of the disorder. Second, patients with suspected or known intracranial lesions, including previously-treated ones, should be followed with special diligence and forewarning. Third, the development of GBM in previously asymptomatic patients makes a strong argument for more aggressive - even uniform - cranial MRI screening of all patients with NF1. Fourth, NF1 patients may be a bellwether for identifying factors that contribute to the pathogenesis of GBM in the general population.

**Non-synonymous germline *CDH1* variants in women with lobular breast cancer.** *K.A. Schrader[1,2], S. Masciari[3], N. Boyd[1], J. Senz[1], P. Kaurah[2], M.B. Terry[4], E.M. John[4], I. Andrulis[4], J. Knight[4], F.P. O'Malley[4], M. Daly[4], P. Bender[4], M.C. Southey[4,5], J.L. Hopper[4,5], N. Tung[6], J. Balmana[7], J. Garber[3], D.G. Huntsman[1,2], kConFab, Breast CFR, BCRF Breast Cancer Genetics Consortium.* 1) Department of Pathology and Laboratory Medicine, UBC, Vancouver, BC; 2) Hereditary Cancer Program, BCCA, Vancouver, BC; 3) Department of Medical Oncology, DFCI, Boston, MA; 4) Breast Cancer Family Registry; 5) Kathleen Cuningham Foundation Consortium for research into Familial Breast Cancer; 6) Beth Israel-Deaconess Medical Center, Boston, MA; 7) Hospital Vall d'Hebron, Barcelona, Spain.

Background: *CDH1* encodes the cell-cell adhesion molecule, E-cadherin, for which loss of expression facilitates the infiltrative and metastatic potential of cancers. Germline mutations in *CDH1* are associated with risk of hereditary diffuse gastric cancer (HDGC), and in this setting female carriers have been estimated to have a 39-50% risk of lobular breast cancer (LBC) by age 80 years. Aim: To determine the frequency of *CDH1* germline mutations in women with multiple or early-onset LBC unselected for family history of gastric cancer. Methods: Through a multicentre collaboration, germline DNA analysis of *CDH1* was undertaken in 384 women recruited through two different approaches; population-based cancer registries (n = 235) and those ascertained from hereditary cancer clinics (n=149). Criteria for selection were a personal history of LBC in women without germline *BRCA1* and *BRCA2* mutations, who were: (1) diagnosed before the age of 45 years or (2) diagnosed after the age of 45 years and had at least two 1st or 2nd degree relatives with breast cancer. Results: Of 369 LBC cases, six had novel non-synonymous variants and one had a previously characterized missense mutation that has been associated with HDGC. One novel variant was detected in two cases, making the proportion of cases with novel changes or a missense mutation, 1.9%. Haplotype analysis indicated that the recurrent change identified in two women could represent an ancient non-synonymous variant. The likely pathogenicities of the novel non-synonymous variants are currently being assessed via biological (functional) analyses. Unreported common silent changes have also been identified and will be measured in control samples to determine if they are related to LBC risk. None of the family cancer histories of the cases with non-synonymous variants and the missense mutation involved gastric cancer. Conclusion: Based on our selection criteria, the proportion of LBC associated with non-synonymous germline *CDH1* variants is small. Without having a family history of gastric cancer or multiple early-onset LBC, the likelihood of a woman with LBC carrying a germline *CDH1* mutation appears to be minimal.

## 1105/W/Poster Board #763

**TIME-trial: timing of genetic counseling and testing in breast cancer. Behavioral and psychosocial effects of rapid genetic counseling and testing in newly diagnosed breast cancer patients: a multicenter study.** *M.R. Wevers[1,2], M.G.E.M. Ausems[2], S. Verhoef[3], E.M.A. Bleiker[1], D.E.E. Hahn[3], E.J.Th Rutgers[4], R. van Hillegersberg[5], F.B.L. Hogervorst[6], R.B. van der Luijt[2], H. Valdimarsdottir[7], N.K. Aaronson[1].* 1) Psychosocial Research and Epidemiology, Netherlands Cancer Institute, Amsterdam, Netherlands; 2) Department of Medical Genetics, University Medical Center Utrecht, Netherlands; 3) Familial Cancer Dept, Netherlands Cancer Institute, Amsterdam, Netherlands; 4) Surgical Oncology Dept, Netherlands Cancer Institute, Amsterdam, Netherlands; 5) Surgery Dept, University Medical Center, Utrecht; 6) Diagnostic Oncology, Netherlands Cancer Institute, Amsterdam, Netherlands; 7) Oncological Sciences, Mount Sinai School of Medicine, New York, USA.

**Background** It is estimated that 5-10% of breast cancer patients carry a BRCA1/2 gene mutation. These women are at an increased risk of second tumors, such as contralateral breast cancer, and therefore may opt for preventive surgery. Usually, genetic counseling and DNA-testing are offered to eligible patients after their primary treatment, and take 4-6 months to complete. However, some laboratories can generate test results within 3 to 6 weeks. Little is known about the effect of such rapid procedures on treatment decisions and psychosocial health. **Methods** The TIME-trial is a randomized controlled trial. In total, 255 newly diagnosed breast cancer patients with at least a 10% risk of having a BRCA mutation, recruited from 12 hospitals in the Netherlands, are randomized in a 2:1 ratio to either rapid genetic counseling (referral for genetic counseling within a week after diagnosis), or to a usual care control group. If indicated, DNA-test results are made available within 3-6 weeks. Primary study outcomes are choice of primary treatment including the uptake of direct bilateral mastectomy and of delayed preventive contralateral mastectomy, cancer risk perception, cancer-related worry and distress, health-related quality of life and decisional satisfaction. Psychosocial assessments take place at study entry, and at 6 and 12 months. **Results** The trial recently opened for patient recruitment. To date, 45 women have been invited to participate in the trial, of whom 36 have agreed and have been randomized (response of 80%). **Conclusion and implications** This study will provide essential information about the impact of rapid genetic counseling and testing on the choice of primary surgical treatment among women with breast cancer whose cancer is likely to have a hereditary basis. Additionally, the study will provide data on the psychosocial consequences of genetic testing and risk-reducing behavior in this high-risk population.

## 1106/W/Poster Board #764

**The difference of HPV (human papillomavirus) DNA genotypes may influence the speed of carcinogenesis in cervical squamous intraepithelial lesions among Japanese patients.** *K. Yamasaki[1], K. Miura[1], S. Miura[1], T. Shimada[1], A. Fujishita[3], T. Sameshima[4], M. Murakami[5], K. Yoshiura[2], H. Masuzaki[1].* 1) Department of Obstetrics and Gynecology, School of Medicine, Nagasaki University, Nagasaki, Japan; 2) Department of Human Genetics, School of Medicine, Nagasaki University, Nagasaki, Japan; 3) Department of Obstetrics and Gynecology, Nagasaki Prefectural Saiseikai Hospital, Nagasaki, Japan; 4) Department of Obstetrics and Gynecology, Nagasaki Atomic Bomb Hospital, The Japanese Red Cross Nagasaki, Nagasaki, Japan; 5) Department of Obstetrics and Gynecology, Sasebo Municipal Hospital, Nagasaki, Japan.

Objectives. Continuous HPV infections are associated with the progression from low-grade squamous intraepithelial lesions (LSIL) to high-grade cervical intraepithelial neoplasia (HSIL). In this study, we determined individual HPV-DNA genotypes in Japanese women and ascertained the temporal changes of HPV infections correlate with the histological results. Methods. Between August 2007 and December 2008, 804 cervical smears on liquid medium were obtained. All cervical smears were evaluated by one particular cytoscreener in the distinct laboratory. The HPV-DNA tests were performed by Linear Array HPV Genotyping Test kit (Roche, Inc., USA). The temporal change of Pap test diagnosis meant the change of category in the Bethesda system, between four groups, “NLM (no intraepithelial lesion or malignancy)”, “LSIL or ASC-US (atypical squamous cells of undetermined significance)”, “HSIL or ASC-H (atypical squamous cells cannot exclude high-grade squamous intraepithelial lesion)” ,and “SCC”. And we defined “progressive change” as histological diagnosis changing more progressive or cytological diagnosis which go to more progressive in atypical squamous cell findings, e.g.; the diagnosis changes from the group of “LSIL or ASC-US” to “HSIL or ASC-H”, and “regressive change” as histological diagnosis changing more regressive or cytological diagnosis which show less regressive in atypical squamous cell findings. Results. 178 cases which were obtained Pap smears and HPV-DNA tests multiple times in the time course manner were recruited to the study. 33 cases (18.5%) showed “progressive change” and forty-five cases (25.3%) showed “regressive change”. We could not observe the changes of pathological diagnosis in other a hundred cases (56.2%). 12 cases of thirty “progressive change” cases were infected with HPV 16 and 18 persistently, and eighteen cases were infected with the other types of HPV except HPV 16 and 18. Whereas only three cases of forty-five “regressive change” cases were infected with HPV 16 and 18 persistently. Other type of HPV were infected continuously in seventeen “regressive change” cases. In this one year the continuous infection of HPV 16 and18 were found significantly more in “progressive change” group ($p \div 0.04$, Fisher’s test). Conclusions. Persistent infection of HPV associated with the progressive changes of cytopathological findings. Especially HPV 16 and HPV 18 may affect those changes more rapidly than other type of HPV in Japanese women.

## 1107/W/Poster Board #765

**New Approaches to Identify and Characterize Splice Variants in *BRCA* genes.** *R.D. Brandao[1,2], K. van Roozendaal[1], D. Tserpelis[1], E.B. Gómez Garcia[1,2], M.J. Blok[1].* 1) Clinical Genetics, University Hospital of Maastricht, Maastricht, Netherlands; 2) GROW - School for Oncology and Developmental Biology, University Hospital of Maastricht, Maastricht, Netherlands.

Genetic screening of *BRCA* genes has been offered to families with breast and ovarian cancer syndrome. Most of the variants found in *BRCA1/2* genes are unclassified variants. A subset of UVs are in intronic sequences or close to exon-intron boundaries and may affect splicing. Putative *BRCA1* and *BRCA2* splice variants, as predicted *in silico*, were studied experimentally using traditional RT-PCR and a new approach based on MLPA technology. Short-term lymphocyte cultures from controls and UV carriers were established with PHA and IL-2 and treated with a nonsense-mediated decay inhibitor, 5h before harvesting. Amplification of cDNA was performed for specific fragments flanking the regions of interest and when possible allele-specific PCR was carried out. We first performed RT-PCR analysis for the following *BRCA2* putative splice variants: c.425G>T, c.6935A>T, c.6842-3T>C, c.6943A>G, c.7976+3del2, c.8350C>T, c.8662C>T, c.8754+3G>C. Variants c.425G>T and c.7976+3del2 give rise to transcripts with deletions of exon4 and exon17, respectively and c.8754+3G>C leads to 46bp of intron retention. Thus these variants were considered to be pathogenic. Additionally, new alternative splicing events were observed in controls, such as c.6842_6937del (exon12 skipping) and c.476_631del (exon 6 and 7 skipping). As these in-frame transcripts are also expressed in healthy controls and have an unknown function, their clinical relevance remains unclear. This has consequences for the classification of c.6935A>T, which leads to increased expression of c.6842_6937del compared to controls. We also evaluated the use of MLPA-technology for the detection of aberrant splice events on well characterized splice-variants, including *BRCA1* exon13 and exon22 deletions. Commercially available MLPA kits for *BRCA1* and *BRCA2* genes were used, in addition to home-made MLPA probe sets. Commercial probe sets include probes located in exons, therefore allowing detection of exon-deletion events in cDNA, whereas home made probes were designed to cross exon-exon boundaries which allow the detection of insertions and deletions at these borders. These approaches proved to be useful for the detection of alternative splice events. In conclusion, we characterized several new pathogenic BRCA2 splice variants and demonstrated that with MLPA technology it is possible to set-up a multiplex screen for semi-quantitative detection of alternative splice events which is widely applicable also for genes other than *BRCA1/2*.

## 1108/W/Poster Board #766

**Development and assessment of hereditary breast cancer genetic screening tools for the Hispanic population of Puerto Rico.** *J. Dutil[1], M. Echenique[2], J. Matta[1], R. Sutphen[3].* 1) Biochemistry, Ponce School of Medicine, Ponce, PR; 2) Hospital Auxilio Mutuo, San Juan, PR; 3) Moffitt Cancer Center, Tampa, FL.

Mutations in the BRCA1 and BRCA2 genes are responsible for the majority of hereditary breast cancers. Knowledge of the incidence and prevalence of BRCA mutations in a specific population or ethnic group is necessary to provide accurate genetic counseling for breast cancer patients and their families. However, these data have not been gathered in the population of Puerto Rico. Our long term objective is to provide the population of Puerto Rico with accurate and efficient tools for the clinical management of hereditary breast cancer. In this particular study, we are conducting a retrospective assessment of the breast cancer patients that have been clinically tested for the BRCA mutations in a high volume surgery practice from San Juan, Puerto Rico. Data collection includes 3-generation family cancer history and results from complete BRCA sequencing. The correlation between BRCA mutation and the model prediction is evaluated by the calculation of the C-statistic. We also hope to identify prevalent BRCA mutations in the population of Puerto Rico. To date, 29 individuals have been tested and 10 individuals found to have a mutation. This project looks for the first time at the characteristics of hereditary breast cancer in Puerto Rico, and assesses the accuracy of existing genetic risk assessment tools in that population. It is expected to have an immediate positive impact on the community as we will gain knowledge about clinical strategies related to hereditary breast cancer in Puerto Ricans.

## 1109/W/Poster Board #767

**Role of rapid sequence whole-body MRI in *SDHB*-associated hereditary paragangliomas.** *K. Jasperson[1], W. Kohlmann[1], A. Gammon[1], A. Shaaban[2], H. Baskin[3], B. Bentz[4], J. Schiffman[1].* 1) High Risk Cancer Clinics, Huntsman Cancer Institute, Salt Lake City, UT; 2) Department of Radiology, University of Utah, Salt Lake City, UT; 3) Department of Radiology, Primary Children's Medical Center, Salt Lake City, UT; 4) Department of Surgery, University of Utah, Salt Lake City, UT.

**Background:** Germline mutations in *SDHB* cause hereditary paraganglioma syndrome. Penetrance for paragangliomas by 35 and 50 years of age is estimated to be 50% and 70%, respectively. Multiple tumors and malignant transformation is common and renal cell carcinomas, benign renal tumors, and thyroid cancers have also been reported. Limited data exists regarding the efficacy of tumor screening in mutation carriers. In addition, there are a number of barriers to screening including high associated costs, time burden, lack of insurance reimbursement, and inadequate sensitivities and specificities for certain screening techniques. **Objective:** To develop and implement an effective screening protocol for hereditary paraganglioma. **Methods:** Radiographic and biochemical screening were offered to members of a large kindred with an *SDHB* mutation. Whole-body MRI using axial ultra-fast T2 half Fourier acquisition single shot fast spin echo "HASTE" technique using a sliding table platform with an integrated phased-array surface coil was performed. The examination included the base of skull to the pelvis. A more comprehensive MRI examination was performed when a lesion was detected. Biochemical screening included plasma catecholamines, fractionated metanephrines, and chromogranin A. **Results:** Six asymptomatic *SDHB* mutation carriers were screened with MRI. Four (66.7%) were found to have lesions; one individual had a carotid body tumor, one had bilateral renal cysts, another had a carotid body tumor and a large 7 cm oncocytoma, and another was found to have a 4 cm thyroid nodule. Five of the six individuals also had biochemical screening, all were normal. **Conclusions:** Our current protocol has overcome a number of the limitations with screening. Whole-body rapid sequence MRI has reduced the costs and time of radiographic screening compared to individual MRIs of each potentially affected body system. Examination time was approximately 12-14 minutes and insurance has approved coverage of whole-body MRI in all individuals screened. In addition, two-thirds of the individuals screened thus far have been found to have SDHB-associated lesions. Expanding this protocol to other at risk individuals will be important to further delineate the impact and effectiveness of screening in paraganglioma syndromes.

## 1110/W/Poster Board #768

**Health Technology Assessment of Genetic Testing for Lynch Syndrome (Hereditary Nonpolyposis Colorectal Cancer, HNPCC).** *A.P. Lea, S.A. Levine, D.J. Allingham-Hawkins.* Hayes Inc., Lansdale, PA.

**Objectives:** Lynch syndrome is caused by sequence variants in the mismatch repair (*MMR*) genes (*MLH1*, *MSH2*, *MSH6* and *PMS2*) and is associated with an increased lifetime risk of cancer, especially colorectal cancer (CRC) and endometrial cancer. This health technology assessment analyzed the evidence for the use of genetic and molecular testing for the diagnosis of Lynch syndrome to evaluate the different diagnostic strategies and to define the patient population that should be screened. **Methods:** A literature search was performed to identify studies published between January 2003 and May 2009 that related to screening for and diagnosis of Lynch syndrome. The evidence provided by these studies was analyzed using the ACCE model, which was developed by the Centers for Disease Control and Prevention (CDC) specifically for assessment of genetic tests. **Results:** The literature search revealed that, in addition to tests for the presence of sequence variants in the *MMR* genes, other tests being researched for screening and diagnosis of Lynch syndrome include immunohistochemical (IHC) analysis to determine the expression of protein products of the *MMR* genes; microsatellite instability (MSI) testing; *BRAF* gene testing (for the variant c.1799T>A, p.V600E) to separate sporadic from familial CRC; and *MLH1* methylation analysis to separate germline from epigenetic hypermethylation of the *MLH1* promoter region in those lacking expression of *MLH1* protein products. Furthermore, several strategies (revised Amsterdam and Bethesda criteria) and computer models (Barnetson, Leiden, MMRpredict, MMRpro, and PREMM$_{1,2}$) that use family history to select patients for Lynch syndrome screening have been investigated. **Conclusions:** Currently available data are insufficient to justify expansion of screening for Lynch syndrome from those patients with a family history of CRC/Lynch syndrome to all patients with CRC. However, computer models have the potential to make better use of available information than the revised Bethesda or Amsterdam criteria in selecting patients for Lynch syndrome screening. As initial screening tests for Lynch syndrome, MSI and IHC analysis have similar sensitivities and specificities. For patients who are MSI and/or IHC positive, *BRAF* and *MLH1* methylation analysis both have the potential to identify those with sporadic CRC rather than Lynch syndrome. Testing for sequence variants in the 4 *MMR* genes is now the definitive diagnosis for Lynch syndrome.

## 1111/W/Poster Board #769

**The Familial Cancer Database online (www.facd.info).** *R.H. Sijmons.* Dept Genetics, Univ Med Ctr Groningen, Groningen, Netherlands.

To support clinicians and genetic counsellors in the genetic differential diagnosis of cancer patients and families we have developed a special online tool. This free tool, the Familial Cancer Database (FaCD), tries to match cancer types and typical non-tumor features observed in a family with those of the more than 450 disorders currently stored in its database. Search features are flexible and allow for filtering results for different levels of evidence that a particular cancer type is associated with a particular syndrome.

FaCD is a non-commercial, academic, project and complies with the international Health on the Net code standard (www.hon.ch). It was launched last year and is presently consulted by clinicians and genetic counsellors from 34 different countries. The contents of the database is updated on a weekly basis with the help of a growing panel of international experts. We invite colleagues to join this panel! The database can be found at **www.facd.info** .

## 1112/W/Poster Board #770

**Reliable Detection of PMS2 Germline Mutations: A Reference Laboratory Experience.** *C.P. Vaughn[1], J. Robles[2], W.S. Samowitz[1,3].* 1) ARUP Institute for Clincal and Experimental Pathology, Salt Lake City, Utah; 2) ARUP Laboratories, Salt Lake City, Utah; 3) Department of Pathology, University of Utah Health Sciences Center, Salt Lake City, Utah.

Lynch syndrome patients harbor a mutation in one of the mismatch repair genes, MLH1, MSH2, MSH6, or PMS2. While screening for mutations in MLH1, MSH2, and MSH6 is fairly straightforward, the detection of mutations in PMS2 is greatly complicated by the presence of numerous pseudogenes. This has presented an obstacle to obtaining reliable data concerning the mutations present in patients whose tumors show isolated loss of PMS2 protein expression, the immunohistochemical (IHC) profile most commonly associated with a germline PMS2 mutation. We used a modification of a long-range PCR method described by Clendenning (Human Mutation, 2006) to evaluate the PMS2 gene in 102 patient samples submitted for clinical testing. Our modification avoids potential interference with the pseudogene PMS2CL by utilizing a long-range product spanning exons 11-15, with the forward primer anchored in exon 10. Long-range PCR was followed by nested PCR using exon-specific primers and Sanger sequencing. Large deletions were identified by MLPA. IHC results were provided by submitting clinicians. We identified deleterious PMS2 mutations in 18 of 50 patients whose tumors showed isolated loss of PMS2 by IHC. In 28 patients whose tumors showed absence of either another protein or combination of proteins, including 20 samples with concurrent MLH1/PMS2 loss, no deleterious mutations were identified. Two additional patients with deleterious mutations were identified from the 24 samples without IHC data. Two of the 18 patients with deleterious PMS2 mutations had biallelic mutations, one homozygous and one compound heterozygous. Nine of the 21 identified mutations were large deletions encompassing one or more exons. Three mutations were seen in more than one individual, all of whom appeared to be unrelated: c.137G>T (in three individuals), c.736_741del6ins11 (in two individuals), and an exon 10 deletion (in two individuals); these three mutations have been previously identified as founder or potential founder mutations. We conclude that long-range PCR can be used to preferentially amplify the PMS2 gene and avoid pseudogene interference, thus providing reliable clinical results. Deleterious mutations were identified in 36% of individuals whose tumors showed isolated loss of PMS2 protein expression. Deleterious mutations were not associated with any other IHC profile, including the concurrent loss of MLH1 and PMS2.

## 1113/W/Poster Board #771

**Macrocephaly as an indicator of PTEN mutations in adults attending a Medical Genetics Clinic.** *R.L. Bennett, K. Hansen, W. Raskind.* Dept Med/Div Med Gen, Univ Washington, Seattle, WA.

Cowden syndrome (CS) is an autosomal dominant disorder affecting approximately 1 in 200,000 individuals. Mutations in the PTEN gene, which encodes for a known tumor suppressor with phosphatase activity, have been identified in 80% of CS patients. CS is characterized by hamartomatous overgrowths of tissues derived from all three germ cell layers as well as an increased risk of breast and thyroid cancers. Macrocephaly (OFC ≥ +2SD) is another clinical feature that has been reported in 38% of individuals with CS. This study was to determine if macrocephaly is a strong indicator of PTEN mutations, and whether or not head circumference can help determine when to order PTEN testing versus BRCA1/2 testing for breast cancer patients. A chart review of adult patients seen at the Medical Genetics Clinic at the University of Washington Medical Center was conducted. Charts were reviewed on 31 patient, all of whom had previous PTEN testing and head circumference measurements taken. Eight of the 31 patients had positive PTEN mutations identified, 22 were negative for PTEN mutations, and one patient had a PTEN variant of unknown significance. 100% of the PTEN positive patients had macrocephaly, with head circumferences ranging from +2.3 to +7.2 SD, while 23% of the PTEN negative patients had macrocephaly. Furthermore, when patients were grouped according to their head circumferences, it was found that the percentage of patients with positive PTEN mutations tended to increase with an increase in head circumference. These results indicate that macrocephaly is an important clinical feature that should be taken into account when considering PTEN testing. They also suggest that PTEN testing in macrocephalic breast cancer patients should be considered prior to BRCA1/2 testing. Because of the small sample size in this study, these results should not be used to exclude individuals from testing, but rather to argue for PTEN testing on the basis of macrocephaly.

## 1114/W/Poster Board #772

**Current BRCA Ordering Practices and Management Recommendations Among Obstetricians and Gynecologists.** *A. Trivedi[1], K. Swan[2], A. Gammon[3].* 1) Dept of Obstetrics and Gynecology, Northwestern University, Chicago, IL; 2) Graduate Program in Genetic Counseling, Northwestern University, Chicago, IL; 3) Huntsman Cancer Institute, University of Utah, Salt Lake City, UT.

OBJECTIVE: This study aimed to investigate current BRCA ordering practices among ob/gyns, assess factors that influence these practices (including the Myriad marketing campaign), and describe ob/gyns' recommendations for cancer risk management based on BRCA results. METHODS: A written survey was mailed to 500 randomly selected ob/gyns who are members of ACOG. RESULTS: 107 (21%) questionnaires were returned. The majority of respondents (67.3%) had not been in contact with a Myriad representative and had not directly ordered BRCA tests (73.8%). Most participants (52.3%) reported feeling uncomfortable ordering BRCA tests. Participants who were in contact with Myriad ordered BRCA tests more frequently ($p<0.001$) and reported feeling more comfortable ($p=0.009$) ordering tests than those who were not in contact with Myriad. Perceived barriers to BRCA test ordering include time needed to order the test, lack of genetic knowledge, lack of confidence, lack of clinical utility, cost of test and possibility of insurance discrimination. Those who have been in contact with Myriad viewed both a lack of confidence interpreting genetic test results ($p=0.030$) and a lack of genetic knowledge ($p=0.048$) as less of a barrier to ordering BRCA tests than those who have not been in contact with Myriad. 85% of participants believe it is their role to discuss cancer risk management with their patients. When assessing participants' management recommendations for a BRCA mutation carrier, an average of 85% of recommendations were consistent with NCCN guidelines. When the scenario was less straightforward with an uninformative BRCA negative test result, there was greater variability among participants and management options were less congruent with NCCN guidelines. CONCLUSION: Our study found that 26% of our participants have directly ordered a BRCA test without referring to a genetics professional, which is much higher than reported in previous studies. Furthermore, this study suggests that Myriad's marketing campaign and perceived barriers to ordering BRCA tests may be influencing participants' BRCA ordering practices. Finally, this study suggests that participants make cancer risk management recommendations that are consistent with NCCN guidelines for a BRCA mutation carrier. However, there is much greater variability in recommendations for a high risk BRCA negative patient.

## 1115/W/Poster Board #773

***BRCA1/2* Mutation Prediction: PENN II Model Performs Well in Clinical Practice.** *K.J. Johnson[1], H. Harvey[2], V.S. Pankratz[3], K. Hunt[4], M.J. Wilson[5], N.M. Lindor[1].* 1) Medical Genetics, Mayo Clinic Rochester, Rochester, MN; 2) Seattle University, Seattle, WA; 3) Biostatistics and Informatics, Mayo Clinic, Rochester; 4) Hematology-Oncology, Mayo Clinic Scottsdale, AZ; 5) Laboratory Medicine and Pathology.

**Background**: Several models have been developed for probablilistic clinical prediction of an individual having a germline *BRCA1/2* mutation, primarily based upon input of cancer history and family history. The PENN II Risk Model, developed at the University of Pennsylvania, is a relatively new web-based model, found at https://www.afcri.upenn.edu:8022/itacc/penn2/index.asp. We sought to compare its performance characteristics with other risk prediction models in our clinical practice. **Methods**: Between 1996 and 2005, probands from 285 unique families from Mayo Clinic had collection of detailed family history, genetic counseling, and *BRCA1/2* testing at Myriad Genetics. Testing consisted of sequencing both genes for all patients, and testing for 5-site rearrangement panel in *BRCA1*, since August 2003. For this study, primary peritoneal cancer was considered equivalent to ovarian cancer and ductal carcinoma *in situ* was not counted as invasive breast cancer. **Results**: 277 of 285 probands were women (so men were not analyzed separately). 195 had breast cancer, with first diagnosis at mean age 45.0 years; 26 had bilateral breast cancer; 45 had ovarian cancer at mean age 51.7 years. Twenty seven probands were Ashkenazi Jewish (9.5%). A Receiver-Operating Characteristic (ROC) curve was constructed for subsets. The area under the curve (AUC) is a global measure of a model's predictive performance. For men plus women, the AUC for *BRCA1* and *BRCA2* combined was 0.787; for women only it was 0.791. For men and women combined, for *BRCA1* only, the AUC was 0.810 and for women only it was 0.808. For men and women combined, for *BRCA2* only, the AUC was 0.722 and for women only it was 0.725. In a prior study, we found AUCs for *BRCA1* and *BRCA2* combined for women only to be 0.73 for LAMBDA model, 0.76 for BRCAPRO, 0.72 for Couch 1.5, and 0.71 for Myriad II [Familial Cancer. 6(4):473-82, 2007]. **Conclusions**: The PENN II Risk Model is a convenient, free, web-based tool for *BRCA1/2* mutation prediction. In the clinic population studied, its performance characteristics, as assessed by area under the ROC curve, compared favorably with other commonly used prediction models.

## 1116/W/Poster Board #774

**Candidate Gene Association Study of Esophageal Squamous Cell Carcinoma in a High-Risk Region in Iran.** *M.R. Akbari[1,2,3], R. Malekzadeh[1], R. Shakeri[1], D. Nasrollahzadeh[1], M. Foumani[2], Y. Sun[2], A. Pourshams[1], A. Sadjadi[1], E. Jafari[1], M. Sotoudeh[1], F. Kamangar[4], P. Boffetta[5], S.M. Dawsey[4], P. Ghadirian[6].* 1) Inst Med Sci, Univ Toronto, Toronto, ON, Canada; 2) Women's College Research Institute, University of Toronto, Toronto, Canada; 3) Institute of Medical Science, Faculty of Medicine, University of Toronto, Toronto, Canada; 4) Division of Cancer Epidemiology and Genetics, National Cancer Institute, Bethesda, Maryland, USA; 5) International Agency for Research on Cancer, Lyon, France; 6) Epidemiology Research Unit Research Centre, CHUM- Hôtel-Dieu, University of Montreal, Montreal, Canada.

There is a region with a high risk for esophageal squamous cell carcinoma (ESCC) in northeast Iran. Previous studies suggest that hereditary factors play a role in the high incidence of cancer in the region. We selected 22 functional variants (and 130 related tagSNPs) from 15 genes which previously have been associated with risk of ESCC. We genotyped a primary set of samples from 451 Turkmens (197 cases and 254 controls). Seven of 152 variants were associated with ESCC at the P = 0.05 level; these SNPs were then studied in a validation set of 549 cases and 1119 controls, including both Turkmens and non-Turkmens. The association for a functional variant, in ADH1B, was confirmed and for a tagSNP, in MGMT, was borderline in the validation set after correcting the p-values for multiple testing. All other five variants which initially were associated with ESCC in the primary sample set were failed in the validation set. The histidine allele at codon 48 of ADH1B gene in the joint data set (primary and validation set) was associated with a significantly decreased risk of ESCC under a recessive model (OR = 0.41, 95% CI = 0.29 to 0.76; P = 4x10-4). The A allele of the rs7087131 variant of MGMT gene in the joint data set was associated with a decreased risk of ESCC under a dominant model (OR = 0.79, 95% CI = 0.64 to 0.96; P = 0.02,). In previous studies, the ADH1B Arg48His variant has been consistently reported in association with ESCC just among alcohol drinkers. Considering that only 4.5 % of our study subjects were alcohol drinkers, our observation is contrary to other studies which report no association between the Arg48His variant of the ADH1B gene and the risk of ESCC among non-drinkers. Our data suggests that, in Northern Iran, ESCC may be related to an environmental factor other than ethanol, but that is also metabolized by ADH1B. Polycyclic aromatic hydrocarbons (PAH) are known environmental factor in the pathogenesis of ESCC. 1-methylpyrene (1-MP) is a carcinogenic PAH which is metabolized to 1-hydroxymethylpyrene (1-HMP) by CYP450 enzymes. Animal studies showed that 1-HMP could be activated by sulphotransferases and forms DNA adducts, but most of 1-HMP is inactivated by ADH1B. It is possible that individuals with two slow-metabolizing Arg alleles at codon 48 of ADH1B gene do not inactivate 1-HMP as efficiently as those who carry one or more His alleles at this codon. In this case, more 1-HMP would be available for forming DNA-adducts.

## 1117/W/Poster Board #775

**A comprehensive Pathway-wide analysis of genetic variability of the mTOR, FAS and related genes and Prostate cancer risk.** *D. Campa, A. Husing, F. Canzian, R. Kaaks.* German Cancer Res Ctr (DKFZ), Heidelberg, Germany.

A Western lifestyle, characterized by low rates of energy expenditure and a high-energy diet rich in animal protein, saturated fats and refined carbohydrates, is associated with high incidence of prostate cancer in men. Recent studies have identified the mTOR (mammalian target of rapamycin) signal transduction pathway as the pathway that integrates various signals, regulating ribosome biogenesis and protein synthesis as a function of available energy and amino acids, and assuring an appropriate coupling of cellular proliferation with increases in cell size. Fatty acid synthesis, another pathway central to cellular proliferation, is regulated by insulin/IGF-I, essentially through the same signalling mechanisms that influence the mTOR pathway. We investigated the genetic variability of 96 key genes in the above mentioned pathways. We tested the association of 1412 tagging SNPs with prostate cancer risk in a study of 815 cases and 1269 controls nested within the European Prospective Investigation into Cancer and Nutrition (EPIC).To our knowledge this is the first report on polymorphisms of these genes and prostate cancer risk. We have found that several SNPs in the PI3K gene family have a statistically significant association with an altered risk of prostate cancer, the best being OR 0.62; p=0,000373.

## 1118/W/Poster Board #776

**Polymorphisms in genes related to Insulin-Like Growth Factor-I (IGF-I) and breast cancer risk in the NCI Breast and Prostate Cancer Cohort Consortium (BPC3).** *F. Canzian[1], D.G. Cox[2], D.O. Stram[3], R. Hoover[4], H. Blanché[5], G. Thomas[4], R. Kaaks[1], the NCI Breast and Prostate Cancer Cohort Consortium (BPC3).* 1) German Cancer Research Center (DKFZ), Heidelberg, Germany; 2) Harvard School of Public Health, Boston, MA USA; 3) University of Southern California, Los Angeles, CA USA; 4) Division of Cancer Epidemiology and Genetics, National Cancer Institute (NCI), Bethesda, MD USA; 5) Fondation Jean Dausset-CEPH - Biological Resource Centre, Paris, France.

Insulin and insulin-like growth factor-I (IGF-I) have been implicated in the development of breast cancer. We hypothesized that polymorphisms in IGF-I-related genes may influence breast cancer risk. We selected 550 tagging single nucleotide polymorphisms (SNPs) in 24 genes of the IGF-I pathway (GHRH, GHRHR, SST, SSTR1, SSTR2, SSTR3, SSTR4, SSTR5, POU1F1, GHR, IGF1, IGFBP1, IGFBP2, IGFBP3, IGFBP4, IGFBP5, IGFBP6, IGFALS, IGF1R, IGF2, IGF2R, INSR, IRS1, IRS2), and tested them for association with breast cancer risk in a large collaboration of prospective studies, the NCI Breast and Prostate Cancer Cohort Consortium (BPC3), which includes the American Cancer Society Cancer Prevention Study II (CPS-II), the European Prospective Investigation into Cancer and Nutrition (EPIC), the Harvard Nurses' Health Study (NHS) and Women's Health Study (WHS), the Prostate, Lung, Colorectal, Ovarian Cancer Screening Trial (PLCO) and the Multiethnic Cohort (MEC). The BPC3 includes 6,292 cases of breast cancer and 8,135 controls. While these genes are strong a priori candidates to harbor breast cancer susceptibility alleles, none of the common polymorphisms tested was significantly associated ($p<0.0001$) with risk, after correction for multiple comparisons. This study had over 80% power to detect associations of relative risk RR=1.2 or greater for common alleles (frequency ≥10%) at $p<0.0001$. The results remained null when cases and controls were stratified by age at diagnosis/recruitment, advanced or non-advanced disease, BMI, with or without inclusion of in situ cases; or restricted to Caucasians. Data on estrogen receptor (ER) status were available for 4,193 cases. Of these, 3,423 (81.6%) were ER positive and 770 (18.4%) were ER negative. Among the ER- cases, a SNP located 3' of GHR was marginally associated with increased risk after correction for multiple testing (ptrend=1.5x10-4). While the IGF-I pathway may be involved in breast cancer development and progression, common variants in any of the individual genes we studied do not contribute substantially to breast cancer risk in Caucasians.

## 1119/W/Poster Board #777

**Cell cycle genes and ovarian cancer susceptibility: a tagSNP analysis.** *J. Cunningham[1], R. Vierkant[1], T. Sellers[2], C. Phelan[2], J. Schildkraut[3], F. Couch[1], X. Wang[1], B. Fridley[1], S. Gayther[4], H. Song[5], E. Hogdall[6], S. Kjaer[6,7], A. Whittemore[8], R. DiCioccio[9], S. Ramus[4], P. Pharoah[5], E. Goode[1].* 1) Dept Lab Med & Pathology, Mayo Clinic & Fndn, Rochester, MN; 2) H. Lee Moffitt Cancer Center and Research Institute, Tampa, FL; 3) Duke University Medical Center, Durham, NC; 4) Translational Research Laboratories, University College, London, UK; 5) Cancer Research United Kingdom and Strangeways Research Laboratory, Cambridge University, Cambridge, UK; 6) Institute of Cancer Epidemiology, Danish Cancer Society, Copenhagen, Denmark; 7) Gynecologic Clinic, Juliane Marie center, Righospitalet, University of Copenhagen, Copenhagen, Denmark; 8) Stanford University School of Medicine, Palo Alto, CA; 9) Roswell Park Cancer Institute, Buffalo, NY.

Dysregulation of the cell cycle is a hallmark of many cancers including ovarian cancer which affects more than 21,000 women in the US annually and is a leading cause of gynecologic cancer mortality worldwide. We identified 39 genes involved in cell cycle regulation that are expressed in ovarian tissue and examined 288 common SNPs in a two-stage study. Caucasian cases ascertained at the Mayo Clinic in Rochester, Minnesota (n=385) or a 48-county region in North Carolina (Duke University, n=444) and ovarian cancer-free Caucasian controls (n=941) were genotyped using an Illumina GoldenGate assay. We found that variants in eight genes (ABL1, CDKN1A, CCND3, E2F2, CDK2, E2F2, CDC2 and CDK7) were associated with risk of epithelial ovarian cancer at $p<0.05$ under at least one genetic model. Seven of these SNPs were then assessed in four additional case-control studies from the US, UK and Denmark, with 1689 cases and 3398 controls in a combined replication set. The association between risk of ovarian cancer and ABL1 rs2855192 found in the original case-control set (OR homozygous minor allele vs. homozygous major 2.81, 95% CI 1.29-6.09, p=0.01) was observed in the other American study population (Stanford University) (OR 3.73, 95% CI 1.30-10.7, p=0.02) and remained suggestive in the combined analysis (OR 1.59, 95% CI 1.08-2.34, p=0.02). This appears to be a recessive effect. No other results remained suggestive in the replication populations. As ABL1 has been implicated in multiple processes including cell division, cell adhesion and cellular stress response, these results suggest that characterization of the role of genetic variation in this gene in other ovarian cancer study populations is warranted.

### 1120/W/Poster Board #778

**European ancestry is positively associated with breast cancer risk both in US and Mexican Latinas.** *L. Fejerman[1], I. Romieu[2], E.M. John[3], E. Lazcano-Ponce[2], S. Huntsman[1], K. Beckman[8], E. Perez-Stable[1,4,5,6], E. Gonzalez Burchard[1,4,9,10], E. Ziv[1,4,6,7], G. Torres-Mejia[2].* 1) Dept Medicine, Univ California, San Francisco, San Francisco, CA; 2) Instituto Nacional de Salud Publica, Cuernavaca, Morelos, Mexico; 3) Northern California Cancer Center, Fremont, CA; 4) Institute for Human Genetics, Univ California, San Francisco, San Francisco, CA; 5) Medical Effectiveness Research Center for Diverse Populations, Univ California, San Francisco, San Francisco, CA; 6) Helen Diller Family Comprehensive Cancer Center, Univ California, San Francisco, CA; 7) Dept Epidemiology and Biostatistics, Univ California, San Francisco, San Francisco, CA; 8) Dept Developmental Biology, Univ Minnesota, Minneapolis, MN; 9) Lung Biology Center, Univ California, San Francisco, San Francisco, CA; 10) Dept Biopharmaceutical Sciences, Univ California, San Francisco, San Francisco, CA.

Women who self-identify as Latinas or Hispanic in the San Francisco Bay Area have a breast cancer incidence that is 35% lower than that for women who self-identify as Caucasians. A large proportion of the difference in incidence disappears in second and third generation immigrants, suggesting a major environmental effect on risk. The degree to which genetic factors play a role is unknown. Latinas are an admixed group with genetic ancestry from Europeans, Indigenous Americans and African populations. We have previously described a significant association between genetic ancestry and risk of breast cancer in a sample of US Latinas from the San Francisco Bay Area who were of Mexican and Central American descent. Higher European ancestry was associated with increased breast cancer risk. Herein, we analyzed a sample of 1,590 Mexican women to determine if our prior results in US Latinas were consistent with those of women from Mexico. We used genetic markers to estimate the ancestry of Mexican women with and without breast cancer and assessed the association between genetic ancestry and breast cancer risk, adjusting for reproductive and other risk factors. We typed a set of 106 ancestry informative markers (AIMs) in 564 Mexican women with breast cancer and 1,026 healthy controls. We estimated genetic ancestry using a maximum likelihood method. Odds ratios (OR) and 95% confidence intervals (CI) for ancestry, modeled as a categorical variable, were estimated using logistic regression and adjusted for known risk factors. Higher European ancestry was associated with increased breast cancer risk in this new and independent sample of Latina women from Mexico. Compared to women with 0-25% European ancestry, the risk was non-significantly elevated among women with 25-50% European ancestry (OR:1.13; 95% CI: 0.84-1.53), and significantly increased for women with 50-75% European ancestry (OR: 1.59; 95% CI: 1.07-2.36), and for women with 75-100% European ancestry (OR: 3.36; 95% CI: 1.10-10.27). The consistent association with genetic ancestry in the US Latinas and Mexican women suggests a potential genetic effect.

### 1121/W/Poster Board #779

**Genetic variation in genes interacting with BRCA1/2 and breast cancer risk in the Cypriot population.** *A. Hadjisavvas[1], M. Loizidou[1], T. Michael[1], E. Bashiardes[2], M. Cariolou[2], K. Kyriacou[1].* 1) Department of Electron Microscopy/Molecular Pathology, The Cyprus Institute of Neurology and Genetics, Nicosia, Cyprus; 2) Department of Cardiovascular Genetics and Laboratory of Forensic Genetics, The Cyprus Institute of Neurology and Genetics, Nicosia, Cyprus.

Inability to correctly repair DNA damage is known to play a role in the development of breast cancer. Single nucleotide polymorphisms (SNPs) of DNA repair genes have been identified which modify the DNA repair capacity, which in turn may affect the risk of developing breast cancer. To assess whether alterations in DNA repair genes contribute to breast cancer, we genotyped 62 SNPs in 29 genes in 1,109 Cypriot women with breast cancer and 1,177 age-matched healthy controls. Five SNPs were associated with breast cancer. SNPs rs13312840 and rs769416 in the NBS1 gene were associated with a decrease in breast cancer risk (OR TT v TC/CC = 0.58; 95% CI, 0.37 to 0.92; p = 0.019 and OR GG vs GT/TT = 0.23, 95% CI 0.06-0.85, p = 0.017 respectively). The variant allele of MRE11A rs556477 was also associated with a reduced risk of developing the disease (OR AA vs AG/GG = 0.76; 95% CI, 0.64 to 0.91; p = 0.0022). MUS81 rs545500 and PBOV1 rs6927706 SNPs were associated with an increased risk of developing breast cancer (OR GG vs GC/CC = 1.21, 95% CI, 1.02 to 1.45; p = 0.031; OR AA vs AG/GG = 1.53, 95% CI, 1.07 to 2.18; p = 0.019, respectively). Finally, haplotype-based tests identified significant associations between specific haplotypes in MRE11A and NBS1 genes and breast cancer risk. Further large-scale studies are needed to confirm these results.

### 1122/W/Poster Board #780

**Polymorphisms in genes involved in the progesterone metabolism modify postmenopausal breast cancer risk associated with menopausal hormone therapy.** *R. Hein[1], S. Abbas[1], D. Flesch-Janys[2], J. Chang-Claude[1].* 1) Cancer Epidemiology, German Cancer Research Center (DKFZ), Heidelberg, Baden-Würtemberg, Germany; 2) Department of Medical Biometrics and Epidemiology, University Medical Center Hamburg-Eppendorf, Hamburg, Germany.

Menopausal hormone therapy (HT) is associated with an increased breast cancer risk among postmenopausal women, with estrogen-progestagen combination therapy showing a higher risk increase than estrogen monotherapy. However, few studies focused on potential effect modification of HT associated breast cancer risk by genetic polymorphisms in the progesterone pathway. We assessed effect modification of HT use by five functional single nucleotide polymorphisms (SNP) in the progesterone metabolizing enzymes *AKR1C3* (rs7741), *AKR1C4* (rs3829125, rs17134592) and *SRD5A1* (rs248793, rs3736316). We used a two-centre population-based case-control study from Germany with 2,502 postmenopausal breast cancer patients and 4,833 matched controls. Multivariate conditional logistic regression stratified by centre and year of birth was used to calculate main and interaction effects of HT, i.e. estrogen-progestagen combination therapy and estrogen monotherapy, and SNPs with regard to postmenopausal breast cancer risk. No genetic main effects were observed. Breast cancer risk associated with duration of combination therapy was significantly modified by *SRD5A1_* rs3736316, showing a decreased risk in carriers of the minor allele (pinteraction=0.012). Odds ratios (OR) and 95% confidence intervals (CI) per 5-year-increment of combined estrogen-progestagen use were 1.19 (1.11-1.28), 1.12 (1.05-1.20) and 1.03 (0.89-1.20) in homozygous carriers of the major allele, heterozygous carriers and homozygous carriers of the minor allele, respectively. The risk associated with duration of use of estrogen monotherapy was significantly modified by *AKR1C3_*rs7741 (pinteraction=0.029) and two SNPs in *AKR1C4* (rs3829125: pinteraction=0.015, rs17134592: pinteraction=0.029). The ORs were significantly increased only in homozygous carriers of the *AKR1C3_*rs7741 minor allele (OR=1.29 (95% CI:1.09-1.53)) as well as in homozygous major allele carriers of the two SNPs in *AKR1C4* (rs3829125: OR=1.10 (95% CI:1.02-1.17); rs17134592: OR=1.09 (95% CI:1.02-1.17)). Postmenopausal breast cancer risk associated with combined estrogen-progestagen therapy is modified by SNPs in *SRD5A1* and with estrogen monotherapy by SNPs in the *AKR1C* genes. .As the *AKR1C* enzymes are not only involved in progesterone but also estrogen metabolism by converting estrone to estradiol a potential effect modification associated with estrogen monotherapy is feasible.

### 1123/W/Poster Board #781

**Genetic polymorphisms in MMP-1, MMP-2, MMP-3, MMP-8, MMP-9, MMP-14, RECK, TIMP-1, TIMP-3, and TIMP-4 and prostate cancer susceptibility and aggressiveness among African American men.** *W. Hernandez[1], S. Hooker[2], R. Kittles[2].* 1) Cancer Biology Program, Division of Biological Sciences, The University of Chicago, Chicago, IL; 2) Department of Medicine, Section of Genetic Medicine, The University of Chicago, Chicago, IL.

One-third of cancers among men each year will be prostate cancer. The risk and mortality of prostate cancer varies significantly across ethnic groups, in the United States; African American men have the highest rates. These population differences suggest genetics may play an important role. Matrix metalloproteinases (MMPs) modulate cell proliferation, apoptosis, and host immune surveillance. In addition, MMPs have the capacity to promote cell migration and tumor invasion by degradation of the extracellular matrix (ECM). Tissue inhibitors of metalloproteinases (TIMPs) and the reversion-inducing cysteine-rich protein with Kazal motifs (RECK) regulate MMP activity and have been shown to play important roles in several types of cancer initiation and aggressiveness. Here we examined the association between polymorphisms within several MMPs, TIMPs, and RECK and prostate cancer susceptibility and aggressiveness. A total of 88 SNPs were genotyped in 575 men, self-described as African American (controls=318, cases=257), using MALDI-TOF Mass spectrometry analysis (Sequenom Inc., San Diego, CA). We found several SNPs that were independently associated (although nominally) with Pca risk and aggressive disease in African Americans. However, epistasis analysis revealed the strongest associations to Pca risk and aggressiveness. The most dramatic decrease (50-fold, P=0.007) was observed among individuals possessing both minor alleles for rs12365082 and rs2285052 within MMP-8 and MMP-2 respectively. We found statistical evidence of gene-gene interactions likely due to the function of MMPs and their inhibitors, TIMPs and RECK, exhibiting epistasis as a mechanism of regulation and may help explain the inconsistency found in previous studies. Our findings demonstrate that, among African American men, polymorphisms in MMPs, TIMPs, and RECK can significantly influence the risk for prostate cancer and aggressive disease. In addition, our study suggests that an epistatic model should be used to study the effect of SNPs within these genes on prostate cancer risk.

**DNA REPAIR GENE POLYMORPHISMS IN CHILDHOOD ACUTE LYMPHOBLASTIC LEUKEMIA.** *E. Leal Ugarte[1], JP. Meza Espinoza[1], V. Peralta Leal[1], M. Reyes Segura[1], JG. Perales Hernández[1], HG. Torres Benavides[1], M. Gutiérrez Angulo[2], N. Macías Gómez[3], P. Barros Núñez[4], J. Durán González[5].* 1) Universidad Autónoma de Tamaulipas, Matamoros, Tamaulipas, Mexico; 2) Centro Universitario de los Altos, U de G, Tepatitlán, Jalisco; 3) Centro Universitario del Sur, U de G, Cd. Guzmán, Jalisco; 4) Centro de Investigación Biomédica de Occidente-IMSS,; 5) University of Texas at Brownsville, EE. UU.

Background. The acute lymphoblastic leukemia (ALL) is the most common cancer found among children, accounting for approximately 25-30% of all pediatric tumors. The etiology of the leukemia is not known; nevertheless, the genetic constitution, the damage to the DNA and the incorporation of viral genes are important agents in the origin of the disease. Polymorphisms of DNA repair genes can alter protein structure and may impair DNA repair capacity. Defects in repairing damaged DNA lead to genetic instability and carcinogenesis. This study was performed to evaluate the effect of two polymorphisms of XRCC1 gene on risk of childhood ALL. Materials and Methods. We genotyped polymorphisms of X-ray repair cross-complimenting group 1 (XRCC1) codon 194 (Arg to Trp) and 280 (Arg to His) in 120 children with ALL and 120 healthy controls in Mexican population using PCR-RFLP method. The allele and genotype frequencies of these polymorphisms were compared between cases and controls using Chi-square or Fisher's exact test. RESULTS. The allele frequencies of polymorphism Arg194Trp were Arg-0.86%, Trp 0.14% and Arg-0.81%, Trp 0.19%, for the polymorphism Arg280His were Arg-0.87%, His 0.13% and Arg-0.86%, His-0.14% in controls and patients respectively, the genotype frequencies of polymorphism Arg194Trp were Arg/Arg-0.67%, Arg/Trp-0.28%, Trp/Trp-0.05% and Arg/Arg-0.72% Arg/Trp-0.25%, Trp/Trp-0.03%, for the polymorphism Arg280His were Arg/Arg-0.72%, Arg/His-0.26%, His/His-0.02% and Arg/Arg-0.74%, Arg/His-0.25%, His/His-0.01% in patients and controls respectively. The allele frequencies were consistent with Hardy-Weinberg equilibrium Discussion. Our study shows that Arg194Trp polymorphism has not association with the development of ALL. Although the allelic frequency of this polymorphism was higher in patients than in controls, no statistically significant difference was found. Even several studies have found that the presence of the polymorphism 194Trp has a protective effect against ALL and other cancers; however, in our study we did not find such effect. The genotypic and allelic frequencies of Arg280His polymorphism were similar in controls and in patients. Our findings are consistent with similar studies reported in other populations. In conclusion our study showed no association of polymorphisms 194Trp and 280His in the development of childhood ALL in the Mexican population.

## 1125/W/Poster Board #783

**Does high calcium intake cause prostate cancer? Advances using a Mendelian randomization approach.** *S.J. Lewis[1], L. Chen[1], L. Zuccolo[1], J.A. Lane[1], J. Donovan[1], A. Cox[2], F. Hamdy[3], D. Neal[4], G. Davey Smith[1, 5].* 1) Department of Social Medicine, University of Bristol, Bristol, United Kingdom; 2) Institute for Cancer Studies, University of Sheffield, Sheffield, UK; 3) Nuffield Department of Surgery, University of Oxford, UK; 4) Department of Oncology, University of Cambridge, Cambridge, UK; 5) MRC Centre for Causal Analyses in Translational Epidemiology, University of Bristol, Bristol, UK.

The recent World Cancer Research Fund/ American Institute for Cancer Research review concluded that diets high in calcium probably increased the risk of prostate cancer, but there was no convincing evidence for any specific food items or nutrients investigated. This uncertainty surrounding calcium and prostate cancer probably stems from measurement error and confounding, which are inherent in all observational studies of diet. Mendelian randomization provides an alternative method, which avoids confounding by using genetic variants as proxies for environmental and lifestyle exposures. Genetic variants exist in the calcium sensing receptor (CASR), which are associated with circulating serum ionized calcium concentration; similarly, TRPV5 is a key protein that regulates $Ca2+$ reabsorption, and variants in this gene have been shown to be associated with calcium influx. We investigated whether genetic variants associated with calcium levels were also risk factors for screen-detected prostate cancer by comparing genotype frequencies of 1600 prostate cancer cases to those of over 3000 controls. We found that the CASR rs1801725 GT and TT genotypes, which have been are associated with a small increase in serum ionized calcium concentration relative to the GG genotype were associated with an increased cancer risk OR =1.17 (95% CI = 1.01-1.35). Similarly a variant (rs2110922) in the SCL8A1 gene, which is involved in sodium/calcium exchange, was associated with prostate cancer risk in this study, OR for TG versus GG = 1.12(95% CI= 0.98-1.27), OR for TT versus GG = 1.20 (95%CI=0.99-1.45), p-value for trend =0.04. No strong evidence was found for associations between variants in TRPV5 and prostate cancer risk, however these variants were rare in our study and consequently we had low power to detect associations. In conclusion, we found some evidence that a variant in the CASR gene, which is associated with greater circulating calcium levels, was associated with an increase in prostate cancer risk, and that a variant in a sodium/calcium exchange gene, of unknown function, was associated with prostate cancer risk. Our findings add support to the hypothesis that calcium is implicated in prostate cancer pathogenesis but they require replication in other studies to confirm that they are not false positives. However, as our results are unlikely to have arisen due to confounding, they are an advance on the observational data that have been published to date.

## 1126/W/Poster Board #784

**Matrix metallopreoteinase-13 gene polymorphism in colorectal cancer.** *J.M. Moreno-Ortiz[1,5], M. Gutierrez-Angulo[1,2], M. Partida-Perez[1,5], J. Peregrina-Sandoval[1,3,5], A.S. Suarez-Villanueva[1], M.A. Cardenas-Meza[4], M. Centeno-Flores[4], V.M. Maciel-Gutierrez[4], M.L. Ayala-Madrigal[1].* 1) Instituto de Genetica Humana, Biologia Molecular y Genomica, CUCS, Universidad de Guadalajara, Guadalajara, Jalisco, Mexico; 2) CUALTOS, Universidad de Guadalajara, Tepatitlan, Jalisco, Mexico; 3) Laboratorio de Inmunobiologia, CUCBA, Universidad de Guadalajara, Zapopan, Jalisco, Mexico; 4) Hospital Civil de Guadalajara Juan I. Menchaca, Guadalajara Jalisco, Mexico; 5) Doctorado en Genetica Humana, CUCS, Universidad de Guadalajara, Guadalajara, Jalisco, Mexico.

Colorectal cancer (CRC) is characterized by enhanced expression and activity of several metalloproteinases (MMPs) including MMP13 (collagenase-3). This metalloproteinase has central roles in modulating extracellular matrix degradation through its direct matrix degrading capability as well as having a key involvement in the activation of other MMPs: MMP2, -3 and -9. MMP13 also has an important role in tumor invasion and metastasis. We tested the correlation of a functional MMP13 promoter polymorphism, -A77G, with suceptibility to CRC in a population of West Mexico. MMP13-A77G was genotyped by polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP) analysis in 47 CRC patients and 125 healthy controls. The genotype and allelotype distributions of MMP13-A77G in CRC patients were not significantly different from those in healthy controls (P>0.05), and showed the A/A, A/G, G/G genotype frequencies: 61.7%, 34%, 4.3% and 49.6%, 37.6%, 12.8% respectively. Odds ratios and P values using logistic regression were calculated to test for association between genotype, allelotype and disease status. The analysis showed no association, even when stratified for gender, however, the A/A genotype frequency in CRC patients tended to be higher than in the controls. These results seem to exclude an important role of the MMP13-A77G in Mexican CRC patients susceptibility, but further studies on a larger sample are warranted to confirm these findings.

## 1127/W/Poster Board #785

**Interactions between cigarette smoking and selected candidate gene polymorphisms in risk for colorectal cancer: a case-only analysis.** *M. Pande[1], CI. Amos[2], DR. Osterwisch[1], ML. Frazier[2].* 1) Epidemiology, The University of Texas M. D. Anderson Cancer Center, Houston, TX; 2) Epidemiology, The University of Texas M. D. Anderson Cancer Center, Houston, TX and Program in Human and Molecular Genetics, The University of Texas Graduate School of Biomedical Sciences at Houston, Houston, TX.

**Objective**: The metabolism of xenobiotics is complex and involves multiple steps and multiple enzymes. Genetic variation in the genes encoding the enzymes as well as the level of exposure to the substrates of these enzymes can alter metabolism and clearance of potential carcinogens and thus may modify cancer susceptibility. This study examined the interaction between cigarette smoking and two non-synonymous metabolic gene single nucleotide polymorphisms (SNPs) *CYP1A1* p.Ile462Val (rs1048943) and *EPHX1* p.Tyr113His (rs1051740) and explored gene-gene interaction between the two SNPs in a series of colorectal cancer cases. The SNPs were selected based on functional significance and suggestion of gene-gene interaction in a prior study. **Methods**: Unconditional logistic regression was used to examine the association between smoking and each of the SNPs and interaction between the two SNPs, in a series of 786 cases of colorectal cancer, using a case only design. **Results**: In the case only analysis, there was significant multiplicative interaction for colorectal cancer risk between smoking and *EPHX1* Y113H (Case only odds ratio [COR] = 1.37, 95% confidence interval [CI] = 1.03 - 1.81, P = 0.03), particularly among heavy smokers with a history of >20 pack years of smoking (COR = 1.52, 95% CI = 1.07 - 2.16, P = 0.02). In addition, there was gene-gene interaction between *EPHX1* Y113H and *CYP1A1* I462V (COR = 1.61, 95% CI = 1.02 - 2.55, P = 0.04). **Conclusion**: Smokers with any variant allele of *EPHX1* were at increased risk for colorectal cancer. Similarly, presence of any variant allele of *CYP1A1* and *EPHX1* together increased susceptibility to colorectal cancer. Genetic and environmental factors may interact to increase colorectal cancer risk; thus the study of gene-environment and gene-gene interactions can help to identify high-risk subgroups.

## 1128/W/Poster Board #786

**Association of OAS1 variants and prostate cancer.** *S.J. Plummer[1], I. Cheng[2], J.S. Witte[3], G. Casey[1].* 1) Dept of Preventive Medicine, USC, Los Angeles, CA; 2) Epidemiology Program, Cancer Research Center of Hawai'i, Honolulu, Hawai'i; 3) Depts of Epidemiology & Biostatistics, and Urology, Institute for Human Genetics, UCSF, San Francisco, CA.

**Background:** The interferon induced antiviral 2-5A pathway has been implicated in the pathogenesis of prostate cancer. Linkage, association, and functional studies implicate *RNASEL*, encoding the terminal enzyme of the 2-5A pathway, as a strong candidate for the Hereditary Prostate Cancer 1 (*HPC1*) gene. We previously reported an association between the *RNASEL* R462Q variant and prostate cancer in a family-based study. The *RNASEL* R462Q variant gene also showed reduced enzymatic activity and deficiency in apoptotic response. However, published results from others regarding the role of *RNASEL* R462Q in prostate cancer risk have been equivocal. One possible explanation for these results is that variants in other genes of the 2-5A pathway might impact the risk of disease. Dimerization and activation of RNase L occurs following binding of 2-5A oligomers produced by the OAS genes in response to viral dsRNA. **Objective:** To further define the role of the 2-5A pathway in prostate cancer, we evaluated the relationship between prostate cancer and genetic variants in *OAS1*--alone and in combination with the *RNASEL* R462Q variant. **Methods:** We studied 1012 men (506 cases of advanced prostate cancer and 506 age, ethnicity, institution-matched controls) that were recruited from medical centers in Cleveland, Ohio between 2001 and 2004. Advanced disease was defined as Gleason ≥ 7, tumor stage ≥ T2c, or PSA ≥10 ng/mL at diagnosis. Five single-nucleotide polymorphisms (SNPs) in *OAS1* and the *RNASEL* R462Q variant were genotyped by the TAQMAN assay and evaluated for their relationship with more advanced prostate cancer. **Results:** Four of the five *OAS1* variants were statistically significantly associated with prostate cancer risk in this population. The strongest association was found with a missense variant, G162S (rs3741981) which significantly reduced the risk of prostate cancer (Odds Ratio CT vs TT=0.67; 95% CI: 0.49-0.90; p=0.009). There was no association with the *RNASEL* R462Q variant in this population and no significant interactions were observed between any of the *OAS1* variants and *RNASEL* R462Q. **Conclusions:** These results indicate that multiple defects in the 2-5A pathway may be involved in the risk of advanced prostate cancer, although further work is needed to determine the relationship between variants in the different genes in this pathway.

## 1129/W/Poster Board #787

**Linking of Utah genealogies to outpatient colonoscopy records defines familial aggregation of colorectal polyps and cancer.**. *T.M. Tuohy[1], R. Pimentel[1], T. Belnap[4], K. Rowe[4], R.W. Burt[1,2], G. Mineau[1,3].* 1) High Risk Cancers Clinic, Huntsman Cancer Institute; 2) Departments of Medicine and; 3) Oncological Sciences, Huntsman Cancer Institute, University of Utah, Salt Lake City, UT; 4) Department of Oncology, Intermountain Healthcare, Salt Lake City, UT, USA.

**Background:**The Utah Population Database (UPDB) is a shared research resource of the University of Utah. It combines Utah genealogies dating back to the 1700s with data from statewide resources, including a cancer registry, hospital claims, as well as birth and death certificates. A project completed in 2008 linked the UPDB to patient demographic records from Intermountain Healthcare which is a non-profit medical system that serves Utah and Southeast Idaho, providing care to approximately 60% of the resident population. The availability of large numbers of linked, electronically searchable medical records offers unique opportunities for improved clinical and outcomes research. We address the question of the extent to which colonic adenomas and hyperplastic polyps co-segregate with colon cancer risk in non-syndromic families. **Methods:** A pilot project was initiated to use this new linked research infrastructure by ascertaining colorectal polyps from Intermountain clinical data. Deidentified medical information was merged with UPDB family structure and statewide cancer data. These combined data sets provided family structure along with cancer histories to investigate familial aggregation. Cox Regression Analysis was used to assess the relative risk of (a) polyp development and (b) colon cancer for first-, second- and third-degree relatives, by polyp type. Custom kinship analysis tools allowed determination of the excess polyp and cancer risk observed in the kindreds of each case, and differentiated high-risk from population-risk families. **Results:** The queries captured data from over 70,000 positive outpatient colonoscopy procedure and pathology reports from over 58,000 deidentified individuals examined between 1995 and 2009. The queries collected data on age, gender, polyp type, size, pathology and were verified by manual review of a randomly selected sample of 200 cases. We identified high-risk kindreds dating to founders born in the late 1700s, with high relative risks for polyp/cancer. Analysis of discrepancies between excess polyp and excess cancer risks within families allowed us to address the possibility that some cancers may arise in the absence of significant excess polyp risk. **Conclusion:** The combination of a large, electronically searchable medical database (and associated tissue specimens) with a linked genealogical resource offers a powerful platform for the development of hypothesis-driven research.

## 1130/W/Poster Board #788

**Family History-Based Risk of BRCA Mutations in the California Population.** *N. Whitehead[1], Y. Li[1], L. Squires[2].* 1) Statistics & Epidemiology, RTI International, Atlanta, GA; 2) Health, Social and Economics Research, RTI International, Rockville, MD.

In 2005, the US Preventive Services Task Force recommended that women at a high risk of deleterious BRCA mutations, based on family history, be referred by primary care providers for genetic counseling and evaluation for testing. It is estimated that 2% of U.S. women have a family history necessitating referral for genetic counseling. The estimated combined frequency of BRCA mutations in the U.S. is approximately 0.25%. We assessed the proportion of women in California at high risk of carrying a BRCA mutation based on family history. We analyzed data from the 2005 California Health Interview Survey CHIS), a population-based telephone survey that collects state and local data on a range of health topics. The 2005 survey included a detailed cancer family history module. We estimated the probability the respondent carried a BRCA mutation using BRCAPRO. We imputed the current age of family members and their age at cancer diagnosis. We estimated the current age as a function of the respondent's age. We estimated the age of cancer diagnosis of family members who had cancer before age 50 years as a random variable from a uniform distribution with a lower limit of the estimated current age and an upper limit of 50 years. The minimum ages for breast cancer and ovarian cancer onset were set at 25 and 35 years, respectively. The minimum estimated probability was 0.0000014% and the maximum was 94%. The 98.5 percentile for the population was 0.63%. Therefore, <1.5% of the population had an estimated probability of BRCA mutations > 1.0%; < 0.5% had a an estimated probability of BRCA mutations > 10.0%. The CHIS data had some other limitations. The respondent's history of ovarian cancer was not available. No information was available on BRCA mutation testing, so the predictive value of the risk estimate could not be determined. CHIS asks respondents about breast cancer twice -during the regular questionnaire and in the family history module, but only asks for age of diagnosis in the family history module. Therefore, we had to estimate the age at diagnosis for women who reported breast cancer only in the regular questionnaire. The methods we used to estimate the age of cancer diagnosis are biased towards underestimating the age of cancer diagnosis, since cancer incidence increases with age. Since younger age at diagnosis is associated with an increased risk of having a BRCA mutation, we may have overestimated the probability of carrying a BRCA mutation.

## 1131/W/Poster Board #789

**Joint Effects of Germ-Line p53 Mutation, MDM2 SNP309, and Gender on Cancer Risk in Family Studies of Li-Fraumeni Syndrome.** *C.C. Wu[1], R. Krahe[2], G. Lozano[2], B. Zhang[2], C.D. Wilson[2], E.J. Jo[1], S. Shete[1], C.I. Amos[1], L.C. Strong[2].* 1) Dept Epidemiology, Univ Texas MD Anderson CA Ctr, Houston, TX; 2) Dept Genetics, Univ Texas MD Anderson CA Ctr, Houston, TX.

Li-Fraumeni syndrome (LFS) is a rare familial cancer syndrome characterized by a high frequency of early-onset and diverse tumor types and an increased frequency of multiple primary tumors. Germ-line p53 mutations have been identified in most LFS families. A high-frequent genetic variant of single-nucleotide polymorphism (SNP) 309 in the MDM2 gene, a direct negative regulator of p53, was recently shown to be a modifier of cancer risk in p53 mutation carriers. Several independent reports in case-control studies showed a significantly earlier age of cancer onset for the SNP309 G-allele carriers than homozygous T-allele carriers by 7-15 years on average. However, mathematical models accounting for p53 mutation, SNP309, and gender have not been explored in family studies. In this study, we used an extension of the usual joint segregation and linkage analysis models for censored age-of-onset traits, which are semi-parametric survival analysis methods based on Cox proportional hazards models. The methods were designed to evaluate the effects of these factors on cancer risk jointly and allow testing of significance for interactions between them. We analyzed the cancer incidence in 19 extended pedigrees with multiple germ-line p53 mutations ascertained through clinical LFS phenotype and included all invasive cancers as a single combined phenotype. The final dataset consisted of 463 individuals and included 127 p53 mutation carriers. The analyses showed that G-allele carriers had an overall 1.6-fold higher relative risk (RR) of developing cancer than non-carriers. Men with p53 mutations had a 18.5-fold higher RR of developing cancer than non-carriers; women with p53 mutations had a 43.8-fold higher RR than non-carriers. Men with both p53 mutations and G-alleles had a 29.7-fold higher RR of developing cancer than those with neither, and women with p53 mutations and G-alleles had a 70.1-fold higher RR than those with neither and a 2.4-fold higher RR than men with p53 mutations and G-alleles. Our investigation revealed that p53 mutation, SNP309 G-allele, and the interaction between p53 mutations and sex had significant effects on cancer risk. In contrast with the outcomes in case-control studies that SNP309 G-allele interacts with p53 mutations, our family study showed that SNP309 was significant only when both p53 and sex were incorporated to the model. This is further evidenced by the correlation (=0.20) between SNP309 and p53*sex in our most parsimonious model.

## 1132/W/Poster Board #790

**Relationship between germ-line copy number variations and sun exposure/host factors in melanoma-prone families without known mutations.** *R. Yang, M.A. Tucker, A.M. Goldstein.* Dept DCEG, NCI, Bethesda, MD.

Genomic copy number variations (CNVs) have recently been recognized as significant sources of genetic variation that may contribute to disease susceptibility. We previously observed that number of copy number gains and number of genes located within CNVs were significantly higher among cutaneous malignant melanoma (CMM) cases compared to unaffected individuals in melanoma-prone families without known mutations. The goal of this study was to examine the association between germline CNVs and major risk factors for melanoma including sun exposure, pigmentation, nevi, and MC1R variables in these melanoma-prone families. We conducted a genome-wide search for CNVs using the Nimblegen 385K whole-genome array-CGH. We analyzed blood-derived genomic DNA from 78 individuals (61 CMM cases and 17 spouses) selected from 30 melanoma-prone families without known mutations. We used the Nexus Copy Number built-in Rank Segmentation algorithm to identify significant CNVs (significance threshold= 0.000001; minimal number of probes per segment=5; log2 ratio=0.2 for low gain, 0.5 for high gain, -0.3 for loss, -0.7 for homozygous loss). We used a T-test and linear regression to test the associations between CNV variables and melanoma risk factors (dysplastic nevi, number of nevi, hair color, eye color, skin color, freckles, solar injury, response to sun exposure, and MC1R variants). We found that, compared to individuals with no or few freckles (mean number of copy number gains/individual, 3.2±2.9), individuals with freckles tended to have more copy number gains (6.2±3.9, P=0.07, moderate freckles; 8.1±5.7, P=0.002, many freckles). Individuals with solar injury also had increased number of copy number gains (4.3±3.7, absent/mild; 6.4±5.2, P=0.11, moderate; 7.8±5.2, P=0.03, severe). We did not find significant associations between any CNVs and the other risk factors evaluated. These results suggest a dose-dependent relationship between freckles and solar injury and germline copy number gains implying that freckles and solar injury may increase melanoma risk through altered genomic rearrangement. We will further identify the unique CNVs that are associated with these exposures and search for candidate genes and pathways that are influenced by these CNVs.

## 1133/W/Poster Board #791

**Building a biorepository for health disparities research using bioinformatics tools.** *G.M. Dunston[1], L. Ricks-Santi[2,3], T. Mason[2], M. Abbas[2], F. Kan[4], M. Faruque[1].* 1) Department of Microbiology Howard University, Washington, DC; 2) National Human Genome Center at Howard University, Washington DC; 3) Howard University Cancer Center, Washington DC; 4) Data Unlimited International, Inc., Rockville, MD.

Background: Biorepositories with linkage to clinical and epidemiological data are valuable resources for facilitating biomedical research. The use of an interactive computer-based laboratory information management system (LIMS) that tracks all aspects of biospecimen collection, processing, and distribution is essential to the development of a biorepository or biobank. For this project, the goals of the National Human Genome Center (NHGC) at Howard University (HU) were: 1) to implement biospecimen collection protocols and long-term storage solutions, and 2) establish a biorepository consistent with the National Cancer Institute (NCI) Best Practices for Biospecimen Resources, and in compliance with the Health Insurance Portability and Accountability Act (HIPAA), Health and Human Services (HHS), and Food and Drug Administration (FDA) regulations. Here we present the experience and approach of the NHGC in cataloguing archival biospecimens and establishing a biorepository for biomedical research that will interface with a high security, web-based study management system for clinical translational research. Methods: First, existing archived biospecimens and paper data were assessed and documented. Archival materials, such as DNA and tissue samples, were inventoried, catalogued, and recorded in a database. Then, a storage organizational strategy was developed and established using a computerized inventory system that tracks the specific position and location of all stored biospecimens. The precise organization of biospecimens encompassed the storage definitions of divisions and sub-divisions, such as location, room, equipment, shelf, rack, box, tube, column, row, and position. Results: Bioinformatics tools and technologies were used to build a biorepository populated largely with specimens, such as DNA and tissue, from African Americans enrolled in cancer (i.e., prostate, breast, and colon), diabetes, asthma, and other health disparity studies at Howard University. Conclusions: The NHGC quality-controlled biorepository at HU is an invaluable resource for molecular epidemiology and clinical translational research focusing on populations of African Descent. Well-documented, secure biospecimens are the direct link of high quality molecular data to biomedical informatics resources. The NHGC biorepository is aimed at expanding and facilitating collaborative research with the global scientific community in achieving personalized medicine.

## 1134/W/Poster Board #792

**Variations in Helicobacter pylori Cytotoxin-Associated Genes are possibly associated with neoplastic progression in gastric cancer.** *C. Rizzato[1], L.J. van Doorne[2], M. Plummer[3], N. Muñoz[3], F. Canzian[1], I. Kato[4].* 1) German Cancer Research Center (DKFZ), Heidelberg, Germany; 2) DDL Diagnostic Laboratory, Fonteijnenburghlaan, Voorburg, The Netherlands; 3) International Agency for Research on Cancer (IARC), Lyon, France; 4) Wayne State University, Karmanos Cancer Institute, Detroit, MI, USA.

Helicobacter pylori (Hp) infection is associated with the development of gastric cancer. Hp is a bacterium that colonizes the human stomach and can establish a long-term infection of the gastric mucosa. Hp infection affects over 50% of the world's population, with a prevalence ranging from 20% in developed countries to over 90% in developing countries. Persistent Hp infection often induces gastritis and is associated with the development of peptic ulcer disease, atrophic gastritis, and gastric adenocarcinoma. Virulent Hp isolates harbor the cag (cytotoxin-associated genes) pathogenicity island (PAI), a 40 kb stretch of DNA that encodes components of a type IV secretion system (T4SS). This T4SS forms a pilus for the injection of virulence factors into host target cells, such as the CagA oncoprotein. In a previous study a very strong association between current infection with cagA-positive Hp strains and the severity of gastric precancerous lesions has been showed. We analyzed the genetic variability in CagA and other selected genes of the Hp PAI, using DNA extracted from frozen gastric biopsies of the participants in a chemoprevention trial in Tachira State, Venezuela, an area with high prevalence of Hp infection and gastric cancer. Because of the high genetic variability of the Hp genome, this requires a thorough optimization of the experimental conditions. The first analysis confirms the presence of high variability in the Hp PAI genes, which warrants further investigations for the risk of neoplastic progression within CagA positive patients.

## 1135/W/Poster Board #793

**Lifetime environmental exposure to tobacco smoke, genetic susceptibility, and risk of lung cancer in non-smoking Taiwanese.** *C. Chang[1], C. Hsiung[1], G. Chang[2], Y. Tsai[3], Y. Chen[4], M. Huang[5], W. Su[6], W. Hsieh[1], P. Yang[7], C. Chen[8,9], C. Hsiao[1].* 1) Division of Biostatistics and Bioinformatics, Institute of Population Health Sciences, National Health Research Institutes, Zhunan, Taiwan; 2) Division of Chest Medicine, Department of Internal Medicine, Taichung Veterans General Hospital, Taichung, Taiwan; 3) Department of Pulmonary and Critical Care, Chang Gung Memorial Hospital, Taipei, Taiwan; 4) Chest Department, Taipei Veterans General Hospital, Taipei, Taiwan; 5) Department of Internal Medicine, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan; 6) Department of Internal Medicine, National Cheng Kung University Hospital, Tainan, Taiwan; 7) Department of Internal Medicine, National Taiwan University Hospital, Taipei, Taiwan; 8) Genomics Research Center, Academia Sinica, Taipei, Taiwan; 9) Graduate Institute of Epidemiology, National Taiwan University, Taipei, Taiwan.

Background: Environmental tobacco smoke (ETS) has been suggested as a risk factor of lung cancer in nonsmokers. The ETS exposure mainly comes from three sources: childhood and adulthood household passive smoking, and adult work-place passive smoking. Although ETS and genetic factors may play important roles on lung cancer risk, the interactive effect between ETS and genetic factors on lung cancer risk needs to be explored. Objects: A large-scale case-control study was conducted to investigate lung cancer risk in relation to childhood and adulthood ETS exposures in Taiwanese nonsmokers. The interactive effect between genetic factors and ETS on lung cancer risk is also explored. Methods: A total of 1,785 non-smoking lung cancer cases and 1,942 non-smoking healthy controls were enrolled from six medical centers in Taiwan between 2002 and 2009. Genetic polymorphisms of hOGG1 Ser326Cys were determined by the MassARRAY system. ETS history was obtained through personal interview based on a structured questionnaire. Multivariate logistic regression analyses were performed to estimate odds ratios (OR) and 95% confidence intervals (CI) for the risk of lung cancer in exposed vs. non-exposed ETS groups. Results: Childhood ETS had non-significant effects on the risk of lung cancer (OR= 1.2, 95% CI= 0.7-2.0) after controlling for adulthood ETS exposure (including adulthood household and work-place). Adulthood household and work-place had independent risk effects on lung cancer (adulthood household: OR= 1.2, 95% CI= 0.9-1.5; work-place: OR=2.8, 95% CI= 2.0-3.8). On the other hand, considering the interaction between hOGG1 gene and ETS for the risk of developing lung cancer, comparing with the Ser/Ser genotype, the Cys/Cys genotype had higher risk in ETS exposure group (OR=2.0, 95% CI= 1.1-3.7), but not in the non-ETS group (OR=1.3, 95% CI= 0.6-2.8). Conclusions: It was concluded that the adulthood ETS has prominent effects on the risk of lung cancer, especially work-place passive smoking. In addition, hOGG1 Cys/Cys genotype has modifying effect on lung cancer risk by ETS exposure status among non-smokers.

## 1136/W/Poster Board #794

**Evaluation of 9p24 risk locus and colorectal adenoma and cancer: a pooled analysis of four studies.** *J.D. Kocarnik[1], C.M. Hutter[1], M.L. Slattery[2], S.I. Berndt[3], L. Hsu[1], D. Duggan[4], J. Muehling[4], B.J. Caan[5], S.A.A. Beresford[1], A. Rajkovic[6], G.E. Sarto[7], J.R. Marshall[8], N. Hammad[9], R. Wallace[10], K. Makar[1], R. Prentice[1], J. Potter[1], R.B. Hayes[11], U. Peters[1].* 1) Division of Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA; 2) Department of Internal Medicine, University of Utah Health Sciences Center, Salt Lake City, UT; 3) Division of Cancer Epidemiology and Genetics, NCI, Bethesda, MD; 4) Translational Genomics Research Institute, Phoenix, AZ; 5) Division of Research, Kaiser Permanente Medical Care Program, Oakland, CA; 6) Department of Obstetrics & Gynecology, Baylor College of Medicine, Houston, TX; 7) Department of Obstetrics & Gynecology, University of Wisconsin, Madison, WI; 8) Roswell Park Cancer Institute, Buffalo, NY; 9) Barbara Ann Karmanos Cancer Institute, Wayne State University, Detroit, MI; 10) Departments of Epidemiology and Internal Medicine, University of Iowa College of Public Health, Iowa City, IA; 11) New York University School of Medicine, New York City, NY.

An initial genome-wide association study identified a novel susceptibility locus for colorectal cancer on chromosome 9p24 (SNP rs719725). However, replication in different study populations led to inconclusive findings. To further evaluate this relationship, we utilized existing data from four study populations that also had detailed data on environmental factors, to explore gene-environment interactions as potential sources of heterogeneity that could explain the inconsistent results. METHODS: To investigate the full spectrum of colorectal cancer we included both colorectal adenoma and colorectal cancer from four studies (total 3891 cases, 4490 matched controls): the Women's Health Initiative (WHI; 656 colorectal cancer cases, 664 matched controls); the Diet, Activity and Lifestyle Study (DALS; 1461 colon cancer cases, 1813 controls); the Prostate, Lung, Colorectal and Ovarian Cancer Screening Trial (PLCO, 1257 adenoma cases, 1385 matched controls); and a Minnesota population-based case-control study (MinnCCS; 517 adenoma cases, 628 controls). Data were restricted to Caucasians only. We used logistic regression to evaluate the association, with minor allele C as the reference group as reported previously in the literature. In all four studies, the MAF was ~37% and controls were in HWE ($p > 0.26$). RESULTS: In the WHI data rs719725 was statistically significantly associated with risk of colorectal cancer, with OR 1.19 (95% CI 1.01-1.40; p-trend 0.04) per A allele. Similarly, the PLCO data provided a marginally significant finding in the same direction for adenoma risk: OR 1.11 (95% CI 0.99-1.25; p-trend 0.07) per A allele. The other two studies provided OR estimates at or near 1.00. We observed no interactions between rs719725 and several key risk factors for colorectal cancer (age, sex, family history, smoking, NSAIDs, alcohol, BMI, physical activity, folate, calcium, red meat, or HRT use). A pooled analysis of our and previous studies (n = 16) gave an OR of 1.07 (95% CI 1.03-1.11) per A allele. CONCLUSIONS: This study can neither prove nor rule out the existence of a risk locus on chromosome 9p24 that is tagged by SNP rs719725. Along with previous publications, these results suggest that the major allele A may be positively associated with colorectal tumors in some populations. Further replication in larger studies seems to be warranted, perhaps followed by studies to identify the disease-related polymorphism being tagged and its possible function.

## 1137/W/Poster Board #795

**JUVENILE POLYPOSIS SYNDROME, HISTOPATOLOGICAL DIAGNOSIS AND CLINICAL FEATURES. A CASE REPORT AT THE HOSPITAL PARA EL NINO POBLANO. MEXICO.** *R. Vargas-Gonzalez[1], J.M. Aparicio-Rodriguez[2,5], L. de la Torre-Mondragon[3], G. Victoria-Morales[3], B.A. Llamas-Guillen[4]*. 1) Pathology; 2) Medical Genetics; 3) Surgery; 4) Pediatrics, Hospital para el Nino Poblano, Puebla, Puebla, Mexico; 5) Estomatology, Benemerita Universidad Autonoma de Puebla, México.

Key words: BMPR1A, EGN, SMAD4, genetics, Juvenile Polyposis Syndrome. ABSTRACT. Juvenile Polyposis Syndrome(JPS) is an uncommon hamartomatous disorder with significant gastrointestinal malignant interaction. Mutations in EGN, SMAD4 and BMPR1A genes, implicated in the Transforming Growth Factor pathway. This study confirms the genetics and clinicopathological features of the JPS. INTRODUCTION. JPS is a clinically and genetically heterogeneous condition, a hamartomatous disorder. It affects approximately one in 150 000 new born children. Both sporadic and familial cases with autosomal dominant inheritance are found. To date, there are no clinical,pathological, immunohistochemical or molecular markers that distinguish sporadic from the syndrome associated Juvenile Polyposis. The JPS is regarded as distinct from solitary juvenile polyps which develop less than 5% of children and adolescents, with no malignant potential. HISTOPATHOLOGY. The Patient in this study was diagnosed as JPS with more than 100 polyps distributed throughout the colon, stomach and small intestine. The polyps range from a few millimeters to a few centimeters in size. Macroscopically, a juvenile polyp has a smooth, spherical red head on a narrow stalk. Microscopic changes are mucin-filled cystic dilatation of the epithelial tubules embedded in abundant lamina propria. The tubules are lined by normal columnar epithelium. The cellular infiltrate of the lamina propria includes myofibroblasts, fibroblasts, and macrophages. Muscularis mucosa is not included within the stroma. GENETICS. JPS is an autosomal dominant condition as mentioned before with incomplete penetrance. Research in JPS has identified three specific gene changes causing disruption of the transforming growth factor (TGF b) signal transduction pathway: EGN, SMAD4 and BMPR1A. CONCLUSION. JPS is characterized by anaemia, rectal bleeding, and particularly in the pediatric population disastrous complications of bowel infarction due to intussusception, as the patient in this study. It also has significant gastrointestinal malignancy potential. The new genetic knowledge regarding EGN, SMAD4 and BMPR1A genes allows for genotypic diagnosis in about 50% of patients with JPS. An early diagnosis is important for an early multidisciplinary medical and surgical treatment to offer the patient a better quality of life.

## 1138/W/Poster Board #796

**N-myc downstream regulated gene 1 (NDRG1) is fused to ERG in prostate cancer.** *M.A. Rubin[1], D.S. Rickman[1], A. Sboner[4], P. Perner[1], C.J. LaFargue[1], Y. Pan[1], M.A. Svensson[1], B.J. Moss[1], N. Kitabayashi[1], A. de la Taille8[6,7], R. Kuefer[5], A.K. Tewari[2], F. Demichelis[1,3], M.S. Chee[8], M.B. Gerstein[4,9,10], D. Pflueger[1,5]*. 1) Departments of Pathology & Laboratory Medicine, Weill Cornell Medical College, New York, NY; 2) Department of Urology Weill Cornell Medical College, New York, NY; 3) Institute for Computational Biomedicine, Weill Cornell Medical College, New York, NY; 4) Department of Molecular Biophysics and Biochemistry, Yale University, New Haven, CT; 5) Department of Urology, University Hospital Ulm, Ulm, Germany; 6) INSERM, Unité 955, Créteil, France; 7) Department of Urology, CHU Mondor, Créteil, France; 8) Prognosys Biosciences Inc., La Jolla, CA; 9) Program in Computational Biology and Bioinformatics, Yale University, New Haven, CT; 10) Department of Computer Science, Yale University, New Haven, CT.

A step towards the molecular classification of prostate cancer was the discovery of recurrent ETS rearrangements, most commonly fusing the androgen-regulated TMPRSS2 promoter to ERG. The TMPRSS2-ERG fusion is observed in around 90% of tumors that over-express the oncogene ERG. The goal of the current study was to complete the characterization of these ERG over-expressing prostate cancers. Using fluorescent in-situ hybridization (FISH) and RT-PCR assays, we screened 101 prostate cancers, identifying 34 (34%) cases with the TMPRSS2-ERG fusion. Seven cases demonstrated ERG rearrangement by FISH without the presence of TMPRSS2-ERG fusion mRNA transcripts. Screening for known 5' partners, we determined that 3 cases harbored the SLC45A3-ERG fusion. To discover novel 5' partners in these ERG over-expressing and ERG rearranged cases, we used paired-end RNA-sequencing (RNA-seq). We first confirmed the utility of this approach by identifying the TMPRSS2-ERG fusion in a known positive prostate cancer case and then discovered a novel fusion involving the androgen-inducible tumor suppressor, NDRG1 (N-myc downstream regulated gene 1) and ERG in two cases. Unlike TMPRSS2-ERG and SCL45A3-ERG fusions, the NDRG1-ERG fusion is predicted to encode a chimeric protein. Like TMPRSS2, SCL45A3 and NDRG1 are inducible by androgen but also by estrogen. This study demonstrates that the vast majority of ERG over-expressing prostate cancers harbor hormonally regulated TMPRSS2-ERG, SLC45A3-ERG, or NDRG1-ERG fusions. Broader implications of this study support the use of RNA-seq to discover novel cancer translocations.

**Clinical Utility in Monitoring Cell Lineage Chimerism after Allogeneic Hematopoietic Stem Cell Transplantation.** *R. Saad*. Pathology, Baylor University Medical Center, Dallas, TX.

Monitoring of the chimeric status of hematopoietic stem cell transplant (HSCT) recipients is of great clinical significance when comparing different conditioning therapies. Short tandem repeats (STR) analysis is the most common method for chimerism monitoring. Engraftment analysis is usually performed on DNA extracted from unfractionated blood or bone marrow samples. Analysis of lineage-specific leukocytes provides useful information in predicting the clinical outcome and plays a critical role in the management of HSCT patient. We have used the GenomeLab Human STR Primer set to assess the dynamics of chimerism within the individual leukocyte subsets in 77 hematopeiotic cell transplant patients after myeloablative and nonmyeloablative regimens. Magnetic anti-CD3, anti-CD15 and anti-CD19 beads were used to capture T cells, myeloid cells and B cells, respectively, from peripheral blood and bone marrow samples prior to isolation of DNA. DNA was extracted on the Beckman Coulter SPRI-TE nucleic acid extractor using the genomic DNA extraction kit. Chimerism analysis performed on specific cellular lineages was most useful in early detection of relapse than unfractionated whole blood analysis due the increased sensitivity in the enriched cell subpopulations. Determination of the level of donor T cells appears to be critical for successful engraftment and could predict graft versus host disease.

## 1140/W/Poster Board #798

**Shortened Telomere Length Correlates with Promoter Methylation Status of p16INK4a/Rb and p53/p21cip1 pathways in Breast Cancer.** *Z. Barekati, R. Radpour, R. Asadollahi, C. Kohler, XY. Zhong.* Biomedicine, University of Basel, Basel, Basel, Switzerland.

Continuous cell growth is a major advanced malignancy hallmark which is correlated with shortened telomere length. Measurement of telomere length is a useful biomarker to elucidate cell replicative history and proliferation in cancerous tissues. The telomere length and promoter methylation status of the p16ink4a/Rb or p53/p21cip1 pathways were examined in different grades of breast cancer. Telomere length was measured in a cohort of 104 samples including 52 cancerous and paired adjacent normal breast tissues by quantitative PCR. Using a novel high-throughput mass spectrometry on MALDI-TOF silico-chips, we determined quantitative methylation changes of TP53, P21 and P16 genes in all studied samples. A two-way hierarchical cluster analysis was used to classify methylation profiles. The result showed significantly shortened telomere length in the cancerous tissues especially in grades two and three of breast cancer ($p<0.001$). Results of the study showed correlation between the ratio of telomere length in the cancerous tissues and the methylation status of analyzed genes. Significant hypermethylation of P16 and P21 promoters in the patients with shortened telomere length was detected ($p<0.001$). No significant correlation has been found between TP53 promoter methylation status and telomere shortening. Inactivation of the p16INK4a/Rb or p53/p21cip1 pathways regarding to the promoter hypermethylation may allow continuous cell division and critical telomere shortening, which induce genome instability, finally leading to malignant transformation. Our results suggest that telomere shortening and inactivation of p16INK4a/Rb or p53/p21cip1 pathways may serve as a potential biomarker for the disease.

**Evaluation of PTEN and Mcl-1 Expressions in NSCLC Expressing Wild Type or Mutated EGFR.** *S. Berker-Karauzum[1], Z. Cetin[1], G. Ozbilim[2], A. Erdogan[3], G. Luleci[1].* 1) Department of Medical Biology , Akdeniz University Faculty of Medicine, Antalya, Turkey; 2) Department of Pathology, Faculty of Medicine, Akdeniz University, Antalya, Turkey; 3) Department of Thoracic Surgery, Faculty of Medicine, Akdeniz University, Antalya, Turkey.

Signaling pathways activated by Epidermal Growth Factor Receptors are important in lung carcinogenesis. New treatment strategies with Epidermal Growth Factor Receptor targeting drugs provided improvements in management of lung cancer. However molecular mechanisms underlying resistance to these drugs needs to be evaluated. Surgically resected samples were obtained from fifty patients with non-small cell lung cancer. PTEN, Mcl-1 and EGFR protein expression levels were evaluated by Western-blot. Direct sequencing were performed to investigate EGFR tyrosine kinase domain mutations. We detected c.2235-2249 (pGlu746-Ala750del) mutation in exon 19 in two patients with adenocarcinoma histology. Elevated expression levels of both Mcl-1 isoforms (Mcl-1S and Mcl-1XL) and EGFR proteins were found in 15 (30%) and 23 (46%) of the cases, respectively. Reduced PTEN protein expression levels were observed in 17 (34%) of the cases. PTEN expression level was reduced in 26% of cases which showed increased EGFR expression. Also, increased expression of Mcl-1 protein was observed in 26% of cases with EGFR overexpression. One of the cases harbouring pGlu746-Ala750del mutation had increased levels of Mcl-1 and decreased PTEN expression levels. Our results indicate that, in addition to lack of PTEN expression, elevated levels of the Mcl-1 protein might be one of the important intrinsic mechanisms protecting non-small cell lung cancer cells from apoptosis induced by several compounds. Therefore, EGFR mutations in conjuction with evaluation of Mcl-1 and PTEN expression levels in large cohorts might provide important clues for improvements of new treatment strategies in non-small cell lung cancer management.

### 1142/W/Poster Board #800

**Is Human Papillomavirus Viral Load in Cervical Intraepitelial Neoplasia a prognostic factor of disease?** *E. Borrayo Carbajal[1], A.E. Suárez Rincón[2], A.E. Bencomo Álvarez[1], H. Montoya Fuentes[1].* 1) División de Medicina Molecular, Centro de Investigación Biomédica de Occidente, Instituto Mexicano del Seguro Social, Guadalajara, Jalisco, México; 2) Hospital General de Zona No 45, Instituto Mexicano del Seguro Social, Guadalajara, Jalisco, México.

Human Papillomavirus (HPV) has been proposed as the most important risk factor for the development of cervical cancer and other tumors. Several factors have been related to the development and progression of cervical disease, from those, the viral type is considered the most important and has already been extensively described. Nevertheless, recent publications has proposed viral load (VL) as an effective diagnostic and prognostic marker for cervical neoplasia. In the present work we report a preliminary comparison of the HPV VL of patients with diagnosis of grade 2 Cervical Intraepithelial Neoplasia (CIN2) versus grade 3 Cervical Intraepithelial Neoplasia (CIN3) and Normal Cytology (NC). In this study we used Cervical samples from Mexican patients diagnosed either as CIN2, CIN3 or NC. DNA extraction and PCR amplification, using consensus primers for HPV E1 ORF as previously reported, were performed to determine the positivity to these viruses in each sample. Hybrid Capture II System (HCIIS, DIGENE, Gaithersburg, USA) was used to estimate VL total number. A QPCR melting curve of the GAPDH gene was performed to obtain a number of cells per sample and the data obtained were normalized using the following formula: VL= Antilog [log(RLUx5000)-log(Total No. of Cells)]. The mean and standard deviation of the number of viral copies per cell shows no significant differences in the distributions between CIN2 vs CIN3, NC vs CIN2 and NC vs CIN3 ($p>0.05$). This differs from the role of VL as a prognostic tool previously proposed. It has been suggested that VL plays an important role in the development of cancer. Nonetheless, according to our preliminary data, VL remains constant along the pathological process, as previously described. The debatable association between VL and the risk of developing Cervical Cancer may be due to different standardization and normalization of the absolute number of viral copies in one sample, as well as to different grouping criteria (i.e. CIN1 vs CIN2 or CIN1 vs CIN 2&3, etc.). These phenomena might explain the inconsistent results among different reports. The need for homologated methods in the normalization of data is evident.

### 1143/W/Poster Board #801

**Interleukin-18 gene polymorphisms and the risk of cervical squamous cell carcinoma.** *T.Y. Chang[1], Y.C. Yang[1,2,4], Y.J. Lee[1,3,5], T.C. Chen[2], S.C. Chang[1], H.W. Chan[1].* 1) Medical Research Department, Mackay Memorial Hospital, Taipei, Taiwan; 2) Department of Gynecology and Obstetrics, Mackay Memorial Hospital, Taipei, Taiwan; 3) Department of Pediatrics, Mackay Memorial Hospital, Taipei, Taiwan; 4) Mackay Medicine, Nursing, and Management College, Taipei, Taiwan; 5) College of Medicine, Taipei Medical University, Taipei, Taiwan.

Cervical cancer is strongly associated with infection by oncogenic forms of human papillomavirus (HPV). However, HPV infection alone is not sufficient for progression to cervical cancer. It is now recognized that host immunogenetic background play an important role in the control of HPV infection and the development of cervical cancer. Interleukin-18 (IL-18) is a multifunctional cytokine that induces interferon-gamma secretion and plays an important role in antitumor immunity. The aim of this study is to investigate the association between *IL-18* gene polymorphisms and the risk of cervical cancer in the Taiwanese population. The *-607 C/A* and *-137 G/C* polymorphisms in the promoter region and *+105 A/C* in the exon 5 were genotyped in 127 cervical squamous cell carcinoma (CSCC) patients and 269 age/sex matched healthy controls by using the Pre-Developed TaqMan Allelic Discrimination Assay. The presence and genotypes of HPV in CSCC patients were determined by PCR. We found no significant association between any polymorphisms or haplotypes examined and overall CSCC risk. In addition, no significant association was observed between HPV-16 positive CSCC patients and controls. Our results suggest that specific variations in the *IL-18* gene did not confer susceptibility to CSCC in the Taiwanese population.

### 1144/W/Poster Board #802

**Genetic polymorphisms in xenobiotic metabolizing enzymes and environmental risk factors in colorectal cancer among Filipinos.** *E. Cutiongco[1], C. Padilla[1], C. Ngelangel[2], V. Bañez[3], M. Roxas[4], C. Silao[1], R. Cortez[1], F. Rocamora[1] for The Philippine Cancer Genetics Study Group.* 1) Institute of Human Genetics, National Institutes Health, University of the Philippines, Manila, Philippines; 2) Institute of Clinical Epidemiology, University of the Philippines, Manila, Philippines; 3) Department of Medicine, Philippine General Hospital, Manila, Philippines; 4) Department of Surgery, Philippine General Hospital, Manila, Philippines.

Colorectal cancer is one of the leading cancers of the world. Based on incidence, it ranks fourth in men and third in women, with over 1 million new cases worldwide (World Cancer Report 2008). In the Philippines, cancers of the colon and rectum ranked 3rd overall, 3rd among males and 4th among females. In 2005, there were 8,585 new cases and 5,558 related deaths (Laudico et al 2005). A number of environmental factors have been reported to increase colorectal cancer risk but genetics has also been identified to play a role in cancer susceptibility. Genetic polymorphisms account for variations in genes coding for enzymes that are responsible for the detoxification of various endogenous and exogenous substrates into harmless compounds, or their metabolic activation into toxic and carcinogenic products. Many of these genes are functionally polymorphic and have different allelic variants which result in variations in susceptibility to cancer among individuals. This is a molecular epidemiological study that looks at the putative association of colorectal cancer susceptibility with environmental factors and genetic polymorphisms in GSTM1, GSTT1, GSTP1, NAT1 and NAT2 genes. A total of 500 Filipino patients, 224 with colorectal cancer and 276 cancer-free were included in the study. Corresponding demographics, medical histories, social histories, diet histories, and occupational exposure data were collected for all subjects. Molecular genotyping was done through PCR-RFLP of target DNA regions. Univariate logistic regression analysis of environmental variables revealed wood dust occupational exposure (OR 2.66; 95% CI 1.21-5.83), UV sunlight exposure (>7/month) (OR 1.99; 95% CI 1.16-3.39) and moldy food exposure (>1/ month) (OR 1.61; 95% CI 1.11-2.35) to be associated with colorectal cancer risk. For the genetic polymorphism studies in the genes involved in the xenobiotic metabolism pathway, univariate analysis showed the NAT2*6B allele (dominant model: OR 1.51, 95% CI 1.06-2.16; recessive model OR 1.87, 95% CI 1.05-3.33) to be independently associated with colorectal cancer risk. After multivariate logistic regression of both genetic and environmental factors initially shown to be associated with colorectal cancer, only UV exposure (OR 2.08, 95% CI 1.21-3.58) was shown to be statistically significant.

**PCA3, the highly specific prostate cancer biomarker, recently evolved within a second gene, BMCC1, which is also upregulated in prostate cancer.** *Z.M. Fang[1], R.A. Clarke[1,2], Z. Zhao[3], A.Y Guo[3], K. Roper[4], L. Teng[2], H. Samaratunga[5], M.F. Lavin[2], R.A. Gardiner[2].* 1) RADIATION ONCOLOGY, St. George Hospital, Kogarah, NSW, Australia; 2) Queensland Institute of Medical Research, Radiation Biology and Oncology, Brisbane, QLD 4029, Australia; 3) Department of Psychiatry and Center for the Study of Biological Complexity, Virginia Commonwealth University, Richmond, VA 23298, USA; 4) Hopkins Marine Station, Stanford University, Stanford, CA 93950, USA; 5) Sullivan & Nicolaides Pathology, Brisbane, Australia University of Queensland Centre for Clinical Research, Brisbane, Australia.

The prostate cancer antigen 3 (PCA3) gene is a highly specific biomarker upregulated in prostate cancer (PCa). We employed cDNA synthesis, RT-PCR and DNA sequencing to identify 4 new transcription start sites, 4 new polyadenylation sites and 2 new differentially spliced exons in an extended form of PCA3. Primers designed from these novel PCA3 exons greatly improve RT-PCR based discrimination between PCa, PCa metastases and BPH specimens. Comparative genomic analyses further demonstrated that PCA3 has only recently evolved in an anti-sense orientation within a second gene, BMCC1 / PRUNE2. BMCC1 has been shown previously to interact with RhoA and RhoC, determinants of cellular transformation and metastasis, respectively. Using RT-PCR we demonstrate that the longer BMCC1-1 isoform - like PCA3 - is upregulated in PCa tissues and metastases and in PCa cell lines. PCA3 and BMCC1-1 levels are also responsive to dihydrotestosterone. Enrichment of two new PCA3 isoforms in PCa tissues improves discrimination between PCa and BPH. The functional relevance of this specificity is now of particular interest given PCA3's overlapping association with the BMCC1 regulator of Rho signalling. Combination testing including PCA3, BMCC1, TMPRSS2-ERG fusions and other PCa biomarkers has real potential for improved diagnosis.

### 1146/W/Poster Board #804

**Association of insertion/deletion polymorphism (Del1518) of MDM2 in Mexican lung cancer patients.** *M. Gallegos[1], L.E. Figuera[2], G. Morgan[3], A.M. Puebla[4].* 1) Dept Med Molec, Guadalajara, CIBO, IMSS, Jalisco, Mexico; 2) Dept. Genetica, CIBO, IMSS; 3) Unidad de radio diagnostico, HE, CMNO, IMSS; 4) Lab. Inmunifarmacologia, CIBO, IMSS.

The MDM2 gene encodes to protein that negatively regulates p53 expression, participate in multiples functions of cell-cycle and modulation of DNA repair. The insertion/deletion polymorphism (Del1518) in the promoter of MDM2 gene has been shown to be associated with lung cancer. In the present study we describe to frequency of Del1518 polymorphism of MDM2 gene in lung cancer patients and health controls from Mexico. In a case-control study of 280 lung cancer patients and 174 controls we observed a frequency of 57% (146/280) and 56% (98/174) of insertion genotype; 38% (107/280) and 34% (59/174) of genotype insertion/deletion and 10% (27/280) and (17/174) of genotype deletion cases and controls respectively, without to be statistically different ($p>0.05$). These results suggest that the Del1518 polymorphism on the MDM2 promoter is not associated with Mexican lung cancer patients.

### 1147/W/Poster Board #805

**Expressions of Peroxiredoxin isoforms during the progression of Endometrial cancer.** *S. Han, I. Oh, M. Jung, W. Choe.* Department of Biochemistry and Molecular Biology, Medical Science and Engineering Research Center for Bioreaction to Reactive Oxygen Species, Biomedical Science Institute, School of Medicine, Kyunghee University, Seoul 130-701, Korea.

Endometrial carcinoma is a common malignant tumor of the human female genital tract, typically affecting women after menopause. Asian nations such as Korea, Japan and China have an incidence that is 4-5 times lower than in western industrialized nations. however, it has been increasing markedly in recent years. One of the family proteins with an antioxidantive function, peroxiredoxin (Prx), so far has revealed six members in mammals. These enzymes share a common reactive Cys residue in the N-terminal region, and are capable of breaking down H2O2 as a peroxidase and involve thioredoxin and/or glutathione as the electron donor. We evaluated the expression of Prx isoforms in normal tissue, endometrial hyperplasia and endometrial cancer. In the present study, We investigated the expression of Prx isoforms in normal endometrium, endometrial hyperplasia and endometrial cancer. We detected that expression of Prx isoforms differs in the normal sample groups : Prx I, II, and III was negative. Prx IV and V was weekly expressed. Prx VI were strongly expressed. Interestingly, endometrial cancer had the strongest expression of Prx I, II, III, IV, and V compared with normal endometrium and endometrial hyperplasia. No difference in staining with intensity by grade of lesion was observed for Prx VI. Therefore, we conclude that Prx I, II, III, IV, and V are upregulated in response to the development of endometrial cancer.

### 1148/W/Poster Board #806

**MicroRNA Profiles in Exosomes Derived from Prostate Adenocarcinomas.** *M. Howell, J. Kimbrough, T. Deng, A. Conrad, P. Ellis, P. Kennedy, T. Tinder, P. Esmay, T. Maney, C. Kuslich.* Caris/MPI, Phoenix, AZ.

MicroRNAs (miRs) are small, non-coding RNAs with critical roles in transcriptional regulation. miRs are present in virtually all nucleated cells, and physiologic expression profiles of miRs, like those of coding RNAs, reflect developmental lineages and differentiation states of specific cells and tissues. Disregulation of miR expression has been correlated with malignant transformation in a variety of cancer types, including prostate cancer (PCa). miR expression profiles in multiple PCa isolates have been shown to differ from those of corresponding non-transformed tissue, suggesting considerable promise for miR signatures as diagnostic biomarkers of PCa. Development of minimally-invasive alternatives to tumor biopsy will further enhance the utility of this diagnostic strategy. One such alternative is to determine miR signatures of tumor-derived exosomes. Exosomes are microvesicles of endocytic origin which, in the plasma of healthy individuals, derive primarily from hematopoietic cells. In cancer patients, tumor-derived exosomes also are present and, since the protein content of exosomes largely reflects that of the parental cell, lineage- and/or tumor-specific antibodies may be used to isolate tumor exosomes for miR analysis. Toward this end, we have begun to implement strategies for immunoselection of PCa-derived exosomes and for the characterization of miR profiles contained therein. Exosomes present in culture medium conditioned by PCa and non-malignant control cell lines have been purified using density gradient centrifugation. The resulting particles were confirmed by EM to possess sizes and morphologies characteristic of exosomes, and immunoblot analysis revealed the presence of multiple spannins known to be enriched in exosomal membranes. Using ELISA and MIA, ten antibodies that bind exosomes purified from several PCa cell lines were identified, and several of these antibodies were used to selectively enrich the respective populations. Total RNA has been isolated from density gradient-purified and immunoselected exosomes, and miRs present in these preparations have been analyzed using: 1) qRT-PCR with selected miR primer and probe combinations; microfluidic TaqMan low-density miR arrays (TLDA); and/or, 3) miR microarrays. Initial analyses reveal significant complexity in these exosomal miR repertoires, and they suggest the potential utility of exosomal miR evaluation in PCa diagnostics.

### 1149/W/Poster Board #807

**The Benefit of Sequencing Analysis to Identify Important KRAS Activating Mutations in Colorectal Cancer.** *U. Jariwala, L. Dejeza-Jamanila, K. Arnold, M. McGinniss, C. Kuslich.* Molecular Diagnostics, Caris Dx, Phoenix, AZ.

KRAS, the human homolog of the Kirsten rat sarcoma-2 virus oncogene, encodes a small GTPase protein, which mediates downstream signaling in the EGFR signaling pathway. Most common activating point mutations occur in codons 12 and 13 and are found in ~40% of colorectal cancers. These mutations render KRAS constitutively active and independent of upstream EGFR activation and are predictive of the failure of EGFR targeted therapies such as cetuximab and panitumumab in patients with metastatic colorectal cancer. The majority of PCR-based mutation analysis methods focus only on mutations contained in codons 12 and 13. Other activating mutations in KRAS have also been identified in codon 61 and these are relevant for predicting response to anti-EGFR therapies. Tumor samples from 394 unselected colorectal cancer patients were analyzed for activating KRAS mutations in exons 2 and 3 by Sanger sequencing. We discovered 58.4% of these tumors were wild type for KRAS while 41.6% of harbored KRAS mutations, a similar overall mutation frequency to what has been previously reported. In addition to finding the 7 mutations most frequently screen for (G12D-14.7%, G12V-8.6%, G12C-4.6%, G12A-2.3%, G12S-1.8%, G12R-0.8%, and G13D-6.3%), we also identified a number of KRAS activating mutations (G12dup, G13R, Q61H, Q61L and Q61K), with a combined frequency of 6.1%, that would not have otherwise been detected by mutation specific PCR-based testing. As these mutations have also been shown to activate KRAS, they too predict failure of anti-EGFR therapies and represent an underserved number of patients that would benefit from therapeutic screening. These data suggest that comprehensive analysis of KRAS mutational status, including additional mutations in codon 13 and codon 61, is warranted for optimal patient selection for cetuximab and panitumumab therapies.

## 1150/W/Poster Board #808

**_ST14_ variants and low matriptase expression predict poor breast cancer survival.** *J.M. Kauppinen[1,2,3], A. Mannermaa[1,2,3], R. Sironen[1,2,3], Y. Soini[1,2,3], T. Nykopp[1], M. Eskelinen[4], V. Kataja[5,6], V.-M. Kosma[1,2,3].* 1) Institute of Clinical Medicine, Pathology and Forensic Medicine, University of Kuopio, Kuopio, Finland; 2) Department of Pathology, Kuopio University Hospital, Kuopio, Finland; 3) Biocenter Kuopio, Kuopio, Finland; 4) Department of Surgery, Kuopio University Hospital, Kuopio, Finland; 5) Department of Oncology, Kuopio University Hospital, Kuopio, Finland; 6) Department of Oncology, Vaasa Central Hospital, Vaasa, Finland.

The aim of this study was to examine the role of *ST14* (matriptase) genetic variation and expression in breast cancer survival and to assess their clinicopathological correlations. 455 invasive breast cancer cases and 446 healthy controls from Eastern Finnish origin in the Kuopio Breast Cancer Project (KBCP) were genotyped for five SNPs in *ST14* gene. Immunohistochemical analyses were performed in tissue microarrays (TMA) consisting of 377 invasive breast cancers from the KBCP cohort. Three variants in *ST14* gene were found to be prognostic factors independently predicting breast cancer survival, worse outcome associating with the rare homozygous genotype ($P$ = 0.001 in Cox multivariate survival analysis). Statistically significant association of the genotypes with typical prognostic clinicopathological parameters (nodal status, tumour grade and clinical stage, $P$ values 0.036, 0.046 and 0.044, respectively) supports the connection with survival. Also *ST14* mRNA levels were lower among the rare homozygous genotypes compared to the common homozygotes ($P$ = 0.009 in independent samples t-test). Negative/low matriptase expression (IHC) associated with poorer survival ($P$ = 0.046 in Cox multivariate survival analysis). This was also supported by association of matriptase expression with several clinicopathological parameters. We conclude that matriptase genetic variants do have prognostic significance in breast cancer and thus influence progression of the disease.

## 1151/W/Poster Board #809

**The Frequency and Distribution of KRAS Mutations in Various Tumor Types.** *C. Kuslich, U. Jariwala, L. Dejeza-Jamanila, M. McGinniss, K. Arnold.* Molecular Diagnostics, Caris Dx, Phoenix, AZ.

Activating mutations in KRAS, the human homolog of the Kirsten rat sarcoma-2 virus oncogene, mediate constitutively activated downstream signaling in the EGFR signaling pathway. Recent evidence from numerous randomized studies has established that colorectal tumors harboring an activating mutation in the KRAS gene do not derive benefit from epidermal growth factor receptor-directed monoclonal antibodies (e.g. cetuximab or panitumumab). However, a comprehensive analysis has yet been undertaken on activating KRAS mutations in tumors from other tissue types where epidermal growth factor receptor-directed therapy may also be used. In this study, a total of 82 tumors from pancreas (n= 13), liver (n= 23), lung (n=32), stomach (n=6) and breast (n= 8) were screened for KRAS mutations in codons 12, 13, and 61 by direct sequencing. The results of this mutational analysis revealed that 69.2% of pancreatic tumors, 39.1% of liver tumors, 18.7% of lung tumors and 16.7% of stomach tumors had activating mutations in KRAS. The breast tumors analyzed were wild type at codons 12, 13, and 61. The distribution of mutations among the codons of the KRAS gene was different by tumor type. Liver tumors had mutations that were identified in codons 12, 13, and 61 at a similar frequency as evident in colon cancer with codon 61 being mutated in 4.3% of tumors analyzed. The lung tumors analyzed had 15.7% of their mutations in codon 12 and only 3% in codon 13 while stomach tumors only had the G12A mutation. Pancreatic tumors had mutations identified in codon 12, with a wider distribution of point mutations within that codon compared to stomach and lung tumors. While larger selected studies are warranted to investigate these findings in greater numbers in the context of each individual disease and subtype, these results add to the considerations involved in the use of resistance and predictive biomarkers.

## 1152/W/Poster Board #810

**Do MGMT polymorphisms are involved in colon polyps formation?** *K.M. Lamperska[1], A. Przybyla[2], W. Kycler[3], A. Mackiewicz[1,2].* 1) Department of Cancer Diagnostics and Immunology, Wielkopolskie Centrum Onkologii, PoznaÅ", Poland; 2) Department of Cancer Immunology, Medical University PoznaÅ", Poland; 3) Department of oncological surgery, Wielkopolskie Centrum Onkologii.

MGMT plays crucial role in defense again toxic effect of alkylation damages in DNA. It is known more than five polymorphisms of MGMT gene,these SNPs are associated with different types of cancer, increase or decrease its risk. These genetic alternations together with environmental factors may modulate MGMT activity. We investigated polymorphisms in MGMT in blood and colon polyps' tissue and the main aim of our study was to check possible association identified genetic changes with colon cancer risk. The blood samples and colon polyp's tissue were obtained from 254 individuals. All patients filled questionnaire including questions about style of life,dietary and cancer diseases. All recognized polymorphisms were compared with control group consisted of 330 healthy individuals. DNA was isolated from blood sample and polyps tissue using standard method. Polymorphisms in MGMT gene were investigated by PCR-SSCP method. The Pearson's chi-square and Fisher's exact test were used to test the differences in genotype and allele distribution. Logistic regression was employed to calculate odds ratio (OR) and 95% confidence intervals (95%CI) and for calculating interactions. Linkage disequilibrium analysis of identified polymorphisms was performed using free online software Haploview version 4.0. All p values was two-sided. We found two polymorphic variants: L84F and K178R. We found significant differences in L84L, L84F and F84F alleles distribution between cases and control group (p=0, 0001).Higher distribution of 84F allele was observed in smoking patients (p=0, 0405) and older (up 60th) patients (p= 0, 0000). We did not find correlation between this polymorphic variant and gender. The frequency of 178R allele did not show statistical differences.Next polyps were divided according degree of dysplasia and size.We did not observed correlation between 84F and high risk polyps.The study group included 23 colon cancer patients and 27 reported colon cancer in family history but we did not finde correlation between these cases and frequency of 84F variant. Finally we conclude that high frequency of 84F allele in group of patients with colon's polyps may suggest the role of the MGMT variant in colon polyp's aetiology.In the other hand we did not find arguments for connection of variant 84F alone with colon cancer development.

## 1153/W/Poster Board #811

**Ultrahigh sensitive, early detection of relapse in non-small cell lung cancer patients using blood specimen.** *Q. Liu[1], N. Hsu[2], X. Liu[1], Y. Wang[1], L. Chen[1], C. Chen[3], Y. Yen[1].* 1) Department of Clinical and Molecular Pharmacology and Translational Research Lab, City of Hope National Medical Center, Duarte, CA; 2) Department of Surgery, Buddhist Taichung Tzu-Chi Hospital, Taiwan; 3) Cancer Center, China Medical University Hospital, TaiChung, Taiwan.

Non-small-cell lung cancer, accounting for about 85% of all lung cancers, is the leading cause of cancer deaths in the United States and worldwide. Despite advances in standardized treatment, non-small-cell lung cancer often has a poor prognosis due to relapse. Our goal is to identify such relapse at a very early stage through ultra-high sensitive detection of cancer-specific somatic mutations in plasma DNA. Specifically, we will use Pyrophosphorolysis Activated Polymerization (PAP), an ultra-high sensitive nucleic acid detection technology, to detect as few as one copy of cancer-specific mutations in 5 mL of plasma. This assay will be over 1000-folds more sensitive than PCR-based methods. In order to target appropriate mutations, we first applied PCR and Sanger sequencing to search for cancer-specific somatic mutations in the EGFR, KRAS, and P53 genes in frozen cancer tissues but not in their paired normal tissues. We identified 22 such somatic mutations in 28 early stage NSLC patients from Taiwan. Second, we developed highly-sensitive PAP assays to target the identified mutations. Using these PAP assays, we already confirmed their presence in the tumor tissues at high frequencies. Furthermore, we also found their presence at very low frequencies in many of the paired normal tissues. Finally, we are applying these assays to detect as few as one copy of the cancer-specific mutations in 5 mL of plasma drawn at multiple time points. Our ultimate goal is to detect the relapse ≥6 months earlier than clinical features. The success of this study will open new opportunities for early detection of relapse in other cancers with great advantages: Ability to detect a single copy of cancer-specific mutations in a large quantity of plasma, Over 1000-folds more sensitive than any current PCR-based methods, Not affected by metastatic status because DNA mutations are intrinsic signatures of cancer cells, Non-invasive testing.

## 1154/W/Poster Board #812

**Profiling critical genetic mutations in clinical tumor samples.** *L. MacConaill[1,2], C. Campbell[1,2], S. Kehoe[1,2], C. Hatton[1,2], L. Niu[1,2], M. Davis[1,2], K. Yao[1,2], M. Hanna[1,2], C. Mondal[1,2], L. Luongo[1,2], A. Bass[2], J. Chan[5], M. Fiorentino[4], K. Polyak[1], M. Kieran[3], K. Ligon[4], C. Stiles[3], W. Hahn[1,2], M. Meyerson[1,2], L. Garraway[1,2].* 1) Center for Cancer Genome Discovery, Dana Farber Cancer Inst, Boston, MA; 2) Department of Medical Oncology, Dana Farber Cancer Inst, Boston, MA; 3) Department of Pediatric Oncology, Dana Farber Cancer Inst, Boston, MA; 4) Center for Molecular and Oncologic Pathology, Dana Farber Cancer Inst, Boston, MA; 5) Departments of Pathology and Laboratory Medicine, Clinical Neurosciences, and Oncology, University of Calgary, Alberta, Canada.

Systematic genetic characterization of clinical tumor specimens is necessary to predict patient outcomes and inform targeted treatment options; however, dependable methods for high-throughput mutation profiling in the clinical arena remain nascent and unproven. We report the implementation of novel mutation detection methodologies to allow accurate, robust and reproducible mass-spectrometric genotyping of a substantial set of known cancer somatic mutations. This platform (the “OncoMap”) interrogates over 500 mutations in 34 known cancer genes- oncogenes and tumor suppressors- many of which are known to predict response or resistance to targeted therapies. We previously reported proof-of-principle using a mass-spectrometric genotyping approach (Thomas et al., 2007)- we now demonstrate the utility of OncoMap in DNA derived from clinical frozen and archival (formalin-fixed, paraffin-embedded; FFPE) material, including patient specimens of gastric, esophageal, endometrial, thyroid, breast, lung and colorectal cancer. We assessed the sensitivity and specificity of our assay panel by comparing KRAS mutant samples (identified using Oncomap) to a “ground-truth” set of Illumina sequencing data on barcoded samples. To highlight the utility of OncoMap on clinical specimens, we also performed mutation profiling on 155 FFPE pediatric low-grade gliomas. We detected many mutations at expected frequencies in common cancers. Importantly, we discovered several rare events in genes not previously described in a cancer type, but for which targeted agents are available or in clinical development. We also demonstrate the utility of OncoMap in identifying common oncogene events in a rare subtype of pediatric cancers- these mutations have immediate clinical impact. Our results demonstrate the clinical feasibility of high-throughput, sensitive and cost-effective cancer mutation profiling that queries a large panel of “actionable” somatic events. OncoMap can be used to identify rare mutations in common cancer types, as well as profiling rare cancers for oncogenic and potentially actionable events.

## 1155/W/Poster Board #813

**Frequency of the fifteen most common SNPs of the RB1 gene in Mexican pediatric patients affected with Retinoblastoma tumor.** *M. Macias-Vega[1], J. Juárez[2], J. Ordaz[2], M. Chávez[3], N. Carranza[4], C. Leal[5], P. Gariglio[6], R. Ocadiz[6], O. Pérez[1].* 1) Lab. Oncología Experimental, Instituto Nacional de Pediatría, Mexico City, Mexico City, Mexico; 2) Departamento de Oftalmología, Instituto Nacional de Pediatría.; 3) Laboratorio de Histomorfología, Instituto Nacional de Pediatría; 4) Laboratorio Clínico, Instituto Nacional de Pediatría; 5) Departamento de Oncología, Instituto Nacional de Pediatría; 6) Departamento de Patología molecular, CINVESTAV.

The single nucleotide polymorphisms (SNPs) of the RB-1 gene have been classified into two groups, low frequency (£ 5%); and high frequency (³ 5%). The combination of 15 of them results in the formation of many different haplotypes, some of them have been considered like risk factors for the hereditary tumor, others like prognostic factor and others associated with the variability to the response to treatment. The aim of this study was to screen the frequency of the 15 most common alleles of the RB1 gene in a case-control study including 73 pediatric patients affected with bilateral and unilateral retinoblastoma and were compared with a group of control cases. All samples were genotyped for the 15 SNPs using the detection system Taqman with forward and reverse primers and FAM and VIC labelled probes. Results show that the common allele is homozygote for the 15 markers into the patients group and only in 12 of control cases, although this difference is not high, is important to note that in five markers (C-779216, C-3042283, C-779170, C-33789354, C-31604223), the common allele has a frequency of 100% and in the control cases it happened only in one marker (C-33789354) while only in two of them the frequency was nearly to 100% (C-779170 85%, C-31604223 95%). Hence exist the possibility that those markers could be non polymorphics. On the other hand we found that in patients group 14 markers showed heterozygosity for common and rare alleles unlike control cases where only 7 markers showed heterozygocity for both. With respect to the rare allele in the patients group we founded allelic homozygocity in 11 markers and in the control cases founded homozygocity only in 6 markers. Is clear that the rare allele occurs with most high frequency in the patients group in heterozygocity and homozygocity conditions so the extensive analysis of the correspondent haplotypes formed by those markers is needed to support the recent statements that the presence of them could modified the development of the retinoblastoma in the non hereditary form, the response to treatment and in the clinical prognostic of the disease . CONACYT-71020, INP-07/040.

## 1156/W/Poster Board #814

**Polymorphisms in RAS in Mexican women with benign breast disease and breast cancer.** *A.P. Mendizabal[1], S.A. Gutierrez[2], X.H. Castro[2,3], L.L. Valdez[5], J.A. Morales[1], J.G. Vazquez[4], J. Sanchez[3], M.C. Moran[3].* 1) Centro Universitario de Ciencias Exactas e Ingenierias, Universidad de Guadalajara, México; 2) Centro Universitario de Ciencias de la Salud, Universidad de Guadalajara, México; 3) Centro de Investigacion Biomedica de Occidente, Instituto Mexicano del Seguro Social, México; 4) Centro Medico Nacional de Occidente. Instituto Mexicano del Seguro Social, México; 5) Facultad de Ciencias Quimicas, Universidad de Colima, México.

Recent information has revealed new roles in the angiogenic processes linked to the rennin-angiotensin system (RAS) pathways. To date few studies have been done on the association between RAS genes and cancer and the majority focus mainly on angiotensin I-converting enzyme (ACE). For breast cancer there are three reports that include the angiotensin II receptor, subtype 1 (AGTR1), only one for angiotensinogen (AGT) and none for renin gene (REN). In the present study we investigate whether polymorphisms on RAS genes besides ACE are associated with breast cancer. For this purpose we compared three groups: breast cancer, general population and a benign breast disease group (BBD). The polymorphisms studied by RFLP-PCR were: REN (BglI), AGT (M235T), ACE (A245T), and AGTR1 (A1166C). Statistical data concerning REN polymorphism, shows that Breast cancer group had different allelic and genotypic distributions from BBD (p=0.036 and p=0.048 respectively) but similar to general population. With a high frequency of individuals carrying A allele BBD group was also different from general population (genotypic and allelic p=0.001). Analysis from a recessive model shows that homozygous for A allele have an increased risk for BBD (OR 4.14). M235T (AGT) and A1166C (AGTR1) were statistically different only in comparisons between general population and breast cancer groups. Differences in M235T genotype frequencies were significant (p=0.048) with less heterozygous in breast cancer group. Relevant allelic A1166C differences were observed where breast cancer group showed an increase of allele A (p=0.036). C allele carriers present a reduced risk of breast cancer (OR 0.53, p=0.0356). A240T polymorphism (ACE) did not show any statistical difference. AGT and AGRT1 polymorphism distributions between breast cancer and BBD groups were similar, and when compared each of both groups with the general population, different associations where shown. This results could be explained if we consider that the benign diseased breast, although not malignant it has developed different morphology from normal tissue and therefore, genotypic differences should be expected. Results of this work agree with previous observations on the possible involvement of this system in breast cancer but it also suggest its participation in other stages and pathologies like benign disease.

## 1157/W/Poster Board #815

**Proteomics discovery of salivary biomarkers for lung adenocarcinoma.** *G.E. Mercado[1], L. Castellanos[1], K.G. Calderon[1], D. Saavedra[2], G. Ponciano[3], O.G. Arrieta[2], J.P. Reyes[1], J. Gallegos[1], G. Jimenez-Sanchez[1].* 1) National Institute of Genomic Medicine (INMEGEN), Mexico City, Mexico; 2) National Cancer Institute (INCan), Mexico City, Mexico; 3) Smoking Cessation Clinic, School of Medicine, UNAM, Mexico City, Mexico.

Lung cancer is the major cause of cancer-related deaths and has a poor prognosis with a 5-yr overall survival of <10%, mostly due to lack of early stage diagnosis. Cigarette smoking is estimated to be responsible for >80% of the cases. Previous studies have demonstrated that former smokers have a higher risk of lung cancer compared to nonsmokers. Early detection of lung cancer would improve the overall survival of this disease. However, there is no validated screening test for lung cancer. To develop an early detection test, we selected saliva as the biofluid of choice due to its accessibility and protein content that provides diagnostic information on a variety of diseases, including cancer. To identify differentially expressed proteins in saliva from individuals with lung adenocarcinoma, whole saliva samples were collected from 6 patients with lung adenocarcinoma and 6 matched healthy controls (male individuals, >40 years, smokers >10 pack year). Proteins and peptides from whole saliva samples were analyzed by two-dimensional gel electrophoresis identifying 20 differentially expressed protein spots. Mass spectrometry analysis identified 63 peptides and revealed fourteen non-redundant proteins in saliva obtained from lung adenocarcinoma patients. Four of these proteins have been previously reported as serum biomarkers of cancer, and two of them were associated with non-small cell lung cancer. These potential biomarkers are being tested in an independent and larger cohort for validation. Patient-based saliva proteomics is a promising approach to searching for cancer biomarkers. Further characterization of these markers may provide the basis for new, noninvasive tests for screening, detection, and monitoring of high-risk individuals.

**ARG194TRP AND ARG399GLN POLYMORPHISMS OF XRCC1 GENE IN MEXICAN PATIENTS WITH COLORECTAL CANCER.** *R. Muñiz[1], J. Peregrina-Sandoval[2,3], M. Partida-Pérez[1], M.L. Ayala-Madrigal[1], N.M. Macías-Gómez[4], E. Leal-Ugarte[5], V. Peralta-Leal[5], J.P. Meza-Espinoza[5], S. Cervantes-Ortiz[6], M. Centeno-Flores[6], V. Maciel-Gutiérrez[6], M. Gutiérrez-Angulo[1,7].* 1) Instituto de Genética Humana , Universidad de Guadalajara, Guadalajara, Jalisco, Mexico; 2) CUCBA, UdeG; 3) Hospital Civil Fray Antonio Alcalde; 4) CUSUR, UdeG; 5) Universidad Autónoma de Tamaulipas; 6) Hospital Civil Juan I. Menchaca; 7) CUALTOS, UdeG.

The XRCC1 gene is mapped in 19q13.2-13.3 chromosome and this encoded a 70 KDa protein. This protein is involved in the repair of the single strand breaking which are originated by ionizing radiation or oxygen reactive species and alkylating agents. The polymorphism rs1799782 is localized in exon 6, replace al aminoacid Arg for Trp in position 194 and its effect on the protein is unknown. The polymorphism rs25487 localized in exon 10, it change the aminoacid Arg for Gln in the position 399 of the protein. The functional analysis of this polymorphism has demonstrated that influences the DNA repair. In this study we analyzed the polymorphisms Arg194Trp and Arg399Gln in patients with Colorectal Cancer (CRC). The polymorphisms were detected by PCR-RFLP's assay in 39 DNA samples from patients with CRC and 120 samples of healthy individuals. The genotype frequencies for patients for Arg194Trp were 82% Arg/Arg, 18% Arg/Trp and 0% Trp/Trp and the frequencies for Arg399Gln were 54% Arg/Arg, 36% Arg/Gln and 10% Gln/Gln. The comparative analysis of the allele and genotype frequencies between patients with CRC and healthy group did not show significant differences ($p>0.05$). However, the comparison among genotype, gender and CRC showed significant differences ($p<0.02$). The Arg194Trp and Arg399Gln polymorphisms was not associated with CRC in Mexican patients.

## 1159/W/Poster Board #817

**NBS1 gene mutations as a cancer risk factor.** *J. Nowak[1], M. Mosor[1], I. Ziolkowska[1], D. Januszkiewicz[1,2].* 1) Inst Human Gen, Polish Academy Sci, Poznan, Poland; 2) University of Medical Sciences, Poznan, Poland.

MRE11, RAD50 and NBS1 (MRN) complex is involved in DNA repair and cell cycle checking signaling. NBS1 being a part of MRN complex plays an important role in genome stabilization. Molecular variants of NBS1 gene may therefore constitue a cancer risk factor. Homozygous mutation 657del5 of the NBS1 gene is responsible for the majority of Nijmegen breakage syndrome. Several studies have focused on searching for an association between NBS1 gene mutations and cancer incidence. Heterozygous carriers of the NBS1 657del5 mutation have been shown to have an increased risk for breast cancer, melanoma, colon and rectum cancer. Other studies have found no association between NBS1 gene mutations Hodgkins's or non-Hodgkin's lymphomas. The aim of the study was to analyze the frequency of a panel mutations of NBS1 gene by screening all 16 exons of this gene along with polymorphisms examination. DNA was isolated from peripheral blood of 135 children with acute lymphoblastic leukemia, 270 women with breast cancer, 176 patients with larynx cancer, 93 with second primary tumors of head and neck, 131 with colorectal carcinoma and 1274 healthy individuals. I171V mutation of NBS1 gene was the most frequent and has been found in 23 patients compared to only 8 in healthy individuals. Other mutations of the NBS1 gene have been observed in lower frequencies.Genotyping data from the six polymorphic loci in NBS1 gene, were used to impute haplotypes. Two of the evaluated haplotypes were associated with significantly increased leukaemia risk ($P=0.0038$ and $P<0.0001$). Our results suggest that some specific haplotypes of the NBS1 gene may be associated with malignancies. Since DNA was a isolated from non-malignant cells, all mutations found in cancer patients appeared to be of germinal origin. It can be concluded that I171V mutation of NBS1 gene is associated with predisposition to malignances and NBS1 allele I171V may be a general cancer susceptibility gene of low or middle risk.

## 1160/W/Poster Board #818

**MicroRNA expression and its usefulness in diagnosis, classification and prediction of patient outcome in colorectal cancer.** *C. Nyiraneza[1], C. Sempoux[2], A. Kartheuser[3], R. Detry[3], K. Dahan[1].* 1) Human Gen, Cliniques Univ St Luc/UCL, Brussels, Belgium; 2) Department of Pathology, Cliniques Univ St Luc/UCL, Brussels, Belgium; 3) Department of Colorectal Surgery, Cliniques Univ St Luc/UCL, Brussels, Belgium.

MicroRNAs (miRNAs) are small non-coding RNAs of 19-24 in length that have been shown to regulate gene expression during crucial cell processes such as apoptosis, differentiation and development. Findings over the past five years have shown a significant number of differentially expressed miRNAs in normal and tumor tissues from cancer patients. The aim of this project is to evaluate the relevance of microRNA profiling in diagnosis, classification and prediction of patient outcome in colorectal cancer (CRC). In our preliminary investigations we examined the expression profile of oncogenic miRNAs such as miR21, miR106a, miR106b, and the tumor suppressor miRNAs miR34 in tumor specimens and matched colon mucosa from CRC patients with complete data on DNA mismatch repair system (MMR) deficiency or sufficiency. We correlated these data with clinicopathological features, and with the immunohistochemical expression profiles of p53 protein and its effectors/ or partners such as MDM2, p21/WAF1 and LATS2 protein. Our findings support a causal role for altered miRNAs expression in colorectal carcinogenesis. Focus on the relevance of miRNA expression profiling in diagnosis, classification and prediction of outcome of colorectal cancer patients warrants further investigations.

## 1161/W/Poster Board #819

**Role of metabolic enzyme gene variants and non-genetic factors in breast cancer risk among Filipinos.** *C. Padilla[1], E. Cutiongco[1], C. Ngelangel[2], C. Silao[1], R. Cortez[1], F. Rocamora[1], O. Bisquera[3], E. Montana[4], J. Asprer[4], R. Joson[5], C. Cajucom[6] for The Philippine Cancer Genetics Study Group.* 1) Institute of Human Genetics, National Institutes of Health, University of the Philippines, Manila, Philippines; 2) Institute of Clinical Epidemiology, University of the Philippines, Manila, Philippines; 3) Department of Surgery, Philippine General Hospital, Manila, Philippines; 4) Department of Surgery, Jose Reyes Memorial Medical Center, Manila, Philippines; 5) Department of Surgery, Ospital ng Maynila, Manila, Philippines; 6) Department of Surgery, Medical Center Manila, Philippines.

Breast cancer is the most common cancer in women worldwide. In the Philippines, it ranks as the 2nd most common cancer among both sexes, and first among women, with incidence rates the highest recorded in any Asian population. Like many other cancers, breast cancer has been associated with both genetic and non-genetic factors. Genetic factors found to be associated with breast cancer risk include polymorphisms the in metabolic genes encoding glutathione-S-tranferases and N-acetyltransferases; while a number of reproductive and environmental variables such as contraceptive use, onset of menarche and menopause have also been shown to be related to the disease. To explore the molecular epidemiology of breast cancer among Filipinos, a total of 668 Filipino female patients, 297 with cancer and 371 cancer-free were studied. Corresponding demographics, medical histories, reproductive histories, social histories, diet histories, and occupational exposure data were collected for all subjects. Polymerase Chain Reaction (PCR) and Restriction Fragment Length Polymorphism (RFLP) were performed to genotype for polymorphisms in GSTM1 (deletion), GSTT1 (deletion), GSTP1 (c.313A>G) and NAT2 (g.481C>T, g.590G>A, g.803A>G, g.857G>A). After age- and sex- matched multivariate analysis for epidemiological factors alone, the following were found to be associated with risk: increasing age at 1st pregnancy, family history of breast cancer, and intake of scalding hot food. Non-genetic factors found to be protective against breast cancer included patis (fermented fish sauce) consumption and inverted smoking. The only genetic polymorphism shown by univariate logistic regression to be independently associated for breast cancer risk was the GSTT1 null genotype for breast cancer. After multivariate analysis for both environmental and genetic variables, the GSTT1 null genotype was not found to be significantly associated with breast cancer and only family history of breast cancer in a 1st degree relative significantly increased risk.

## 1162/W/Poster Board #820

**ADIPOQ 45T/G polymorphism in Mexican patientes with Colorectal Cancer.** *M. Partida[1], M.L. Ayala-Madrigal[1], J. Peregrina-Sandoval[2,5], N.M. Macías-Gómez[3], J.M. Moreno-Ortiz[1], A.S. Suárez[1], M.A. Cárdenas[4], E. Cabrales[5], F. Cerda[5], M. Gutiérrez-Angulo[1,6].* 1) Instituto de Genética Humana, Universidad de Guadalajara, Guadalajara, Jalisco, Mexico; 2) Laboratorio de Inmunobiología, CUCBA, UdeG; 3) CUSUR, UdeG; 4) Hospital Civil Juan I. Menchaca; 5) Hospital Civil Fray Antonio Alcalde; 6) CUALTOS, UdeG.

Epidemiology studies showed an association between obesity and colorectal cancer and they have been suggested that hormones derived from adipose tissue can significantly influence on the growth and proliferation of tumors, in fact, some researchers reported an association between the levels of adiponectin and the increase in the risk of colorectal cancer. The polymorphism +45T/G is localized in exon 2, is a synonymous mutation and it has been suggested that is disequilibrium linkage with another polymorphism. This variant has been associated with breast, endometrium, stomach, lung and colorectal cancer (CRC). In this study we analyzed the polymorphism +45T/G in patients with CRC and healthy individuals. We genotyped 45 patients with CRC and 111 healthy individuals. The analysis of the polymorphism were done by PCR-RFLP's assay. The genotype frequencies for patients were 76% TT, 24% TG and 0% GG, and the frequencies for healthy individuals were 67% TT, 30% TG and 3% GG. The allele and genotype frequencies were in Hardy-Weinberg equilibrium. The association analysis did not show any significant differences, however, the allele G was less frequent in patients than healthy individuals (18% and 12%, respectively). The polymorphism +45T/C was not associated with CRC risk in Mexican patients.

## 1163/W/Poster Board #821

**TGFBR1 haplotypes and risk of non-small cell lung cancer.** *B. Pasche[1], Z. Lei[2], R. Liu[2], J. Zhao[2,3], Z. Liu[2], X. Jiang[2], W. You[4], X. Chen[2,5], X. Liu[2], K. Zhang[6], H. Zhang[2].* 1) Div Hematology/Oncol, Univ Alabama, UAB Comprehensive Cancer Center, Birmingham, AL; 2) Laboratory of Medical Genetics, School of Basic Medicine & Biological Sciences, Medical College of Soochow University, Suzhou, P. R. China; 3) Department of Surgery, The First Affiliated Hospital, Medical College of Soochow University, Suzhou, P. R. China; 4) Division of Clinical Medicine, Wuxi Third People's Hospital, Wuxi, P. R. China; 5) Department of Surgery, Shanghai Hospital for Pulmonary Diseases, Shanghai, P. R. China; 6) Department of Biostatistics, School of Public Health, The University of Alabama at Birmingham, Birmingham, AL.

Transforming growth factor beta (TGF-β) receptors are centrally involved in TGF-β-mediated cell growth and differentiation and are frequently inactivated in non-small cell lung cancer (NSCLC). Constitutively decreased type I TGF-β receptor (TGFBR1) expression is emerging as a novel tumor-predisposing phenotype. The association of TGFBR1 haplotypes with risk for NSCLC has not yet been studied. We tested the hypothesis that single nucleotide polymorphisms (SNPs) and/or TGFBR1 haplotypes are associated with risk of NSCLC. We genotyped six TGFBR1 haplotype tagging SNPs (htSNPs) by PCR-restriction fragment length polymorphism (PCR-RFLP) assays and one htSNP by PCR-single strand conformation polymorphism (PCR-SSCP) assay in two case-control studies. Case-control study 1 included 102 NSCLC patients and 104 healthy controls from Suzhou. Case-control study 2 included 131 patients with NSCLC and 133 healthy controls from Wuxi. Individuals included in both case-control studies were Han Chinese. Haplotypes were reconstructed according to the genotyping data and linkage disequilibrium (LD) status of these seven htSNPs. None of the htSNP was associated with NSCLC risk in either study. However, a four-marker haplotype CTGC was significantly more common among controls than among cases in both studies (P=0.014 and P=0.010, respectively) indicating that this haplotype is associated with decreased NSCLC risk (adjusted OR, 0.09; 95% CI, 0.01-0.61 and adjusted OR, 0.11; 95% CI, 0.02-0.59, respectively). Combined analysis of both studies shows a strong association of this four-marker haplotype with decreased NSCLC risk (adjusted OR, 0.11; 95% CI, 0.03-0.39). This is the first evidence of an association between a TGFBR1 haplotype and risk for NSCLC.

## 1164/W/Poster Board #822

**Prognostic Importance of Single Nucleotide Polymorphisms in IL-6, IL-10, IFN-γ, TGF-β1 and TNF-α Genes in Chronic Myeloid Leukemia (Ph+).** *M. Pehlivan[1], S. Pehlivan[2], K. Ozdilli[3], F.O. Savran[4], L. Kaynar[5], T. Sever[2], M. Yilmaz[1], B. Eser[5], Y. Duvarci-Ogret[4], C. Kis[1], V. Okan[1], M. Cetin[5], M. Carin[4].* 1) Gaziantep University, Medical Faculty, Hematology, Gaziantep, Turkey, MD; 2) Gaziantep University, Medical Faculty, Medical Biology and Genetics, Gaziantep, Turkey, PhD; 3) Halic University, Institute of Health Sciences, Istanbul, Turkey, MD; 4) Istanbul University, Medical Faculty, Medical Biology and Genetics, Istanbul, Turkey, PhD; 5) Erciyes University, Medical Faculty, Hematology, Kayseri, Turkey, MD.

The aim of this study was to explore the association between polymorphisms of five cytokines and clinical parameters in patients with Philadelphia positive (Ph+)-chronic myeloid leukemia (CML). We analyzed five cytokines ( IL-6, IL-10, IFN-γ, TGF-β1, TNFα ) in 60 cases with CML (Ph+) and 74 healthy controls. Cytokine genotyping was performed by the polymerase chain reaction sequence-specific primer method. Univariate and multivariate analyses were performed to test for correlations with clinical outcomes. All data were analyzed using SPSS version 14.0 for Windows. The median follow up time was 49.3 months (range 6.1-168.4) and the median duration of imatinib was 39.5 months (range 5.2-103.4) for these patients. No significant differences were detected between CML group and healthy controls in the distributions and numbers of genotypes and alleles in TNF-α, TGF-β1, IL-10 and IFN-γ genotypes whereas GG allele in IL-6 was found to be significantly high in CML but GC allele was found to be low (p=0.010, 0.002, respectively). The frequency of a high IL-6 (-174) producing GG genotype was significantly more common in the patients compared to the controls (p=0.010). Analyzing associations with event-free survival time, we found the GG genotypes of IL6-174 to be related to a lower EFS [AA-AG versus GG Cox proportional hazard ratio 0.140 (p=0.019, [95% CI: 0.027-0.726]). While the polymorphism in IL6 gene was observed to diverge from the Hardy-Weinberg Equilibrium (HWE), it was observed that the polymorphisms of other cytokine genes did not diverge from HWE. Conclusions: The relationship between cytokine genotyping and clinical parameters in CML (Ph+) was investigated for the first time in this study. Our results suggest that IL6 and IL-10 may be useful markers for CML prognosis. These results need to be replicated in larger series and examined in CML.

## 1165/W/Poster Board #823

**Analysis of the Molecular Factors Controlling Human Osteosarcoma Response to Chemotherapy.** *K. Sol-Church, D.L. Stabley, S.M. McCahan, D. Kamara, A. Kolb.* Nemours Biomedical Research, Alfred I duPont Hospital for Children, Wilmington, DE.

Osteosarcoma (OS) is the most common primary malignant bone tumor in children and young adults. Despite the progress made in adjuvant chemotherapy, the overall survival rate remains around 60 percent. New promising therapeutics such as R1507, a fully humanized monoclonal anti-IGF1R antibody available in clinical trials, is effective in inhibiting the growth of a subset of human osteosarcoma tumors engrafted into mice. However, while some of these xenograft tumors respond to therapy, others show little to no growth inhibition. We hypothesized that changes observed in the gene expression and microRNA complement (miRNAome) of these tumors may help elucidate the mechanism of resistance or salvage in OS and identify biomarkers of response that will provide new avenues for the development of prognostic and therapeutic tools. During the present study, we have characterized at the molecular level a panel of six osteosarcoma xenograft tumors that respond differently to R1507 therapy. Our preliminary data suggests that inhibition of IGF signaling induces expression of EGFR, which may maintains tumor growth. Using expression analysis tools, we have identified additional changes in R1507-treated vs. untreated tumors that have potential as prognostic markers of response. In addition, using the hypothesis-free strategy afforded by the SOLiD System Next Generation Sequencing, we have determined the tumors' miRNAome and identified changes induced by R1507 treatment. The combined results from this study will reveal important aspects of tumor biology and identify molecular targets that may be exploited for the development of new therapeutics for OS.

**Human papillomavirus DNA in plasma of patients with HPV16 DNA-positive uterine cervical cancer.** *S. Takako[1], Y. Naohiro[2], Y. Kentaro[1], M. Kiyonori[1], M. Hideaki[1].* 1) Obstetrics and Gynecology, Nagasaki University Graduate School , Nagasaki, Japan; 2) Molecular Microbiology and Immunology, Nagasaki University Graduate School, Nagasaki, Japan.

Introduction : The squamous cell carcinoma antigen (SCCA) is considered the most accurate serologic tumor marker for uterine cervical carcinoma. However, serum SCCA levels were found to correlate significantly with clinical severity of atopic dermatitis and chronic renal failure. The present study was conducted in patients with human papillomavirus (HPV)16 DNA-positive uterine cervical cancer to determine the plasma level of HPV16 DNA and the diagnostic values of plasma HPV DNA in these patients. Materials and methods : Thirty-six HPV16-positive patients with cervical intraepithelial neoplasia (CIN) or uterine cervical SCC were recruited in this study. The diagnosis was cervical cancer in 11 patients, high-grade squamous intraepithelial lesions (HSIL) in 21, low-grade squamous intraepithelial lesions (LSIL) in 1 and negative for intraepithelial lesion or malignancy (NILM) in 3 patients. Before any treatment, blood samples were collected from all patients. For analysis of HPV DNA in plasma of patients with cervical cancer, qPCR fluorescent assay for HPV16 was performed using HPV16 primers and SYBR Green dye using the LightCycler 480 SW1.5 apparatus. Results : Plasma HPV16 DNA was detected in only 27.3% of patients with HPV16-positive cervical cancer and in none of normal controls. The copy number of plasma HPV16 DNA was significantly higher in patients with invasive cancer than in those with cervical intraepithelial neoplasia (CIN3), microinvasive cancer and in normal individuals. Summary : These results indicated that plasma HPV DNA level could be potentially used as a marker of low-invasive cervical cancer tumors in patients with normal SCCA levels before treatment.

**de novo methylation in DLBCL frequently occurs proximal to genes that are poorly expressed in normal progenitor cells.** *X. Wang[1], T. Greiner[2], B.L. Pike[1], D.J. Weisenberger[3], K.D. Siegmund[4], U. Sinha[5], M. Muschen[6], P.W. Laird[3], J.B. Fan[7], J.G. Hacia[1].* 1) Department of Biochemistry and Molecular Biology, University of Southern California Los Angeles, CA, USA; 2) Departments of Pathology and Microbiology University of Nebraska Medical Center Omaha, NE, USA; 3) Department of Surgery University of Southern California Los Angeles, CA, USA; 4) Department of Preventive Medicine University of Southern California Los Angeles, CA, USA; 5) Department of Otolaryngology, Head and Neck Surgery University of Southern California Los Angeles, CA, USA; 6) Leukemia Research Program Children's Hospital Los Angeles Los Angeles, CA, USA; 7) Illumina, Inc. San Diego, CA, USA.

Epigenetic profiling studies have identified methylated loci in diffuse large B-cell lymphoma (DLBCL). However, it is unclear what proportion represents de novo methylation acquired during tumorigenesis in contrast to methylation present in normal precursor B-cells. We used BeadArray assays to identify methylated loci in activated B-cell like (ABC-DLBCL), germinal center B-cell-like (GCB-DLBCL), and normal precursor B-cells. We identified 81 candidate loci predicted to show de novo methylation in >20% of GCB-DLBCL cases. All candidate loci were proximal to genes that are poorly expressed or silent in normal germinal center B-cells. Our results are consistent with the hypothesis that DNA methylation is more frequently involved in the maintenance rather than the initiation of gene silencing in cancer. We propose that similar to de novo genetic changes found in tumors, the majority of de novo methylation events we observed are neutral and not causally involved in tumoriogenesis. However, this would not affect their potential value as clinical biomarkers. A major challenge remains to identify the subset of de novo epigenetic changes that are functionally significant in DLBCL.

## 1168/W/Poster Board #826

**Digital Counting of Gene Copy Number in Clinical Settings.** *S. Ishikawa[1,2], T. Sakatani[2], M. Fukayama[2], H. Aburatani[1].* 1) Genome Science Division, Univ. of Tokyo, Tokyo, Japan; 2) Department of Pathology, Graduate School of Medicine, Univ of Tokyo, Tokyo, Japan.

Detection gene copy number is important in several clinical settings. Technology for sensitive and robust detection of copy number aberration is especially indispensable in the situation where the abnormal fraction is lower with more normal component. High-density oligonucleotide microarray and qPCR may be routinely used for detection of copy number aberration. However, these techniques are not reliable enough to detect copy number change with high normal background. To address these issues, we introduced two methods for "digital" copy number count, (1) Illumina Genome Analyzer and (2) Fluidigm Nanofluidic Chip for genome-wide and targeted approach. (1) To assess copy number by counting frequency of short read within defined window, we developed algorithm to modify raw data using genome-wide hit number of these short reads and other experimental conditions. Digital count of short read generated by Illumina Genome Analyzer successfully got HCT116 cell copy number comparable with but more reliable than high density oligonucleotide microarray. (2) We did serial dilutions of genome sample mixed with TaqMan® reagents and finely partitioned each dilution within 48 separate, on-chip 770 grids of reaction chambers. As signal is produced only in chambers containing copies of the target sequence, the positives in each chamber grid are digital-counted and evaluated for statistical significance. The presentation will includes the detection of CNV and cancer gene amplification and its comparative experiments using high density oligonucleotide microarray. Nanofluidic digital array technology can reliably quantitate an absolute copy number with high normal background.

## 1169/W/Poster Board #827

**Genetic variants in the candidate genes of the apoptosis pathway and susceptibility to chronic myeloid leukemia.** *D. Kim[1, 2], W. Xu[3], C. Ma[3], X. Liu[4], K. Siminovitch[4], H.A. Messner[2], J.H. Lipton[2].* 1) Hematology/Oncology, Samsung Medical Center, Seoul, Korea; 2) Chronic Myelogenous Leukemia Group, Department of Hematology/Medical Oncology, Princess Margaret Hospital, University Health Network, University of Toronto,Toronto, Ontario, Canada; 3) Department of Biostatistics, Princess Margaret Hospital, University Health Network, University of Toronto,Toronto, Ontario, Canada; 4) Analytical Genetics Technology Centre, University Health Network, Toronto, ON, Canada.

Chronic myeloid leukemia (CML) is a clonal myeloproliferative disorder, characterized by the presence of BCR/ABL fusion gene. It is unclear which cellular events drive BCR/ABL gene translocation or initiate leukemogenesis in CML. Previous observations showed that intriguing detection of BCR/ABL fusion gene at a very low level in the blood of normal healthy individuals, suggesting that only a minor fraction of spontaneous Ph translocations progress to CML, or that BCR/ABL fusion gene is essential but not sufficient to lead to the leukemogenesis without additional second cellular or molecular events. Also, Bcl-2 promotes survival of hematopoietic stem cells and more frequent expression of bcl-2 was known to be associated with progression of CML from chronic phase to advanced stage. Accordingly, apoptosis-related pathway may involve in the leukemogenesis of CML. In the present study, we evaluated 80 SNP markers involved in the 6 major candidate pathways that have been proposed to provoke leukemogenesis in CML such as pathways of apoptosis (n=30), angiogenesis (n=7), myeloid cell growth (n=14), xenobiotic metabolism (n=13), WT1 signaling (n=7), interferon signaling (n=4) and others (n=5) in 170 CML patients and 182 healthy controls. Sequenom MassARRAY platform was used for genotyping and Haploview version 3.32 and WHAP version 2.09 were used for statistical analysis. In a single marker analysis, following SNPs were identified to be associated with increasing risk of CML including *VEGFA*, *BCL2*, *CASP7*, *JAK3*, *CSF3* and *HOCT1*. In the multivariate logistic model with these SNPs and covariates, only *BCL2* (rs1801018) was significantly associated with the susceptibility to CML (p=0.05; adjusted-OR 2.16, [1.01-4.68]). In haplotype analyses, haplotype block of *BCL2* consistently showed significant association with increasing susceptibility to CML. Risk allele analysis showed that a greater number of risk alleles from *BCL2* SNP correlated to increasing risk of CML (overall p=0.1, OR 1.84, [1.06-3.22] for 3-4 risk alleles vs. 0-1 risk alleles). In summary, the current study indicated that BCL2 SNP seemed to be associated with increasing susceptibility to CML.

## 1170/W/Poster Board #828

**Cumulative Genetic Risk Predicts Platinum/Taxane-Induced Neurotoxicity.** *S. McWhinney-Glass[1, 5], S.J. Winham[2,5], J.Y. Revollo[1,5], J. Paul[3], R. Brown[4], A. Motsinger-Reif[2,5], H.L. McLeod[1,5].* 1) Schools of Pharmacy and Medicine, University of North Carolina, Chapel Hill, NC; 2) Bioinformatics Research Center and Department of Statistics, North Carolina State University, Raleigh, NC; 3) Cancer Research UK Clinical Trials Unit, University of Glasgow, Glasgow; 4) Department of Oncology, Imperial College London, London; 5) Institute for Pharmacogenomics and Individualized Therapy, University of North Carolina, Chapel Hill, NC.

Platinum/taxane-based chemotherapy is the standard of care for many cancers, including lung and ovarian. However, the utility of these chemotherapeutic drugs is often limited due to severe neurotoxicity. Previous studies have identified potential clinically-relevant genetic factors associated with chemotherapy-induced neurotoxicity, but the value of these variants is limited by a lack of replication. Additionally, interventions such as the administration of neuroprotectant agents to minimize or circumvent the neurotoxic effects require further studies to determine if there is a significant reduction of symptoms. For these reasons, we sought to identify genetic risk factors for chemotherapy-induced neurotoxicity. We conducted a candidate-gene association study to evaluate 1569 SNPs in 58 candidate genes in 914 ovarian cancer patients from the SCOTROC1 ovarian cancer Phase III trial treated with platinum-based chemotherapy. For analysis, the dataset was randomly split into test/validation sets, each set composed of 50% of the controls (grades 0/1 neurotoxicity) and 50% of the cases (grades 2/3/4 neurotoxicity). Significant associations with four SNPs in *SOX10, BCL2, OPRM1*, and *TRPV1* that confer a significant risk for chemotherapy-induced neurotoxicity were identified and replicated in the validation sample. Permutation testing was used to correct for multiple testing and variable selection concerns. Individuals with 0 risk genotypes have a reduction in incidence of neurotoxicity of 84.9% compared to individuals with all 4 risk genotypes. According to our multiplicative model, the odds of developing neurotoxicity increase by a factor of 2.34 for every increase of risk genotypes possessed (corrected p-value=0.007). The strength of this model indicates the strength of an additive trend in risk genotypes. None of the 4 significant SNPs were associated with progression-free survival or overall survival. This decouples the theoretical link between neurotoxicity and tumor control. Indeed, this data indicates that intervention or prevention strategies for platinum/taxane neurotoxicity based on these four genetic variants are not likely to adversely influence the efficacy of the chemotherapeutic agent. A genetic test for the risk genotypes in *SOX10, BCL2, OPRM1,* and *TRPV1* may serve as a valuable prediction tool for clinicians to approximate the level of risk for neurotoxicity for each individual based on the number of risk genotypes that they harbor.

## 1171/W/Poster Board #829

**Glutathione S-transferase P1 genetic polymorphism: A potential risk factor for the development of childhood ALL in Poland.** *J.J. Pietrzyk, A. Madetko-Talowska, M. Bik-Multanowski.* Chair of Pediatrics, Jagiellonian University, Krakow, Poland.

The presence of some metabolically important genetic polymorphisms may contribute to the risk of acute lymphoblastic leukemia (ALL), which is the most common pediatric malignancy. Glutathione S-transferases are enzymes involved in detoxication of xenobiotics, including environmental carcinogens. The aim of this study was to evaluate the role of GSTP1*B (c.313a>g) polymorphism of glutathione S-transferase P1 gene which results in reduced activity of glutathione S-transferase P1, as a risk factor for ALL in Polish population. Methods The study population consisted of 1000 healthy newborns representative for Polish population. DNA samples were isolated from dried blood spots (remainder parts of newborn screening cards). Genotyping for the detection of the GSTP1*B polymorphism was performed using PCR-RFLP method. Population allelic frequency of the polymorphism was compared with the one observed in a group of 400 children with ALL (data published in Pediatr Blood Cancer 2009;3:364-368). Fisher's exact test and odds ratio with 95% confidence interval were used for data analysis. Results We found that GSTP1*B (313G) allele was significantly more frequent among the individuals with ALL in comparison to the general population (OR:1,54; 95% CI 1,30-1,83; p-value: 0,0001). Details on genotyping are shown in the table.

| | Genotypes/Cases: c.313aa/c.313ag/ c.313g | Allelic frequency (c.313g) |
|---|---|---|
| ALL | 140 / 219 / 41 | 0.37 |
| Controls | 510 / 417 / 73 | 0.28 |

Our results suggest that GSTP1*B genetic variant is associated with increased risk of ALL. Further studies are needed to confirm the above findings in other populations. Study was sponsored by government research grants NN407232934 and PBZ-KBN-090/P05/06/2003.

## 1172/W/Poster Board #830

**Direct detection of rare circulating tumor cells in blood by competitive allele-specific TaqMan-based PCR (castPCR).** *C. Chen, R. Tan, J. Chan.* Genomic Assays R & D, Life Technologies, Foster City, CA.

Circulating tumor cells in blood from metastatic breast and lung cancer patients have been reported as a surrogate marker for tumor response and shorter survival. Detection of these rare tumor cells in blood is the key to early cancer diagnosis. Here we report a new competitive allele-specific TaqMan-based PCR (castPCR) method for rare mutation detection. castPCR combines allele-specific TaqMan qPCR with allele-specific MGB blockers to suppress amplification of the wild type allele, resulting in better specificity. We have successfully designed and validated castPCR assays for 48 cancer-related SNPs of Ras, EGFR, Kit, pTEN, and p53. Results demonstrate that castPCR not only maintains the wide dynamic range, high sensitivity, and reproducibility but also improve the specificity of allelic TaqMan assays for up to 1 in 1,000,000. Results of detecting circulating tumor cells in cancer patient samples will be presented.

## 1173/W/Poster Board #831

**Yields of viral and circulating nucleic acids using the new large volume QIAamp Circulating Nucleic Acid Kit.** *M. Horlitz, T. Hartinger, A. Lucas, J. Schaper, M. Sprenger-Haussels.* QIAGEN GmbH, Hilden, Germany.

Introduction: Fragmented DNA and mRNA originating from tumors or infections circulate as cell-free nucleic acids in plasma, serum and other cell-free body fluids. Access to these molecules for analysis could allow for specific detection of certain disease states based on a simple blood sample. In this study the extraction efficiency of a new large volume nucleic acid extraction kit for free-circulating DNA & RNA, miRNA, and nucleic acids from viral particles, was compared to established extraction methods. Materials/ Methods: Endogenous circulating nucleic acids were extracted from pooled plasma using the QIAamp Circulating Nucleic Acid (CNA) Kit (5 ml sample; N=12). DNA yield was quantified by 18S rDNA-specific duplex qPCR (two separate targets, 66 bp and 500 bp long) ; mRNA yields were measured by qPCR specific for GAPDH, c-fos, β-globin. The QIAamp MinElute Virus Kit (1 ml; N=12) served as the reference protocol. For endogenous miRNA extraction from plasma, an optimized protocol was tested (3 ml; N=12). miRNA yields were quantified by QIAGEN miScript (miR16, miR103) and Applied Biosystems TaqMan (miR16, miR30b) assays. HBV, HCV, HIV-1 particles (all WHO standard material) were added to pooled EDTA plasma in a 6-step, 2-fold dilution series (N=16 per concentration). After nucleic acid extraction using the CNA Kit (5 ml sample, 30 μl elution), viral nucleic acids were detected by qPCR to determine hit rates. Results: For both free-circulating DNA and free-circulating mRNAs, the yield was 6-9-fold higher compared to the MinElute Virus protocol for all genetic targets. The optimized miRNA extraction protocol was found to deliver significantly increased miRNA yields ($\Delta$Ct from 2 to 7) compared to the CNA standard protocol for the 4 miRNA assays used. For viral nucleic acids, 95% detection rates calculated by probit regression analysis were: HBV DNA 0.3 IU/ml, HCV RNA 7.2 IU/ml, HIV-1 RNA 14.2 IU/ml. Conclusions: The results demonstrate that the new extraction protocol can serve as a sample preparation solution for processing up to 5 ml plasma, it allows for small elution volumes, and can extract and concentrate (volume ratio sample/eluate of up to 250:1) circulating cell-free DNA and mRNA, circulating miRNA, and viral nucleic acids for applications in biomarker and viral infection research. The applications presented here are for research use only. Not for use in diagnostic procedures.

### 1174/W/Poster Board #832

**DIFFERENTIAL ASSOCIATION OF CYTOCHROME P450 3A4 GENOTYPES WITH ONSET OF BREAST TUMORS.** *D. McDaniel[1], T. Thurber[2], C. Berry[2], X. Zhou[3], S. Bigler[3], R. Vance[4], W. Barber[5].* 1) Dept Surgery/Neurology; 2) School of Medicine; 3) Pathology; 4) Dept Medicine/Cancer Center; 5) Dept. Surgery, Univ Mississippi Med Ctr, Jackson, MS.

Background: Growth of >50% of breast tumors are hormone-dependent and breast adipose tissue is a local source for both estrogen (E) and E-receptors. Estrogens are produced through the activity of Cytochrome P450 aromatase. Particularly, P450 3A4 is involved in the metabolism of several drugs including Tamoxifen, used in breast cancer therapy. The goal of our study was to validate the role of CYP 3A4 gene polymorphism and the association with tumor stage, grade and hormonal receptor status including estrogen-receptors, progesterone-receptors and human epidermal growth factor (HER-2/neu) in African American and Caucasian patients with breast cancer. Methods: Patients who had undergone biopsy procedures for diagnosis or for partial or radical mastectomy were recruited in this study. Genotypes were detected using SNP analysis. The mRNA transcripts were screened by a RT-PCR. Clinical data including tumor staging, pathology grades and family history were evaluated. Results: The GG alleles were significantly increased in African American patients requiring biopsy as compared with healthy controls (p<0.001). However, there was no significant difference between the genotypes comparing the benign vs. ductal carcinomas in situ (DCIS) or infiltrating ductal carcinomas (IDCA). The African American patients with a pathology diagnosis of fibroadenomas, 50% carried the AA alleles as compared with 23% AG and 28.6% GG alleles. Patients (58%) with stage II tumor diagnosis carried the GG genotype as compared with 20% and 29% AA and AG genotypes respectively. The HER-2/neu receptors were increased in patients with AG or GG. The mRNA expression was reduced in patients with IDCA vs. DCIS or benign tumors (Benign vs. IDCA, p<0.0009; DCIS vs. IDCA, p<0.005). Likewise, it lower in patients with HER-2/neu positive tumors (p<0.0024, OR-2.13). Conclusion: A novel aspect of our report is that the expression levels of CYP 3A4 is associated at least with disease sub-category. The data suggest that testing for the determination of CYP 3A4 alleles in concert with the receptors would increase the power of early diagnosis, and early management of patient care.

### 1175/W/Poster Board #833

**Interaction of CYP1B1 gene variant (N453S) with carcinogen metabolism in cigarette smoke increases lung cancer risk.** *M. Haznadar[1], T. Church[2], M. Geisser[2], K. Anderson[3], N. Caporaso[5], S. Hecht[4], B. Van Ness[1].* 1) GCD, University of Minnesota, Minneapolis, MN; 2) Environmental Health Sciences, University of Minnesota, Minneapolis, MN; 3) Epidemiology, University of Minnesota, Minneapolis, MN; 4) Department of Medicinal Chemistry, University of Minnesota, Minneapolis, MN; 5) NCI, Bethesda, MD.

The purpose of this study was to examine single nucleotide polymorphisms (SNPs) in genes important to the metabolism of NNAL and PheT, carcinogenic metabolites from cigarette smoke. In a previous case-control study, a significant correlation was found between the serum levels of total NNAL and a prospective lung cancer risk. Given the association of NNAL levels as a marker of metabolism of smoking carcinogens, and SNPs in cytochrome P450 genes associated with drug and carcinogen metabolism, we examined risk by interaction of SNPs and metabolic biomarker levels.

A case-control study was nested in the Prostate, Lung, Colorectal, and Ovarian Cancer Screening Trial. 100 lung cancer cases and 100 controls who smoked at time of enrollment were selected. The baseline serum levels for total NNAL, cotinine, and PheT were analyzed in all subjects. DNA was extracted from banked lymphocytes and SNPs in 3 genes involved in NNAL and PheT metabolism were determined (CYP1B1, EPHX1, GSTP1). Logistic regression was used to determine if there was an interaction between each SNP and the levels of carcinogenic biomarker as a risk for lung cancer.

A SNP in CYP1B1 (N453S) was found to significantly interact with NNAL in increasing the risk for lung cancer. The minor variant doubles the slope of the risk for lung cancer with increasing serum NNAL levels. The main effect (OR=0.133; 95%, CI=0.024,0.737) and interaction effect (OR=1.020; 95%, CI=1.002,1.038) are both statistically significant for SNP N453S. This SNP has been shown to decrease intracellular levels of CYP1B1 protein, presumably by decreasing its stability and half life. Most of the carcinogenic effects of polycyclic aromatic hydrocarbons present in tobacco smoke are mediated by the aryl hydrocarbon receptor (AhR), a ligand-dependent transcription factor that regulates tobacco-induced expression of carcinogen metabolic enzymes. While CYP1B1 has not previously been implicated in NNAL metabolism, it does alter induction of CYP1A1 by AhR, and CYP1A1 has been implicated in the activation of NNAL and DNA adduct formation.

A common polymorphism of CYP1B1 may play a role in the risk of lung cancer through interaction with NNAL metabolism. This interaction provides a novel example of pathways influencing gene-environmental exposure as a risk for this disease.

### 1176/W/Poster Board #834

**Generation of Controls for an Allele Specific PCR Assay for Detection of the T315I Mutant Allele in the BCR-ABL1 Kinase Domain Found In Imatinib Resistant Patients with Chronic Myeloid Leukemia.** *D. Payne[1], R. Garcia[1], C. Tirado[1], E. Keohanne[2].* 1) UT Southwestern, Dallas, TX; 2) University of Medicine and Denistry, New Jersey.

Background: Chronic myeloid leukemia (CML) patients resistant to Imatinib (IM) have mutations in the Kinase Domain (KD) of the BCR-ABL1 protein. Thus far, a minimum of 40 different KD mutations have been identified with T315I as the most frequent KD mutation in CML patients. Methods: We generated controls for the wild type (WT315) and T315I mutant alleles in the BCR-ABL1 Kinase Domain present in IM resistant patients. Initially, a BCR-ABL-1 cDNA was generated from a K-562 cell line. To generate the wild type (WT315) and T315I controls, an ASO-PCR assay designed by Willis et al. (2005) was used for detection of both wild type and mutant alleles. The cDNA generated from the K-562 cell line served as template for the forward primer shortabl (F) and reverse primer WT315 (R) to generate the WT315 control. Similarly, the T315I control was generated by using WT315 DNA as template for shortabl F and the reverse mutant primer T315I + 5 R. Results: Using a BCR-ABL1 PCR assay, a 332 base pair (bp) fragment was amplified with the K-562 DNA confirming the presence of the BCR-ABL1 sequence. Subsequent allele specific amplification showed a 160 bp fragment corresponding to the wild type control, WT315 amplified by primers shortabl F and WT315 R using K562 cDNA as the template. Later, a 160 bp band corresponding to the mutant control was amplified by primers shortabl F and T315I + 5 R using WT315 DNA as the template (the single base mismatch between the mutant primer and wild type template was overcome by decreasing annealing temperature to 55°c, decreasing number of PCR cycles to 25, and by adding 5 bases to the reverse primer past the 3' end of the wild type allele). ASO-PCR validation showed: a 160 bp band corresponding to the amplified T315I DNA by the primers shortabl F and T315I R + 5, while there was no amplified band for the T315I DNA by the primers shortabl F and WT315 R. In this study, the ASO-PCR had a detection limit of 1/100. DNA sequencing and detection of the T315I mutation from a patient further validated controls. Conclusion: The ongoing problem with many molecular assays is the relative absence of positive control material. We used several approaches for generating control material all of which failed prior to the final approach. The last approach incorporates an extended primer with the single base pair change followed by 5 bases. This approach is a simple and an inexpensive method for developing control material for ASO PCR assays.

### 1177/W/Poster Board #835

**Identification of regulatory genetic variation that affects drug response in childhood acute lymphoblastic leukemia (ALL).** *A. Kiialainen[1], J. Nordlund[1], L. Milani[1], A. Lundmark[1], U. Liljedahl[1], G. Lönnerholm[2], A-C. Syvänen[1].* 1) Department of Medical Sciences, Uppsala University, Uppsala, Sweden; 2) For the Nordic Society of Pediatric Hematology and Oncology (NOPHO), and Department of Children's and Women's Health, Uppsala University, Uppsala, Sweden.

Acute lymphoblastic leukemia (ALL) is the most common form of childhood cancer. Although treatments for ALL currently exist, some patients do not benefit from them, while others suffer from unnecessary side effects. In order to gain insight into regulatory genetic variation that affects drug response in ALL, we have recently determined the allele-specific expression (ASE) levels of over 8000 genes in RNA-samples from 197 ALL patients whose in vitro drug responses against ten anti-cancer drugs are known (Milani et al., Genome Research 2009). By genotyping SNPs in coding regions of genes in DNA and RNA (cDNA) and comparing the allelic ratios in RNA with those in genomic DNA from heterozygous individuals, we have detected ASE with high confidence in 400 genes. Guided by the allele-specific differences in gene expression, we have chosen a subset of 56 genes displaying ASE for re-sequencing. We are sequencing the whole genes, including exons, introns, and some of the 5' and 3' non-coding sequence. We are using Nimblegen sequence capture arrays for template preparation of DNA samples from ALL patients and the Genome Analyzer (Solexa/Illumina) for sequencing the genes. We align the sequences and perform SNP calling with the MAQ software (Heng Li, Sanger Institute). In the 3 Mb target region that we are sequencing, we find up to 4000 SNPs per sample. After sequencing, we plan to genotype the regulatory variants discovered by sequencing in a larger set of patient samples. We will correlate the genotypes with the allele-specific expression levels as well as with the drug response patterns of the patient cells.

## 1178/W/Poster Board #836

**Sensitive detection of KRAS mutations using mutant-enriched PCR and reverse-hybridization teststrips.** *G. Kriegshaeuser[1], B. Holzer[2], B. Rauscher[1], E. Schuster[2], F. Kury[1], R. Zeillinger[2], C. Oberkanins[1].* 1) ViennaLab Diagnostics, Vienna, Austria; 2) Molecular Oncology Group, Department of Obstetrics and Gynaecology, Medical University of Vienna, Austria.

The KRAS gene encodes the human cellular homolog of a transforming gene isolated from the Kirsten rat sarcoma virus. Like the other members of the ras gene family, the KRAS protein is a 21 kD GTPase and an early player in many signal transduction pathways. While wildtype KRAS plays a vital role in normal cellular signaling processes, mutated forms of the gene are potent oncogenes that are found in many human cancers. The most critical region of the KRAS gene for oncogenic activation are mutations in codons 12 and 13, causing the protein to accumulate in the active GTP-bound state. KRAS mutations were shown to be also predictive for the response to cancer therapy with certain anti-EGFR monoclonal antibodies (panitumumab, cetuximab) and tyrosine kinase inhibitors (erlotinib, gefitinib). We have developed a novel reverse-hybridization assay (StripAssay) targeting 10 frequent mutations in codon 12 and 13 of the KRAS gene. The test is based on PCR in the presence of a suppressor for wild-type KRAS amplification (mutant-enriched PCR), followed by hybridization of PCR products to teststrips presenting a parallel array of allele-specific oligonucleotide probes. The hybridization and detection steps can be carried out fully automated using available instrumentation. The performance of the StripAssay was evaluated on DNA obtained from cultured cell lines, from formalin-fixed paraffin-embedded (FFPE) tissue and from stool. Using serial dilutions of DNA from various KRAS-mutated tumor cell lines into normal DNA, each of the 10 mutations was shown to be detectable at levels as low as 1%. DNA samples containing various proportions of mutated KRAS were analyzed by the StripAssay in direct comparison to real-time PCR, dideoxy sequencing and pyrosequencing. While all methods correctly identified samples containing 25% mutated DNA, dideoxy sequencing and pyrosequencing failed to detect levels of 12.5% or lower. Both the StripAssay, as well as real-time PCR, unambiguously identified 10%, 5% and 1% of KRAS-mutated DNA in the presence of excess wild-type DNA. The simultaneous detectability of 10 different mutations with excellent sensitivity will make the StripAssay a very useful tool for the assessment of the KRAS mutation status in cancer patients. (oberkanins@viennalab.co.at).

## 1179/W/Poster Board #837

**Association of XPD Polymorphisms with Severe Toxicity in Non-Small Cell Lung Cancer Patients in a Chinese Population.** *W. Wu[1], W. Zhang[2], R. Qiao[2], D. Chen[1], H. Wang[1,3], Y. Wang[1], S. Zhang[1], G. Gao[1], A. Gu[2], J. Shen[2], J. Qian[1], W. Fan[1], L. Jin[1], B. Han[2], D. Lu[1].* 1) State Key Laboratory of Genetic Engineering and Key Laboratory of Contemporary Anthropology, School of Life Sciences, Fudan University, Shanghai, China; 2) Department of Respiratory Disease, Shanghai Chest Hospital, Shanghai Jiaotong University, Shanghai, China; 3) Department of Neurological Surgery, Brain Tumor Research Center, The First Clinical Medical School of Harbin Medical University, Harbin, China.

Purpose: Platinum agents cause DNA cross-linking and adducts. Xeroderma pigmentosum group D (XPD) plays a key role in the nucleotide excision repair pathway of DNA repair. Genetic polymorphisms of XPD may affect the capacity to remove the deleterious DNA lesions in normal tissues and lead to greater treatment-related toxicity. This study aimed to investigate the association of three polymorphisms of XPD at codons 156,312, and 711 with the occurrence of grade 3 or 4 toxicity in advanced non-small cell lung cancer patients. Experimental Design: We used matrix-assisted laser desorption /ionization time-of-flight mass spectrometry to genotype the three polymorphisms in 209 stage III and IV non-small cell lung cancer patients treated with platinum-based chemotherapy. Results: The variant homozygotes of XPD p.Arg156Arg (rs238406) polymorphism were associated with a significantly increased risk of grade 3 or 4 hematologic toxicity [adjusted odds ratios (OR) = 3.24, 95% confidence interval (CI) = 1.35-7.78, P for trend =0.009], and more specifically, severe leukopenia toxicity (P for trend = 0.005). No statistically significant association was found for the three polymorphisms and grade 3 or 4 gastrointestinal toxicity. Consistent with these results of single-locus analysis, both the haplotype and the diplotype analyses revealed a protective effect of the haplotype 'CG' (in the order of p.Arg156Arg- p.Asp312Asn) on the risk of grade 3 or 4 hematologic toxicity. Conclusions: This investigation, for the first time, provides suggestive evidence of an effect of XPD p.Arg156Arg polymorphism on severe toxicity variability among platinum-treated non-small cell lung cancer patients.

## 1180/W/Poster Board #838

**The association of promoter variations in *HMOX1* and *UGT1A1* genes with colorectal cancer.** *A. Jiraskova[1,2], J. Novotny[3], L. Novotny[4], B. Pardini[5], A. Naccarati[5], P. Vodicka[5], H.A. Schwertner[6], J. Hubacek[7], L. Vitek[1,2].* 1) 4th Department of Internal Medicine; 2) Department of Clinical Biochemistry and Laboratory Diagnostics; 3) Department of Oncology; 4) Institute of Hygiene and Epidemiology, and 3rd Department of Internal Medicine, 1st Faculty of Medicine, Charles University in Prague, Czech Republic; 5) Institute of Experimental Medicine, Academy of Sciences of the Czech Republic; 6) Clinical Research, Wilford Hall Medical Center, San Antonio, USA; 7) Institute of Clinical and Experimental Medicine, Prague, Czech Republic.

Background: Enzymes heme oxygenase-1 (HO-1, encoded by *HMOX1*) and bilirubin UDP-glucuronosyltransferase (*UGT1A1*), both involved in the heme catabolic pathway, play an important role in the oxidative stress defence. HO-1 is the rate-limiting enzyme in heme catabolism that converts heme to biliverdin. Two functional polymorphisms, a (GT)n repeat variation and T-413A single nucleotide polymorphism (SNP), in the promoter of *HMOX1* gene have been associated with different clinical phenotypes. *UGT1A1* gene product catalyses glucuronidation of serum bilirubin. (TA)n repeat variation modulates *UGT1A1* transcriptional activity and quantity of the enzyme available to conjugate serum bilirubin, which is known as a potent antioxidant. *UGT1A1* and *HMOX1* promoter variations affecting serum bilirubin levels may be predictive of genetic susceptibility to oxidative damage and cancer. The objective of this study was to determine whether these variations affect development of colorectal cancer (CRC). Methods: The study was performed on 442 CRC patients (182 female) and 493 healthy age- and sex-matched controls (203 female). The (GT)n and (TA)n dinucleotide variations were determined by fragment (size-based) analysis using an automated capillary DNA sequencer (CEQ8000, Genetic Analysis System, Beckman Coulter). The length variations of (GT)n repeats were classified into short S ($n < 27$), medium M ($n = 27\text{-}32$) and long L ($n \geq 33$) subgroups. Results: No significant differences in frequencies of L-allele and L-allele carrier (S/L, M/L, L/L), M-allele and M-allele carrier (M/M, M/L, M/S), and S-allele and S-allele carrier (S/S, S/L, S/M) between control and CRC group were found. Similarly, no significant association between A-413T SNP and development of CRC was observed. However, gender-associated differences of (TA)n polymorphism in *UGT1A1* were observed. Higher frequency of (TA)6/(TA)6 genotype was found in CRC male patients (OR = 1.52; p = 0.019), but not in CRC female patients (OR = 1.08; p = 0.78). Conclusions: Results of our study suggest that (GT)n variations and A-413T SNP in *HMOX1* do not provide protection against CRC. Nevertheless, (TA)6/(TA)6 genotype of *UGT1A1*, associated with lower serum bilirubin levels, may increase a risk for development of CRC in male population.

## 1181/W/Poster Board #839

**The epidermal growth factor receptor (EGFR) and K-ras gene mutation detection in cancer cell lines using a multiplex genomic SNP/Insertion and Deletion(Indel) genotyping system.** *R. Fang, D. Wang, J. Shewale, P. Brzoska, M. Furtado.* Applied Markets, Applied Biosystems, Foster City, CA.

Human cancer cell lines have proven to be excellent models for studying many aspects of cancer development and also provided a powerful system for assessing the sensitivity to anticancer drugs. The genotype information about mutations for genes which are involved in cancer development in these cells will be valuable for cancer research. We have developed a multiplexed SNP and Indel detection assay for 29 and 5 somatic mutations in epidermal growth factor receptor EGFR and K-ras genes, respectively, which are frequently found in human cancers. The genotyping system is based on an initial PCR amplification followed by an oligonucleotide ligation reaction; the alleles were detected by capillary electrophoresis. The system is sensitive, accurate, easy to use and amenable for automation and high throughput processing. DNA was extracted from tumor cell lines using PrepFiler kit and genotyped. DNA preparations from 48 ATCC and 60 NCI tumor cell lines were also genotyped. The EGFR and K-ras mutations were discovered in some of the investigated tumor cell lines with specific pattern. These mutated genotypes were further confirmed by the Sanger sequencing chemistry. The information generated from this study will be definitely useful when these cell lines are used as models for cancer study and cancer drug screening.

## 1182/W/Poster Board #840

**Pharmacogenomic modeling for predictions of patient outcomes in myeloma.** *B. Van Ness[1], M. Haznadar[1], C. Ramos[1], M. Gosse[1], V. Kumar[2], M. Steinbach[2], B. Durie[3], J. Crowley[4], A. Hoering[4], D. Johnson[5], G. Morgan[5], S. Janz[6].* 1) Dept Genetics, Cell Biol & Dev, Univ Minnesota, Minneapolis, MN; 2) Dept Computer Science and Electrical Engineering; 3) Hematology/Oncology, Cedars-Sinai Cancer Center, Los Angeles, CA; 4) Cancer Research & Biostatistics, Seattle, WA; 5) Heamatology-Oncology, Institute of Cancer Research, London, UK; 6) Dept Pathology, Univ Iowa, Iowa City , IA.

Purpose: While myeloma is still considered a fatal disease, new therapeutic approaches, including combination of drugs that target different intracellular pathways, have shown marked improvements in response and survival. Yet there are wide variations in responses seen among the patient population. One major source is the variation in chromosomal abnormalities and the genes deregulated among the plasma cell (PC) tumors. Another may be in inherited variations (SNPs) that can have a major influence on drug distribution, transport and metabolism. We are taking several approaches to model the impact of both tumor genetic variations and inherited genomic variations on patient outcomes. Methods: Using well established cell lines we are examining variation in cellular response to dexamethasone, melphalan, bortezomib (Velcade), and bcl-inhibitors. Variation in cytotoxicity assays are correlated to common patterns of gene expression or genome wide SNPs to develop models of pathways influencing cellular response. Our laboratory has developed a transgenic mouse model targeting overexpression of c-myc and bcl-xL in late B cells, that results in early expansion of non-malignant PCs, followed by development of clonal plasma cell malignancies in 100% of the mice. This model is being used along with established HAPMAP cell lines to examine response. Results and Conclusions: Cell surface markers, chromosomal abnormalities, and gene expression profiles of the mouse plasma cell tumors demonstrate a very similar profile and heterogeneity to human myelomas. The mouse PC tumors can be adoptively transferred to syngenic recipient mice, and grown in culture. The advantage of this model is that the impact of tumor heterogeneity can be assessed in a common genetic background in the mice with an intact immune system. Disease progression is variable among human and mouse tumors, and our results show association with patterns of gene expression, as well as heterogeneity of response to current drug therapies. Through the Bank On A Cure project of the International Myeloma Foundation, we show that inherited genomic variations in genes associated with drug response also influence therapeutic outcomes, including: survival, disease related complications (extent of bone disease), and adverse events (thrombosis). The presentation will include analytical approaches, and statistical refinements necessary to assess predictive value and integration of the various models.

## 1183/W/Poster Board #841

**Excision repair cross-complementing and Breast Cancer.** *M. Hosseini[1], M. Houshmand[2], A. Ebrahimi[3].* 1) Asst Prof, Dept Science, Islamic Azad Univ, Tehran, Iran; 2) National Institute for Genetic Engineering and Biotechnology (NIGEB), Tehran, Iran; 3) Special Medical Center, Tehran, Iran.

Excision repair cross-complementing 1, are important in DNA nucleotide excision repair and lie on chromosome 19q13.2-q13.3has been associated with breast cancer risk, but previous studies have been relatively small yet. Excision repair cross-complementing 1 gene is reported to be associated with increased risk of breast cancer. This study evaluates the influence of genetic polymorphism of Excision repair cross-complementing 1 on breast cancer susceptibility. A polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP) method was used to detect the polymorphism, and the genotypes identified were assigned as homozygous wild type (GG), heterozygous variant (GT), and homozygous variant (TT). Probably a statistically significant increased risk in carriers of homozygous T allele was found in woman ($P < 0.001$) in comparison with G . However, no significant association between the genotype and breast cancer risk was observed among women with strong family history yet. We genotyped 560 cases of primary breast cancer and population controls, all age of Iranian women, for the Excision repair cross-complementing1, polymorphism studied. Small overall association was found between ERCC1 and breast cancer risk, for the TT carriers compared to the GG carriers until today.

## 1184/W/Poster Board #842

**Subtype discovery and network analysis in neuroblastoma by gene expression profiling.** *F. Abel, D. Dalevi, R. Jornsten, S. Nilsson.* Mathamatical Statistics, Mathematical Scienses, Gothenburg, Vastra Gotaland, Sweden.

Neuroblastoma (NB), a childhood tumor originating from neural crest cells in the sympathetic nervous system, has a complex biological heterogeneity depending on clinical stage and age at diagnosis. Around 30% of tumors show amplification of the oncogene MYCN, and around 15% show mutations or amplification of the familial predisposition gene Anaplastic Lymphoma Kinase (ALK). To determine whether the previously established types of neuroblastoma tumors could be identified by gene expression profiling, we used oligonucleotide microarrays (HU133A from Affymetrix) to analyze the pattern of genes expressed in tumor tissue from 45 patients originating from Ireland, Belgium and Sweden. Principal Components Analysis (PCA) identified each of the prognostically important neuroblastoma subtypes, including Type 1 constituting of favourable tumors with high NTRK1 expression, Type 2A constituting of unfavourable tumors with high frequency of 11q deletion and elevated ALK expression, and Type 2B constituting of unfavourable tumors with very high expression of MYCN and ALK. In addition, a fourth neuroblastoma subgroup was identified based on its unique expression profile. This fourth group was comprised of high stage tumors with a high degree of patients that were dead-of-disease. Moreover, the fourth subgroup showed low expression of MYCN and ALK, but very high expression of two tyrosine kinases which have shown to play roles as oncogenes in other cancer forms. In order to identify progression-associated genes and to elucidate the underlying cellular networks in the four different subgroups, we calculated the mutual dependence of each gene pair based on the expression profiles from all 45 patients (i.e. mutual information). In conclusion, we intend to develop a single platform of expression profiling to enhance the accurate subgroup and risk classification of neuroblastoma patients. Moreover, we intend to map the disease-causing cellular pathways within each tumor subgroup in order to identify suitable clinical targets.

## 1185/W/Poster Board #843

**Polymorphisms of methylenetetrahydrofolate reductase gene and susceptibility to adult lymphoblastic leukemia in Chinese population.** *L. Bao[1], C. Wu[2], L. Lv[2], H. Fu[2].* 1) Divison Human Gen, Cincinnati Child Hosp Med Ctr, Cincinnati, OH; 2) Fudan University, Shanghai, China.

Methylenetetrahydrofolate reductase (MTHFR) is a major enzyme in the folate metabolism. Two common polymorphic variants on the MTHFR gene, C677T and A1298C, result in reducing MTHFR enzymatic activity and may also influence the susceptibility for developing acute lymphoblastic leukemia (ALL). However, results from previous studies in different populations remain controversial with some showing the genetic variants as risk factors for ALL while others suggesting them as protective variants against ALL. Most reported investigations focused on relationship of the MTHFR variants with development of childhood ALL. Here, we report a case-control study of 127 adult ALL cases in Chinese population to study the correlation between the MTHFR genetic variants and adult ALL susceptibility. Polymerase chain reaction-restriction fragment length analyses show that the frequency of the C677C/1298AC haplotype was lower among ALL patients compared the one in controls, conferring a 2.9-fold decrease in risk of ALL [odds ration (OR), 0.35; confidence interval (CI) 95%, 0.165-0.727]. No significant differences in frequencies of either of the MTHFR genotypes or other haplotypes between ALL and control groups were found. Our findings suggest that it is the MTHRF C677C/A1298C halpotype rather than any of the MTHFR genotypes alone or other haplotypes that may decrease susceptibility for developing ALL in Chinese adults.

**Glutathione S-transferase P1 variants (SNP at codon 105) in combination with the p53 codon 72 polymorphism and COX-2 variants (G-765C) on the risk of esophageal squamous cell carcinoma: A case-control study in Iranian population.** *F. Biramijamal[1], G. Irvanloo[2].* 1) Medical Genetics, NIGEB, Tehran, Iran; 2) Cancer Institute, Tehran-Iran.

Background: The incidence of esophageal squamous cell carcinoma (ESCC) is high in Iran. Increasing risk of esophageal cancer is depend on geographic differences. The specific genetic factors which are involved in development of this type of cancer is not clear exactly. It is shown that single nucleotide polymorphisms (SNPs) are important to change susceptibility of esophageal cancer. These variations in specific genes including Cyclooxygenase-2 (COX-2), p53 tumor suppressor gene and Glutathione S-transferase P1, affect on risk of ESCC, however, environmental factors must be considered during investigation. The p53 protein is considered a key combination in countering stress messages such as DNA damage and is involved in the etiology of malignant disease. The polymorphism at codon 72 of the p53 gene (CCC, proline/CGC, Arginine) is frequent among different populations and involved in various types of cancers. The Cyclooxygenase-2 (COX2) gene plays an important role in inflammation and carcinogenesis process. It is shown that polymorphism of this gene at promoter (-765 G>C) associated with cancers. In addition, Glutathione S-transferase P1 (GST-P1) is important enzyme in detoxification and polymorphism at codon 105 (Ile>Val) is involved in susceptibility of different types of cancers. In this study, we analyzed the effect of genetic polymorphism of GST-P1 at codon 105 in combination with p53 and COX-2 genes variants on the risk of ESCC in Iran. Methods: In this study, we investigated GST-P1, p53 and COX-2 polymorphisms among ESCC patients compared with healthy controls. PCR-RFLP performed for genotyping (for 199 healthy controls and 60 patients) and confirmed by sequencing. Conclusions: Our finding suggested that Ile allele of GST-P1gene combined with C allele of COX-2 gene, and, Arg allele of p53 gene increased risk of ESCC. Additionally, the results of the study indicated that COX-2 genotype alone may play an important role in developing esophageal tumor among ESCC patients.

## 1187/W/Poster Board #845

**A common SNP associated with non-Hodgkin Lymphoma influences protein binding at the *H2AFX* promoter.** *K.L. Bretherick[1], S. Leach[1], S.B. Montgomery[2], J.P. Banath[3], S.J.M. Jones[2], P.L. Olive[3], A.R. Brooks-Wilson[1].* 1) Genome Sciences Centre, British Columbia Cancer Research Centre, Vancouver, BC, Canada; 2) Wellcome Trust Sanger Institute, Hinxton, UK; 3) Medical Biophysics Department, British Columbia Cancer Research Centre, Vancouver, BC, Canada.

The tendency for non-Hodgkin lymphoma (NHL) tumors to carry chromosomal translocations suggests that this cancer may arise from an attenuation of DNA repair systems that protect against such defects. This is supported by the finding that a common G/A SNP (rs2509049) located upstream of *H2AFX*, which encodes a histone involved in response to DNA double-stranded breaks, is associated with risk for NHL. Bioinformatic analyses predict that the G allele is part of a binding site for the replication-associated E2F-1 transcription factor, whereas the A allele is more consistent with a binding site for CREB1, which is not replication specific. *H2AFX* is expressed from two transcripts, a 0.6 kb transcript with processing signals typical of replication-linked histone genes, and a 1.6 kb poly(A)-tailed transcript that is transcribed independently of replication. We predict that rs2509049 genotype influences expression of *H2AFX*, altering DNA repair capacity and modifying NHL risk. To assess this hypothesis, we examined the impact of rs2509049 A and G alleles on transcription factor binding and gene expression. Gel shift assays with purified nuclear extract from HeLa and BJAB cell lines suggest differential protein binding at the A and G alleles. Specifically, the A allele exhibits low affinity for two protein complexes, one of which also binds to the G allele with higher binding affinity. Relative allelic expression assessed by quantitative sequencing of cDNA from rs2509049 heterozygous cell lines revealed no difference in expression of the two alleles. This analysis, however, did confirm the presence of an intron in the 1.6 kb transcript which, although annotated in the UCSC Genome Browser, has not previously been reported in the literature. Differential protein binding between A and G alleles supports the hypothesis that rs2509049 is a functional SNP. It is possible that the expression analyses are not sensitive enough to detect subtle differences between genotypes, or that this SNP affects another aspect of gene expression such as timing or tissue specificity. Further analysis of functional differences between genotypes may explain the association with NHL risk.

## 1188/W/Poster Board #846

**Rapid and Sensitive detection of K-RAS Mutations using PNA-Mediated Real-Time PCR Clamping.** *M. Cho, J.J. Choi, H. P.* Institute of Bioscience, PANAGENE Inc., Yuseong-gu, Daejeon, Korea.

K-RAS mutations may indicate prognosis and drug response, and many new cancer therapies are being targeted to the K-RAS pathway. Many studies suggest that in lung cancer patients the K-RAS mutation status is strong predictor of resistance to therapy with tyrosine kinase inhibitors. Therefore, it is important that a minority of K-RAS mutations detect fast and accuracy for predict drug response and prognosis. To detect a minority of mutant K-RAS alleles among abundant wild-type alleles, we developed a high sensitivity and simple method for detection of K-RAS point mutations using PNA-mediated real-time PCR clamping. PNA mediated real-time PCR clamping relies on the following two unique properities of PNA probes. 1) PNA-DNA duplexes generally have greater thermal stability than the corresponding DNA-DNA duplex and 2) PNA oligomers are not recognized by DNA polymerases and consequently can serve as sequence selective clamp during PCR amplification. In this paper, one-step PNA-mediated real-time PCR clamping method was optimized for accuracy detection of K-RAS mutations in exon 12 and 13 with high sensitivity. The PNA clamps used in this study was a 21 to 23mer complementary to wild type K-RAS sequence and 5uM concentrations of PNAs. Our PNA-mediated real-time PCR clamping method was simple, robust and sensitive with detection limit approximately 0.1% mutant alleles using 1ng to 50ng of normal DNA as the template. It is particularly useful for tumors containing abundant non-neoplastic cells. We concluded that PNA mediated PCR clamping might be a useful supplement of standard PCR amplification in low concentration mutation alleles. PNA-mediated real-time PCR clamping is a rapid, reliable, and economical method for K-RAS mutation detection in clinical diagnosis.

## 1189/W/Poster Board #847

**Lack of germ-line mutations in SDHD in familial carcinoid tumors.** *L. Deng[1], V. Palka[1], O. Hashmi[1], L. Liang[1], J. Tischfield[1], C. Shao[1], N. Gardner[2].* 1) Dept Genetics, Rutgers Univ, Piscataway, NJ; 2) School of Nursing, Rutgers Univ, Newark, NJ.

Carcinoids are neuroendocrine tumors, mainly located in gastrointestinal and bronchial-pulmonary systems. While carcinoid tumors are relatively rare, with an incidence reported to be 4 per 100,000 in United States and 1.9 / 100,000 worldwide, there is a much higher incidence among the first degree relatives of the carcinoid patients, indicating the involvement of genetic components in its initiation and pathogenesis. Mutations in succinate dehydrogenase complex, subunit D (SDHD), were reported to be associated with paraganglioma, pheochromocytoma and gastrointestinal stromal tumors. To test whether germ-line mutations in SDHD are responsible for familial carcinoid tumors, we collected peripheral blood samples from 15 individuals in eight families with familial carcinoid tumors and performed direct sequencing of SDHD. All exons and exon-intron junctions in SDHD were sequenced. No mutation was detected in any of the subjects analyzed, indicating that SDHD mutation carriers are not common among carcinoid patients, even for familial cases. Sequencing analysis of other candidate genes, such as MEN1, is being conducted.

**Integrated Network Analysis of Genetic and Epigenetic factors in Glioblastoma.** *H. Dong[1,2], L. Luo[2], H. Siu[1], Y. Xiao[3], S. Hong[1], G. Peng[1], X. Fang[4], R. Chen[5], D. Wheeler[5], L. Jin[1], M. Xiong[2].* 1) State Key Laboratory of Genetic Engineering and MOE Key Laboratory of Contemporary Anthropology, School of Life Sciences and Institutes of Biomedical Sciences, Fudan University, Shanghai, 200433, China; 2) Human Genetics Center, University of Texas School of Public Health, Houston, TX 77030, USA; 3) Department of Computing and Information Technology,Shanghai (International) Database Research Center, Fudan University Shanghai, 200433,China; 4) School of mathematical sciences, Peking University, Beijing, 100871, China; 5) Dept. of Molecular and Human Genetics Baylor College of Medicine, Houston, TX, 77030, U.S.A.

Glioblastoma arises from complex interactions between a variety of genetic, epigenetic alterations and environmental perturbations. To perform integrated genetic and epigenetic analysis in glioblastoma studies, a total of 601 genes were sequenced for detection of somatic mutations in 179 tumor and matched normal tissues pairs; expressions of 12,042 genes were measured in 243 tumor tissue samples and 10 normal tissue samples and 1 cell line; expressions of 470 human miRNA were profiled in 240 tumor tissue sample and 10 normal tissue samples and a total of 2,994 genes were examined for methylation in 239 tumor tissue samples and 1 cell line in TCGA pilot project. We used system biology approach as a general framework to develop several novel statistical methods for joint genetic and epigenetic data analysis. We identified significant association of somatic mutations in five genes TP53, PTEN, EGFR, FKBP9, CHEK2 strongly affected the expression of 147 differentially expressed genes, 68 of which were under-expressed in tumor tissue and 79 were over-expressed in tumor tissue. The mutations in these five genes also significantly affected the expression of 5 human miRNAs: mir-106a, mir-17-5p, mir-20a, mir-504, mir-99b, which in turn target 32 of the 165 genes. We also identified significant association of LOH in seven genes NRAP, MKI67, C10orf54, C9orf66, MYO3A, PRAME, EGFR, which influenced expressions of 201 genes and 25 miRNA, a total of 98 miRNA with p-value<1.06E-4 and 1,221 genes with p-value<4.15E-6 were differentially expressed. We constructed miRNA interaction networks including 333 miRNAs and 563 interactions after a Bonfferroni correction p-values of 8.51E-7 for declaring interaction. We constructed miRNA co-expression networks including 375 miRNAs and 441 edges by partial correlation methods. We also constructed gene co-expression and interaction networks. We used paired expression profiles of miRNAs and mRNAs to identify functional miRNA target relationships and found 1,094 miRNA-target gene pairs discovered by regression and sequence-based prediction algorithm. We analyzed the network properties and test the association of network with cell function and disease phenotype. We finally identified an integrated network that connected significant mutations, CNVs, altered gene expression, miRNA and methylation, which act together to alter regulation and metabolism and finally lead to the emergence of glioblastoma.

## 1191/W/Poster Board #849

**The regulation of epithelial characteristics by miR-200 promotes the development of late stage metastasis.** *D. Dykxhoorn[1,2], Y. Wu[2], H. Xie[3], A. Lal[3], F. Petrocca[2], D. Martinvalet[2], B. Lim[3,4], J. Lieberman[2].* 1) The John T. Macdonald Foundation of Human Genetics and the Department of Microbiology and Immunology, Miami Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL 33136 USA; 2) Immune Disease Institute and Department of Pediatrics, Harvard Medical School, Boston, MA 02115 USA; 3) Stem Cell and Developmental Biology, Genome Institute of Singapore, Singapore; 4) Department of Medicine, Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA 02115 USA.

The development of metastasis requires that cells from the primary tumor acquire genetic or epigenetic variations that allow them to successfully complete the steps in the metastatic process including intravasation, survival and arrest in the circulatory system, extravasation and the formation of macroscopic secondary tumors. MicroRNAs have been shown to play important roles in many cellular processes and dysregulation of their expression patterns can have pathogenic consequences including promoting tumor and metastatic development. To determine if miRNAs play a role in the latter stages of metastatic development, tumor colonization of distant sites, miRNA expression patterns were analyzed from a series of isogenic mouse breast cancer cell lines with distinct metastatic capabilities. Several members of the miR-200 family were found to be highly expressed only in the cells capable of forming macroscopic metastasis. This was surprising since miRNAs from this family had been previously shown to promote epithelial characteristics through the targeted silencing of the transcriptional repressor Zeb2 and, as a consequence, increased expression of E-cadherin. The transgenic expression of miR-200 in mammary tumor cells that were normally unable to colonize distant sites resulted in decreased Zeb2 and Snail expression, increased E-cadherin expression, and the formation of lung and liver metastasis. These results suggest a role for the miR-200 family in enhancing the epithelial characteristic of cells and promoting the transition from micrometastasis to macroscopic tumors.

## 1192/W/Poster Board #850

**Modulation of Biomarkers of Oxidative Stress by Berry Treatment in High "At-risk Normal" Tissues from Oral Squamous Cell Carcinoma Patients.** *J.M. Ferguson[1,4], T.J. Knobloch[1,2], L.K. Uhrig[1,2], B.C. Casto[1,2,5], B.M. Warner[1,2,4], D.E. Schuller[1,3,5], E. Ozer[1,3,5], A. Agrawal[1,3,5], C.M. Weghorst[1,2,5].* 1) The Ohio State University, Columbus OH; 2) College of Public Health; 3) College of Medicine; 4) College of Dentistry; 5) Comprehensive Cancer Center.

PURPOSE: The oral cavity experiences high levels of exogenous and endogenous oxidative stress. Elevated levels of reactive oxygen species have been associated with oral squamous cell carcinoma (OSCC), and can activate carcinogenic transcription factors and signal transduction pathways. Black raspberries represent a food-based chemopreventive agent rich in polyphenolic compounds, which have been shown to reduce oxidative stress and inflammation. Cell culture and animal studies have shown altered gene expression in tumors following exposure to lyophilized black raspberries (LBR) or their extracts. Consistently, these chemopreventive studies show the ability of LBR to modulate genes prominently associated with oxidative stress. In OSCC cells exposed to LBR extract in culture, we have shown a down-regulation of a series of stress related biomarkers. To transition these *in vitro* findings into an *in vivo* setting, we have used the hamster cheek pouch (HCP) model of OSCC to demonstrate suppression of oral tumor lesion incidence and multiplicity (Anticancer Res 22, 2002) following dietary LBR treatment. The role of these pre-clinical studies is to translate into a human patient-based clinical investigation. Consequently, the aim of our ongoing Phase 1 Clinical Trial is to evaluate the molecular changes in oral cavity tissues following short-term, locoregional, oral exposure to LBR troches.

METHODS: According to protocols approved by the IRB of The Ohio State University, biopsy-confirmed OSCC patients were administered three LBR troches 4x/day (4.3g cumulative dose) between pre-surgical enrollment and their normally scheduled surgery. Biopsies were obtained from tumor and distant high "at-risk normal" tissues at enrollment and during surgical resection, after an exposure range of 6.8-20.8 days. Using a partial interim cohort of patients, a validated Biotrove OpenArray assay was used to assess stress related genes for LBR-dependent expression changes.

RESULTS: Decreased expression of multiple stress related genes (*HMOX1, HSPB1, NFE2L2, and NQO1*) was seen in the high "at-risk normal" tissue samples after LBR treatment, indicating that berry exposure may be reducing the risk of carcinogenesis by eliminating the harmful effects of reactive oxygen species.

## 1193/W/Poster Board #851

**Comparison of gene expression in primary breast tumors from node-negative and node-positive women.** *L.A. Field[1], B. Love[2], B. Deyarmin[1], J.A. Hooke[3], R.E. Ellsworth[4], C.D. Shriver[3].* 1) Clinical Breast Care Project, Windber Research Institute, Windber, PA; 2) Invitrogen, Carlsbad, CA; 3) Clinical Breast Care Project, Walter Reed Army Medical Center, Washington, DC; 4) Clinical Breast Care Project, Henry M. Jackson Foundation for the Advancement of Military Medicine, Windber, PA.

Background: Lymph node status is one of the most useful prognostic indicators in breast cancer and influences the course of treatment that will be used. Nodal status is currently determined using sentinel lymph node biopsy (SLNB), an invasive surgical procedure that can disrupt the lymphatic system and lead to secondary complications such as seroma and neuropathy. In this study, we have compared gene expression profiles from primary breast tumors from node-negative and node-positive women to determine if a molecular signature exists that can distinguish between patients whose breast tumors have metastasized to the lymph nodes and those that have not. Such a discovery could prevent the unnecessary need for SLNB in those women without lymph node metastases and potentially allow for the development of therapeutics to prevent metastasis from the breast to the lymph nodes. Methods: Tumor cells were removed from primary breast tumors from patients with (n=20) and without (n=20) lymph node metastases using laser microdissection and RNA isolated using the RNAqueous Micro kit (Ambion). RNA was amplified in two rounds using the MessageAmp II aRNA Amplification kit (Ambion). Fragmented aRNA was applied to Affymetrix HG U133A 2.0 arrays. A Mann-Whitney U test was used to determine significance. Microarray data were generated in the same manner for a second validation set containing 20 node-positive and 22 node-negative patients. Results: The probe lists for the two sets of microarray data were compared and 22 probes representing 21 genes were found to be common to both lists ($P < 0.05$). Fifteen of these genes had higher expression in primary breast tumors from node-negative patients while 6 genes had higher expression in node-positive patients. Discussion: The gene expression differences identified here may be responsible for determining whether cells from the primary breast tumor will disseminate to the lymph node. Genes with higher expression in node-negative patients function in nucleosome assembly, metabolism, insulin secretion and signaling, transcription, transport, and apoptosis. Genes with higher expression in tumors with lymph node metastases function in regulation of transcription, signal transduction, transport, cell differentiation, and microtubule organization and movement. These genes may represent new molecular targets to which drugs can be developed to prevent metastasis of breast cancer to the lymph node.

**Gender-dependent differences in UGT2B17 expression in human tissues.** *C. Gallagher, R. Balliet, J. Muscat, P. Lazarus.* Penn State Cancer Institute, Departments of Pharmacology and Public Health Sciences, Penn State College of Medicine, Hershey, PA, USA.

UGT2B17 is a phase II metabolizing enzyme involved in the glucuronidation of androgens as well as exogenous compounds including the tobacco carcinogen NNAL and cancer treatment drugs including suberoylanilide-hydroxamic-acid (SAHA). UGT2B17 is expressed in many tissues including liver, lung, and prostate and is down-regulated by androgens in prostate tissue. Due to the fact that this gene metabolizes and is regulated by androgens, we hypothesized that there may be gender differences in the expression and activity of this gene. We performed reverse-transcription PCR on 77 human liver RNA samples and assayed the expression of UGT2B17 cDNA using real-time PCR. We then assayed microsomes from these same human liver samples (HLMs) for activity against NNAL and SAHA using ultra-performance liquid chromatography (UPLC). We demonstrated that liver specimens from men with at least one intact UGT2B17 allele exhibited an 8-fold higher expression of UGT2B17 mRNA than women (P-value < 0.001). In addition, HLMs from men with at least one intact UGT2B17 allele exhibited a 2-fold higher glucuronidation activity against NNAL (P-value < 0.02) and a 2-fold higher glucuronidation activity against SAHA (P-value = 0.001). When stratifying this data by UGT2B17 deletion genotype, similar patterns were observed for glucuronidation of both substrates; individuals with 2 copies of the UGT2B17 gene exhibited higher glucuronidation activity than individuals who have 1 or 0 copies of the UGT2B17 gene for both men and women. Due to the fact that the deletion polymorphism of UGT2B17 has been shown to be associated with increased lung cancer risk specifically in females, expression of UGT2B17 was also examined in adjacent normal lung tissue from 60 lung cancer patients (35 males and 25 females). In contrast to the results from liver, women have 2-fold higher levels of expression of UGT2B17 then men in lung tissue (P-value = 0.027). These data are consistent with a hormonal regulatory mechanism for UGT2B17 in humans and suggest that glucuronidation activities, at least for UGT2B17, may differ with gender. These results suggest that expression and activity of UGT2B17 differ between men and women, and that the differences vary by tissue type, similar to previous observations in rodents. This data may have implications in gender differences in cancer risk and may also have pharmacological implications in the dose of cancer therapy drugs (such as SAHA) given to men and women.

## 1195/W/Poster Board #853

**Germline epimutations in suspected Lynch syndrome.** *A. Gylling[1], S. Ollila[2], O. Vierimaa[3], H.J. Järvinen[4], J.-P. Mecklin[5], P. Peltomäki[1].* 1) Dept of Medical Genetics, University of Helsinki, Helsinki, Finland; 2) Department of Biological and Environmental Sciences, Genetics, University of Helsinki, Helsinki, Finland; 3) Department of Clinical Genetics, Oulu University Hospital, Oulu, Finland; 4) Second Department of Surgery, Helsinki University Hospital, Helsinki, Finland; 5) Department of Surgery, Jyväskylä Central Hospital, Jyväskylä, Finland.

In a majority of families/cases suspected of having hereditary nonpolyposis colorectal cancer/Lynch syndrome, but not fulfilling the Amsterdam criteria, point mutations or large genomic rearrangements in DNA mismatch repair (MMR) genes are not found. The role of germline epimutations was evaluated in 43 index patients who were mutation-negative by genomic sequencing, testing for a prevalent population-specific founder mutation and large genomic rearrangements, and selectively lacked MMR protein expression (MLH1, 31; MSH2, 7; MSH6, 5) in tumor tissue. Methylation-specific multiplex ligation-dependent probe amplification (MS-MLPA) was used to detect epimutations. Germline epimutations of MLH1, one of which coexisted with a genomic deletion, occurred in 3 patients (3/31, 10%) and were accompanied by monoallelic expression in mRNA. No epimutations were found in MSH2 or MSH6. A previous study (Ligtenberg et al 2009) reported that deletions of the most 3' exon of the EPCAM/TACSTD1 gene can lead to secondary methylation and inactivation of MSH2, which is often mosaic in somatic tissues. In analogy, a similar mechanism might be valid for MLH1 through deletion of the most 3' exon of LRRFIP2. No germline deletions were found in the LRRFIP2 gene among 31 cases with absent MLH1 protein in tumor tissue, including the 3 epimutation cases, or in the TACSTD1 gene in 7 cases lacking MSH2 protein in tumors. In conclusion, germline epimutations explain a definite but relatively small proportion (10%) of Lynch syndrome suspected cases lacking the MLH1 protein in tumor tissue. In contrast to point mutations and large genomic rearrangements, which are associated with strong family histories for Lynch syndrome, epimutations occur in patients with multiple early-onset tumors without any significant family history. The identification of such defects is important for the diagnosis, counseling and management of the patients and their families.

## 1196/W/Poster Board #854

**The Hippo Pathway Effector, Yap, Functions as a Potent Oncogene in Ovarian Cancer.** *C. Hall[1], P. Szafranski[2], M. Zhao[2], R. Wang[2], S. Orsulic[4], S. Goode[1,2,3].* 1) Dept of Molecular & Human Genetics; 2) Dept of Pathology; 3) Dept of Molecular and Cellular Biology, Baylor College of Medicine, Houston, TX; 4) Women's Cancer Research Institute, Cedars-Sinai Medical Center, Los Angeles, CA.

The recently discovered Hippo pathway regulates cell polarity and tumorigenesis in Drosophila, yet its relevance to human cancer remains unclear. Human homologs of each member of the pathway from the cell membrane to the nucleus have been identified and Yap, a downstream transcriptional coactivator, has been reported to function as both a tumor suppressor and an oncogene. To determine the role of the Hippo pathway in Human Ovarian Cancer (OvCa) we assessed the level of nuclear Yap (active) and phospho-Yap (inactive) in an OvCa tissue array. We found that patients with either high levels of nuclear Yap or low levels of phospho-Yap have approximately 40% lower 5 year survival (p=.011 and .032). Expression of activated Yap, but not dominant negative or knockdown of Yap, in an immortalized ovarian surface epithelium cell line conferred resistance to apoptosis, faster wound healing, and the ability to grow in soft agar. Together, these data support the role of Yap as an oncogene in OvCa as in Drosophila. In order to determine the mechanism of Yap activation, we tested several hypotheses. First, we found that Yap is phosphorylated in 10/10 cell lines indicating that the upstream Hippo pathway remains functional in OvCa. Using QPCR we did not detect increased Yap in 10 OvCa cell lines and 16 OvCa tumors indicating Yap mRNA is not overexpressed in OvCa. In these same samples we also did not detect Yap mutations indicating Yap is not activated by mutation. Finally, we tested if loss of 14-3-3-sigma, a known inhibitor of Yap, could result in activation of Yap even in the presence of inhibitory signals from the Hippo pathway. 14-3-3-sigma is known to be lost by promoter hypermethylation and this loss correlates with poor patient outcome in OvCa. We find a very strong correlation between the presence/absence 14-3-3-sigma and the cytoplasmic/nuclear localization of Yap in 10 OvCa cell lines. We are currently testing if treatment with azacitidine can restore 14-3-3-sigma expression and proper Yap localization in OvCa cell lines. In support of this hypothesis, Bast et al. recently demonstrated that azacitidine pretreatment of patients with platinum resistant OvCa can reverse platinum resistance and improve overall survival. Together, this data represents the first clinical correlation for the Hippo pathway, the establishment of Yap as potent oncogene in OvCa, and new potential therapeutic avenues for the treatment of ovarian cancer.

## 1197/W/Poster Board #855

**Analysis of the genomic structure of chronic myelogenous leukemia using a paired-end-tag (PET) sequencing approach.** *A.M. Hillmer[1], K.P. Ng[2], A.S.M. Teo[1], Y. Fei[1], W.H. Lee[1], P.N. Ariyaratne[1], A. Shahab[1], V. Cacheux-Rataboul[1], G. Bourque[1], X. Ruan[1], W.K. Sung[1], C. Chuah[2], S.T. Ong[2], Y. Ruan[1].* 1) Genome Inst Singapore, Agency of Science Technology & Research, Singapore, Singapore; 2) Cancer & Stem Cell Biology Program, Duke-NUS Graduate Medical School, Singapore, Singapore.

A balanced, reciprocal translocation involving the long arms of chromosomes 9 and 22 is the major genomic alteration in the etiology of chronic myelogenous leukemia (CML), and gives rise to the Philadelphia chromosome and Bcr-Abl fusion gene. Although targeted therapy against the Bcr-Abl kinase has led to highly effective treatment for patients with chronic phase (early-stage) CML (CP), patients with blast phase (late-stage) CML (BP) inevitably develop drug-resistance (DR), and almost always succumb to their disease. The etiologies of disease progression from CP to BP, and DR are unknown, but it is likely that structural rearrangements in the CML genome contribute to these phenomena. We have developed a paired-end-tag (PET) sequencing strategy to study structural variations in the human genome. In addition to the identification of copy number changes, which can also be discovered by array based technologies, the PET sequencing approach has the capability to identify and characterize copy number neutral structural changes. We have applied this technology to construct comprehensive karyo-genomic maps from the K562 BP cell line, as well as four patients representing individuals with CP and BP CML, and DR. We found the Bcr-Abl fusion gene in all samples, except those from patients with a major molecular response to therapy. These results confirm the capability and validity of the technology to identify structural changes in a genome-wide manner. The data also provide unique insights about CML genomic architecture at different stages of disease, and provide a comprehensive list of structural variations following disease progression. These variations are of potential relevance for an improved understanding of the pathogenesis of CML progression and/or DR.

## 1198/W/Poster Board #856

**Phosphorylation of PI3K/AKT/mTOR signaling pathway members is heritable and associated with variants on chromosomes 3 and 14.** *J.E. Hutz*[1,2], *H.L. McLeod*[2]. 1) Institute of Pharmacogenomics and Individualized Therapy, University of North Carolina, Chapel Hill, NC; 2) Division of Statistical Genomics, Washington University in St. Louis, St. Louis, MO.

The PI3K/AKT/mTOR signaling pathway is activated in a large percentage of all cancers, and its activation is almost universally associated with poorer clinical outcomes. Many somatic mutations in pathway members have been identified, but little is known about the effects of inherited variation in this signaling pathway. To assess whether pathway activation is a heritable trait, phosphorylated and total levels of three key proteins in the pathway (AKT1, p70S6K, 4E-BP1) were measured by ELISA in 122 related lymphoblastoid cell lines from 14 CEPH families. Interestingly, the phenotypes with the highest heritability were the ratios of phosphorylated to total protein for two of the pathway members: AKT1 ($h^2$=0.18) and p70S6K ($h^2$=0.23). Despite moderate heritabilities and sample size, linkage analysis identified several intriguing peaks. The AKT1 phenotype had a maximum LOD score of 1.77 on chromosome 14, near the *AKT1* gene, as well as a peak of 1.44 on chromosome 3p. The chromosome 3 peak overlapped with the best peak for the p70S6K phenotype (LOD=2.23). CANDID, a candidate gene selection algorithm, identified *miR-203*, *AKT1* and *HSP90AA1* as the top candidates on chromosome 14 and *RAF1*, *VHL*, *KAT2B*, *RAB5A* and *GRM7* as the top candidates on chromosome 3. These cell lines were genotyped for tag SNPs as well as potentially functional SNPs in these genes, and a mixed model was used to test for association. Statistically significant evidence for association was found for SNPs in *HSP90*, *RAF1*, and *KAT2B*. Analysis of these SNPs is underway and will soon produce data for (1) possible functional significance, (2) replication in a separate set of cell lines, and (3) association with cancer-related phenotypes in a clinical sample. This data provides the first evidence that phosphorylation levels of key signaling proteins are influenced by inherited variants. The completion of further analyses of these variants may yield valuable insights into cancer pathogenesis.

## 1199/W/Poster Board #857

**Silencing of TPM3 by RNA interference influences invasive potential of human hepatocellular carcinoma cell lines.** *C. Hye-Sun*[1,2], *X. Hai-Dong*[1,2], *S. Seung-Hun*[1,2], *J. Seung-Hyun*[1,2], *C. Yeun-Jun*[1,2]. 1) Department of Microbiology, The Catholic University of Korea, Seoul, Korea; 2) Integrated Research Center for Genome Polymorphism,The Catholic University of Korea, Seoul , Korea.

**Purpose:** In previous study, we already founded that Tropomyosin 3(TPM3) has the oncogenic potential in Hepatocellular carcinoma (HCC) using array-CGH with 1Mb resolution. To elucidate biological functions and molecular mechanisms of TPM3 in HCC, we performed silencing of TPM3 expression using RNA interference (RNAi) method.

**Experimental design:** TPM3-siRNAs were transfected into the HCC cell lines, HepG2 and SNU-475 overexpressing TPM3. To verify the sequence specificity of siRNA, we prepared negative control groups (siRNAs with no significant homology to any known sequences in human genome) and mock control group (just treated reagent). The cells were analyzed by real-time RT-PCR, western blotting for genes expression such as TPM3. Cell growth capacities were detected by colonyformation and anchorage-independent assay. Cell proliferation activity and Cytotoxicity with anti-cancer drug were measured by WST-1 and MTT assay, respectively. Moreover effects of TPM3 on metastatic potentials were examined using matrigel-coated or uncoated polycarbonate membrane.

**Results:** After the TPM3-siRNA transfection, the expression of the TPM3 mRNA was significantly reduced compared to negative control. Western blotting also revealed an obvious reduction of TPM3 protein level in the TPM3 siRNA group. Down-regulation of TPM3 inhibited HCC cell growth, anchorage-independent growth and increased sensitivity for cancer-drug. Furthermore silencing TPM3 resulted in suppression migration and invasion capacities.

**Conclusions:** On the basis of our in vitro data, we suggested that TPM3 plays an important role in the metastatic process in HCC. RNA interference-mediated depletion of TPM3 may be an attractive strategy for the treatment of malignancy HCC.

## 1200/W/Poster Board #858

**Aberrant expression of *let-7* microRNA leads to overexpression of Dicer in oral squamous cell carcinomas.** *A. Jakymiw*[1], *R. Patel*[1], *N. Deming*[1], *I. Bhattacharyya*[2], *C. Stewart*[2], *P. Shah*[1], *D. Cohen*[2], *E. Chan*[1]. 1) Oral Biology, University of Florida, Gainesville, FL; 2) Oral and Maxillofacial Surgery and Diagnostic Sciences, University of Florida, Gainesville, FL.

Recently, several reports have demonstrated that Dicer, an RNase III endonuclease involved in microRNA (miRNA) maturation, is up-regulated in prostate and precursor lesions of lung adenocarcinomas. Furthermore, Dicer protein levels have been reported to be regulated by *let-7*, a miRNA whose expression level has been reported to be reduced in lung cancer. Objectives: To determine whether Dicer is aberrantly expressed in oral squamous cell carcinomas (OSCCs) due to altered expressions of *let-7*. Methods: Dicer protein and mRNA levels were examined by Western blot analysis and real-time-PCR, respectively, in a panel of head and neck squamous cell carcinoma (HNSCC) cell lines, including OSCC cell lines, and compared to normal primary gingival epithelial cells (pGECs). The *let-7* expression levels were analyzed by real-time-PCR. In addition, Dicer protein levels were examined in paraffin embedded OSCC tissues by indirect immunofluorescence studies. Lastly, an OSCC cell line was transiently transfected with either chemically synthesized *let-7* or small interfering RNA (siRNA) targeting Dicer to evaluate the effect on Dicer levels and cell proliferation. Results: Dicer protein was found to be overexpressed in a panel of HNSCC cell lines compared to pGECs. Moreover, Dicer protein was found to be high in OSCC tissues in comparison to normal gingival epithelial tissues. Interestingly, the levels of Dicer mRNA were not significantly up-regulated in all the HNSCC cell lines suggesting a post-transcriptional form of gene regulation. *Let-7* levels were reduced in HNSCC cell lines in comparison to pGECs and transfection of *let-7* resulted in the downregulation of Dicer expression. Lastly, silencing of Dicer inhibited cell proliferation. Conclusion: Dicer is up-regulated in OSCCs due to the aberrant expression of *let-7* miRNA and appears to be important for cell proliferation.

## 1201/W/Poster Board #859

**Development of stem cell based genetic pre-clinical models of astrocytomas.** *D. Kamnasaran*[1,2]. 1) Department of Pediatrics, Laval University, Quebec, Canada; 2) Pediatrics Research Unit, Laval Hospital Research Centre, Quebec, Canada.

Astrocytomas (gliomas) are the most frequent tumors prevalent in adults, and the second most common type of tumors among children. Unfortunately, despite current therapies the prognosis is still poor. One of the major reasons for such poor prognosis is the current paucity of genetic pre-clinical models that recapitulate the genetic, pathological and treatment responses reminiscent in the human tumors. Current in-vitro models such as glioma stem cells are very problematic as a result of having low clonality and variable therapeutic responses. In an effort to explore alternative robust in-vitro models of astrocytomas, we have developed the first non-neural stem cell based genetic model of astrocytomas from murine embryonic stem cells. Specifically, we observed that the "synthetic astrocytes" derived from murine embryonic stem cells are more representative in the origin of astrocytomas, even at high clonality, compared to mature somatic astrocytes. Furthermore, these "synthetic astrocytes" seem to be very similar to immature or progenitor astrocytes. Similar findings are also observed with "synthetic astrocytes" differentiated from murine neural stem cells. Overall, these "synthetic astrocytes" have an intrinsic property of enhanced proliferation that may potentiate an ease towards transformation. We have noted that the genetic alterations of these synthetic astrocytes with candidate astrocytomagenesis genes can potentiate intracranial astrocytomas in Nod-Mice, unlike mature astrocytes harboring the same cocktail of mutations. In addition, we undertook functional random mutagenesis screens on these "synthetic astrocytes" using gene trapping, and have been able to develop novel genetic pre-clinical models of astrocytomas. This body of work augments the use of stem-cell based pre-clinical models to decipher the genetic and pathological basis of astrocytomagenesis. Moreover, these models can also be utilized for future therapeutic targeting applications.

## 1202/W/Poster Board #860

**Paclitaxel suppresses the viability of MCF-7 through AMPK-mediated EF1α and FoxO3 regulation.** *J. Kim, J. Lee, J. Jung, S. Lee, S. Park, H. Kim.* Korea University College of Medicine, Seoul, Korea.

Paclitaxel (Taxol), a potent drug of natural origin isolated from the bark of the Pacific yew, is widely used in the treatment of ovarian, lung and breast cancer. Up to now, however, there is little information regarding the anti-cancer mechanism of paclitaxel. In order to understand the molecular mechanisms, we investigated the relationship between Taxol and AMPK, a key energy sensor kinase. In results, paclitaxel suppressed the viability of breast cancer MCF7 cells and increased phosphorylation of AMPK. Taxol also down-regulated EF1αwell known transcription factor. Paclitaxel increased the phosphorylation of FoxO3 (Forkhead box O3), a transcription factor for tumor suppression, and its downstream target p21. Moreover, phosphorylation of FoxO3 was suppressed in the presence of AMPK specific inhibition, Compound C, suggesting the involvement of AMPK in paclitaxel-mediated FoxO3 phosphorylation. Furthermore, knock-down of either EF1α or AMPK make cancer cell more susceptible to paclitaxel-mediated FoxO3 induction and caspase-3 activation. Finally, paclitaxel-induced EF1α suppression was not observed in AMPK knout-down cells. All together, these results suggest that paclitaxel may have anti-tumor effects in breast cancer through activation of the AMPK-EF1α-FoxO3 signal pathway.

## 1203/W/Poster Board #861

**Copy number alterations in Korean stomach cancers.** *Y.I. Kim, W.S. Park, S.W. Nam, S.H. Lee, N.J. Yoo, J.Y. Lee, S.H. Kim, B.H. Lee, Y.S. Choi, S.Y. Kim.* Department of Pathology, College of Medicine, The Catholic University of Korea, Seoul, Korea.

Gastric carcinoma is one of the most frequent malignant tumors in Korea. Development of gastric carcinoma is associated with environmental factors and genetic factors. Traditionally, studies on the development of stomach cancers were focused on genetic or epigenetic alterations of specific genes found in malignant tissues. These studies revealed many tumor-related genes participating in the development of stomach cancers. However, role of other area in human genome is still unknown in terms of stomach cancer development. To delineate genome-wide alterations in stomach cancers, we studied copy number alterations in Korean gastric cancers using microarry-based CGH (aCGH). As a result, we found sixty loci of common copy number gain and twenty loci of common copy number loss. Among the copy number gains, MYC, CCNE1 and ERRB2 genes were included. JAK2, CDKN2A and CDKN2B were found in the loci showing copy number loss. The aCGH findings were correlated with the results of quantitative real-time PCR using genomic DNA extracted from tumor tissues and fluorescent in situ hybridization (FISH) using formalin-fixed paraffin-embedded tumor tissues.

## 1204/W/Poster Board #862

**Microsatellite variability, CGI methylation and differential expression patterns in colon cancer.** *M.J. Kovach, C.B. Wiese.* Biological & Environmental Sci, Univ Tennessee, Chattanooga, TN.

The overall goal of this study is to investigate the hypothesis that the genes in the molecular pathway(s) of cancer progression are subject to transcriptional regulation by microsatellite repeat sequence variability. It is our hypothesis that the accumulation of these variants through defects in mismatch repair or the normal aging process contribute to cancer progression by influencing gene expression and chromatin remodeling as it relates to the positioning of regulatory elements, mRNA stability and methylation status of CpG islands. We propose that microsatellite repeat elements represent a normal, but as yet uncharacterized, mechanism of gene regulation in which polymorphisms in microsatellite repeats function to control the local secondary structure of the genome and mRNA transcripts; structures predicted to be important in the recruitment and binding of transcriptional accessory and processing proteins that influence the rate of transcription and transcript stability. Fourteen colon cancer cell lines were evaluated for Microsatellite Instability (MSI), CGI methylation and gene expression of 6 candidate oncogenes. Replication Error prone (RER+) cell lines showed a higher level of MSI than RER- cell lines. More specific, an increase in mean percent variation was observed in RER+ samples for microsatellites located in the first intron (32%) and middle introns (24%). The higher variability noted for microsatellites in the first intron may reflect important mutations in the pathogenesis of cancer. Microsatellites located within the last intron and 3'UTR had the least tolerance for mutations; sequence conservation suggestive of a region of functional and/or structural importance. There was an inverse relationship between the level of MSI and length of the repeat unit; mononucleotide and dinucleotide repeats showed the greatest variation. Among dinucleotide repeats, a 32% increase in variability was observed for those capable of complimentary base pairing. Methylation studies indicated that CpG islands overlapping promoters were hypomethylated, suggestive of the pattern of active gene expression. In contrast, CpG islands located internally were largely hypermethylated and consistent with the reported global hypermethylation of internal regions of genes. Abnormal methylation, and predicted gene repression of *THBS1* and *STK11*, known tumor suppressor genes involved in angiogenesis inhibition, is consistent with the establishment of cancer and tumor growth.

## 1205/W/Poster Board #863

**Comprehensive regulatory mechanisms of the MSMB gene associated with prostate cancer susceptibility.** *H. Lou[1], H. Li[1], M. Yeager[2,3], S. Anderson[1], M. Dean[1].* 1) Cancer & Inflammation Program, NCI/FCRDC, Frederick, MD; 2) Core Genotyping Facility, Advanced Technology Program, SAIC-Frederick, Inc., NCI-Frederick, Frederick, MD; 3) Division of Cancer Epidemiology and Genetics, Center for Cancer Research, NCI, NIH, Department of Health and Human Services (DHHS), Bethesda, Maryland.

The significant single-nucleotide polymorphism (SNP) located at 10q11.2 (rs10993994), 57 bp upstream of the transcription start site of the *MSMB* gene, is the most strongly associated marker with prostate cancer risk identified by genome-wide association studies (GWAS). Recent functional work has shown that the different alleles of the promoter SNP, rs10993994, influence *MSMB* expression. To investigate the regulatory mechanisms of the *MSMB* gene, we determined the methylation status of the *MSMB* gene by using bisulphite sequencing. A higher methylation level in a 273 bp GC rich region 2.8 kb upstream of the ATG of the *MSMB* was observed in prostate cancer DU145 cells which have a low level of *MSMB* expression. In contrast, lower methylation levels were confirmed in cell lines with high *MSMB* mRNA expression. In an additional experiment, we investigated the distal and proximal promoter sequences of the *MSMB* gene to characterize the regulatory elements. The distal elements inhibited promoter activity in prostate cancer cells, but enhanced promoter activity in breast cancer cells. A 320 bp length of the proximal promoter sequence of the *MSMB* gene exhibited highest promoter activity. Together, our mapping study and functional analyses implicate the regulation of expression of *MSMB* as a plausible mechanism accounting for the association identified at this locus. Both genetic and epigenetic mechanisms are involved in the regulation of *MSMB* activity.

## 1206/W/Poster Board #864

**Genetic Predisposition for unilateral Vestibular Schwannoma.** *N. Lüblinghoff, W. Maier, R. Lazig, R. Birkenhäger.* Otorhinolaryngology H&N Surg, University Medical Center Freiburg, D-79106 Freiburg, Killianstr. 5, Germany.

Background: A vestibular schwannoma (VS) is a benign tumor originating from Schwann cells (SC) of the vestibular nerve and located in the cerebello pontine angle or the inner auditory canal. The tumor results from an overproliferation of SC that wrap around nerve fibres, often causing gradual hearing loss, tinnitus and dizziness. It can also interfere with the facial nerve causing paralysis by compression. Early detection of the tumor is sometimes difficult because the symptoms may be subtle and may not appear in the beginning. There are two types of VS: unilateral and bilateral. The genetic background of this tumor is not completely known. Until now there is only a single gene known for bilateral VS leading to neurofibromatosis type 2 (NF2). This gene is located on Chromosome 22, about 60 % of the patients have mutations in the NF2 gene. The average age of onset is 18 to 24 years. Almost all patients develop bilateral VS by the age of 30. Unilateral VS account for approximately 8 % of all cranial tumors. Symptoms may develop at any age, but usually occur between the age of 30 to 60. The exact cause of unilateral VS is unknown, most occur spontaneously. It is our aim to identify genes and factors that are specifically involved in the development of unilateral VS. Methods: Our study group consists of 79 patients (from 77 independent families) of which 17 have bilateral VS (NF2), 58 a unilateral VS and 2 an initial suspicion of a VS. All 79 patients are clinically clearly defined. Genetically we performed a mutation analysis on the NF2 gene by PCR based individual exon and intron-transitions sequencing of the NF2 gene. A genome-wide haplotype analysis was accomplished on the whole genome and on the tumor tissue by utilizing the Affymetrix GeneChip 500 K SNP mapping array. Results: So far we identified 5 different missense/nonsense and splice mutations in NF2 gene which all lead to a loss of function of the gene product Merlin and the appearance of VS [IVS2+1G>A (2x) ,c.809A>G-(Glu270Gly), c.532C>T(p.Gln178ter), c.1396C>T(p.Gln466ter), IVS15+1G>A]. We further identified several polymorphisms in the NF2 gene that do not seem to cause VS. Conclusions: Until now we do not clearly know whether genomic predispositions or exclusively somatic mutations are responsible for unilateral VS; or if additional genomic alterations e.g. loss of LOH's areas or suppressor genes are responsible for the development of this special kind of VS.

## 1207/W/Poster Board #865

**The role of NER pathway in DNA recovery of head and neck squamous cell carcinomas.** *I. Majsterek[1,2], D. Pytel[2,3], M. Markiewicz[1], T. Sliwinski[1], P. Rusin[1], J. Olszewski[4], A. Morawiec-Sztandera[5], J. Szemraj[6].* 1) Department of Molecular Genetics, University of Lodz, Lodz, Poland; 2) Department of Chronopharmacology, Medical University of Lodz, Lodz, Poland; 3) The Abramson Family Cancer Research Institute, Department of Cancer Biology, University of Pennsylvania, Philadelphia, PA, USA; 4) Department of Otolaryngology and Oncology, Medical University of Lodz, Lodz, Poland; 5) Department of Head and Neck Cancer, Medical University of Lodz, Lodz, Poland; 6) Department of Medical Biochemistry, Medical University of Lodz, Lodz, Poland.

Head and neck squamous cell carcinomas (HNSCC) comprise about 6% of all malignant neoplasms. One of the major risk factor of HNSCC is tobacco smoking. There are approximately 4 thousand chemical compounds identified in tobacco smoke. Many of them like polycyclic aromatic hydrocarbons (PAHs) and aromatic amins (AA) are well known carcinogens which form adducts with DNA. Cells remove those adducts mainly by using nucleotide excision repair (NER). We examined DNA repair efficiency in peripheral blood lymphocytes obtained from HNSCC patients and healthy subjects as well as HTB-43 larynx and CRL-1628 tongue squamous cancer cells. NER activity was assessed in the cell extracts by use of an UV-irradiated plasmid as a substrate. After in vitro repair the incorporation of [gamma 32P]-dAMP during strand resynthesis as equivalent to NER efficiency was quantified by densitometry. Results obtained from these experiments indicate that there is a decrease in the efficacy of NER in HTB-43, CRL-1628 cells and HNSCC lymphocytes compared to healthy controls. In conclusion, we suggest that NER pathway is critical for DNA recovery of HNSCC cells what in turn may be responsible for higher susceptibility to mutagenesis and cancer transformation. This work was supported by grant N301 099 32/3581 from Polish Ministry of Science and Higher Education.

**IL18, LUM, PTGER4 and SPHK1 are transcriptional targets of ETV6, a tumour suppressor implicated in childhood leukemia.** *C. Malouf[1,2], S. Langlois[1], J. Larose[1], D. Sinnett[1,3].* 1) Division of Hematology, Research Center CHU Sainte-Justine, Montreal, Canada, H3T 1C5; 2) Department of Biochemistry, Faculty of Medicine, University of Montreal, Montreal, Canada, H3T 1J4; 3) Deparment of Pediatrics, Faculty of Medicine, University of Montreal, Montreal, Canada, H3T 1C5.

Acute Lymphoblastic Leukemia (ALL) is the most frequent pediatric cancer accounting for ~25% of all cases. The most frequent genetic alteration that has been associated with ALL is the t(12;21) ETV6-AML1 translocation, which results in the formation of the chimeric transcription factor ETV6-AML1. Deletion of the residual allele of ETV6 has been observed in 20-40% of pre-B ALL, which strongly suggests that ETV6 functions as a gene tumour suppressor. ETV6 is a transcriptional repressor that belongs to the ETS family of transcription factors with very few known targets. We previously identified 87 genes that were co-modulated following expression of ETV6. The expression of four of these genes, interleukin-18 (IL18), lumican (LUM), prostaglandine E2 receptor EP4 subtype (PTGER4) and sphingosine kinase 1 (SPHK1) was significantly correlated with that of ETV6. Using gene reporter assays and chromatin immunoprecipitation in Jurkat (leukemic T lymphocyte) and HeLa (cervical) cells, we confirm that IL18, LUM, PTGER4 and SPHK1 are transcriptional targets of ETV6. ETV6 has two functional domains specific to the Ets family, a pointed helix-loop-helix domain mediating protein interactions and oligomerization and an ETS DNA-binding domain. We found that both functional domains are necessary to repress the activity of the IL18, LUM, PTGER4 and SPHK1 promoters. Transcriptional repression of these targets by ETV6 takes place in a small region close to the basal promoter and, unlike other Ets factors, does not require a consensus ETS-binding site (EBS). The validation of four novel transcriptional targets of ETV6 that are frequently up-regulated in childhood ALL will help us to elucidate the molecular functions of ETV6 in physiological and pathophysiological conditions.

**Molecular analysis of endometrial tumorigenesis in Lynch syndrome and sporadic cases.** *T.T. Nieminen[1], A. Gylling[1], W.M. Abdel-Rahman[2], K. Nuorva[3], M. Aarnio[4], L. Renkonen-Sinisalo[5], H.J. Järvinen[5], J-P. Mecklin[4], R. Butzow[6,7], P. Peltomäki[1].* 1) Med Gen, Univ Helsinki, Helsinki, Finland; 2) College of Health Sciences, University of Sharjah, Sharjah, United Arab Emirates; 3) Department of Pathology, Jyväskylä Central Hospital, Jyväskylä, Finland; 4) Department of Surgery, Jyväskylä Central Hospital, Jyväskylä, Finland; 5) Second Department of Surgery, Helsinki University Hospital, Helsinki, Finland; 6) Department of Obstetrics and Gynecology, Helsinki University Central Hospital, Helsinki, Finland; 7) Department of Pathology, Helsinki University Central Hospital, Helsinki, Finland.

PURPOSE. Endometrial carcinoma (EC) is common in the population and the most frequent extracolonic malignancy in hereditary nonpolyposis colorectal carcinoma (HNPCC)/Lynch syndrome. We characterized endometrial hyperplasias, precursor lesions of endometrioid EC, to identify molecular markers of malignant transformation and tumor progression. EXPERIMENTAL DESIGN. Serial specimens of normal endometrium, simple hyperplasia (SH) , complex hyperplasia without atypia (CH), complex hyperplasia with atypia (CAH), and EC obtained during a ten-year surveillance of DNA mismatch repair (MMR) gene mutation carriers (together 71 samples) were analyzed for MMR protein expression, microsatellite instability (MSI), and promoter methylation of tumor suppressor genes. Results were compared to a sporadic reference series of endometrial specimens taken for non-malignant reasons (133 samples). RESULTS. Among MMR gene mutation carriers, decreased MMR protein expression was present in 7% in normal endometrium, 40% in SH, 100% in CH, 92% in CAH, and 100% in EC. MSI frequencies were lower (6%, 17%, 67%, 39%, and 64%, respectively). Among 24 tumor suppressor genes, the number of methylated loci increased from normal endometrium to SH to complex hyperplasia (CH/CAH) in both Lynch syndrome and reference series. The most frequently methylated genes were CDH13, RASSF1A, and GSTP1. In MMR gene mutation carriers, MMR and methylation defects appeared up to 12 years prior to EC. CONCLUSIONS. Increased methylation (and abnormal MMR in Lynch syndrome patients) classifies normal endometrium and SH into one category, and CH, CAH, and EC into another, suggesting that - contrary to a traditional view - CH and CAH are equally important as precursor lesions of EC. Furthermore, in genetically predisposed individuals, molecular changes are detectable in even normal endometrial tissue several years before EC.

### 1210/W/Poster Board #868

**Understanding genetic selection in the breast cancer genome.** *N.I. Park[1], P.K. Rogan[2,3], J.H.M. Knoll[1,4].* 1) Pathology; 2) Biochemistry; 3) Computer Science, University of Western Ontario; 4) London Health Sciences Centre, London, ON, Canada.

Confronted with frequent chromosome instability and gene mutation, the minimal genome of a tumor cell would have to maintain the ability of self-renewal and differentiation, plasticity, unlimited growth potential, and the ability to form tumors de novo. We are examining selective forces in the breast cancer genome, with respect to specific pathways, to determine if the minimal genome encodes proteins that are consistently targets of therapeutic drugs. Computational analysis of the genomes of 243 previously reported breast tumors (*Gen Res.*2006.16:1465) revealed 2,089 unstable (amplified and/or deleted) and 2,114 stable (or quiescent) genomic regions. Unstable regions contained 1,500 single copy (sc) intervals (>10bp), corresponding to 427 protein coding genes (CCDS database). Stable regions contained 84,843 sc intervals >100bp in length and 9,839 sc intervals >500bp long, corresponding to 2,503 genes. This corresponded to 1,891 (>100bp) and 622 (>500bp) genes in the NCBI Entrez database. 428 genes were identified which were common to both sets of sc interval-related, quiescent regions. This set was characterized according to gene ontology and pathway analysis. GO analysis showed that stable regions were enriched relative to unstable ones for genes encoding nucleosome assembly proteins, interferon receptor binding, intermediate filament components, monooxygenase activity, and neuropeptide signaling (p≤0.01). This gene set is enriched for pathways in which some of the functions are targeted by therapeutics: NK-cell mediated cytotoxicity (Cetuximab), cytokine-cytokine receptor interaction, antigen processing and presentation (Pegasys), toll-like receptor signaling, regulation of autophagy, cell adhesion pathways and Jak-STAT signaling (Avastin). Analyses of gene ontologies and pathways for coding genes in >500bp sc quiescent intervals suggest enrichment of genes encoding oxygen transport, defense response, tubulin binding, molybdopterin cofactor metabolism, and regulation of DNA repair (p≤0.01). *PARP4* was among the genes enriched for DNA repair regulation and DNA metabolism. The GO and pathways for >100bp sc quiescent intervals include several other members of this gene family. PARP-inhibitors appear to be effective for targeting ER/PR/HER2 negative breast tumors. This study suggests that conservation of this minimal gene set may explain the effectiveness of potential chemotherapeutic agents and interactions in breast cancer.

### 1211/W/Poster Board #869

**Copy number variation in low- and high-grade breast tumors.** *H. Patney[1], J. Kane[1], J. Weyandt[1], J. Hooke[2], C. Shriver[2], R. Ellsworth[3].* 1) Clinical Breast Care Project, Windber Research Inst, Windber, PA; 2) Walter Reed Army Medical Center, Washington DC; 3) Henry M. Jackson Foundation for the Advancement of Military Medicine, Windber, PA.

**Objective** Histological grade classifies breast carcinomas into low-, intermediate- and high-grade. Developmental pathways for high-grade disease remain controversial; clinical data have been used to describe both linear models, in which high-grade tumors evolve from low-grade precursors, as well as models that depict low- and high-grade carcinomas as distinct molecular diseases. Genome-wide copy number alterations were examined in low- and high-grade breast tumors to identify genetic changes associated with the etiology of low- and high-grade breast carcinomas. **Methods** Tumors were diagnosed and characterized by a single, dedicated breast pathologist. DNA was isolated after laser microdissection from low- (n= 20) and high-grade (n=57) tumors. Genotype data were generated using Human Mapping 250K Sty arrays (Affymetrix). Copy number alterations and LOH were detected using Genotyping Console 3.0.2 (Affymetrix). **Results** The number of chromosomal arms with alterations was significantly higher (P<0.005) in high- (mean 12 chromosomal arms, range = 0-30 arms) compared to low-grade (average 5 chromosomal arms, range = 1-18 arms). The most frequent alterations in low-grade disease were gains of chromosomes 1q and 16p and loss of 16q in 55%, 40% and 60% of samples, respectively. These alterations were frequently simple and included the entire chromosomal arm. Alterations on chromosomes 2, 3, 4, 9, 10, 14, 16 18, 19 and 21 were rare or undetected. In contrast, patterns of alterations were complex in high-grade tumors, frequently with alternating gains and losses on a single chromosomal arm. The most common alterations in high-grade tumors were gain of chromosome 1q (63%) with gain of 8q, 17q and 20q in >40% of tumors. Chromosome 8p was the most frequently lost arm (49%) with additional loss of chromosomes 5q and 17p in >40% of tumors. Loss of 16q occurred significantly (P<0.005) less frequently in high (25%) compared to low-grade tumors (60%). **Conclusion** Low- and high-grade breast tumors are genetically different. Gain of chromosome 1q was common in both low- and high-grade tumors, and may be an early event in tumorigenesis. Given the significantly lower rate of loss of chromosome 16q in high- compared to low-grade tumors, high-grade disease may not arise from dedifferentiation of low-grade but rather represent a separate disease defined by unique genetic alterations.

### 1212/W/Poster Board #870

**Screening for germline mutations of DNA mismatch repair (MMR) genes in colorectal cancer patients: Implications for a population specific detection strategy for Lynch syndrome.** *M. Ravnik-Glavac[1,2], G. Berginc[2], D. Glava[2].* 1) Institute of Biochemistry, Faculty of Medicine, Vrazov trg 2, University of Ljubljana, Ljubljana, Slovenia; 2) Department of Molecular Genetics, Faculty of Medicine, Vrazov trg 2, University of Ljubljana, Ljubljana, Slovenia.

Colorectal cancer (CRC) is one of the commonest cancers wordwide. The risk factors for CRC are both environmental and genetic. Approximately 75% of CRCs are sporadic; the rest are hereditary or belong to a familial syndromes. Identification of familial forms of CRC and their genes have enabled the development of several models of carcinogenesis. Molecular diagnostics tools are available on a routine basis for the commonest hereditary colon cancer syndromes including Lynch syndrome. Microsatellite instability (MSI) is present in more than 90% of Lynch syndrome cases, and is therefore a feasible marker for the disease. Mutations in MLH1, MSH2, MSH6 and PMS2, which are one of the main causes of deficient mismatch repair and subsequent MSI, have been linked to the disease. In order to establish the role of each of the 4 genes in Slovenian Lynch syndrome patients, we performed MSI analysis on 593 unselected CRC patients and subsequently searched for the presence of point mutations, larger genomic rearrangements and MLH1 promoter hypermethylation in patients with MSI-high tumours. We detected 43 (7.3%) patients with MSI-H tumours, of which 7 patients (1.3%) harboured germline defects: 2 in MLH1, 4 in MSH2, 1 in PMS2 and none in MSH6. Twenty-nine germline sequence variations of unknown significance and 17 deleterious somatic mutations were found. MLH1 promoter methylation was detected in 56% of patients without detected germline defects and in 1 (14%) suspected Lynch syndrome patients. Due to the specific absence of germline defects in MSH6, we adapted the Lynch syndrome detection strategy for the Slovenian population of CRC patients, whereby germline alterations should be first sought in MLH1 and MSH2 followed by a search for larger genomic rearrangements and PMS2 mutations, and when no germline defects are found, mutation analysis of the MSH6 gene should be performed. Our study demonstrates that the incidence of MMR mutations in a population should be known prior to the application of one of several suggested strategies for detection of Lynch syndrome.

### 1213/W/Poster Board #871

**Evaluation of hormone receptor, erbb2 and chromosome 16 status in transition areas from in situ to invasive breast carcinomas.** *R.M. Rodrigues-Peres[1], S.F.M. Derchain[2], J.K. Heinrich[1], K.P. Serra[2], J.H. Yoon[3], G.A. Pinto[1], M. Alvarenga[2], F.A. Soares[4].* 1) CAISM - Women's Hospital - State University of Campinas - UNICAMP, Campinas, SP, Brazil; 2) Department of Obstetrics and Gynecology, Faculty of Medical Sciences, State University of Campinas - UNICAMP, Campinas, SP, Brazil; 3) Faculty of Medical Sciences, State University of Campinas - UNICAMP, Campinas, SP, Brazil; 4) Hospital do Câncer AC Camargo, São Paulo, SP, Brazil.

There is evidence indicating that the transition from ductal carcinoma in situ (DCIS) to invasive ductal carcinoma (IDC) is regulated by a restrict number of genes. It remains unknown whether erbB-2 and hormone receptor status predict the invasive potential of DCIS. By the other hand, as chromosome 16 is one of the most altered chromosomes in breast cancer and frequently presented in an aneuploid status, we investigated whether its ploidy status could be used as a marker of genetic instability in in the specific areas of breast tumors which share both components of DCIS and IDC, concomitantly, indicating a possible transition. 107 cases of breast malignancies harboring contiguous regions of DCIS and IDC were selected. TMA (tissue microarrays) were mounted with separate cores, one from the DCIS and other from the neighboring IDC, from the original paraffin block. ErbB-2 and ER/PR status were assessed using conventional immunohistochemistry techniques and chromosome 16 status was verified through FISH using a centromeric probe. Clinicopathological data from the patients and from the disease were retrieved out of the patients' medical records. Results: Chromosome 16 status did not differ between the areas. Approximately 35% of the invasive areas were erbB-2 2+ or 3+, compared to 47% of their in situ counterparts. The expression of erbB-2 did not differ in the in situ and in the invasive components of the breast tumors (p=0.12). The PR status was not statistically different comparing the in situ and invasive regions of the tumors (p=0.06). By contrast, there was a slight imbalance in ER status (p= 0.04). The intraclass correlation coefficient (ICC) disclosed good agreement in sample-by-sample comparisons of erbB-2 (ICC = 0.61), PR (ICC= 0.61) and ER (ICC=0.70) expression in the in situ and invasive components. Our findings suggest that the expression of erbB-2 and ER/PR does not differ accross the in situ and invasive components of breast malignancies, especially in the transition region from one component to the other. It is expected that the molecular alterations which take place before the morphologic tissue changes persist in the invasive forms of breast tumors. The ocurrance of concomitant epigenetic factors may explain why some in situ tumors develop to an invasive phenotype, while other in situ tumors with similar molecular characteristics do not have the same evolution, supporting the hypothesis for a multifactorial basis for disease progression.

## 1214/W/Poster Board #872

**Loss of nucleolar tumor suppressor function plays a role in breast cancer initiation.** *S. Rossetti[1], A.T. Hoogeveen[2], J. Esposito[1], N. Sacchi[1].* 1) Cancer Genetics Program, Roswell Park Cancer Inst, Buffalo, NY; 2) Dept. Clinical Genetics, Erasmus MC, Rotterdam, The Netherlands.

Altered nucleolar function and aberrant transcription of ribosomal genes (rDNA) are common in cancer. However, whether increased ribosomal RNA (rRNA) synthesis is an initiating cause rather than a mere consequence of cell transformation is poorly understood. MTG16a (CBFA2T3), a member of the MTG family of transcriptional co-repressors, is a suppressor of breast tumorigenesis with a nuclear/nucleolar localization. We found that knock down of MTG16a in human mammary epithelial cells leads to impaired acinar morphogenesis in vitro, a phenotype indicative of cell transformation. We could specifically trace this phenotype to the loss of MTG16a nucleolar function by expressing a mutant MTG16 protein able to re-localize wild type MTG16a from the nucleolus to the nucleoplasm. We further demonstrated that MTG16a plays a role in rDNA repression by gain-of-function and loss-of-function evidence. We identified two candidate mechanisms of MTG16a-mediated rRNA repression. First, MTG16a can interact both with the rDNA promoter and the major component of the Nucleolar Remodeling Complex (NoRC), which is known to impose repressive chromatin changes at rDNA regulatory regions. Second, we demonstrated that MTG16a effectively counteracts MYC-driven, RNA Polymerase I-mediated, rRNA transcriptional activation in cells over expressing MYC. In conclusion, our data support the conclusion that loss of MTG16a tumor suppressor function in the nucleolus plays a role in breast cancer initiation by inducing increased rRNA synthesis. This work was supported by the Susan Komen Foundation (NS and SR).

## 1215/W/Poster Board #873

**Epigenetic silencing of a tumor suppressor network reveals doubled edged effects of master cell signals.** *N. Sacchi, S. Rossetti.* Cancer Genetics Program, Roswell Park Cancer Institute, Buffalo, NY.

Epigenetic silencing of tumor suppressor genes is common in breast cancer cells. We found that an aberrant signaling of retinoic acid (RA) via the RA receptor alpha (RARA) results in the concerted epigenetic silencing of a tumor suppressor gene network downstream of RARA. This network includes the RA receptor beta 2 (RARB2), which mediates RA growth-inhibitory action, and TGFBR2, the main receptor of transforming growth factor beta (TGFB). Unexpectedly, we observed that both RA and TGF beta signals, which have anticancer effects in normal cells, exacerbate the tumor phenotypic features of cancer cells that underwent loss of RARB2 and TGFBR2 tumor suppressor activities. Apparently, as a consequence of epigenetic silencing of canonical receptors, master signals such as RA and TGFB, exploit alternate targets to promote, rather than inhibit, tumorigenesis. This work was partially supported by the National Cancer Institute grant NCI R01-CA127614-01 (NS).

## 1216/W/Poster Board #874

**Identification of Novel VHL-Regulated Proteins Using Proteomic Profiling in Transgenic *Drosophila*.** *T.N. Seagroves[1,2], S. Doronkin[3], I. Djagaeva[3], L.T. Reiter[4].* 1) Dept. of Pathology, University of Tennessee Health Science Center, Memphis, TN; 2) Center for Cancer Research; 3) Dept. of Anatomy and Neurobiology, University of Tennessee Health Science Center, Memphis, TN; 4) Dept. of Neurology, University of Tennessee Health Science Center, Memphis, TN.

Von Hippel-Lindau (VHL) syndrome affects ~1/36,000 individuals as a result of mutations in the tumor suppressor gene *VHL*. Type 1 VHL patients develop renal cell carcinoma (RCC) without pheochromocytoma; type 2A or 2B patients develop pheochromocytoma without or with high risk for RCC and pancreatic tumors, respectively. The majority of patients also develop hemangioblastomas in the nervous system. As RCC is highly refractive to current therapies, and up to 80% of sporadic RCCs harbor mutations in *VHL*, understanding how VHL promotes tumorigenesis is critical to develop novel therapeutics. VHL is known to mediate the proteosome-dependent turnover of the Hypoxia-Inducible Factor (HIF) transcription factors, directly contributing to the VHL phenotype. However, there have been limited proteomic screens to identify novel VHL-regulated proteins, and, no profiling has been attempted using a whole model organism without tissue bias. We utilized the GAL4/UAS system to create *Drosophila* (fruit flies) that over-express high levels of VHL or Vhl (the fly ortholog) globally in response to heatshock. We also developed two methods using flies to assay for biological function of the 25 VHL-regulated candidate proteins identified in our screen. First, we analyzed the consequences of hypoxic exposure or genetic manipulation of the HIF/VHL pathways upon the migration of border cells in the *Drosophila* ovary, which is a model of metastasis. In response to 1%$O_2$ or VHL/Vhl over-expression, border cells entered a diverse migratory mode, ranging from blocked border cell migration (BCM) to an unprecedented acceleration. In contrast, loss of function or over-expression of *sima* (the ortholog of HIF-1$\alpha$) modulated BCM in a non-linear, dose-dependent manner. Mosaic clone analysis revealed that HIF transcriptional activity is specifically required in the leading cell of the BC cluster since loss of either *sima* or *tgo* (the HIF-1$\beta$ ortholog) produced BCM phenotypes. Second, we found that modulation of Vhl expression in the peripheral sensory neurons of larvae disrupted dendritic arborization (DA). We are currently assaying how proteins identified in our profiling screen modulate these VHL/Vhl-dependent BCM and DA phenotypes. Functional analysis of candidate proteins in *Drosophila* may ultimately reveal pathways conserved in humans that are amenable to therapeutic intervention.

## 1217/W/Poster Board #875

**P21 (Waf1/Cip1) Gene Polymorphism, Protein Expression of P53, P21 and MDM2 in Esophageal Squamous Cell Carcinoma in Northeastern Iran.** *N. Taghavi[1], F. Biramijamal[1], MR. Abbaszadegan[3], M. Sotoudeh[2], H. Khademi[2], R. Malekzadeh[2].* 1) Dept. of Medical Genetics, National Institute of Genetic Engineering & Biotechnology (NIGEB), Tehran, Iran; 2) Digestive Disease Research Center, Tehran University of Medical Sciences, Tehran, Iran; 3) Division of Human Genetics, Immunology Research Center, Bu-Ali Research Institute, Mashhad University of Medical Sciences, Mashhad, Iran.

Background: The incidence of Esophageal Squamous Cell Carcinoma [ESCC] is very high in northeastern Iran. However; the genetic predisposing factors in this region have not been clearly defined. P21 (waf1/cip1) gene involves in cellular growth arrest, induced by p53 tumor suppressor gene. The p21 polymorphism, in codon 31 (p21 C98A, dbSNP rs1801270) may affect the protein expression and play a role in cancer susceptibility. Methods: The role of p21 polymorphism on the risk of ESCC in relation to P21, P53 and MDM2 protein expression was evaluated in a case-control study in northeastern Iran. The current analyses include 60 ESCC patients (aged 35-83), and 60 age and sex matched controls, enrolled from 2006-2007. Genotyping of p21 polymorphism was determined using PCR-RFLP method and the expression of p21, p53 and MDM2 proteins was analyzed by immunohistochemistry for 38 of the recruited cases and controls. Results: The p21 polymorphism was not associated with ESCC formation ($P>0.05$). However, tobacco smoking may have synergistic interaction with P21 polymorphism in ESCC carcinogenesis. The expression of p21 and p53 proteins was significantly higher in cases ($P=0.031$ for p21 and $P=0.0001$ for p53). P21 genotype did not correlate with p21 or p53 protein expression ($P> 0.05$). In addition, we found a significant difference in cases between smokers and non-smokers in p53 overexpression ($P=0.045$). Conclusion: Our data suggests; the p21 polymorphism at codon 31, is not genetic susceptibility biomarker for ESCC in northeastern Iran. However, its interaction with tobacco smoking, suggests some environmental factors may be involved in association with the p21 polymorphism in ESCC development in northeastern Iran. This polymorphism and p53 overexpression may consequently be a candidate genetic marker for screening ESCC risk in association with exposure to particular environmental carcinogens in this region of Iran.

## 1218/W/Poster Board #876

**Silencing of tumor suppressor genes *RASSF1A*, *SLIT2* and *P16*, through genomic loss and promoter hypermethylation in hereditary breast carcinomas.** *T. Tapia[1], C. Alvarez[1], E. Castillo[1], A. Corvalan[2], M. Camus[2], M. Alvarez[2], MP. Carvallo[1].* 1) Department of Cell and Molecular Biology, P. Universidad Catolica de Chile; 2) Centro de Cancer, Faculty of Medicine, P. Universidad Catolica de Chile, Santiago, Chile.

Breast cancer is one of the most common cancers in women worldwide and the second cause of death by cancer in Chile. The molecular mechanisms responsible for the progression of breast cancer remain still unknown, although several studies have been performed in order to identify genes participating in this process. It has been well established that tumor suppressor gene silencing is one important event in tumor development, and that it may occur through epigenetic modifications or genomic alterations. We analyzed 50 breast tumor biopsies through array-CGH and found several chromosomal losses involving tumor suppressor genes. Among these *RASSF1A* (chromosome 3p21.3) and *SLIT2* (chromosome 4p15.2), have been reported to be silenced by hypermethylation of its promoters in several tumors including sporadic breast carcinomas. Another gene silenced by this epigenetic alteration is $P16^{INK4A}$, a tumor suppressor gene that actively regulates cell cycle progression. We studied the methylation status of *RASSF1A, SLIT2* and *P16* gene promoters in 47 hereditary breast tumors. These regions were amplified by MS-PCR, from sodium bisulphite modified tumor DNA, by using specific primers for the methylated and not methylated conditions. Our results show that 61.3 % of hereditary tumors present promoter hypermethylation for *RASSF1A* , 86 % for *SLIT2* and a 2.6 % for *P16*. Five tumors showing genomic loss at the *RASSF1A* locus also presented promoter hypermethylation. In the case of *SLIT2* , correlation between genomic deletion and methylation was found in two tumors. These observations suggest inactivation of both alleles by different mechanisms in these two genes. Six tumors showed only the methylated *SLIT2* product, and five tumors showed only the methylated *RASSF1A* product, not presenting genomic losses at these loci. These observations are in agreement with an epigenetic modification of both alleles as a molecular mechanism for gene silencing. The present observations are consistent with the participation of *RASSF1A* and *SLIT2* hereditary breast tumor progression. Financed by Fondecyt 1080595.TTapia is a Conicyt Doctoral fellow.

## 1219/W/Poster Board #877

**Rare, evolutionarily unlikely missense substitutions in ATM confer increased risk of breast cancer.** *S.V. Tavtigian[1], D. Babikyan[1], A. Hartmann[2], S. Healey[3], F. Le Calvez-Kelm[1], F. Lesueur[1], G.B. Byrnes[1], S.C. Chuang[1], M. Hashibe[1], A. Thomas[4], C. Voegele[1], J. Hall[5], S. Sangrajrang[6], J.L. Hopper[7], M.C. Southey[7], I.L. Andrulis[8], E.M. John[9], P.J. Oefner[2], G. Chenevix-Trench[3], Australian Cancer Study, BCFR, kConFab.* 1) Genetic Cancer Susceptibility, Intl Agency Res Ctr, Lyon, France; 2) Institute of Functional Genomics, University of Regensburg, Regensburg, Germany; 3) Queensland Institute of Medical Research, Brisbane, Australia; 4) Department of Biomedical Informatics, University of Utah School of Medicine, Salt Lake City, UT, USA; 5) Institue Curie, Recherche, INSERM U612, Orsay, France; 6) Research Division, National Cancer Institute, Bangkok, Thailand; 7) Centre for MEGA Epidemiology, University of Melbourne, Carlton, Victoria, Australia; 8) Cancer Care Ontario, Fred A. Litwin Center for Cancer Genetics, Samuel Lunenfeld Research, Mount Sinai Hospital, Toronto, ON, Canada; 9) Northern California Cancer Center, Fremont, CA, USA and Department of Health Research and Policy, Stanford University School of Medicine, Stanford, CA, USA.

The susceptibility gene for Ataxia telangiectasia, ATM, is also an intermediate-risk breast cancer susceptibility gene. However, the spectrum and frequency distribution of ATM mutations that confer increased risk of breast cancer have been controversial. To assess the contribution of rare variants in this gene to risk of breast cancer, we pooled data from seven published ATM case-control mutation screening studies including a total of 1544 breast cancer cases and 1224 controls with data from our own mutation screening of an additional 987 breast cancer cases and 1021 controls. Using an in silico missense substitution analysis that provides an ordered ranking of missense substitutions from evolutionarily most likely to least likely, we carried out analyses of protein truncating variants, splice junction variants, and rare missense variants. We found marginal evidence that the combination of ATM protein truncating and splice junction variants contribute to breast cancer risk. In contrast, there was stronger evidence that a subset of rare, evolutionarily unlikely missense substitutions confer increased risk. On the basis of subset analyses, we hypothesize that rare missense substitutions falling in and around the FAT, kinase, and FATC domains of the protein may be disproportionately responsible for that risk, and that a subset of these may confer higher risk than do protein truncating variants.

## 1220/W/Poster Board #878

**Genome-wide copy number analysis of NF1-MPNSTs using a high resolution Affymetrix SNP6.0 platform.** *M. Upadhyaya[1], G. Spurlock[1], L. Kluwe[2], N. Thomas[1], A. Guha[3], V. Mautner[2], J. Yan[4].* 1) Medical Genetics, Cardiff University, Cardiff, Wales, United Kingdom; 2) Department of Neurosurgery, University Clinic Hamburg-Eppendorf, Hamburg, Germany; 3) The Arthur and Sonia Labatt Brain Tumor A Research Centre, The Hospital for Sick Children, University of Toronto, Toronto, Ontario, Canada; 4) Almac Diagnostics, Durham, North Carolina USA.

Neurofibromatosis type 1 (NF1), a familial cancer syndrome affecting 1 in 3,500 individuals worldwide, is characterised by the development of benign and malignant peripheral nerve sheath tumours. NF1 patients have a 7-13% lifetime risk of developing an aggressive malignant peripheral nerve sheath tumour (MPNST) that results in significant morbidity and mortality. MPNST usually develop from either an existing benign plexiform neurofibroma, or a focal subcutaneous neurofibroma. MPNSTs are difficult to diagnose as the clinical symptoms of cancerous tumours overlap with benign neurofibromas. Surgical intervention is a potentially hazardous method of determining whether a deep-seated lesion is benign or malignant.. Genomic DNA analysis has identified copy number alterations in many solid tumours including MPNSTs, where such changes are predicted to confer a selective advantage for cell proliferation and clonal expansion, both essential aspects of tumorigenesis. This is the first study aimed at identifying diagnostic and prognostic tumour-specific markers associated with MPNST using high resolution Affymetrix SNP 6.0 microarray platform. DNA from 15 NF1 derived MPNST and 5 benign plexiform neurofibromas (PNF), all with paired blood samples, were analysed for loss-of-heterozygosity (LOH) and genomic copy number variants (CNV). Data were processed using Affymetrix Genotyping Console 2.1 and analyzed via Partek Genomics Suite 6.4 for quality control. Hidden Markov Model (HMM) and Genomic Segmentation algorithms were used to detect amplified and deleted genomic regions. The genomic aberrations identified in MPNST DNA showed specific CNV and LOH changes, with no similar aberrations evident in PNF DNA. This study confirmed previous genes associated with MPNST but also identified several additional genes: PDGFRB (5q31-q32), ITGB8 (7p15.3), PDGFA and RAC1 (7p22) and MMP12 (11q22.3). Biological pathway analysis was used to identify potential target genes of clinical significance and significantly 8 genes (ACTB, ACTG1, LIMK1, PRKCA, PTK2, RAC1, ROCK2, TRIO) all involved in cytoskeletal remodelling and cell adhesion were found to be significantly amplified in MPNST. This is thus the first study to highlight specific pathway in the development of MPNSTs. These genes and their products are potential therapeutic and prognostic targets in these malignant tumours, which currently lack an effective treatment or reliable prognostic and diagnostic markers.

## 1221/W/Poster Board #879

**The secretory small GTPase Rab27B regulates invasive tumor growth and metastasis through extracellular HSP90α.** *W. Westbroek[1], D. Maynard[1], A. Hendrix[2], O. De Wever[3], M.C. Seabra[4], W.A. Gahl[1].* 1) Med Gen Branch, NHGRI/MGB/NIH, Bethesda, MD; 2) Dept Med Oncology, ghent University Hospital, Ghent, Belgium; 3) Lab of Exp Cancer Res, Ghent University Hospital, Ghent, Belgium; 4) Dept Mol Med, NHLI, Imperial College, London, UK.

Tumors achieve invasive growth by delivering factors into the tumor microenvironment; the molecular mechanisms for secretion of these pro-invasive factors remain largely unknown. One likely process involves vesicle exocytosis. Key players in exocytic and endocytic membrane trafficking include small Rab GTPases. Rabs are post-translationally modified by geranylgeranylation for membrane interaction and serve as molecular switches, oscillating between their GTP-bound active and GDP-bound inactive state. Our studies on various secretory Rab GTPases revealed that over-expression of Rab27B in several breast cancer cell lines promoted cell cycle progression, F-actin reorganization, and invasion into matrigel. By establishing MCF-7 cells that stably expressed wild type Rab27B, constitutively active Rab27B-Q78L (defective in GTP hydrolysis), dominant negative Rab27B-T23N (defective in GTP binding), and the geranylgeranyl mutant Rab27B-GER, we determined that Rab27B-mediated invasion was achieved when Rab27B was geranylated and in its active GTP-bound state. Our in vivo xenograft mouse model showed that nude mice injected with MCF-7 Rab27B or Rab27B-Q78L developed invasive xenografts that were 8-fold larger than the non-invasive MCF-7 Rab27B-T23N or Rab27B-GER xenografts. Proteomic analysis of Rab27B-positive purified vesicles and the secretome of MCF-7 Rab27B identified heat shock protein HSP90α as a key pro-invasive factor. By ELISA assays and western blotting, we showed that HSP90α secretion was upregulated in the conditioned media prepared from MCF-7 Rab27B and Rab27B-Q78L. In addition, treatment with an HSP90α neutralizing antibody reversed the in vitro invasive phenotype of MCF-7 Rab27B cells, while treatment with recombinant HSP90α of MCF-7 cells induced invasion in a dose-dependent manner. Finally, we examined endogenous Rab27B expression status in 60 different clinical samples derived from breast cancer patients by real time quantitative PCR and immune-histology. We showed that upregulation of endogenous Rab27B mRNA and protein correlated with lymph node metastasis, tumor grade and positive ER-status. In summary, we identified Rab27B as an important player in invasion and metastasis; Rab27B could be a critical marker in the signature of ER-positive breast cancers with poor prognosis. Considerable therapeutic potential may reside in efforts to control Rab27B levels and modulate Rab27B-regulated pathways through pharmacologic or genetic interventions.

## 1222/W/Poster Board #880

**Pathway Analysis of Genes with Copy Number Aberrations in Cancers.** *Q. Zhang[1], L. Ding[2], D. Larson[2], L. Lin[2], I. Borecki[1], M. Province[1].* 1) Divsion of Statistical Genomics, Washington University School of Medicine, St Louis, MO; 2) Genome Center, Washington University School of Medicine, St Louis, MO.

DNA copy number aberration (CNA) is a significant hallmark of genomic abnormality in tumor cells. Genes with CNAs in cancer patients may play important roles in oncogenesis. To understand the pathway distribution of genes in CNA regions, we conducted both gene-based and KEGG pathway-based analysis on DNA array data for 357 lung cancer (adenocarcinoma) patients and 193 brain cancer (glioblastoma) patients from the tumor sequencing project (TSP) and the cancer genome atlas (TCGA), respectively. We identified 3421 (out of 15427) genes and 3132 (out of 23100 genes) that have significant CNAs (FDR<0.05 and Frequency>0.05) in lung cancer patients and brain cancer patients, respectively. A pathway enrichment analysis indentified 25 significant CNA-enriched pathways (most related to metabolism and cellular processes) , including the pathways of Starch and Sucrose Metabolism, Fatty Acid Biosynthesis, Amino Acid Metabolism, Signaling Molecules and Interaction, Regulation of Autophagy, T Cell Receptor Signaling, Adipocytokine Signaling, Hematopoietic Cell Lineage, Cell Adhesion Molecules, Progesterone-mediated Oocyte Maturation, etc. The differences of pathway enrichment between cancer types, smoking status, genders, tumor grades and stages were also be investigated and reported.

## 1223/W/Poster Board #881

**Modeling the human 8p11-myeloproliferative syndrome in NOD/SCID mice.** *H. Ågerstam[1], M. Järås[1], A. Andersson[1], P. Johnels[1], C. Lassen[1], D. Gisselsson[1], T. Olofsson[2], J. Richter[2], X. Fan[3], M. Ehinger[4], T. Fioretos[1].* 1) Department of Clinical Genetics, Lund University, Lund, Sweden; 2) Department of Hematology, Lund University Hospital, Lund, Sweden; 3) The Rausing Laboratory, Lund University Hospital, Lund, Sweden; 4) Department of Pathology, Lund University Hospital, Lund, Sweden.

The 8p11 myeloproliferative syndrome (EMS), also referred to as stem cell leukemia/lymphoma, is a chronic myeloproliferative disorder clinically characterized by leukocytosis, eosinophilia, splenomegaly, and a short chronic phase that rapidly progresses into aggressive acute myeloid or lymphoblastic leukemia. At the molecular level, EMS is characterized by fusion of at least eight different 5' partner genes to the 3' part of the *FGFR1* gene, resulting in constitutive activation of the tyrosine kinases in FGFR1. The aim of this study was to address the functional consequences of ectopic *FGFR1* expression in the potentially most relevant cellular context, that of normal primary human hematopoietic cells. For this purpose we used normal human $CD34^+$ cells from umbilical-cord blood and retrovirally transduced them with *ZMYM2/FGFR1* (previously known as *ZNF198/FGFR1*) or *BCR/FGFR1*. The cells were grown in suspension culture and in methylcellulose medium or transplanted into NOD/SCID mice. The phenotype of the differentiating cells in vitro and in vivo was analyzed by flow cytometry. Bone marrow and spleen sections from transplanted mice were analyzed by histopathology and immunohistochemisty. Expression of *ZMYM2/FGFR1* or *BCR/FGFR1* in normal human $CD34^+$ cells lead to increased cellular proliferation and differentiation towards the erythroid lineage in vitro. In the xenotransplantation NOD/SCID assay, *BCR/FGFR1* induced several features of human EMS, including expansion of several myeloid cell lineages and accumulation of blasts in bone marrow. Moreover, bone marrow fibrosis together with increased extramedullary hematopoiesis was observed. This study suggests that *FGFR1* fusion oncogenes, by themselves, are capable of initiating an EMS-like disorder, and provides the first humanized model of a myeloproliferative disorder transforming into acute leukemia in mice. The established in-vivo EMS model provides a valuable tool for future studies of this disorder.

## 1224/W/Poster Board #882

**Soft tissue alterations of oral cavity in Neurofibromatosis type 1 (NF1).** *E-M. Jouhilahti[1], V. Visnapuu[1,2], T. Soukka[2], S. Peltonen[3], R-P. Happonen[2], J. Peltonen[1,3].* 1) Institute of Biomedicine, Department of Cell Biology and Anatomy, University of Turku, Kiinamyllynkatu 10, 20520 Turku, Finland; 2) Department of Oral Diseases, Turku University Central Hospital, Lemminkaisenkatu 2, 20520 Turku, Finland; 3) Department of Dermatology, University of Turku, Kiinamyllynkatu 8, 20520 Turku, Finland.

BACKGROUND: Type 1 neurofibromatosis (NF1) is the most common one gene syndrome. It is caused by a mutation in the NF1tumor suppressor gene. NF1 syndrome is characterized by benign cutaneous neurofibromas which consist mostly of Schwann cells and fibroblasts. OBJECTIVE: The aim of the study is to analyze the oral soft tissue growths and compare them with NF1-related cutaneous neurofibromas. SUBJECTS AND METHODS: A total of 110 Caucasian patients with neurofibromatosis type 1 were included in this study with clinical oral examination. The patients were recruited to the study among the patients attending the NF1 clinic at the Department of Dermatology and Department of Oral Diseases, Turku University Central Hospital, as well as among members of the Finnish NF patient organization. All patients fulfilled the NIH diagnostic criteria for NF1. Oral soft tissue tumors were removed from 8 patients. Three tissue samples represented plexiform neurofibromas and five samples were solitary nodules. The plexiform manifestations were located in lower surface of tongue (1), in the gingiva (1) and on the mucosa under the tongue. The solitary tumors were located in the right border of tongue (2), in the lower surface of tongue (1) in the palate (1) and in the gingiva (1). The tissue samples were fixed in 10 % neutral formalin and embedded in paraffin. Sections, 5 μm thick, were cut and stained with hematoxylin-eosin (HE) and Masson's trichrome. In addition, a panel of selected biomarkers was used for immunocytochemistry in which the avidin-biotin method was used. RESULTS: All tissue samples analyzed contained variable amounts of S100 positive Schwann cells and type IV collagen positive collagenous matrix. Nestin was expressed by spindle like cells in solitary tumors locating in the border of the tongue and in the gingiva. CONCLUSION: The soft tissue alterations of oral cavity of NF1 patients show characteristics of both cutaneous and plexiform neurofibromas. The solitary tumors locating in the border of the tongue and in the gingiva resembled cutaneous neurofibromas based on the immunohistochemical analysis.

## 1225/W/Poster Board #883

**Absence of correlation between *COL1A1-PDGFB* molecular subtype and the clinico-histological features of *Dermatofibrosarcoma Protuberans*: analysis of 35 new cases and review of 137 cases from the literature.** *D. Giacchero[1,2,3], G. Maire[1,2], F. Berthier[4], N. Ebran[1,2], A. Carlotti[5], P. Celerier[6], JM. Coindre[7], E. Esteve[8], S. Fraitag[9], D. Ranchère-Vince[10], P. Saiag[11], P. Terrier[12], JP. Lacour[3], F. Pedeutour[1,2].* 1) Laboratory of Solid Tumor Genetics, Nice University Hospital, Nice, France; 2) CNRS, UMR 6543, Faculty of Medicine, Nice, France; 3) Dermatology, Nice University Hospital, Nice, France; 4) Department of Medical Information, Nice University Hospital, Nice, France; 5) Department of Pathology, Cochin University Hospital, Paris, France; 6) Department of Dermatology, Le Mans Regional Hospital, Le Mans, France; 7) Department of Pathology, Bergonié Institute, Bordeaux, France; 8) Department of Dermatology, Orleans Regional Hospital, Orléans, France; 9) Department of Pathology, Necker University Hospital, Assistance Publique-Hôpitaux de Paris, Paris, France; 10) Department of Pathology, Centre Léon Bérard, Lyon, France; 11) Department of Dermatology, Ambroise Paré University Hospital, Boulogne, France; 12) Department of Pathology, Gustave Roussy Institute, Villejuif, France.

The translocation t(17;22) resulting in C*OL1A1-PDGFB* fusion gene is found in dermatofibrosarcoma protuberans (DFSP) and its clinico-pathological variants. The chimeric *COL1A1-PDGFB* transcript shows a great variability of the *COL1A1* breakpoint from exon 6 to exon 49, contrasting with the consistent involvement of the *PDGFB* exon 2. The clinical or histological variations have never been assessed in regards to the *COL1A1* breakpoint position. Using RT-PCR and sequence analysis, we molecularly characterized the *COL1A1-PDGFB* breakpoints of 35 novel DFSP. We also retrospectively reviewed 137 cases with clinical information and molecular data. In a total of 172 cases of DFSP with molecular data, 38 different exons of *COL1A1* were involved in the fusion gene. Exons 25, 29, 32, 40, 46 and 47 were the most frequently involved exons (n≥ 10). Eight exons were described in unique cases. Among the 35 new cases analyzed, we identified 3 novel *COL1A1* breakpoints involving exons 9, 14 and 39. This study, pooling 172 cases in total, analyzes the largest series of DFSP with molecular data. Analyzing all cases, and with respect to the small number of patients for each group of breakpoints, we have not found any significant correlation between the *COL1A1* breakpoint localization and any clinical or histological features. The knowledge of the *COL1A1* breakpoint position does not give insights for the patient's care management. In the context of molecular routine diagnosis test, the identification of the *COL1A1-PDGFB* rearrangement is therefore sufficient, and could be evaluated alternatively by fluorescence in-situ hybridization (FISH).

## 1226/W/Poster Board #884

**Comparison of clonal patterns of chromosomal aberrations between DCIS and invasive breast cancer lesions of the same patient using a panel of ten FISH probes.** *K. Heselmeyer-Haddad[1], L. Berroa[1], C. Ortiz-Melendez[1], S. Valentine[1], S. Tewelde[1], K. Calzone[1], R. Christensen[2], P. Soballe[3], A. Schaffer[4], S. Prindiville[5], T. Ried[1].* 1) Genetics Branch, CCR, NCI, NIH, Bethesda, MD; 2) Department of Pathology, National Naval Medical Center, Bethesda, MD; 3) Department of General Surgery, Naval Medical Center, San Diego, CA; 4) Computational Biology Branch, NCBI, NIH, Bethesda, MD; 5) Coordinating Center for Clinical Trials, Office of the Director, NCI, NIH, Bethesda, MD.

Ductal carcinoma *in situ* (DCIS) refers to lesions with malignant epithelial cells that have not invaded the surrounding stroma. These lesions are confined to the ducts of the breast. It is thought that DCIS represents a stage that precedes invasive ductal carcinoma (IDC). However the linkage between these two lesions is still obscure. In order to analyze the patterns of genetic alterations as an approach to understand the correlation between DCIS and IDC, we developed four panels of FISH probes. The panels contained 5 oncogenes (COX2, MYC, CCND1, HER2, ZNF217) and 3 tumor suppressor genes (DBC2, CDH1, p53) specific for breast tumorigenesis and two centromeric probes (CEP10, CEP4) as a control for the ploidy of the cells. Objectives: Determine gain and loss patterns of the gene probes within DCIS and IDC, compare similarities in the genetic make-up of the DCIS and the corresponding IDC lesion, characterize clonal evolution from the DCIS lesion to IDC.

The database of the "Susceptibility to Breast Cancer Study" conducted at the National Naval Medical Center and National Cancer Institute, was searched for cases of breast carcinoma with neighboring DCIS. Archived paraffin blocks were analyzed by a pathologist. Representative areas for invasive cancer and DCIS were micro-dissected and disintegrated. One cytospin for each lesion was hybridized with four FISH probe panels subsequently. A relocation software allowed for counting the same 150-200 nuclei for all four sets of probes. In collaboration with NCBI, algorithms were developed to compare clonal patterns. Preliminary data show that there are cases which exhibit the exact same major clone in both the DCIS lesion and the corresponding IDC lesion. However, many of the cases displayed differences in the major clones for DCIS and IDC. These findings suggest that the clonal evolution from DCIS to IDC differs from case to case, indicating that in some cases major clones present in the DCIS are also successful in the IDC while in others the major clone(s) of the DCIS is/are replaced by clones with a different oncogene and tumor suppressor gene combination in the IDC. This study will improve our understanding of the molecular events that are involved in the progression from pre-invasive to invasive cancer and may lead to the development of prognostic biomarkers that can predict this transition.

## 1227/W/Poster Board #885

**Genome-wide SNP-array and Mutational Analysis of Genes Involved in RAS-signaling in Chronic Myeloid Leukemia treated with Dasatinib and Rapidly Developing AML with Monosomy 7 in Philadelphia-negative cells.** *N. Larsson[1], M. Ekblom[2], H. Lilljebjörn[1], C. Lassen[1], J. Richter[2], T. Fioretos[1].* 1) Clinical Genetics, Lund University, Lund, Lund, Sweden; 2) Department of Hematology, Lund University Hospital, Lund Sweden.

Despite the recent success of tyrosine kinase inhibitors (TKI) in the treatment of chronic myeloid leukemia (CML), some patients (2-17%) develop clonal cytogenetic changes in the Philadelphia (Ph-) negative cell population. A fraction of these patients, in particular those displaying trisomy 8 or monosomy 7, are at risk of developing a myelodysplastic syndrome (MDS) or acute myeloid leukemia (AML). Consequently, there is a need to characterize the clinical features of such cases and to increase our understanding of the pathogenetic mechanisms underlying the emergence of clonal cytogenetic changes in Ph-negative cells. So far, most cases reported have received treatment with imatinib. Herein, we describe a case of CML who rapidly developed monosomy 7 in Ph-negative cells 14 months after the initiation of dasatinib, a second generation TKI. Two months later the patient developed a fatal AML. Retrospective investigations by fluorescent in situ hybridization revealed that the monosomy 7 clone appeared already two months after the initiation of dasatinib treatment. Genome-wide 500 K single nucleotide polymorphism (SNP) array analysis of the monosomy 7 clone, revealed no acquired submicroscopic copy number changes. Given the strong association between monosomy 7 and mutations of genes involved in the RAS pathway in juvenile myelomonocytic leukaemia, we also screened for pathogenetic variants in KRAS, NRAS, and PTPN11, but did not detect any changes.

## 1228/W/Poster Board #886

**Homologous Recombination in Skin Fibroblasts.** *I. Tereshchenko, L. Serrano, N. Goldsmith, K. Patel, A. Shawki, X. Jiang, B. Zheng, A. Brooks, S. Buyske, J. Tischfield.* Rutgers, The State University of NJ, Piscataway, NJ.

Using an in vivo mouse assay we have demonstrated that the major mechanism of loss of heterozygosity (LOH) in somatic cells is mitotic recombination (MR). To categorize the subchromosomal regions that manifest different frequencies of mitotic recombination in mouse primary skin fibroblasts, we performed genotyping of both STS and SNP markers. MR on mouse chromosome 8 occurs non-randomly and demonstrates age-specific characteristics. The fraction of crossover events originating in the region between 119 Mb and 125 Mb was elevated two-fold in mice aged 7-9 months compared to those aged 2-3 months (0.87 vs 0.41, respectively; P<0.001), while the overall frequency of MR did not change significantly (mean frequencies of $4.3x10^{-5}$ and $6.4x10^{-5}$, respectively). Also, the activity of MR did not correlate with the distribution of fragile sites on mouse chromosome 8. Moreover, repression of MR in particular subchromosomal regions apparently has functional and structural relevance. For example, we did not observe MR activity in the evolutionarily conserved non-coding region positioned between two members of the cadherin gene family, *CDH11* and *CDH5*, on the chromosomal band boundary 8qD2/D3. Indeed, this 324.1 Kb region has also been considered a desert of meiotic recombination. We hypothesize that the specific sequence composition, chromatin structure, and nuclear localization of this subchromosomal region suppressed MR in mouse fibroblasts. In contrast, a mitotic recombination hotspot was mapped to a euchromatic region situated between 120.677 Mb and 124.082 Mb on 8qE1. We speculate that transcriptional co-regulation of the evolutionarily conserved gene clusters and the presence of extensive regions of subchromosomal sequence homology in the inbred parental mouse strains promotes homologous chromosome interaction and facilitates MR in the primary skin fibroblasts of the C57/129 F1 hybrids. Elevated MR may have acute biological consequences that lead to tumorigenicity. Indeed, regions that manifest a high degree of MR on chromosome 8 also demonstrate elevated LOH in mouse mammary carcinomas and, furthermore, LOH in syntenic human chromosomal regions is consistently associated with breast and prostate cancers.

## 1229/W/Poster Board #887

**A new way of maintaining telomere in CML: Alternative lengthening of telomere.** *O. Samassekou[1], J. Hébert[2,3], J. Yan[1].* 1) Dept Medical Genetics, Department of Pediatrics, Faculty of Medicine and Health Sciences, Universite de Sherbrooke,3001 12th Avenue North, Sherbrooke, J1H 5N4, Quebec, Canada; 2) Leukemia Cell Bank of Quebec and Division of Hematology, Maisonneuve-Rosemont Hospital,3001 12th Avenue North, Sherbrooke, J1H 5N4, Quebec, Canada; 3) Department of Medicine, Université de Montréal,Montreal, Quebec H3C 3J7, Canada.

Chronic myeloid leukemia (CML) is a neoplasia characterized by a proliferation of a myeloid cell lineage and a translocation t(9;22). As most of cancer, the telomere length in CML cells is shorter than normal blood cells. However, currently no data are available about the specific telomere length in CML. We studied the telomere length on each chromosome in 21 CML and 13 normal samples. After obtaining metaphases from CML and normal cells, in situ hybridization with peptide nucleic acid probes was performed. The fluorescence intensity of each specific telomere was converted in kb according to the telomere restriction fragment technique (TRF) result for each sample. The individual telomere lengths of CML samples were compared to those of normal ones. The individual telomere lengths in CML cells were ranging from 1.70 kb to 24.83 kb. We surprisingly noticed an elongation or maintenance of specific telomere on 10p, 14p, 17p, 18p and 19p. This lengthening was confirmed by TRF which showed specific distinguishable bands from the smear. Contrary, in CML cells, all individual telomeres on chromosome long arms were shortened. To understand the difference of individual telomere length maintenance in CML, we measured the telomerase activity by real time polymerase chain reaction. We found an increase of telomerase activity in 70% cases. However, this augmentation could not explain the huge difference between short and long telomeres on one hand and between the homologous chromosomes on the other hand. Moreover, the samples which had basal telomerase activity showed some individual long telomeres. To further understand the mechanism by which these telomeres were maintained or elongated, we studied the alternative lengthening of telomere (ALT). We found that in more than 50% of the samples the presence of t-circles by doing 2D gel and single strand telomere DNA which can be either TTAGGG or CCCTAA strands. These finding are considered to be some of ALT features. Besides the action of the telomerase to maintain telomere length, ALT is another mechanism to conserve telomere length in CML. ALT might be the first mechanism to maintain telomere length in CML before the reactivation of telomerase, and these two mechanism might synergistically act on individual telomeres. It is important to take into account the two mechanisms maintaining telomere length when targeting the telomerase by therapeutic agents because the telomerase activity can hide the ALT mechanism.

## 1230/W/Poster Board #888

**Strand-specific RNA sequencing of HepG2 cells identifies genes that are differentially expressed, alternatively spliced and allelically imbalanced in response to TGF-beta.** *B. Tuch[1], C. Barbacioru[1], O. Wallerman[2], R. Andersson[7], A. Moustakas[3], C.H. Heldin[3], N. Eriksson[6], S. Stanley[1], J. Gu[4], S. Kuersten[4], M. Barker[1], J. Komorowski[7,8], K. McKernan[5], F.M. De La Vega[1], C. Wadelius[2].* 1) Life Technologies, Foster City, CA; 2) Dept. of Genetics and Pathology, Uppsala University, Sweden; 3) Ludwig Institute for Cancer Research, Uppsala, Sweden; 4) Life Technologies, Austin, TX; 5) Life Technologies, Beverly, MA; 6) Uppsala Clinical Research Center, Uppsala University, Sweden; 7) Linnaeus Centre for Bioinformatics, Uppsala University, Sweden; 8) Interdisciplinary Centre for Mathematical and Computer Modelling, Warsaw University, Poland.

Transforming growth factor beta (TGF-beta) is a secreted protein that controls many complex behaviors of tumor cells. In early stage adenomas TGF-beta acts as a tumor suppressor, whereas in advanced carcinomas it promotes tumor cell invasiveness and metastasis. HepG2, a human hepatocellular carcinoma cell line, has lost responsiveness to the tumor suppressive action of TGF-beta and when treated with TGF-beta, these cells show enhanced motility and invasiveness. Thus, HepG2 cells provide a good model for advanced tumor cells. RNA sequencing (RNA-Seq) can provide a detailed view of the dynamic transcriptional landscape of cells experiencing environmental perturbation and was therefore applied here to study TGF-beta response. We serum starved HepG2 cells for 24 hours and then treated for 1 hour with 2.5 ng/ml TGF-beta1 or with vehicle control. Total RNA was isolated, depleted of rRNA, fragmented and then used to create strand-specific cDNA libraries with the SOLiD Whole Transcriptome Protocol. Approximately one billion 50 bp reads were sequenced with the SOLiD System, over half of which could be aligned to the human genome. The aligned transcriptomes cover roughly 4% of each strand of the genome and more than half of the reads align within the exonic regions of annotated transcripts. The expression level of each gene was defined and 349 genes were determined to be differentially expressed between the two conditions. These include both previously established and novel targets of the TGF-beta pathway. The 50 bp length of the sequenced fragments permitted us to accurately align reads to splice junctions. In all, ~5 million reads aligned to ~90,000 splice junctions in both the control and stimulated conditions, which allowed us to determine the effects of TGF-beta on alternative splicing in fine detail. Finally, by genotyping HepG2 cells, we have identified over 300,000 heterozygous SNP positions, which we have employed to examine allele-specific gene expression in our RNA-Seq data. We observed many differences in the balance of expressed alleles between TGF-beta treated and untreated cells, which could be explained by linked SNPs in cis-regulatory elements. We are now comparing these results to ChIP-Seq data gathered under the same conditions to understand the relationship between allele-specific binding of transcriptional regulators and allele-specific expression of nearby genes.

**Extracolonic tumor spectrum in 276 patients with MUTYH-associated polyposis (MAP): a widening phenotype.** *S. Aretz[1], N. Jones[2], D. Christian[1], C. Engel[3], M. Nielsen[4], A. Kaufmann[1], V. Steinke[1], H.F. Vasen[5], P. Propping[1], J.R. Sampson[2], F.J. Hes[4], S. Vogt[1].* 1) Institute of Human Genetics, University of Bonn, Bonn, Germany; 2) Institute of Medical Genetics, Cardiff University, Cardiff, UK; 3) Institute for Medical Informatics, Statistics and Epidemiology, University of Leipzig, Leipzig, Germany; 4) Centre for Human and Clinical Genetics, LUMC, Leiden, the Netherlands; 5) Department of Gastroenterology and Hepatology, LUMC, Leiden, The Netherlands.

Background: MUTYH-associated polyposis (MAP) is a recently described autosomal recessive condition characterized by the appearance of multiple colorectal adenomas and a lifetime risk of colorectal cancer of up to 100%. The attenuated or atypical form of familial adenomatous polyposis (FAP) is the most important differential diagnosis. To date, no systematic evaluation of extracolonic MAP manifestations has been reported. Methods: In a collaborative multicenter European study a large cohort of MAP patients (276 cases from 181 apparently unrelated families) was recruited. Based on medical records and anamnestic information the extracolonic tumor spectrum and incidence were evaluated to assess cumulative lifetime risks and compared with general population rates to obtain standardized incidence ratios (SIRs). Results: The median age at evaluation was 54 years. Duodenal polyposis occurred in 17%; the relative risk of duodenal cancer was very high (SIR 129; 95%CI 16-466), while the lifetime risk was 4%. The incidence of extraintestinal malignancies as a whole was almost doubled (SIR 1.9; 95%CI 1.4-2.5) with a lifetime risk of 38%. We found a low to moderate but significant increase in the incidence of ovarian, bladder and skin cancers (SIR 5.7, SIR 7.2, and SIR 2.8, respectively), and a trend suggesting an increased risk of breast cancer. Mean ages at onset were 52-60 years. In contrast to FAP no desmoid tumors were observed. Interestingly, sebaceous gland tumors (SGT) that are characteristic of the Muir-Torre syndrome, a phenotype variant of hereditary non-polyposis colon cancer (Lynch syndrome, HNPCC) occurred in five patients. No genotype-phenotype correlation was identified. Conclusions: The relative risks of a several extraintestinal malignancies were increased, however, no predominant lesion was observed. The spectrum of cancers and their relatively advanced age at onset suggest that specific intensive surveillance recommendations other than frequent gastrointestinal endoscopies are unlikely to be helpful in MAP. The tumor spectrum is wide and points to a phenotypic overlap with Lynch syndrome. SGTs might serve as diagnostic marker lesion in some cases. The study was supported by the German Cancer Aid (Deutsche Krebshilfe), the Dutch Digestive Diseases Foundation, and the Wales Gene Park and Cancer Research Wales.

Constitutional DNA copy number variations (CNVs) are a significant form of genetic variation which have been associated with a number of neuropsychiatric conditions, but have been less studied in cancer. Li-Fraumeni syndrome (LFS) is an autosomal dominant disorder, often associated with germline mutations of the TP53 tumor suppressor gene, which strongly predisposes to various cancers. In a previous genomewide profile of CNVs in DNA of peripheral blood of LFS families (Shlien A, et al 2008) we showed that the number of CNVs per genome is largely invariable in the healthy population, but increased in TP53 mutation carriers. Here, in a replication cohort analyzed on arrays with greater coverage (1.8 million probes), we show that: 1) CNV deletions are more frequent than duplications in mutation carriers (p=3.28 x 10-5); 2) the number of CNVs exceeds 300 in carriers (vs. 154 in controls); and 3) the difference in CNVs persists in these individuals' tumors. Having shown an excess of CNVs in LFS patients, we looked for evidence of pathogenic CNVs in patients lacking TP53 mutations. Our diagnostic labs screened ~500 patients with diverse diagnoses for DNA dosage changes using clinical CGH or MLPA. Eight probands were identified harboring microdeletions at TP53 (17p13.1) that were not detectable by karyotyping. Probands presented with a spectrum of phenotypes ranging from malignancies of the bone and adrenal gland to hypotonia, developmental delay and dysmorphic features. Remarkably, none of the four patients with developmental delay have presented with cancer, or any sign of cancer susceptibility, and none of the four TP53 deletion patients affected with cancer had any cognitive impairment or congenital anomalies. Therefore, while they overlap, 17p13.1 CNVs are associated with different phenotypes. To explore the biological basis of this difference we fine-mapped the breakpoints of these CNVs using a high-throughput qPCR assay. We note that breakpoints *within* TP53 are associated with cancer, while breakpoints *outside* TP53 (i.e. encompassing, but not limited to the gene) are associated with developmental delays. 17p13.1 deletions, which we determined arise by NHEJ, can be *de novo* or inherited and show no overt parent-of-origin bias. These results indicate that the TP53-associated cancer phenotype can be modified by the extent of the genomic alteration at this locus, and suggest novel mechanisms of genetic regulation of neoplastic and developmental phenotypes.

## 1233/W/Poster Board #891

**Gastric Adenocarcinoma and Proximal Polyposis of the Stomach; a new syndrome.** *N. Wayte[1,2], D. Worthley[1,3], K. Phillips[4], N. Lindor[5], D. Huntsman[6], F. Carneiro[7], G. Chenevix-Trench[1], G. Suthers[4].* 1) The Queensland Institute of Medical Research, Brisbane, Australia; 2) School of Chemical and Molecular Biosciences, the University of Queensland, Brisbane, Australia; 3) RBWH Clinical Research Centre, Brisbane, Australia; 4) Familial Cancer Unit, SA Pathology, Adelaide, Australia; 5) Department of Medical Genetics, Mayo Clinic, Rochester, Minnesota, USA; 6) Department of Pathology, Genetic Pathology Evaluation Centre of the Prostate Research Centre, Vancouver General Hospital; 7) Institute of Molecular Pathology and Immunology of the University of Porto (IPATIMUP), Porto, Portugal.

Gastric cancer is a rare event in several well-characterised general cancer syndromes, such as Li-Fraumeni and Lynch syndromes, but most familial aggregation occurs in a range of gastric cancer-specific syndromes: hereditary diffuse gastric cancer (~30% due to CDH1 mutations), familial diffuse gastric cancer, and familial intestinal gastric cancer (<10% due to BRCA2 mutations). Fundic gland polyps are composed of normal gastric corpus/fundus--type epithelium arranged in a disorderly configuration, and occur only in the gastric body and fundus. Although usually benign, dysplastic changes can occur in fundic gland polyps, particularly in the context of Familial Adenomatous Polyposis. Long term use of proton pump inhibitors is associated with an increased frequency of fundic gland polyps. We have identified four families with a novel autosomal dominant syndrome of fundic gland polyposis and predisposition to gastric cancer of the intestinal type. The largest and first family to be characterised in detail was ascertained in Australia after referral of the proband following an episode of melaena, but with no known family history of gastroenterological disease. Upper gastrointestinal endoscopy revealed florid proximal gastric polyposis and histopathology showed predominantly fundic gland polyps with variable dysplasia including intramucosal carcinoma. Follow up of the rest of the family over four generations indicated that it has a novel autosomal dominant syndrome of gastric polyposis, and recently two young affected women developed intestinal gastric cancer. The key features of this novel syndrome are the presence of hundreds of fundic gland polyps carpeting the gastric body and fundus with complete sparing of the antrum, the dysplastic foci on the surface of many of these fundic gland polyps and the predisposition to intestinal gastric cancer. There are 16 affected family members; penetrance is incomplete and/or age related, and with variable age of onset. We have also identified three smaller families in North America with the same syndrome, but with a higher frequency of gastric cancer, probably reflecting ascertainment bias. We have called the syndrome Gastric Adenocarcinoma and Proximal Polyposis of the Stomach (GAPPS) in reference to the fundic gland polyposis in the proximal part of the stomach and high risk of gastric cancer.

## 1234/W/Poster Board #892

**Identification of copy number variable regions (CNVRs) associated with risk of prostate cancer in Mexican-Americans.** *A. Blackburn[1], J. Gelfond[2], H.H.H. Göring[3], J. Beuten[4,6], I. Thompson[5], R.J. Leach[1,6], D.M. Lehman[7].* 1) Department of Cellular and Structural Biology, Univ of Texas Health Science Center, San Antonio, TX; 2) Department of Epidemiology and Biostatistics, Univ of Texas Health Science Center, San Antonio, TX; 3) Southwest Foundation for Biomedical Science, Department of Genetics, San Antonio, TX; 4) Greehey Children's Cancer Research Institute, Univ of Texas Health Science Center, San Antonio, TX; 5) Department of Urology, Univ of Texas Health Science Center, San Antonio, TX; 6) Department of Pediatrics, Univ of Texas Health Science Center, San Antonio, TX; 7) Department of Medicine, Univ of Texas Health Science Center, San Antonio, TX.

The role of heritable structural variation in risk for prostate cancer is still unknown. We performed a genome-wide study in 100 prostate cancer cases and 67 age matched male controls of Mexican American origin using an array developed by deCODE Genetics and Illumina, surveying copy number variable regions (CNVRs) and complex regions that include segmental duplications, megasatellites, and regions lacking annotated SNPs. The prostate cancer cases were either participants of the San Antonio Biomarkers of Risk of Prostate Cancer (SABOR) cohort, or a parallel study of prevalent prostate cancer from the same metropolitan population recruited using the same means. Following normalization and batch correction of the microarray genotyping data, quality control tests were performed and duplicate samples were consistent for >98% of the markers. Association tests were conducted on the allele counts based on the normalized array intensities for each polymorphic marker using logistic regression analysis with age included as a covariate in the model. A likelihood ratio test was performed comparing the null hypothesis of no association to the two-sided alternative hypothesis of association. To correct for possible confounding by hidden population stratification due to admixture, a principle components methodology was used that is similar to the method implemented in EIGENSTRAT. All principle components (among the top 20) that were found to be significant predictors of prostate cancer status at the 0.05 significance level were selected for inclusion in the subsequent association analyses. The 26 closest genes to the most significantly associated variants were identified as a gene set. Next, we used a Robust Probe-level Linear Model to normalize Affymetrix HG-U95Av2 expression data from GEO for 16 disease-free prostate tissue samples, and 20 prostate tumor tissue samples and their adjacent normal prostate tissue samples, using affylmGUI in R. Using Gene Set Enrichment Analysis (GSEA) it was determined that this CNVR gene set showed enrichment in tumor tissue and in adjacent normal tissue compared to disease free normal tissue. The genes, including PTPRN2 and HINT1, that contribute to the core enrichment in both GSEA comparisons are currently being confirmed in the entire cohort of Mexican-American SABOR subjects using quantitative PCR assays. This study is one of the first to support evidence for CNVR differences in heritable risk for prostate cancer.

## 1235/W/Poster Board #893

**New common low penetrance genes predicting high naevus counts are associated with melanoma risk.** *M. Falchi[1, 2], N. Hayward[3], D. Duffy[3], J. Newton Bishop[4], T. Pastinen[5], A. Cervino[1], Z. Zhao[3], P. Deloukas[6], N. Soranzo[1, 6], D. Elder[7], J. Barrett[4], N. Martin[3], T. Bishop[4], G. Montgomery[5], T. Spector[1], V. Bataille[1, 8].* 1) Dept of Twin Res & Gen Epidem, King's College, London, United Kingdom; 2) Dept of Genomics Medicine, Imperial College London, UK; 3) Queensland Institute of Medical Research, Queensland, Australia; 4) Leeds Institute of Molecular Medicine, University of Leeds, UK; 5) Dept of Human and Medical Genetics, Mc Gill University, Montreal, Canada; 6) Human Genetics Dept, Wellcome Trust Sanger institute, Cambridge, UK; 7) Dept of Pathology and Laboratory Medicine, University of Pennsylvania, Philadelphia, USA; 8) Dermatology Dept, West Herts NHS Trust, Hertfordshire, UK.

Twin studies have shown that nevi numbers are heritable. We conducted a genome-wide association study for total body nevus count (all naevi above 2 mm in diameter counted by trained examiners) using 297,108 tag SNPs in 1,524 Caucasian female twins from the Twin's UK database. We identified strongly associated variants in MTAP, a gene adjacent to the familial melanoma susceptibility locus CDKN2A on 9p21 (lead SNP rs4636294, P = 3.4 x 10-15). We further identified PLA2G6 on 22q13.1 (lead SNP rs2284063, P = 3.4 x 10-8). Our results were validated in an independent cohort of 4,107 Australian adolescent twins of both sexes. Both loci were also associated with melanoma risk in 3,131 melanoma cases from two independent studies in the UK and Australia (allele specific odds ratio (OR) = 1.23 at rs10757257, P = 3.4 x 10-8 ; OR = 1.23 at rs132985, P = 2.6 x 10-7 ). About one subject in 11 is homozygous for the variant at both loci and show twice the number of nevi compared to those homozygous for the wild alleles and this is also associated with a two fold increase in melanoma risk. These data provide the first evidence for common, low penetrance melanoma alleles whose effect is mediated through nevus number and highlight the use of intermediate phenotypes in the discovery of disease genes.

**Pathways And Genes Associated With Ependymoma Location, Grade And Subgroups Reveal A New Ependymomal Subgroup Located In The Posterior Fossa Called Biphasic-Cerebriform Ependymomas.** *C. Godfraind[1], T. Palm[2], F. Chapon[3], I. Salmon[4], M. Coutelier[2], C. Lacroix[5], F. Gray[6], F. Scaravilli[7], C. Vandenbroecke[8], D. Ellison[9], D. Figarella-Branger[10], M. Vikkula[2].* 1) Div Pathology, Univ Catholique de Louvain, Brussels, Belgium; 2) Laboratory of Human Molecular Genetics, de Duve Institute, Université catholique de Louvain, Brussels, Belgium; 3) Laboratory of Pathology, CHU-Caen, France; 4) Laboratory of Pathology, Erasme University Hospital, Université Libre de Bruxelles, Brussels, Belgium; 5) Laboratory of Pathology, Hopital Kremlin-Bicêtre, Paris, France; 6) Department of Pathology, APHP Hôpital Lariboisière, Université Paris VII, Paris, France; 7) Institute of Neurology, London, United Kingdom; 8) Department of Pathological Anatomy, Ghent University Hospital, Ghent, Belgium; 9) Department of Developmental Neurobiology, St. Jude Children's Research Hospital, Memphis, USA; 10) Department of Pathology and Neuropathology, La Timone's Hospital, AP-HM, and EA3281 Université de la Mediterrannée, Marseille, France.

*Purpose of the study* : Unravelling specific signatures of ependymoma sub-groups and understanding molecular alterations involved in their tumorigenesis. *Materials and Methods*: A series of 34 frozen ependymomas were analysed using Affymetrix HG-U133 Plus 2.0 arrays. Obtained data were compared with histological features. *Results*: Spinal cord ependymomas demonstrated a HOX gene signature, whereas intra-cranial tumors had Notch, Hedghog and BMP pathways upregulation. High expression levels of the oncogenes SOX2, HDAC1, NPM1, YAP1 and JAG1 were observed in PF ependymomas when compared to normal brain. Grade II ependymomas were associated with up-regulation of dyneins, and grade III with activation of the Wnt and E2F1 pathway, cell cycle, adherens junction dysfunction, apoptosis and angiogenesis. Hierarchical clustering and Correspendance analysis established the presence of three molecular sub-groups of posterior fossa (PF) ependymomas, while WHO only recognizes two. One of them regrouped tumors with specific histology characterized by biphasic and cerebriform appearance, which is either WHO grade II or III. They also demonstrated activation of genes implicated in glycogene metabolism and central nervous system development. We suggest to name this newly identified sub-group of children PF ependymomas "biphasic-cerebriform ependymoma". *Conclusion*: These data illustrated heterogeneity of ependymomas and assigned gene signatures to tumor locations and grades. They reinforced the notion of these tumors to derive from cancer stem cells bearing radial glial cell phenotype. In this context, Hox, Notch and Hedghog pathways play a role in maintenance and renewal of cancer stem cells, and BMP in their differentiation. This, together with the genes up-regulated in posterior fossa ependymomas, pinpoints Notch pathway as a major player of ependymoma tumorigenesis, and Wnt of high grade oncogenesis. Identification of three molecular subgroups in PF ependymomas, among which, the newly identified biphasic-cerebriform pattern, may partly account for discordance in histological ependymoma grading.

## 1237/W/Poster Board #895

**Epigenetic annotation of the ABO blood group susceptibility locus identified by GWAS in pancreatic cancer.** *J. Jia, I. Collins, H. Parikh, A. White, R. Stolzenberg-Solomon, P. Hartge, R. Hoover, S. Chanock, L. Amundadottir, the PanScan Consortium.* Division of Cancer Epidemiology and Genetics, National Cancer Institute, National Institutes of Health, Bethesda, MD 20892.

Pancreatic cancer is a highly lethal cancer with a survival rate of less than 5% at 5 years. Few well established risk factors are known and improved diagnostic and therapeutic modalities are desperately needed. PanScan is an ongoing genome wide association study (GWAS) of pancreatic cancer conducted within the framework of the NCI-sponsored Cohort Consortium and the Pancreatic Cancer Case-Control Consortium (PANC4). It includes a total of 4,000 pancreatic cancer cases and 4,000 controls. Susceptibility loci from PanScan are currently being investigated in our laboratory to understand the biological basis of the association signals discovered. One of these loci is in the vicinity of the ABO gene on Chr9q34 where four SNPs (rs505922, rs495828, rs657152 and rs630014) have been associated with a significantly increased risk of pancreatic cancer but they are strongly correlated (r2=0.18-0.93). To investigate the epigenetic germ-line alterations observed in the ABO GWAS locus, we have conducted chromatin immunoprecipitation (ChIP) experiments followed by qPCR to tag histone modifications that mark promoters, enhancers and silencers (H3K4me1, H3K4me3 and H3K27me3) in six pancreatic cell lines derived from normal and malignant pancreatic tissues. Differential patterns of histone modifications marks have been observed in preliminary studies involving two well-characterized cell lines derived from a pancreatic cancer (Panc-1) and from normal pancreatic cells (hTERT-HPNE). In the ABO region, we observed strong silencing (H3K27me3) histone modification marks in the hTERT-HPNE cell line but strong activating (H3K4me1) signal in the Panc1 cell line. Interestingly, these correspond to the genomic area where the SNPs with the strongest association signal for pancreatic cancer risk are located. In ChIP-seq (ChIP sequencing) experiments, we have begun to comprehensively catalogue histone modifications marks on a genome wide level in pancreatic cell lines. Together with RNA-seq analysis, designed to interrogate the full transcriptome profile in a series of pancreatic cell lines, we have begun to see patterns that could provide plausibility for the association signal in this region and thereby, establish a first step in the characterization of the molecular phenotype of the susceptibility alleles in ABO for pancreatic cancer risk.

## 1238/W/Poster Board #896

**Genome-wide association study for colorectal cancer in German familial cases and replication of candidate markers in independent cohorts.** *J. Lascorz[1], A. Försti[1, 2], N. Kunkel[1], B. Chen[1], K. Hemminki[1, 2], German HNPCC Consortium, NGFN Plus CCN Group.* 1) Division of Molecular Genetic Epidemiology, German Cancer Research Center (DKFZ), Heidelberg, Germany; 2) Center for Family and Community Medicine, Karolinska Institute, Huddinge, Sweden.

Genetic susceptibility of colorectal cancer (CRC) accounts for ~30% of its aetiology. Rare, high-penetrance germline mutations in a few genes (mainly APC and DNA mismatch repair genes) account for less than 5% of CRC cases. Much of the remaining variation in genetic risk is supposed to be attributable to common susceptibility loci, each exerting a small influence on risk. We carried out a genome-wide scan (GWAS) in 371 German familial CRC cases and 1263 healthy controls using the Affymetrix Genome Wide Human SNP 6.0 Array. Polymorphisms with MAF <0.05, call rate <95%, or Hardy-Weinberg equilibrium exact p-value <10-5 in the control group, as well as samples with call rate <90%, were excluded. A total of 875 SNPs showed at least one p-value (allele, genotype, dominant, recessive or trend) <10-4, and careful visual inspection of genotype cluster plots reduced this number to 523 reliable genotyped markers. Out of them, we selected polymorphisms for replication using additionally the following criteria: several SNPs within/close to a gene, location in candidate genes or in already known risk loci for CRC, and coding polymorphisms. In order to select the best candidate markers, results of the initial 875 SNPs were also compared with another unpublished GWAS performed in 400 CRC cases and 400 controls of German origin. So far, genotyping of 47 selected SNPs has been completed in a German replication cohort of 655 familial CRC cases and 760 controls using KASPar assays. Six SNPs have shown association in this replication cohort, two of them located in the known risk loci on 8q24.21 and 11q23, the other four in so far undescribed loci, with allele ORs ranging between 1.2 and 1.3. Further replication of these four markers in two additional cohorts of German origin is currently ongoing.

## 1239/W/Poster Board #897

**Three loci identified as testicular germ cell tumour susceptibility loci by genome wide association study; further investigation examining maternal and imprinting effects.** *E.A. Rapley[1], J. Nsengimana[5], C. Turnbull[1], A. Al Olama[2], E. Dermitzakis[3], R. Linger[1], R. Huddart[4], A. Renwick[1], D. Hughes[1], S. Hines[1], S. Seal[1], J. Morrison[2], P. Deloukas[3], N. Rahman[1], D.F. Easton[2], D.T. Bishop[5], M.R. Stratton[1,2], The UK Testicular Cancer Collaboration.* 1) Section Cancer Genetics, Inst Cancer Research, Sutton, Surrey, United Kingdom; 2) Cancer Research UK, Genetic Epidemiology Unit, Strangeways Research Laboratory, Cambridge CB1 8RN, UK; 3) The Wellcome Trust Sanger Institute, Hinxton, CB10 1SA, UK; 4) Academic Radiotherapy Unit, Institute of Cancer Research, Sutton, Surrey, SM2 5PT, UK; 5) Section of Epidemiology & Biostatistics, Leeds Institute of Molecular Medicine, Leeds, LS9 7TF, UK.

Testicular Germ Cell Tumour (TGCT) is the most common cancer in men ages 15-45 years. Family history is a major risk factor with the estimated the risk to brothers to be 8-10 fold, much higher than the familial risks for most other cancer classes which are generally ~2-fold. We recently conducted a genome-wide association (GWA) study in TGCT. 307,666 SNPs were genotyped in 730 cases and 1,435 controls from the UK; associations were replicated in a further 571 cases and 1,806 controls. We found strong evidence for susceptibility loci on chromosome 5(per allele OR=1.37(95% CI 1.19-1.58), p=$3x10^{-13}$), chromosome 6 (OR=1.50(95% CI 1.28-1.75), p= $10^{-13}$) and chromosome 12 (OR=2.55(95% CI 2.05-3.19), p=$10^{-31}$). The gene responsible for the association on chromosome 12 may be KITLG, important in the biology of germ cells. The other loci implicate the SPRY4 gene on chromosome 5 and BAK1 on chromosome 6. Using a family-based dataset from Leeds we evaluated possible maternal and imprinting effects at these loci. The dataset consisted of 147 family trios, 86 incomplete trios and 285 unrelated controls. A family based test (using a log-linear method, LEM software) was used to test the affect from alleles carried by cases (main/child effect), maternal and imprinting effects. Further assessment of main/child effect and maternal effect was made using a non-family approach (using an unconditional logistic regression model and ignoring family information, STATA software) Main/child effects were confirmed on all the loci tested (p=.0006 on chr5, p=.009 on chr6 and p=$9.9x10^{-8}$ on chr12) in keeping with the GWA data. The imprinting effect was not significant for these SNPs. Maternal effects at the chromosome 12 loci were marginally significant or close to significance when using the family (p=.06) or the non-family tests (p=.04), or the combined data(p=.06). We identified three susceptibility loci for TGCT. The strongest association was demonstrated for SNPs within the KITLG, the other loci are in the vicinity of genes which are activated or repressed by this pathway. There is no evidence of imprinting or maternal effects on chromosomes 5 or 6 but there may be a maternal effect for the loci on chromosome 12. The three loci account for 7%; of the sibling risk and 10%;of the risk to offspring of cases of TGCT. Our results suggest that there are other common variants with similar effects to those identified on chromosomes 5 and 6 to be detected by additional association studies.

## 1240/W/Poster Board #898

**Evaluation of reported GWAS hits in a large, population-based series of contralateral breast cancer.** *S.N. Teraoka[1], A.S. Reiner[2], X. Liang[2], J.L. Bernstein[2], R.W. Haile[3], L. Bernstein[4], P. Concannon[1], The WECARE Study Consortium.* 1) Dept Biochem & Molec Gen, University of Virginia, Charlottesville, VA; 2) Dept Epidemiology & Biostatistics, Memorial Sloan-Kettering Cancer Center, New York, NY; 3) Dept Preventive Medicine, Keck School of Medicine, University of Southern California, Los Angeles, CA; 4) Dept Cancer Etiology, City of Hope National Medical Center, Duarte, CA.

Genome-wide association studies (GWAS) have identified single nucleotide polymorphisms (SNPs) in several genomic regions that are associated with breast cancer. To assess the role of these common variants in risk of developing second primary breast cancer, we genotyped 24 SNPs that were significantly associated with breast cancer in final or earlier stages of published GWAS, in 2103 subjects in the WECARE Study. The WECARE Study is a multi-center, population-based, case-control study designed to examine gene-environment interactions and risk of contralateral breast cancer (CBC). The study population included 708 women with CBC (cases), and 1395 women with unilateral breast cancer (UBC) (matched controls), all of whom were ascertained through five population-based cancer registries in the U.S. and in Denmark. Controls were matched 2:1 on birth year, year of breast cancer diagnosis, registry, race, and counter-matched on registry-reported radiation exposure. Among SNPs representing 19 genomic regions screened, rs2981582 (in *FGFR2*) was significantly associated with CBC; per allele rate ratio (RR) = 1.3, 95% confidence interval (CI) = 1.1-1.7, homozygous RR = 1.4, 95% CI = 1.1-2.0), as was rs7313833 (near *PTHLH*); per allele rate ratio (RR) = 1.3, 95% confidence interval (CI) = 1.1-1.5, homozygous RR = 1.6, 95% CI = 1.2-2.3. Additionally, homozygosity for the minor alleles at SNPs rs13281615 (8q24) (RR = 1.5, 95% CI = 1.1-2.0), rs3803662 (near *TNRC9 (TOX3)* (RR = 1.4, 95% CI = 1.0-2.0), rs13387042 (2q35) (RR = 1.4, 95% CI = 1.0-1.8), and rs11235127 (near *TMEM135*) (RR = 2.3, 95% CI = 1.3-4.0) were associated with increased CBC. These preliminary findings demonstrate that common risk variants identified in GWAS studies also contribute to risk of CBC. Candidate genes in the vicinity of these identified risk loci include *PTHLH*, encoding a hormone involved in breast morphogenesis and breast cancer cell invasiveness, and *TMEM135*, reported to be regulated in response to Tamoxifen treatment in the mouse. Previously we showed that Tamoxifen use in the WECARE Study reduced the risk of CBC (multi-variable adjusted RR = 0.7, 95% CI = 0.5-0.9). In the current study, our results suggest that the effect of Tamoxifen is modified by the *TMEM135* SNP, such that the protective effect of Tamoxifen appears to be predominately among those carrying the common GG genotype (RR = 0.6, 95% CI = 0.4-0.8).

## 1241/W/Poster Board #899

**LOHAS: Loss-Of-Heterozygosity Analysis Suite.** *H.C. Yang[1], L.C. Chang[1], R. Huggins[2], C.H. Chen[1].* 1) Institute of Statistical Science Academia Sinica, No 128, Academia Road, Nankang, Taipei, Taiwan; 2) Department of Mathematics and Statistics, The University of Melbourne, Melbourne, VIC 3010, Australia.

Detection of loss of heterozygosity (LOH) plays an important role in genetic, genomic and cancer researches. We develop statistical methods to estimate LOH intensity, identify samples with unusual genome structure, and map the genomic segments involving LOH or chromosomal aberrations based on single-nucleotide-polymorphism (SNP) data. The methods are also applied to study long contiguous stretches of homozygosity (LCSH) in general populations. We analyze genome-wide SNP data from a leukaemia study and the HapMap Project. Important leukaemia-associated LOH regions and population-specific LCSH regions are successfully identified. Sub-types of the disease and sub-populations of the study samples can be un-supervisedly classified using our methods. The developed algorithms are packaged into software Loss-Of-Heterozygosity Analysis Suite (LOHAS).

## 1242/W/Poster Board #900

**Pathway analysis of breast cancer genome wide association study highlights two canonical signaling cascades.** *I. Menashe, D. Maeder, S. Bhattacharjee, M. Rotunno, P.S. Rosenberg, N. Chatterjee.* Division of Cancer Epidemiology and Genetics, National Cancer Institute, NIH, Rockville, MD.

Genome-wide association studies (GWAS) have identified genetic variants associated with breast cancer susceptibility, however these studies focus on relatively few highly significant loci while less attention is given to other genotyped markers. Employing pathway analysis to existing GWAS data may shed light on biological processes involved in breast cancer, and illuminate new candidate genes. Therefore, we employed a pathway-based approach to the breast cancer GWAS data of the National Cancer Institute (NCI) Cancer Genetic Markers of Susceptibility (CGEMS) that includes 1145 cases and 1142 controls. Pathways were retrieved from three resources: the KEGG pathway database, BioCarta, and the NCI Protein Interaction Database (PID). We restricted our analysis to pathways with 10-100 genes and excluded *FGFR2* that is highly associated with breast cancer in this GWAS. Association between single nucleotide polymorphisms (SNPs) and breast cancer was assessed using the Cochran-Armitage test for trend. Each gene was represented by its most strongly associated SNP. Finally, we used a weighted Kolmogorov-Smirnov (KS) procedure to identify pathways enriched with gene-based association signals.

A total of 478 pathways containing 4142 genes, (157/2956, 221/1357, and 104/1418 pathways/genes for KEGG, BioCarta, and PID respectively) were included in our study. Interestingly, the most strongly associated pathways ($P_{KS} < 0.05$) shared overlapping genes. To further explore this phenomenon, we used a clustering algorithm to identify pathways with similar gene content and assess the excess of association signals within each cluster. Consequently, pathways containing the signaling cascade of the genes GRB2*, SOS1, HRAS, RAF1, MAP2K1* and *MAPK3* and pathways containing the signaling cascade of the genes *WNT1, FZD1,DVL1, GSK3B, APC* and *CTNNB1*, were significantly more likely to be enriched with association signals than expected by chance ($P = 0.0051$ and $P = 0.0365$ respectively). These results suggest that genetic variations associated with these two canonical signaling cascades may modulate breast cancer susceptibility. Additional studies are needed to replicate our findings and investigate the details of these associations.

## 1243/W/Poster Board #901

**Comparison of the repair kinetics of the UVA- and UVB-induced cyclobutane pyrimidine dimers in the genome of human keratinocytes and its relation to expression of DNA repair genes.** *M. Karbaschi, M.S. Cooke, M.D. Evans.* Dept. Cancer Studies and Molecular Medicine. Robert Kilpatrick Clinical Sciences Building. University of Leicester. LE2 7LX, UK.

Solar ultraviolet radiation (UVR) by inducing DNA photo-lesions, has become the prime cause of most skin cancers. These cancers could be prevented if we protect ourselves from UVR. UVR comprises three main regions: UVC is absorbed by the ozone layer and does not affect the skin. UVB is directly absorbed by DNA and induces different forms of lesions like cyclobutane pyrimidine dimers (CPDs). In contrast with UVB, UVA is indirectly absorbed by DNA. It has long been considered that the UVA component of solar UVR carries a minimal risk for skin carcinogenesis, as it does not lead to the formation of CPD, not least because DNA does not absorb UVA. However, more recently, UVA-induced formation of CPD has been demonstrated, thought to be via a photosensiter-based mechanism. UVA is suspected to play a key role in induction of skin tumors and may be even more important than UVB in mutagenesis. Most sunscreens filter out UVB absorption, but they cannot block most of UVA, so they do not help to prevent skin cancer. A better assessment of the routes by which UVA and UVB induce CPDs, may lead to prevention of skin cancer. This study focuses upon the differential formation and, importantly, repairs of CPD induced by UVA versus UVB. Firstly, formation of UVA-induced CPDs versus UVB-induced CPDs in genome of human keratinocytes (HaCaT cell line) was compared by use of the highly sensitive single cell gel electrophoresis (T4endoV modified comet assay) in HaCaT keratinocyte cell line. Then, the repair rate of CPDs induced by UVA and UVB was also compared by comet assay. Finally, before and after irradiation with UVA and UVB, a comparison of the expression levels of genes coding for components of the nuclotide excision repair pathway, by Q-PCR, was done. The data suggests that, following irradiation, levels of CPD and ALS were significantly higher in the cells irradiated with UVB, compared to UVA. However, for the first time, we noted the rate of repair for UVA-induced CPD to be much faster than the rate of UVB-induced CPD.

## 1244/W/Poster Board #902

**Overexpressed Cyclophilin B Protects cancer cells from ROS-Mediated Cell Death.** *K. Kim, S. Kim, W. Choe.* Department of Biochemistry and Molecular Biology, Medical Science and Engineering Research Center for Bioreaction to Reactive Oxygen Species, Biomedical Science Institute, School of Medicine, Kyunghee University, Seoul 130-701, Korea.

Cyclophilins (Cyps) were identified as cellular binding proteins for the immunosuppressive drug cyclosporine A (CsA) and are constitutively expressed in most tissues. Cyclophilins are multifunctional proteins that are involved in protein folding, mitochondrial functions, interaction with CD147, the immune system, and cancers . One of these family, Cyclophilin B is found mainly in the ER lumen, and it has peptidyl-prolyl cis-trans isomerase (PPIase) activity that catalyzes protein folding reactions in cells. Reactive oxygen species (ROS) are generated as by-products of the mitochondrial respiratory process. They have emerged as an important signaling molecule based on their unique biochemical properties. It consists of various radicals, which might exert different effects on cellular signaling. Low levels of ROS regulate cellular signaling and play and important role in normal cell proliferation. In cancer cell biology, it has been appreciated for a number of years that ROS production is increased in cancer cells. Also ROS are thought to play multiple roles in tumor initiation, progression and maintenance. In contrast to their role in opposite site, ROS appear to activate and modulate cancer cell death. ROS levels are increased in cells exposed to various stress agent, including anticancer drug, and they promote cell death by stimulation pro apoptotic signaling molecules. In this study, we determined the potential role of role of Cyclophilin B as a protector cancer cells from oxidative stress. With two cancer cell lines, Huh7 (Human Hepatoma) and MCF7 (Human Breast Cancer cell), we performed immunoblotting and MTT Assay after treatment with most common but strong oxidative stress chemical, $H_2O_2$ for 24 Hours. According to our results, overexpressed CypB increased cell viability though activation of ERK pathways. Also overexpressed CypB reduced ROS generation.

## 1245/W/Poster Board #903

**The Clinical Implications of Breast Cancer Risk Polymorphisms in FGFR2, TNRC9 and MAPKKK1 in the Context of Family History.** *A.J. Martin[1], S. White[1], A. Onen[1], J. Gale[1], H. Talbot[1], P. Quinlan[2], L. Baker[2], L. Jordan[3], C. Purdie[3], A. Ashfield[2], A. Thompson[2], J. Dunlop[4], J.N Berg[1].* 1) Human Genetics, Centre for Oncology and Molecular Medicine, University of Dundee, United Kingdom DD1 9SY; 2) Department of Surgery and Molecular Oncology, University of Dundee; 3) Department of Pathology, Tayside University Hospitals Trust, Dundee; 4) East of Scotland Genetics Service,Tayside University Hospitals Trust, Dundee.

The majority of familial predisposition to breast cancer is inherited in a multifactorial fashion, rather than caused by known high penetrance genes such as BRCA1 or BRCA2. However, it is uncertain how testing for multifactorial genetic polymorphisms can be used to improve risk assessment for unaffected women with a family history of breast cancer. United Kingdom guidelines, set by the National Institute of Clinical Excellence stratify such women into 3 risk groups, using family history alone; Group 1, or population risk comprising those with less than 3% 10-year-risk at age 40 of developing breast cancer; Group 2 or moderate risk comprising those with a 10-year-risk of developing breast cancer between 3% and 8%; and Group 3 (high risk) who are those with a 10 year risk of greater than 8%, and who are likely to carry a mutation in a high penetrance gene. The 3 most significant single nucleotide polymorphisms (SNPs) that have been identified to date as risk factors for breast cancer are rs2981582 in FGFR2, rs3803662 near TNRC9 and rs889312 near MAPKKK1. Individually these SNPs confer a small increase in risk in breast cancer. To understand whether these SNPs are relevant in clinical practice, we calculated genotype relative risks for combined genotypes using data from the Tayside Breast cancer patient cohort. Relative risks varied from 0.52 for patients with no risk alleles at these loci to 3.08 for those with 5 or 6 risk alleles. We used the BOADICEA risk assessment tool to determine 10 year and lifetime risks of breast cancer for 160 unaffected women attending the clinic for a family history of breast cancer. Assuming a multiplicative interaction between family history and genotype in this patient cohort, and by taking a weighted average by genotype, we estimated the proportion of women who would have a significant change in risk group. Using the 3 locus genotype in addition to family history, 29% of women in the clinic would be assigned to a different category compared to using family history alone. 17% would be assigned a higher risk and 12% a lower risk category. We conclude that the amount of risk modification offered by genotyping at currently known multifactorial loci is sufficient to modify risk when combined with other risk parameters. Testing for SNPs in FGFR2, TNRC9 and MAPKKK1 would lead to better targeting of treatment and screening for patients with a family history of breast cancer. (This work is supported by the EU FP7 project ‘HAMAM’).

## 1246/W/Poster Board #904

***XRCC1* Arg399Gln polymorphism in acute lymphoblastic leukemia.** *J.P. Meza-Espinoza[1], E. Leal Ugarte[1], V. Peralta Leal[1], D. Ruiz Diaz[1], M. Gutierrez Angulo[2], N. Macias Gomez[3], P. Barros Nuñez[4], J. Duran Gonzalez[5].* 1) Universidad Autónoma de Tamaulipas, Matamoros, Tamps. Mexico; 2) Centro Universitario de los Altos, Universidad de Guadalajara; Tepatitlan, Jalisco, Mexico; 3) Centro Universitario del Sur, Universidad de Guadalajara; Cd. Guzman, Jalisco, Mexico; 4) Centro de Investigacion Biomedica de Occidente del Instituto Mexicano del Seguro Social, Guadalajara, Jalisco, Mexico; 5) University of Texas at Brownsville; Brownsville TX, USA.

**Background.** The genome integrity is of vital importance for the correct functionality of the cell, and the DNA repair systems have key roles in its maintenance. Deficient capacity reparation of DNA has been associated with cancer and birth defects. Polymorphisms in DNA repair genes are very common and may result in interindividual variation in DNA repair capacity, therefore them could play a role for the susceptibility to cancer. The X-ray repair cross-complementing group 1 (XRCC1) gene plays a role in the DNA repair. This gene carries polymorphisms that produce amino acids substitutions, for instance Arg399Gln, therefore has been associated with risk to several neoplasias, including acute lymphoblastic leukemia (ALL). **Objective.** Determine the influence of the *XRCC1* Arg399Gln polymorphism on the development of childhood ALL in Mexican patients. **Subjects and methods.** We studied 120 Mexican children with ALL and a control group composed by 120 healthy subjects. Both groups were mestizos of the Mexican West. All of them were genotyped for the *XRCC1* Arg399Gln polymorphism by means of polymerase chain reaction and restriction fragment length polymorphism using the endonuclease *Hpa* II. Comparison of allele and genotype frequencies between patients and controls was realized by Chi-square test. Hardy-Weinberg equilibrium was determined by Fisher exact test. **Results.** The allele frequencies in the control group was 73.7% and 26.3% for Arg-allele and Gln-allele, respectively; whereas in patients were 68.3% for Arg and 31.7% for Gln. The genotype frequencies in the control group were 54.2% for wild homozygous, 39.2% for heterozygous, and 6.6% for polymorphic homozygous; whereas in the ALL patients were 47.5%, 42.5%, and 10%, respectively. **Conclusion.** The allele frequencies were consistent with Hardy-Weinberg equilibrium (p=1.0; Fisher exact test). No significant differences were observed in allele frequencies between patients and controls (p=0.23; Chi square); moreover, we did not find association for ALL childhood with heterozygous or polymorphic homozygous genotypes. Our findings suggest that Arg/Gln or Gln/Gln variants do not increase the risk for childhood ALL in Mexican mestizos patients, which is discordant of some reports in other populations; namely India, Thailand, and China. Perhaps these differences could be fortuitous; however, such discordances may rather be due to the diverse genetic backgrounds.

## 1247/W/Poster Board #905

**Loss of Heterozygosity Analysis in Wilms Tumor.** *R. Padilla[1], M. Haruta[2], S. Berosik[1], A. Chhibber[1], C. Davidson[1], A. Felton[1], R. Fish[1], S.C. Hung[1], B. Johnson[1], M. Kondo[1], J. Lee[1], A. Pradhan[1], L. Joe[1].* 1) Life Technologies, Foster City, CA; 2) Saitama Cancer Center Research Institute, Ina, Saitama, Japan.

Loss of heterozygosity (LOH) is used to help elucidate the molecular mechanisms underlying the development of pediatric tumors such as Wilms tumor, hepatoblastoma, and neuroblastoma. LOH is the loss of the second of two alleles when the first allele may be inactivated, sometimes the result of an inherited germ-line mutation. WT1, a tumor-suppressor gene, encodes proteins critical to protecting kidney cells from cancer during kidney development. In many Wilms tumor cases, the first allele is inactivated by a mutation within the WT1 gene itself, whereas the second allele is subject to inactivation by LOH at one or more nearby polymorphic markers§. To investigate the LOH of contiguous genes implicated in Wilms' tumorigenesis, DNA samples from 26 subjects with suspected Wilms tumor were analyzed. Specific assays have been developed whereby the regions of interest are amplified using one fluorescently-labeled and one unlabeled PCR primer for each locus interrogated. Samples of normal tissue were obtained from either peripheral blood or normal renal tissue adjacent to the tumor from the same individual. We present data from LOH assays performed on Wilms tumor samples using a new capillary electrophoresis workflow. Peak height ratios of healthy and tumor samples were compared to successfully identify and flag LOH candidate samples. This methodology would also be useful to a single researcher or a consortium of investigators with multiple instruments who require consistent and comparable results from each instrument.

## 1248/W/Poster Board #906

**Prostate cancer genome anatomy dissected from the tumors of Caucasian and African-American men reveals known and novel risk genes that may account for the health disparity.** *A. Pearlman[1], C. Campbell[1], S. Shajahan[1], L. Hao[1,2], J. Melamed[1], H. Ostrer[1].* 1) Human Genetics, NYU Langone Medical Center, New York, NY; 2) Center of Genome Informatics, University of Medicine and Dentistry in New Jersey, Newark, NJ.

A well known health disparity exists between the prostate cancer cases of Caucasian and African-American men. Men of African descent have an increased incidence, earlier onset, and more aggressive form of disease as compared with men of predominantly European origin. As part of our efforts to identify somatic alterations that are predictive of ethnic differences or prognosis and to aid the identification of tumor suppressor genes we conducted an array CGH study using Affymetrix SNP Array 6.0, on paired normal and tumor tissue from 9 African American (AA) and 20 Caucasian American (CA) men. The ethnicities of the samples were verified through principal component analysis of the SNP genotypes relative to the HapMap populations. The groups were matched for Gleason score (range 6-9) and stage (T2b-T4), however, the AA group had a marginally lower age at prostatectomy (AA = 59±6 vs. CA = 65±6, p = 0.05). Each patient's normal sample was used as a reference for the paired tumor and copy-number alterations were scored. A ranked list of genes was generated by mapping each probe on the array to the nearest up/downstream gene, and combining the copy number scores across all associated probes for each gene. For the combined set of tumors, the top ranked gene, CSMD1 (deleted in 19/29 samples, Z=137), has been identified as a tumor suppressor gene linked to carcinoma and neoplasm metastasis. SGCZ, our 2nd ranked gene (deleted in 19/29 samples, Z=125) has been proposed to be involved in cytoskeleton organization. The 3rd ranked gene (deleted in 19/29 samples, Z=84), CDH13, was recently, identified in a Genome Wide Association Study and shown to be hyper-methylated, with transcript down-regulated in a variety of cancers. Ranked 5 (deleted in 16/29 samples, Z=79) is the putative prostate cancer tumor suppressor MSR1. The AA subset showed a number of differences when compared to the CA group, including significant deletions from chromosome 8p11-22, and 6q14.2-22.31. In addition, the CA group showed a deletion covering chromosome 21q22.2, containing the DSCAM gene, whereas the AA group did not show this effect. Overall, the total number of copy-number events was similar in the two subgroups (AA 8.2% and CA 8.4%, p = 0.70). There were no significant differences when examining the number of amplifications or deletions separately. Thus, differences in disease between the AA and CA groups may be accounted for by the locations, rather than quantity, of events.

## 1249/W/Poster Board #907

**Whole transcriptome sequencing of three oral cancers.** *D. Smith[1], B. Tuch[2], R. Laborde[1], M. Barker[2], F. de la Vega[2].* 1) Lab Med & Path/Exper Path, Mayo Clinic, Rochester, MN; 2) Life Technologies, Foster City, CA.

Cancers of the head and neck comprise 6 percent of all human malignancies and the majority of these are squamous cell carcinomas. Previous studies of gene expression in these cancers used microarray analysis to identify a number of aberrantly expressed genes. A powerful new approach to analyze the entire transcriptome of samples is based upon massively parallel sequencing to generate gibabases of sequence data. We utilized the SOLiD/AB next generation DNA sequencer to analyze and compare the entire transcriptome of three oral tongue cancers to normal oral tongue tissue from the same patients. Using the novel SHREK protocol, which preserves transcript strandedness across the entire gene length, for the preparation of libraries from ribo-RNA depleted samples we obtained 100 Gbs of whole transcriptome sequence. We demonstrate that this RNA-seq protocol is a powerful tool for analyzing changes across the entire transcriptome during cancer development. We have demonstrated that gene expression profiling results obtained by sequencing are largely concordant with microarray data using identical samples. These data indicate advantages of RNA-Seq, and its' ability to preserve transcript strandedness thus it was very useful in identifying differentially regulated, antisense transcripts. MMP1 is an example of a secreted matrix metalloproteinase that breaks down the interstitial collagen and exists as an anti-sense transcript that was detected as dysregulated by sequencing but was not by our microarray experiment. Additionally, sequencing has proven to be much more effective at identifying differential expression of genes expressed at low levels in tissue. One example is the oncogene HMGA2, with an increase in expression of only 1.5-fold detected by microarray as compared to a 206-fold increase detected by sequencing. RNA-Seq also readily identifies differential expression of transcript isoforms. This depth of sequencing will not only identify differential expression of transcripts, but also allow for detection of mutations within many of the detected transcripts, allowing the detection of mutations that may be used to screen for the development of specific cancers. Finally, this data also can be analyzed to detect novel transcripts including many potential non-coding transcripts. This technology can transform the way that cancer is analyzed and may offer important insights into the specific alterations that underly the development of cancers of the oral.

## 1250/W/Poster Board #908

**Analysis of the BRCA1 Promotor Polymorphism, rs11655505, as a Breast Cancer Risk Factor in the Tayside Breast Cancer Cohort.** 
*H.R. Talbot[1], L.B. Jordan[2], C.A. Purdie[2], A.M. Ashfield[3], P.R. Quinlan[3], A.J. Martin[1], L. Baker[3], C. Palmer[4], R. Tavendale[4], A.M. Thompson[3], J.N. Berg[1].* 1) Human Genetics, Centre for Oncology and Molecular Medicine, University of Dundee, United Kingdom DD1 9SY; 2) Department of Pathology, Tayside University Hospitals Trust, Dundee; 3) Department of Surgery and Molecular Oncology, University of Dundee; 4) Biomedical Research Institute, University of Dundee.

Single nucleotide polymorphisms (SNPs) in the BRCA1 gene may contribute to a multifactorial predisposition to breast cancer. SNP rs11655505, which lies within the BRCA1 promoter region has been shown to increase BRCA1 promoter activity. One association study has suggested that the rare 'T' allele protects against breast cancer in Chinese women. We analysed rs11655505 in a cohort of population breast cancer patients recruited from the Tayside region of Scotland. We genotyped 426 breast cancer patients, taken from the Tayside Breast Cancer Cohort, and 399 control subjects using Applied Biosystems allelic discrimination assays. No significant association between rs11655505 genotype and breast cancer was identified, (chi-squared test for trend =1.63, p=0.2020), odds ratios, comparing each genotype to wild-type (C/C) homozygote frequencies were non-significant, 1.31 (95% confidence interval 0.981 to 1.75) for C/T heterozygotes and 1.136 (95% confidence interval 0.680 to 1.898) for T/T homozygotes. No correlation between clinical features or tumour pathology and rs11655505 genotype was found. This included analysis for tumour grade, oestrogen receptor status, triple negative vs. non-triple negative tumour status, nodal metastasis, tumour size and age of onset. These findings suggest that rs11655505 does not protect against breast cancer development within the Scottish population. This may reflect a genuine difference between the Scottish and Chinese populations, with rs11655505 occurring within different haplotypes in the two populations. In this case rs11655505 would be expected to tag a different SNP that is responsible for the protective effect in the Chinese population. Alternatively rs11655505 may have a more modest effect than estimated in the first study and this would require a much larger case-control study to identify any effect. In either case, there is no evidence that analysis of rs11655505 in the Scottish population would contribute to estimating a patient's risk of developing breast cancer. (This work was undertaken in Collaboration with the Tayside Tissue Bank and was supported by Breast Cancer Research Scotland).

## 1251/W/Poster Board #909

**Electronic Medical Records: Opportunity for Genetic Patient Ascertainment.** 
*E. Parkhurst, S. Abboy.* Dept Genetics, Kaiser Permanente, West Los Angeles, CA.

BACKGROUND: About 5-10% of breast, ovarian, and colorectal cancer is due to hereditary cancer syndromes. Previous studies have shown that a minority of patients with risk factors for hereditary cancer syndromes are referred for genetic counseling and testing; about 20-30% of eligible colon cancer patients and about 45% for early onset breast cancer. PURPOSE: A pilot study was conducted to determine how many patients with early onset cancer diagnoses are being referred to our genetics clinic and if emailing those at-risk patient's providers could be an effective way to increase referrals of appropriate patients. METHODS: We ran queries of the relational database for the Kaiser Permanente electronic medical records system. Search criteria were by age and ICD9 code; ≤ age 45 for breast cancer, male breast cancer at any age, and ≤ age 50 for colon and uterine cancers. Messages were sent by email to the primary care provider and oncologist of living, eligible patients who had not yet been referred to genetics clinic. Emails regarding 96 different patients were sent to 62 different providers. RESULTS: The database search found 178 patients with early onset cancer; 125 with breast cancer, 34 with colon cancer, 10 with uterine cancer and 9 with male breast cancer. Of those, 50 (40%) breast cancer patients had been previously referred for genetic counseling, but only 5 (15%) colon cancer patients, 1 (11%) male breast cancer case, and 0 uterine cancer patients. Of the 32 referrals sent in response to our emails, 5 were sent by the patient's oncologist, and 27(84%) were from the patient's primary care provider, either internal medicine or family medicine. CONCLUSION: Our hospital's genetic cancer referral rates are similar to what other studies have shown. Primary care providers were more responsive to outreach than oncologists. Providers were more likely to refer for early onset breast cancer than other cancers and future provider training should focus on more than just breast cancer indications for referral. With a response rate of 33% we concluded that an email to the patient's provider is not sufficient to ensure referral of appropriate patients. As more healthcare organizations move towards electronic medical records, database searches may become a powerful tool for case finding or improving referrals in other genetics clinics.

## 1252/W/Poster Board #910

**Biallelic mutations in *FANCD1/BRCA2* identified in the course of genetic counseling for hereditary breast and ovarian cancer.** 
*E. Schalles, C. Cullinane.* Todd Cancer Institute, Long Beach Memorial Medical Center, Long Beach, CA.

Monoallelic and biallelic *BRCA2* mutations are associated with distinctive phenotypes and increased risk of malignancy. In 1995 monoallelic *BRCA2* mutations were linked to hereditary breast and ovarian cancer (HBOC) and in 2002 biallelic *BRCA2* mutations were discovered in patients identified with Fanconi anemia complementation group FA-D1. Since then, fewer than 30 individuals with biallelic mutations in *FANCD1/BRCA2* have been reported in the literature. We present a family with biallelic mutations in *FANCD1/BRCA2* ascertained through genetic counseling for HBOC. A 44 year old Hispanic female diagnosed with unilateral invasive ductal breast carcinoma at age 43 was identified as a carrier of the deleterious *BRCA2* mutation, 886delGT and was subsequently referred for cancer genetic counseling. During the consultation a four-generation pedigree was obtained. The patient reported that her daughter had been diagnosed with Wilms' tumor at 3 1/2 years old and passed away at age 11 from leukemia. We consequently provided cancer genetic counseling to her 47 year old Hispanic husband who proceeded with genetic testing and was found to carry the deleterious *BRCA2* mutation, 2971del5. Medical records confirmed that in 1996 their daughter underwent a right radical nephrectomy due to Wilms' tumor and in September 2003 was diagnosed with acute myelogenous leukemia; she passed away in November 2003 from multi-organ system failure. Records also indicate that she had an imperforate anus, microcephaly and multiple skin hyperpigmentations, depigmentations and café-au-lait spots. The *BRCA2* mutation, 886delGT was not identified in our patient's mother. There was limited knowledge of her paternal health history. Her husband reported that his mother was diagnosed with breast cancer at age 59 and passed away at age 64 and his maternal grandmother had a history of breast cancer and passed away at age 65. He also had limited knowledge of his paternal health history. While a rare occurrence the identification of biallelic mutations in *FANCD1/BRCA2* is obviously a possibility within an HBOC genetic counseling situation. Further identification and reporting of individuals who are carriers of biallelic mutations in *FANCD1/BRCA2* will contribute to the characterization of the phenotypic spectrum associated with this cancer syndrome. In addition, counseling practices may be modified depending on how individuals are ascertained, either directly with a FA-D1 diagnosis or through HBOC families.

## 1253/W/Poster Board #911

**Expanding the spectrum of mutations associated with the PTEN promoter.** 
*RK. Basran[1], TA. Maher[1], B. Wu[1], Z. Wang[1,2], JM. Milunsky[1,2,3].* 1) Center for Human Genetics; 2) Department of Pediatrics; 3) Department of Genetics and Genomics, Boston University School of Medicine, Boston, MA.

The phosphatase and tensin homolog (*PTEN*) gene is a tumor suppressor gene located on the long arm of chromosome 10. The *PTEN* gene encodes a lipid phosphatase that negatively regulates the phosphatidylinositol 3-kinase (PI3K)/AKT (protein kinase B) pathway. Mutations within the *PTEN* gene are associated with PTEN Hamartoma Tumor syndrome (PHTS), an autosomal dominant disorder characterized by hamartomatous tumors. Clinically PHTS includes Cowden syndrome (CS, MIM 158350), Bannayan-Riley-Ruvalcaba syndrome (BRRS, MIM 153480), Proteus syndrome (PS, MIM 176920) and Proteus-like syndrome. Mutations in the *PTEN* gene have also been identified in children with autism spectrum disorders (ASDs) and macrocephaly. In addition to sequence variations in the coding exons and flanking intronic regions, mutations have also been reported in the 600 base pair promoter region of the *PTEN* gene and account for approximately 10% of *PTEN* mutations in individuals with CS. There have been a limited number of reports describing *PTEN* promoter mutations in individuals with ASDs and macrocephaly. Currently, our laboratory's molecular testing strategy for the analysis of the *PTEN* gene includes; sequence analysis of the nine coding exons, intron-exon boundaries and promoter region and dosage analysis using multiplex ligation dependent probe amplification (MLPA). Among the 112 individuals referred to our laboratory for molecular testing of the *PTEN* gene, we identified three previously reported intragenic mutations and four heterozygous promoter alterations. Two of the promoter variants, -903 G→A and -1026 C→A, identified in seven individuals, have been previously reported as polymorphisms. The remaining two novel promoter variants, -975 G→A and -1059 C→G, were identified in two patients referred to our laboratory for autism with macrocephaly and CS, respectively. Further clinical and genetic analysis of the two probands with novel *PTEN* promoter mutations and family members will provide insight regarding the wide clinical spectrum associated with mutations within the *PTEN* gene. These findings also highlight the importance of performing promoter mutation analysis to improve the detection rate of PHTS and other clinical disorders associated with the *PTEN* gene.

### 1254/W/Poster Board #912

**Screening of BRCA1 and BRCA2 mutations in 300 patients by qPCR-HRM, a combined method for point mutation and large rearrangement detection.** *F. Coulet[1], M. Eyries[1], F. Pires[1], E. Rouleau[2], C. Lefol[2], C. Colas[1], A. Hardouin[3], R. Lidereau[2], F. Soubrier[1].* 1) Oncogenetic laboratory, APHP-GH Pitié Salpêtrière, Paris, Ile de France, France; 2) Oncogenetic laboratory, Centre René Huguenin, INSERM U735, Saint Cloud, Ile de France, France; 3) Laboratory of Clinical and Oncological Biology, Centre François Baclesse, Caen, Normandie, France.

Screening of the two major breast and ovarian cancer susceptibility genes BRCA1 and BRCA2 are time-consuming and must include exploration of genomic rearrangements that represent 5 to 15% of the alterations observed in these genes. We evaluated a method combining both point mutations detection by High Resolution Melting (HRM) which monitors the fluorescence of double strand DNA with saturating dye and large gene rearrangements detection by allelic quantification with semi-quantitative analysis (qPCR). The two analyses could be done on the same thermocycler run (qPCR-HRM). We evaluated the sensitivity of the qPCR-HRM technology by analysing 201 known point variants scattered over all amplicons of BRCA1 and BRCA2 genes and seven large gene rearrangements involving one or several exons of BRCA1 or BRCA2; 100% of the variants were detected. Furthermore, a retrospective study was done with 44 patients previously BRCA1 tested by DHPLC, all the variants were detected by HRM analysis and 4 supplementary homozygous polymorphisms were identified by HRM analysis. Finally, a prospective study was done with 300 patients allowing 27 deleterious mutations, 33 unclassified variants and three genomic rearrangements to be detected. qPCR-HRM is a simple, sensitive and rapid closed tube method that does not require modified PCR primers. The major advantages of this method is the simultaneous detection of point mutations, large scale gene rearrangement and absence of amplification of one allele, a combined approach which is critical in genetic diagnosis.

## 1255/W/Poster Board #913

**Fusion of the *FUS* and *CREB3L2* genes in a ring chromosome in low-grade fibromyxoid sarcoma.** *H. Bartuma[1], M. Isaksson[1], A. Collin[1], H. Domanski[2], N. Mandahl[1], F. Mertens[1].* 1) Department of Clinical Genetics, Lund University Hostpial, Lund, Sweden; 2) Departments of Cytology and Pathology, Lund University Hospital, Lund, Sweden.

Low-grade fibromyxoid sarcoma (LGFMS) is a rare, low-grade malignant soft tissue tumor that often is mistaken for either more benign or malignant tumor types. Commonly, this tumor affects young adults and typically arises in the deep proximal extremities or trunk with frequent recurrences and can metastasize to the lungs many years later. A recurrent balanced translocation between chromosomes 7 and 16, t(7;16)(q32-34;p11), has been identified and has been shown to lead to the expression of a *FUS/CREB3L2* fusion gene in almost all reported cases. Furthermore, this gene fusion is so far specific for LGFMS. Previously, supernumerary ring chromosomes have been identified in LGFMS, but it has not yet been formally demonstrated that ring chromosomes harbor the *FUS/CREB3L2* fusion gene. Here, we report the genetic findings in an LGFMS from the lung from a 77-year-old man. Banding analysis revealed a ring chromosome, and further studies with fluorescence in situ hybridization and RT-PCR showed that the ring contained material from chromosomes 7 and 16, that the FUS gene was present in two rearranged copies, and that it expressed the *FUS/CREB3L2* fusion gene.

## 1256/W/Poster Board #914

**Comparative evaluation of CNV analysis in breast cancer using different population references.** *A. Hidalgo[1], S. Rodriguez-Cuevas[2], L. Uribe-Figueroa[1], F. Guisa-Hohenstein[2], C. Rangel-Escareno[1], G. Ortiz-Ramos[1], R. Mojica-Espinosa[1], V. Quintanar-Jurado[1], S. Romero-Cordoba[1], R. Rebollar-Vega[1], S. March-Mifsut[1], G. Jimenez-Sanchez[1].* 1) National Institute of Genomic Medicine (INMEGEN), Mexico City, Mexico; 2) Fundación Mexicana de Fomento Educativo para la Prevención y Detección Oportuna del Cáncer de Mama (FUCAM), Mexico City, Mexico.

Copy Number Variation (CNV) analysis is a powerful strategy to discover cancer related genes. A specific pattern of DNA gains and losses has been described for breast cancer. However, this information is very limited in women from Mexican or Hispanic origin. The use of high-resolution platforms for CNV analysis poses several challenges, including false copy number calls due to normal CNV, particularly when a diploid control from a different population is used. We analyzed 50 tumor tissues with >70% tumor cells and peripheral blood pairs from Mexican women without prior treatment, using the Affymetrix 6.0 Gene Chip to describe CNV alterations in these tumors (Partek Genomics Suite). To evaluate the influence of different population references in the analysis, we compared results from these tumors with the following references: 1) normal paired tissue from the same individuals, 2) CNV data from the HapMap samples (n=270), and 3) CNV data from 240 Mexican Mestizo population controls. Our first comparison, tumor/normal paired analysis, identified amplifications in the 8q24.11-q24.12 region in 25 (50%) samples and deletions in 13q14.2 and 16q21 in 20 (40%) of the samples as the most common alterations. To evaluate the efficiency of other potential references, we performed two additional comparative analyses. The second comparison included peripheral blood DNA against data from the HapMap samples and identified 8,059 CNV 1kb in size with less than 1 or more than 3 copies. Of these, 1,899 were not in the Database of Genomic Variants (DGV), 250 of these regions were present in >50% of the normal samples. Our third scenario compared peripheral blood samples with the Mexican population reference. We found 15,478 CNV regions, of which 3,176 were not present in the DGV. Of these, 350 were present in >50% of the normal samples. When the tumors were compared against the Mexican or the HapMap reference samples, we found an increased number of CNV present in all tumors indicating that the difference correspond to normal CNV changes present in the reference DNA samples. Our results indicate that CNV analysis is sensitive to the population reference used being tumor/normal paired the closest reference, followed by a reference with a similar population background, since a multiethnic reference generates a significant number of false positives, as opposed to real somatic changes in the tumors.

## 1257/W/Poster Board #915

**Whole-genome array-CGH analysis in MDS/AML patients: Characterization of chromosomal abnormalities and detection of cryptic aberrations.** *P. Li, R. Bajaj, K. Wilcox, F. Xu.* Dept Gen, Yale Univ Sch Med, New Haven, CT.

Whole genome oligonucleotide array comparative genomic hybridization (array-CGH) using Agilent's 44K oligonucleotide array (CGH4410B) has been used in clinical diagnosis of constitutional chromosomal and genomic imbalances with an average resolution of 300-500 Kb (5-7 contiguous probes) and 99% specificity and sensitivity. To evaluate the clinical validity and analytical outcome of this genomic approach for detecting acquired somatic abnormalities, we have applied array-CGH on 30 MDS and AML cases with recognized chromosomal abnormalities in >50% of analyzed metaphase cells. This genomic analysis detected all gains of chromosomes 1, 4, 5, 6, 7, 8, 11, 13, 14, 19 and 20, as well as losses of chromosomes Y, 7, 8 and 18. A total of 103 deletions (43 Kb to 135 Mb, average size: 19.143 Mb), 28 duplications (48 Kb to 118 Mb, average size: 21.883 Mb), seven triplications (average size: 9.432 Mb), two dmin amplifications (3-4 Mb) and six marker chromosomes were further characterized with defined breakpoints and genomic contents. Clinical significant recurrent or overlap deletions at 5q (involving the RPS14 gene), 12p12.3 (ETV6 gene), 13q14.3 (miR-15a/16-1), 17p13 (TP53 gene), 17q11.2 (NF1 gene) and 20q were noted in 10 cases (10/30, 33%), seven cases (23%), four cases (13%), four cases (13%), four cases (13%) and three cases (10%), respectively. All three deletions at 17q11.2 were undetectable by routine chromosome analysis and were confirmed by FISH using BAC clones for the NF1 gene. With the exception for one case with a secondary 9p deletion, all chromosomal imbalances in 29 cases (29/30, 97%) and additional complex or cryptic genomic aberrations in 23 cases (77%) were detected by array-CGH analysis. These results indicated that array-CGH could be a valuable tool for cancer cytogenetic and genomic diagnostics.

## 1258/W/Poster Board #916

**A Novel Chromosomal Alteration in A Patient of Unclassifiable Myelodysplastic/Myeloproliferative Neoplasm with Thrombocytosis.** *J. Lin[1,2,3,4], M. Guo[1], R. Girard[4], R. Nagwekar[1], A. Pigal[1], H.O. Shah[1,2].* 1) Dept Pathology, Nassau Univ Medical Ctr, East Meadow, NY; 2) Health Sciences Center, Stony Brook, SUNY; 3) New York College of Osteopathic Medicine, NY; 4) American University of the Caribbean, Netherlands Antilles/ Coral Gables, FL.

Cytogenetic studies have a major role in the evaluation of patients with myelodysplastic syndrome (MDS). About 50% of MDS cases have clonal cytogenetic abnormalities, including +8, -5, del(5q), -7, del(7q) and del (20q). There is no cytogenetic or molecular genetic finding specific for myeloproliferative neoplasm, unclassified(MDS/MPN,U). We report a case of MDS/ MPN,U with thrombocytosis. A 71 year old woman with a past medical history of anemia was admitted as severe anemia. At the time of admission, the patient had complains of weakness and headache. The complete blood count at admission revealed the complete blood count showed hypochromicnormocytic anemia, leukopenia, dysgranulocytopoiesis, and an important finding of thrombocytosis with WBC 2.5 k/mm3, N 28%, L 50%, M 9%, 4 % blast; RBC 1.4 million/mm3, Hgb 3.7 g/dL, Hct 11.5%, MCV 80.4fL, RDW 16.7%, platelet 1237 k/mm3 . A CT scan of abdomen revealed hepatomegaly. Bone marrow biopsy showed a cellularity of 60%, demonstrated 16% blasts and revealed granulocytic series dysplastic change. The megakaryocytes were very prominent with dysplasia showed up to 37 cells/HPF. Cytogenic analysis of bone marrow cells revealed a specific alteration has not yet been reported. The composite karyotype of the bone marrow cells disclosed: abnormal female karyotype 46,XX,add(13)(p13)?c[17]. Final diagnosis for this woman was Myelodysplastic Syndrome / Myeloproliferative Neoplasm, Unclassifiable. This is a case of rare proportions. Although the precise mechanisms for pathogenesis is not yet clear, it is important to recognize this disorder because dysplastic and proliferative features may both need to be considered to achieve the best regimen for therapy.

## 1259/W/Poster Board #917

**Primary Ewing Sarcoma/Primitive Neuroectodermal Tumor of Soft Tissue in the Perinephric Region.** *H.O. Shah[1, 3], G. Fan[1], N. Chen[1], L. Freedman[1,3], J.H. Lin[1,2,3], No.* 1) Dept Pathology, Cytogenetics, Nassau Univ Med Ctr, East Meadow, NY; 2) New York College of Osteopathic Medicine, Old Westbury, NY; 3) Department of Pathology, State University of New York at Stony Brook, Stony Brook, NY.

Primary Ewing's sarcoma/primitive neuroectodermal tumor (PNET) of soft tissue is a rare entity. We describe a primary Ewing's sarcoma/PNET of soft tissue in the perinephric region in a 36 year old man who was admitted as acute pyelonephritis. CT scan revealed left renal enlargement with multiple hilar masses and a posterior left perinephric nodule. CT-guided fine-needle aspiration biopsy of the posterior left perinephric nodule showed characteristic cytological and histological appearances of a small round blue cell tumor with focal Homer-Wright rosette formation. The tumor cells showed diffuse positivity with CD99, vimentin, BCL2, NSE (neuron specific enolase), and synaptophysin but were negative for muscle markers (desmin, myogenin, and smooth muscle actin), melanoma markers (S-100, HMB 45, Mart-1, and tyrosinase), epithelial markers (pankeratin, epithelial membrane antigen, CK7 and CK117), and lymphoid markers (CD45, CD3, and CD20). Fluorescence in situ hybridization analysis using dual-color DNA probes for the Ewing Sarcoma breakpoint region 1 (EWSR1) on chromosome 22q12 revealed a rearrangement of EWSR1 locus, confirming the diagnosis of Ewing's sarcoma/PNET. To our knowledge this is the first intact documentation of primary Ewing's sarcoma/PNET of soft tissue in the perinephric region with an immunohistochemical penal and cytogenetic analysis.

## 1260/W/Poster Board #918

**Copy number of hTERC (3q26) in pediatric patients with acute lymphoblastic leukemia at diagnosis detected by FISH.** *A. Corona-Rivera[1,2], H.J. Pimentel-Gutiérrez[1], C. Ortega de la Torre[1], V. Soto-Chávez[2], F. Sánchez-Zubieta[2], L. Bobadilla-Morales[1,2].* 1) Lab de Citogenetica Genotoxicidad y Biomonitoreo, Instituto "Dr. Enrique Corona Rivera", Universidad de Guadalajara, CUCS, Guadalajara, Jalisco, Mexico; 2) Unidad de Citogenética, Servicio de Hematología Oncología Pediátrica, División de Pediatría, Nuevo Hospital Civil "Dr. Juan I. Menchaca", Guadalajara, Jalisco, México.

Telomeres are the ending portion of chromosomes which limit them. Telomerase gene is located in 3q26 (Nowak, et al., 2006). Telomerase maintain the telomere length and is associated with cell cycle. Short telomeres and a high telomerase activity (ALL, AML, CML and Non Hodgkin lymphoma) is related to a severe hematologic neoplasia like, this suggest that telomere length and telomerase activity may be useful for monitoring disease. In ALL increase in telomerase activity related to *hTERC* amplification has been observed with FISH (Nowak, 2006). However SNP Microarrays studies and DNA sequencing did not find 3q gain in 225 ALL patients (Mullinhan et al., 2007). The aim of this study is to characterize copy number of *hTERC* gen (3q26) in pediatric patients with ALL. We included patient with ALL at diagnosis. Bone marrow sample was obtained to perform routine karyotype and *hTERC* FISH. We scored cells on 65 patients most of them with ALL diagnosis. Observations were done on 1000 cells per patient. The FISH pattern observed in patient samples was 2 Green (3cep)/2 Red (3q26 *hTERC*), that indicated no amplification. In one patient the most common pattern was 2G/3R, indicating a gain in 3q26. Triploidy and tetraploidy were observed in 4 patients, which was concordant with the Karyotype. It seems that there is no hTERC gain at diagnosis in pediatric ALL patients.

## 1261/W/Poster Board #919

**Recurrent Aberrations in High Grade B-Cell Lymphomas with Concurrent 8q24/ MYC Rearrangements and t(14;18).** *R. Garcia, N. Uddin, I. Villalobos, S. Holdridge, C. Chastain, J. Doolittle, C. Tirado.* UT Southwestern, Dallas , TX.

Simultaneous 8q24/ MYC rearrangements of Burkitt's lymphoma (BL) and t(14;18) of Follicular lymphoma (FL) occur rarely in high grade B-cell lymphomas, and are associated with an aggressive clinical outcome. These dual translocations or double hit event (DH) in HGLs have been reported in transformed FL, BL, acute lymphoblastic leukemia (ALL), diffuse large B-cell lymphoma (DLBCL) and plasmablastic myeloma. The objective of this study was to determine frequent chromosome alterations with concurrent 8q24/ MYC and t(14;18) rearrangements. Simultaneous 8q24 alterations and t(14;18) with specific morphological patterns (BL/ALL, FL and DLBCL) were searched from the Mitelman database (from 1981-2007). We identified a total of 25, 35 and 39 cases for FL, BL/ALL and DLBCL respectively. Each morphologic entity was first evaluated for frequent alterations, and also for paired aberrations that happen more frequently together than expected from their probability of random distribution. The strength of association of paired aberrations with the five highest chi square values are reported here. Results were then compared with the Fisher Exact Test and chi square to determine differences in different morphologic groups. In FL, the 8 most frequent alterations were +7, +12, t(2;8), +X, +21, -13, -X and +Y. Statistically significant paired aberrations within the FL dataset included: -X/+7, -X/+12, +21/-13, +12/+7 and -X/ t(2;8). In DLBCL, the 9 most recurrent alterations included +7, t(8;22), +12, -15, +11, +21, +X, -X, add(8)(q24) and the statistically significant paired aberrations with were +11/-15, +12/+X, t(8;22)/-15, -X/-15, -X/+7. Similarly, t(8;22), +7, +20, +8, +X, +12, t(2;8), +11 were the 8 most frequent aberrations in the BL group; and the main pairs with statistical significance within this group were +20/+8, +11/+20, +8/+7, +20/+7 and +X/+20. Comparison between morphologic groups showed a higher frequency for t(8;22) in both BL and DLBCL than FL (18 and 15 vs 4 events respectively); however, only BL showed a statistically significant association ($p < .05$). Other findings included a significantly higher frequency for pair rearrangement +8/+20 in BL compared to both DLBCL and FL (4, 0, 0 respectively; $p < .05$). Taken together, findings in this study help to outline frequent alterations, statistically significant pairs of aberrations within specific morphologic groups and identify significant differences between DH high grade B-cell lymphomas.

## 1262/W/Poster Board #920

**A Case of Triple Hit Lymphoma.** *K. Geiersbach[1], M. Sennett[2], S. Shetty[1].* 1) Department of Pathology and ARUP Laboratories, Salt Lake City, UT; 2) Department of Pathology, Northwest Texas Hospital, Amarillo, TX.

**Clinical Background**: A 49 year old female with a 23 pack-year history of smoking and COPD presented with fever, pneumonia, and cranial nerve palsy. CT scan showed bilateral pneumonia and significant mediastinal lymphadenopathy. Mediastinoscopy was performed and a biopsy of the left lower paratracheal node was obtained. **Laboratory Findings**: Analysis by flow cytometry showed a clonal population of neoplastic cells. Cells coexpressed CD19, CD20, and CD10, showed surface lambda light chain restriction, and partial positivity for FMC-7 and CD23; CD5 was negative. By histopathology and immunohistochemistry, the neoplasm consisted of medium sized B lymphocytes which were strongly BCL2 positive and weakly BCL6 positive. Proliferative index by Ki-67 was 90%. Bone marrow was hypercellular (99%); blood and bone marrow were infiltrated with malignant lymphocytes. Pathology diagnosis was rendered as high grade B cell lymphoma of germinal center origin. Subsequent cytogenetic analysis of the peripheral blood revealed a complex karyotype containing 3 translocations: t(2;18)(p12;q21), t(3;?)(q27;?), and t(8;14)(q24;q32), as well as deletions of 13q and 16q. By FISH, the 8;14 translocation was shown to result in disruption of the MYC locus on 8q24 and the IGH@ locus on 14q32, consistent with an IGH/MYC fusion. FISH also showed rearrangements of BCL6 (3q27) and BCL2 (18q21). **Discussion**: The findings are consistent with a very rare entity, triple hit lymphoma, an IGH-rearranged lymphoma with simultaneous rearrangements of the MYC, BCL6, and BCL2 loci. This entity is grouped with double hit lymphoma, within the WHO category of "B-cell lymphoma, unclassifiable, with features intermediate between diffuse large B-cell lymphoma and Burkitt lymphoma." This case further clarifies the laboratory findings in triple hit lymphoma and may contribute to knowledge of its prognostic significance.

## 1263/W/Poster Board #921

**A case of congenital leukemia that probably arose from acquired double trisomy, 48,XX,+18,+21.** *N. Itoh[1], H. Kuniba[1], H. Kawara[2], O. Shimokawa[2], N. Harada[2], M. Egashira[1], M. Tagawa[1], Y. Funakoshi[1], M. Okada[1], T. Kondoh[1], H. Moriuchi[1].* 1) Pediatrics, Nagasaki University, Nagasaki, Japan; 2) Kyushu Medical Science, Nagasaki, Japan.

Congenital leukemia is very rare and occasionally associated with a variety of chromosomal abnormalities. 11q23/MLL rearrangement or AML1/RUNX1 (21q22.3) gene mutation is found in some patients; however, molecular mechanisms of in utero leukemogenesis remain obscure. We here report a newborn patient with congenital leukemia that probably arose from acquired double trisomy of chromosomes 18 and 21. A 24-year-old woman was admitted for hydrops fetalis. She was on 33 weeks + 0 day of her second pregnancy. She had a healthy 3-year-old boy and no miscarriage. Immediately she underwent emergency cesarean section, giving birth to an infant weighing 2542 g with asphyxia. After cardiopulmonary resuscitation, she was transferred to the NICU. Physical examinations showed generalized edema, cyanosis and normal female genitalia, but no malformation. The initial white blood cell (WBC) count was 188,100/¨μl with 92% blast cells (CD34+/CD19-/CD10-/CD2-/CD3-; PO negative). Bone marrow examination could not be performed due to severe hydrops. Complete blood exchange was performed twice, which reduced WBC count to 11,000/μl temporally; however, she died on day 11 after birth from multiple organ failure. Autopsy studies revealed massive leukemic infiltration into liver, the small intestine, spleen, kidneys and lungs and no malformation or visceral anomaly. G-banded chromosomal analysis without PHA stimulation showed 48,XX,+18,+21 in all peripheral blood (PB) cells (20 metaphases) tested, which was confirmed by FISH analysis of 300 interphase nuclei. Whole genome array comparative genomic hybridization analysis of the DNAs extracted from autopsied liver and bone tissue revealed the karyotypes of arr18p11.32q23(18,339-76,089,909)x3,21q11.2q22.3(14,859,742-46,932,616)x3 and arr(1-22,X)x2, respectively. 11q23/MLL rearrangement was not found in any of PB cells tested (100 metaphases) by FISH analysis. Direct sequencing of AML1/RUNX1 gene revealed no mutation in the patient, and real-time PCR excluded the possibility of AML1/RUNX1 gene copy number change. Based on the above data, we speculate that the double trisomy arose from somatic non-disjunction, not from germinal cells, and contributed significantly to leukemogenesis in this patient; however, we don't know yet how it happened. It also remains unknown if all blood cells or possibly all mesoderm-derived cells exhibited the double trisomy and if it arose directly from normal karyotype or went through either single trisomy.

## 1264/W/Poster Board #922

**Identification of Genomic Alteration Events and Associated Gene Expression Profiles for MSS and CIMP-negative Colon Tumors by High Resolution Genome-Wide SNP and Gene Expression Arrays.** *L. Loo[1], I. Cheng[1], M. Tiirikainen[1], G. Okimoto[1], A. Lum-Jones[1], A. Seifried[1], S. Gallinger[2], S. Thibodeau[3], G. Casey[4], L. Le Marchand[1].* 1) Cancer Research Center of Hawaii, Honolulu, HI; 2) Mount Sinai Hospital, University of Toronto, Toronto, Ontario Canada; 3) Mayo Clinic College of Medicine, Rochester, MN; 4) University of Southern California, Los Angeles, CA.

**Background:** Colon cancer is the result of a multi-step process involving the accumulation of genetic and epigenetic alterations, leading to the transformation of normal colon epithelium to adenocarcinoma. Recent advances in microarray technology have lead to higher resolution scans for detecting specific regions of allelic gains and losses by single nucleotide polymorphism (SNP) arrays. In addition, when combined with high resolution gene expression arrays, these genomic alterations can be correlated with alterations in gene expression. **Objective:** To identify frequent copy number alterations (CNA) and associated gene expression profiles in 40 paired colon adenocarcinomas and normal tissue, utilizing high-density SNP and gene expression arrays. **Methods:** DNA and RNA were extracted from 40 fresh frozen paired colon tumors and normal tissue collected by the Colon Cancer Family Registry. We focused on microsatellite stable (MSS) and CpG island methylator phenotype (CIMP)-negative colon tumors, the most common molecular subtype. Genomic profiles were identified by genotyping both tumor and normal tissue with the Affymetrix Genome-Wide Human SNP 6.0 array, containing >1.8 million genetic markers. Gene expression profiles in tumors were identified by utilizing the Affymetrix GeneChip Human Exon 1.0 ST array, interrogating >1 million exons. Preliminary genomic alteration and gene expression analysis was performed with the Partek Genomics Suite software. **Results:** We identified broad regions of CNAs that occur at high-frequency (>50%) in several chromosomal regions: 7p, 7q, 13q, 20p, 20q, Xp, Xq (gains) and 8p, 17p, 18p, 18q (losses). In addition, CNAs occurring in 20-50% of the tumors were observed at 8q (gain) and 14q (loss) and focal events at 1q (gain), and 5q and 16p (loss). We also detected allelic imbalance associated with a subset of these sites of frequent CNA events. Preliminary results from the integration of CNA and gene expression data indicate that a subset of these frequent CNA events is associated with disruptions to gene expression. **Conclusions:** Our high-resolution analysis has identified specific molecular alterations in this common subtype of colon cancer. This genome-wide characterization of both genomic alterations and gene expression may help identify key genes and pathways involved in colon cancer. We will present detailed results from this integrated and comprehensive genetic profiling of MSS and CIMP-negative colon cancers.

## 1265/W/Poster Board #923

**Frequent Aberrations of Chromosomes 1 and 12 in Childhood and Adolescent Germ Cell Tumors.** *X. Lu, Y. Zhao, Y. Wang, M. Folsom, R. Naeem, R. Egler, A. Pappo, J. Hicks, P. Rao.* Texas Children's Hospital Cancer Ctr, Department of Pediatrics, Baylor College of Medicine, Houston, TX.

Pediatric germ cell tumors are heterogeneous and relatively rare tumors that account for approximately 3% of pediatric malignant tumors. To understand the genetic basis of these tumors, we performed G-banding, fluorescence in situ hybridization (FISH) and multicolor spectral karyotyping (SKY) analyses on 39 patients comprised of 18 benign teratomas, 10 malignant mixed germ cell tumors, nine yolk sac tumors, and one dysgerminoma and one seminoma enrolled at Texas Children's Hospital Cancer Center between 2003 to 2009. Frequent chromosomal aberrations involving chromosomes 1 (1p deletion/1q gain) and 12 (isochromosome 12p) were found in 13 (33%) cases including nine males and four females. Near triploidy/tetraploidy, gain of isochromosome 12p and loss of chromosomes 1p, 4, 5, 9, 10, 11, 13, 14, 18 and 19 were detected in nine (90%) malignant mixed germ cell tumors. In nine yolk sac tumors analyzed, chromosome abnormalities were detected in seven patients that include near triploidy/tetraploidy with recurrent 1p deletion, gains of 1q, 2, 7, 9, 12, 14, and isochromosome 12p (N=2). Twelve of 18 benign teratomas of infants and children were chromosomally normal and only six patients showed abnormal karyotypes without isochromosome 12p. Cytogenetic aberrations rate is significantly higher in adolescent patients (87%) compared to pediatric patients (42%). The gain of an isochromosome 12p and 1p deletion/1q gain were more frequent in the tumors from adolescent boys. Clinical correlation studies are warranted to better assess tumor aggressiveness and chemotherapy treatment in childhood or adolescent germ cell tumors.

## 1266/W/Poster Board #924

**Patient with APL had PML/RARA fusion by FISH but no t(15;17) translocation by G-banding mid-way through treatment.** *J. Mangel[1], I. Chin-Yee[1], K. Howson-Jan[1], S. Collins[1], J. Xu[2].* 1) Hematology; 2) Cytogenetics; London Health Sciences Centre and University of Western Ontario, Canada.

A 37 year old man previously treated for testicular carcinoma presented with easy bruising, shortness of breath, fever and cough. He was found to be pancytopenic (WBC 0.6, neut 0.2, Hb 102, plat 23), and his bone marrow (BM) aspirate and biopsy were consistent with a diagnosis of acute promyelocytic leukemia (APL), microgranular variant. At diagnosis, BM cytogenetics showed the diagnostic translocation t(15;17)(q22;q21) by G-banding in 75% (12/16) of the metaphase cells. The patient underwent standard induction chemotherapy with all-trans retinoic acid (ATRA) 45 mg/m2, daunorubicin 60 mg/m2 x 3days, and cytarabine 100 mg/m2 x 7 days. ATRA was discontinued prematurely because the patient developed severe oral ulcerations rendering him unable to swallow pills. By day 28, blood counts had recovered, but repeat BM aspirate still suggested ongoing leukemia. Cytogenetics identified t(15;17) by G-banding in 60% (15/25) of the metaphase cells, and PML/RARA fusion by FISH was found in 86% (172/200) of interphase cells. Interestingly, in the absence of any further interim treatment, a repeat BM aspirate one week later showed fewer blasts, a lower percentage of FISH gene fusion positivity (52.5%, 105/200, of the interphase cells), but no t(15;17) by G-banding in 25 metaphase cells. The patient resumed treatment with ATRA, and repeat BM aspirate performed 5 weeks later confirmed morphological remission, with both negative FISH and G-banding on that sample. The failure to detect t(15;17) by G-banding in the 3rd BM while FISH testing remained positive is puzzling. It is unlikely to be due to random sampling error, given that such a high proportion (52.5%) of the cells were positive by FISH. We hypothesize that the t(15;17) tumor cells failed to proliferate in this patient due to suppression of mitosis in response to treatment. Further investigation into the effects drugs might play on mitosis of tumor cells would be of interest. Both FISH and cytogenetics are usually performed at diagnosis in patients with suspected APL, but this case highlights the need for performing FISH analysis for PML-RARA gene fusion in the follow-up setting in patients with APL, even in patients with negative findings by G-banding.

## 1267/W/Poster Board #925

**CYTOGENETIC ANALYSIS OF THE L5178-Y MOUSE LYMPHOMA CELL LINE.** *J. Peregrina[1,2], J.M. Moreno-Ortiz[3], M.L. Ayala-Madrigal[3], M. Gutiérrez-Angulo[3,4], M. Partida-Pérez[3], R. Ramírez-Ramírez[3], E. Flores-Torales[1].* 1) Biología Celular y Molecular, Universidad de Guadalajara, Zapopan, Jalisco, Mexico; 2) Hospital Civil Fray Antonio Alcalde; 3) Instituto de Genética Humana, UdeG; 4) CUALTOS, UdeG.

The cell line L5178Y is derived from a thymic tumor induced in a DBA/2 mouse by methylcholanthrene and adapted to ascitic form. It is kept by serial intraperitoneal transplantation in ascitic phase in mice with H-2d/d haplotype. In this process, the cell line acquires a variety of numerical and structural aberrations that modifying their tumorigenic properties probably with phenotypes more aggressive. Although the karyotype of original cell line is unknown, it has been described in three sublines L5178Y-S, L5178Y-R and L5178Y TK+/-3.7.2C with different results that shown the independent chromosomal evolution and genetic instability of the original cell line. In this work we realized the chromosomal analysis in the cell line L5178Y. The lymphoma cells (cryopreserved) were cultured in RPMI-1640 supplemented with 20% fetal bovine serum at 37°C with CO2 to 5% during 24 hours. The harvesting protocol was as follows: colcemid 0.05 μg/ml for 40 min, KCl 0.075 M for 15 min, both incubated at 37°C, and the cells were washing with cold carnoy's solution. The chromosomes were spread on slides and kept at 37°C for chromosome aging. The comparative analysis was done with normal chromosomes obtained from mouse balb-c bone marrow cells, cultured and harvested with the same conditions. The chromosomes were stained with Giemsa-Trypsin protocol. The comparison of banding patterns between BALB-C mouse and L5178 cell line chromosomes showed a modal number of 40 and 56 chromosomes respectively. The chromosomal aberrations were the follows: the 1, 6, 7, 10, 12, 13, 14, 16, and 18 chromosomes were apparently unchanged. The numerical abnormalities were seen for 8, 9, 11, 15, 17 and 19 chromosomes. The chromosomes 2, 4, 9 showed an additional segment and the 5 chromosome with deletion of distal segment. Moreover, ten markers chromosomes were found. The increased genetic instability in malignant cell of tumor maintained within in vivo systems are due mainly to continuous exchange of microenvironments. Given this, expansive techniques by means of in vitro harvests and cryopreservation have been used to prevent the generation of different clones.

**Deletions involving Chromosomal Band 9p in Acute Lymphoblastic Leukemia.** *S.N.J. Sait[1], A.W Block[1], M.L. Brecher[2], E.W. Wang[3], M. Wetzler[3], G. Deeb[4].* 1) Clinical Cytogenetics Lab, Roswell Park Cancer Inst., Buffalo, NY; 2) Department of Pediatrics, Roswell Park Cancer Inst., Buffalo, NY; 3) Department of Medicine, Roswell Park Cancer Inst., Buffalo, NY; 4) Department of Pathology, Roswell Park Cancer Inst., Buffalo, NY.

Deletions involving the chromosomal band 9p21 [del(9p)] have been reported in a subset of acute lymphoblastic leukemia (ALL). Although del(9p) has not been designated as a separate diagnostic and prognostic subclass in the current WHO classification (2008); it has been shown that patients with these abnormalities might fall into a separate prognostic group in adult and pediatric B-cell ALL. The del(9p) is often missed by conventional cytogenetics (CC) and represent a heterogeneous group with deletions of variable sizes and additional chromosome abnormalities. We report our experience with a cohort of 15 patients seen at Roswell Park Cancer Institute. Deletions seen were both mono- and bi-allelic and confirmed by fluorescence in situ hybridization (FISH) using the Vysis/Abbott Molecular LSI p16/CEP 9 dual color probe set. The del(9p) was seen in both pediatric (5/15) and adult (10/15) ALL patients with a male:female ratio of 9:6. Based on flow cytometry analyses; 3/15 patients had a T and 12/15 a B-lineage with typical immunophenotypes except for aberrant dim CD13/CD33 myeloid antigen expression in 2 cases. In 7 patients, the del(9p) was the sole abnormality and in 5, these deletions could not be detected by conventional cytogenetics. In 2 patients this abnormality was initially identified by array comparative genomic hybridization (aCGH). Since similar abnormalities have been seen in both B and T lineage ALL, they do not represent a specific lineage marker. The prognostic significance of this abnormality is still controversial and is classified as standard risk, however, classifying them as normal karyotype might be misleading. As this is a subtle abnormality that could be missed by conventional cytogenetics, adjunct molecular cytogenetic technologies should be used identify the presence of the del(9p) especially in normal karyotype ALL.

## 1269/W/Poster Board #927

**Genome-wide allelic imbalance in prostate cancer: Comparison of aggressive and non-aggressive disease.** *Y. Tai[1], I. Cheng[2], G. Chen[3], S. Plummer[3], C. Neslund-Dudas[4], G. Casey[3], B. Rybicki[4], J. Witte[1].* 1) UCSF, San Francisco, CA; 2) University of Hawaii, Honolulu HI; 3) University of Southern California, Los Angeles, CA; 4) Henry Ford Health System, Detroit MI.

Introduction: Prostate cancer is a complex, heterogeneous disease that may be asymptomatic and latent among some men and more aggressive among others. The underlying biological mechanisms driving these differences in disease sub-groups are largely unknown. Thus, to characterize genomic alterations among prostate tumors and compare differences by disease aggressiveness, we conducted a genome-wide survey of allelic imbalance of prostate tumors, using the Illumina 1M SNP array. Methods: DNA was extracted from 64 freshly frozen prostate tumors and paired blood samples (32 aggressive and 32 non-aggressive disease) from prostate cancer patients undergoing radical prostatectomy treatment at the Henry Ford Health System. Illumina 1M-Duo bead arrays comprised of ~1.2 million markers were genotyped for each patient. To identify losses/gains and allelic imbalance (AI), we used the software BAFsegmentation. We compared the percentages of losses/gains and AI for each chromosomal arm to those from the remaining arms, and compared the percentage of the chromosomal arm consisting of losses/gains and AI regions between aggressive and non-aggressive samples. Results: Eleven of the 44 chromosome arms showed significantly higher percentages of regions with loss and AI than the rest of the genome. Chromosome arms 2p, 3q, 5q, 7q, 8p, 8q and 12p showed significantly (p value less than 0.05) higher percentages of regions that were both gain and AI, compared to the rest of the genome. Furthermore, chromosome arms 1p, 2p, 2q, 3p, 4q, 15q and 16q showed significantly higher percentages of loss and AI regions among aggressive tumors in comparison with non-aggressive tumors. There were no such differences observed for gain and AI. Conclusions: Higher percentages of regions with AI and loss were observed in many chromosomal arms compared to the rest of genome. Regions with AI and loss on 7 chromosomal arms may be related to prostate cancer aggressiveness. Future work will localize AI among subregions in order to pinpoint loci potentially involved with tumor aggressiveness.

## 1270/W/Poster Board #928

**The detection rate of chromosome abnormalities in CLL can be improved by performing both conventional metaphase analysis and FISH.** *E. Van Assche[1], P. De Schouwer[2], P. Zachee[3], K. Vermeulen[4], Z. Berneman[4], K. Bryssinck[1], E. Devos[1], J. Wauters[1], B. Blaumeiser[1].* 1) Dept Medical Genetics, Univ Hospital Antwerp, Wilrijk, Belgium; 2) Clinical Laboratory, ZNA Stuivenberg, 2060 Antwerp, Belgium; 3) Hematology, ZNA Stuivenberg, 2060 Antwerp, Belgium; 4) Hematology and Hemostasis, Univ Hospital Antwerp, Wilrijk, Belgium.

B-cell chronic lymphocytic leukemia (B-CLL) is the commonest leukemia of the adult population in Western countries. CLL has a variable prognosis, which is associated with various parameters including genetic parameters. Conventional metaphase analysis (CMA) of bone marrow cells of B-CLL patients is often hampered by low mitotic activity of malignant B-cells in culture. Consequently, clonal aberrations detected by CMA, are only found in 40-50% of patients. Therefore, fluorescence in situ hybridization (FISH) on interphase nuclei is often used as this technique does not require proliferating cells. Using FISH, clonal aberrations are detected in more than 80% of CLL patients, depending on the number of chromosomal targets interrogated. Recent studies suggest that a complex karyotype, including chromosome translocations, is also an important marker of poor prognosis in CLL. According to Mayr et al. (2006) the mitotic activity of CLL cultures can be increased considerably by adding CpG-oligodeoxynucleotides (CpG-ODN) and IL-2 to the culture medium. Last year we introduced this new culture technique in our lab. Initially, cultures of bone marrow and blood samples of CLL patients were set up with our conventional bone marrow medium on the one side and with the addition of CpG-ODN and IL-2 in the culture medium, on the other side. Since the failure rate of the cultures with CpG-ODN and IL-2 dropped spectacularly (from 46 to 10%) we considered that it was justified to use only this culture medium for the CLL samples. In our unselected patient population, 46 of 51 cases could be successfully stimulated for metaphase generation. Of 46 cases, 33 showed chromosomal aberrations after CMA. FISH analysis was successful in all 51 cases and 34 were abnormal for the 4 regions (11q22.3, 13q14.3, CEP12 and 17p13.1) we interrogated. The most frequent abnormality was 13q14.3 deletion, which was observed in 19 (37%) patients. In 16/19 cases the cryptic deletion, not visible by standard G-banding, was detected by FISH analysis only. In 27 patients additional aberrations, including structural, and complex aberrations, were detected by CMA and not by FISH. Our results, demonstrate an increased detection rate of abnormalities in CLL by using CMA. FISH analysis can further increase the detection rate of cryptic abnormalities. However neither CMA nor FISH can detect all the abnormalities, demonstrating the complementary nature of these 2 techniques and the necessity to perform both.

## 1271/W/Poster Board #929

**New culture methods for cytogenetic investigations of chronic lymphocytic leukaemia.** *C.E. Wren[1], H. Moriarty[2], K.A. Marsden[1], E.M. Tegg[1].* 1) Royal Hobart Hospital, Hobart, Tasmania, Australia; 2) Charles Sturt University, Wagga Wagga, NSW, Australia.

Aim: To determine which culture method (24 hour unstimulated; 72 hour with additional fetal calf serum; 72 hour with IL-4, 72 hour with LPS; 72 hour with TPA; 72 hour with CpG-oligonucleotide DSP30+IL-2) yielded the highest culture success rate, mitotic index, banding resolution and abnormality rate in patients with chronic lymphocytic leukaemia (CLL). Methods: This is a blind retrospective study that included patients presenting to the haematology department of the Royal Hobart Hospital from the 1st of January 2008 to 30th of September 2008. A peripheral blood EDTA sample was used as the study sample for cytogenetic analysis. Results and Discussion: 24 patients (consisting of 11 newly diagnosed and 13 known patients were included in this study), yielding a total of 45 samples. Overall the conventional cytogenetic (CC) culture success rate was 100.0% with an abnormality rate of 62.5% (n=24). This study also compared CC abnormality rates with fluorescence in-situ hybridization (FISH) results using probes for CLL (LSI D13S319 / 13q34 / CEP 12: LSI ATM / p53). FISH detected an abnormality rate of 75.0% (n=24). The combined CC and FISH abnormality rate was 87.5% (n=24). The cytogenetic abnormalities in the newly diagnosed patients were also correlated to CD38 expression, ZAP70 expression and clinical stage but no correlation was found. Conclusion: EDTA peripheral blood samples are an excellent source of material for CC culture in patients with CLL. The use of a combination of 3 cultures types for each patient (72 hour with TPA; 72 hour with CpG-oligonucleotide DSP30+IL-2; 72 hour with TPA and CpG-oligonucleotide DSP30+IL-2) resulted in a 100% culture success rate, high mitotic index and high abnormality rate (62.5%).

## 1272/W/Poster Board #930

**Case with a complex karyotype including t(8;14) and t(14;18) and preservation of follicular pattern in a transformed lymphoma.** *J. Xu[1], L. Minuk[2], K. Howson-Jan[2], K. Rizkalla[3].* 1) Cytogenetics; 2) Hematology; 3) Pathology; London Health Sciences Centre and University of Western Ontario, Canada.

A 48-year-old male presented with abdominal pain and had diffuse intra-abdominal, mediastinal and cervical adenopathy. His bone marrow (BM) showed 80% infiltration with neoplastic lymphocytes positive for Bcl-2 and Ki-67 (90%) and expressing CD19/dim CD10, CD20, and bright kappa light chains. Biopsy of a right sided neck node showed follicular lymphoma (FL), predominantly grade III/III with transformation, associated with diffuse areas. He was given 1 cycle of CHOP-R chemotherapy and managed for tumor lysis syndrome with rasburicase and temporary hemodialysis. After finding the t(8;14), treatment was changed to modified Magrath protocol with intensified intrathecal chemotherapy for CNS involvement. He had up to cycle 2A of treatment and developed progressive neurologic abnormalities secondary to leptomeningeal spread of lymphoma. Craniospinal radiation therapy was given but discontinued after 12 fractions due to progressive asthenia and pancytopenia. He died of progressive lymphoma 6 months after original diagnosis. G-banding showed a complex karyotype in both lymph node (LN) and BM. The LN had +X,+5, t(5;9)(q13;p13), der(8)t(6;8)(p11.2;p11.2), t(8;14)(q24.1;q32), add(11)(q21), add(12)(q13),del(13)(q32),t(14;18)(q32;q21). The BM had the same aberrations as in the LN and additionally, dup(1)(q21q42). All aberrations but dup(1) and t(5;9) were seen in every abnormal cell and thus they are likely primary events in the tumorigenesis. Both t(8;14) and t(14;18), "a double-hit", are seen in 100% (25/25) of the LN cells and 58% (15/26) of the BM cells. FISH of the BM showed fusion of CMYC/IGH and IGH/BCL2. t(8;14) is associated with Burkitt's lymphoma (BL) whereas t(14;18), with FL or diffuse large B-cell lymphoma (DLBCL). Notably t(5;9) and breakpoints 5q13 and 6p11.2 seen in this case are not common findings in BL, DLBCL or FL. A double-hit is reportedly associated with poor prognosis. The BM morphology is consistent with leukemic infiltrate and the LN shows residual FL in a background of diffuse lymphoma with minimal Burkitt's features. This case has follicular component (not all diffuse) and with this component, the proliferation rate is not that high. This finding raises 2 possibilities: 1. FL with blastic transformation associated with CMYC translocation; or less likely 2. composite FL and BL. We hypothesize that in addition to the double hit, other 8 aberrations observed might have also played a role in the histopathologic features in our case.

**GSVD comparison of genome-wide array CGH data from patient-matched normal and tumor TCGA samples reveals known and novel copy number alterations in GBM.** *C. Lee[1], O. Alter[1,2,3].* 1) Department of Biomedical Engineering, The University of Texas at Austin, Austin, TX; 2) Institute for Cellular and Molecular Biology, The University of Texas at Austin, Austin, TX; 3) Institute for Computational Engineering and Sciences, The University of Texas at Austin, Austin, TX.

Glioblastoma multiforme (GBM) is the most common type of primary brain tumor in adults. GBM is characterized by aggressive growth and treatment resistance, with median survival times of approximately one year after initial diagnosis. As do other cancers, GBM tumors exhibit a range of copy number alterations (CNAs), many of which play roles in the pathogenesis and development of the disease. Here, we describe the use of the generalized singular value decomposition (GSVD) [1,2] to identify copy number alterations (CNAs) in GBM using array CGH data from patient-matched normal and tumor samples provided by The Cancer Genome Atlas (TCGA). The GSVD computation simultaneously separates the two (i.e., normal and tumor) datasets of genome-wide copy number into one set of "probelets" and two corresponding sets of "arraylets." Each probelet describes a mathematically decoupled pattern of CNAs across the patients, and the two corresponding arraylets describe the corresponding, mathematically decorrelated, patterns of CNAs across probes in the normal and tumor genomes, respectively. Analysis of the arraylets that correspond to probelets of almost negligible significance in the normal dataset allows identification of specific genomic regions containing CNAs prevalent in tumors. The analysis of the corresponding probelets may reveal specific tumor subtypes or clinical phenotypes, that these patterns of CNA characterize. Unlike other copy number analysis methods, GSVD is not limited to analyzing each sample individually and allows identification of CNAs without first having to perform computationally-expensive segmentation and breakpoint identification in each sample. We show that the GSVD of TCGA array data identifies known CNA regions important in GBM, including regions of 4q12 (containing PDGFRA), 7p11.12 (containing EGFR), 9p21.3 (containing CDKN2A), and 12q14.1 (containing CDK4). Additionally, previously unknown CNA regions are revealed, including a segment of 2p24.3 containing genes whose overexpression is known to play roles in the onset of other brain cancers, and segments of 14q32.33 and 19q12 containing genes responsible for regulating apoptosis and cell-cycle progression. These results demonstrate the utility of the GSVD for comparative analyses of genome-wide copy number data in disease-related contexts. ## 1274/W/Poster Board #932

**ABL Amplification in a Patient with Precursor T-Lymphoblastic Lymphoma.** *G. Sun[1], J. Katzel[2], A. Mazumder[2].* 1) Cytogenetics, Genzyme Gen, New York, NY; 2) St. Vincent Comprehensive Cancer Center, New York, NY.

Precursor T-cell lymphoblastic leukemia/lymphoma (precursor T-LBL) accounts for approximately 2% of all adult NHL. For the majority of patients conventional cytogenetic analysis is unable to detect clonal chromosomal abnormalities. However, the addition of fluorescence in situ hybridization (FISH) testing has identified several new genetic aberrations. One recently identified FISH abnormality is the episomal amplification of the NUP214-ABL1 fusion oncogene. Our patient is a 39 woman who presented with night sweats and superior vena cava syndrome. CT scan revealed a large mass in the anterior mediastinum causing compression of the SVC as well as bilateral pleural effusions. The hemogram and smear revealed only an elevated WBC count of 21k with 70% neutrophils. LDH was slightly elevated. Thoracentesis was diagnostic for precursor T-LBL. She responded to steroids and radiation therapy. Once stabilized, a bone marrow biopsy was performed that confirmed the diagnosis. Cytogenetics revealed a normal female 46,XX karyotype. However, FISH testing from the bone marrow aspirate, using a panel of probes for T cell receptor alpha (TRA) at 14q11.2, p16 at 9p21, TP53 at 17p13.1, MYC at 8q24, MLL at 11q23 and BCR/ABL at 9q34/22q11.2 revealed a positive result for TRA (44% of cells). This represented a homologous deletion of the p16 gene (43%) and for episomes (6-30 copies in 42% of cells) by the BCR/ABL probe. The latter was confirmed to be NUP214-ABL1 fusion amplification by an NUP214-ABL1 probe. The patient was started on chemotherapy according to the HYPER CVAD regimen. After 1 cycle of therapy she had no radiographic evidence of disease. Dasatanib was also added to the regimen when the results of NUP214-ABL testing became available. Since FISH testing for the TRA was positive indicating a translocation involving this gene, the original cytogenetic slides were re-analyzed and found two of thirty metaphases showed clonal abnormalities:46,X,t(X;3)(q28;p21),t(10;14) (q24;q11.2). The t(10;14)/TLX1-TRA is the most commonly seen translocation in adult T-ALL and often associated with NUP214-ABL1 episomal amplification. This case is the first reported patient with amplification of the NUP214-ABL1 fusion gene presenting clinically as a lymphoma. Our results also confirm the value of FISH testing for patients with T-ALL/precursor T-LBL, providing valuable information diagnostic as well as therapeutic information.

## 1275/W/Poster Board #933

**Analysis of overdispersion patterns in a study into the monoclonal origin of multiple sporadic basal cell carcinomas.** *F. Quehenberger[1], E. Heitzer[2], P. Wolf[3].* 1) Institue of Medical Informatics, Statistics and Documentation, Medical University of Graz, Graz, Austria; 2) Department of Internal Medicine, Medical University of Graz, Graz, Austria; 3) Department of Dermatology, Medical University of Graz, Graz, Austria.

INTRODUCTION: There have been reports that not only basal cell carcinomas are of monoclonal origin, but also multiple lesions within a patient (Shulman et al. 2006). They found identical X-chromosome inactivation patterns and identical LOH patterns near the PTCH gene. In our study, however, by comparing the mutation patterns and LOH at the PTCH gene, we found no case which would have suggested monoclonal origin of lesions (Heitzer et al, 2009). Here we present the conclusions from the analysis of overdispersion from that study. METHODS: Tissue from three basal cell carcinomas and normal skin from each of six patients was genotyped at six SNPs near the PTCH gene. Overdispersion or clustering is observed if LOH occurs more often within the same patient than by chance alone or, if LOH has occurred, the same allele is lost more often than expected by chance alone. The permutation test based on score statistic of Tarone (1979) was used to test for overdispersion. The significance level was 0.05. The minimum over SNPs of the test statistic was used in order to correct for multiplicity. RESULTS: There was no significant overdispersion in the occurrence of LOH, but significant overdispersion in the allele that was lost. CONCLUSIONS: Although the study included only a small number of subjects, a small number of lesions per subject and not all of the SNPs were informative, statistically significant overdispersion could be established. If a part of a chromosome is lost, there is a strong tendency that it occurs at the same chromosome on different lesions. Loss of the same allele does not imply monoclonal origin of multiple basal cell carcinoma.

**Integrated analysis of copy number alteration and RNA expression profiles of cancer using a high-resolution whole-genome oligonucleotide array.** *S. Jung[1,2], S. Seung-Hun[1,2], Y. Seon-Hee[2], C. Hye-Sun[1,2], L. Sug-Hyung[3], C. Yeun-Jun[1,2].* 1) Department of Microbiology, The Catholic University of Korea, Seoul, Korea; 2) Integrated Research Center for Genome Polymorphism, The Catholic University of Korea, Seoul, Korea; 3) Department of Pathology, The Catholic University of Korea, Seoul, Korea.

Recently, microarray-based comparative genomic hybridization (array-CGH) has emerged as a very efficient technology with higher resolution for the genome-wide identification of copy number alterations (CNA). Although CNAs are thought to affect gene expression, there is no platform currently available for the integrated CNA-expression analysis. To achieve highresolution copy number analysis integrated with expression profiles, we established human 30K oligoarray-based genome-wide copy number analysis system and explored the applicability of this system for integrated genome and transcriptome analysis using MDAMB-231 cell line. We compared the CNAs detected by the oligoarray with those detected by the 3K BAC array for validation. The oligoarray identified the single copy difference more accurately and sensitively than the BAC array. Seventeen CNAs detected by both platforms in MDA-MB-231 such as gains of 5p15.33-13.1, 8q11.22-8q21.13, 17p11.2, and losses of 1p32.3, 8p23.3-8p11.21, and 9p21 were consistently identified in previous studies on breast cancer. There were 122 other small CNAs (mean size 1.79 Mb) that were detected by oligoarray only, not by BAC-array. We performed genomic qPCR targeting 7 CNA regions, detected by oligoarray only, and one non-CNA region to validate the oligoarray CNA detection. All qPCR results were consistent with the oligoarray-CGH results. When we explored the possibility of combined interpretation of both DNA copy number and RNA expression profiles, mean DNA copy number and RNA expression levels showed a significant correlation. In conclusion, this 30K oligoarray-CGH system can be a reasonable choice for analyzing whole genome CNAs and RNA expression profiles at a lower cost.

## 1277/W/Poster Board #935

**Integrative molecular profiling combined with in silico pathway analyses identify 6p amplification as a driver of tumorigenesis in osteosarcoma.** *J. Squire[1,2], M. Yoshimoto[1], J. Martin[1], B. Sadikovic[3], S. Chilton-MacNeill[3], P. Thorner[3], P. Nuin[1,4], M. Zielenska[3].* 1) Department of Pathology and Molecular Medicine, Richardson Labs, Queen's University, Kingston, Canada; 2) NCIC Clinical Trials Group, Kingston, ON, Canada; 3) Department of Pediatric Laboratory Medicine, the Hospital for Sick Children, Toronto, Canada; 4) Ontario Cancer Biomarker Network, Toronto, ON, Canada.

An unusually high frequency of chromosomal rearrangements characterizes osteosarcoma (OS) oncogenesis, and the resulting biological heterogeneity is thought to confer adaptability to aggressive treatment regimens. As the molecular basis of genomic rearrangements in cancer is highly clinically relevant, but poorly understood, our aims were to enhance understanding of its role in OS and to identify a distinct genomic region uniquely subject to such rearrangements and associated with OS tumorigenesis. Our recent progress has identified a number of distinct genomic regions that are uniquely subject to chromosomal instability, and are associated with OS-tumour progression and varying clinical response. These conclusions were based on our recent integrative microarray analysis of epigenomic, genomic, and gene expression profiles in OS. We have prioritized the genomic 6p12-21 amplicons for subsequent in silico experiments based on their known tumour biology and role in human and mouse OS. Copy number changes demonstrating gain within the 6p12-21 region were validated on formalin-fixed paraffin-embedded OS specimens using interphase fluorescence in situ hybridization with locus-specific BAC probes spanning both the RUNX2 locus as well as regions flanking the RUNX2 locus. Based on the aCGH and gene expression findings, the RUNX2 and CDC5L genes were suggested to be the target of the 6p amplicon. Interestingly, previous conditional mouse OS data sets showed overexpression of murine runx2, and bioinformatics approaches demonstrated homology between human 6p and mouse chromosome 17 segments, which contain the murine gene runx2. In silico analysis identified paired intrachromosomal segmental duplications and genomic variations surrounding 6p amplicons, suggesting that defects in homology-dependent repair pathways in OS cells may be the reason for the variation in breakpoints at 6p12-21 if the segmental duplications are involved in error-prone recombinational repair events. Overall, our observations highlight the plasticity of the human genome and the potential impact of segmental duplications on genomic rearrangement susceptibility. These findings provide an entry point for the development of targeted therapeutic strategies based on the genomics and key molecular pathways of genes such as RUNX2 that may be driving osteosarcoma progression.

## 1278/W/Poster Board #936

**Formation of secondary structure contributes to chromosome instability at fragile site FRA16B.** *A. Burrow, A. Marullo, L. Holder, Y.H. Wang.* Wake Forest University School of Medicine, Winston-Salem, NC.

Fragile sites are specific chromosomal loci that are especially susceptible to DNA breakage following conditions of partial replication stress. Rare fragile sites, which are present in less than 5% of the population, are inherited in a Mendelian manner and are associated with human genetic disorders. In contrast, common fragile sites have been observed in all individuals and are frequent sites of rearrangements in cancer cells. While the molecular basis underlying fragile site fragility remains elusive, most fragile DNAs examined thus far contain frequent, AT-rich flexibility islands capable of forming highly stable secondary structures. To understand the mechanism of breakage at fragile sites, the cause of instability at fragile site FRA16B has been examined. FRA16B contains a 33 bp AT-rich minisatellite element, and its expression can be observed following treatment with chemicals that induce both types of fragile sites. Furthermore, the repeat is predicted to form a stable hairpin structure. To date, there is no physical evidence of alternative DNA structures formed at AT-rich fragile sites, which comprises the majority of fragile sites, emphasizing the importance of determining whether fragile DNAs are able to form secondary structures *in vitro*, and to investigate the contribution of secondary structure formation on chromosome instability. The ability of FRA16B to form a secondary structure *in vitro* was examined in this study, and we found that upon reduplexing, FRA16B forms alternative structures, characterized by bands of reduced electrophoretic mobility in polyacrylamide gels. Furthermore, the effect of secondary structure formation on replication efficiency and instability of FRA16B plasmids was examined in mammalian cells using a SV40 replication system. Depending on both the replication orientation and distance from the origin, FRA16B constructs replicated less efficiently compared to the control, and demonstrated an increased number of instability events, including large base pair deletions, based on a mutation assay performed in *E. coli*. Comparison of the deletion sites with predicted secondary structures revealed that the deleted regions occurred at sites of extensive secondary structure, including multiple hairpins. These results strongly suggest that the secondary structure-forming potential of FRA16B contributes to its fragility by stalling DNA replication, and this mechanism may be shared among other fragile DNAs.

## 1279/W/Poster Board #937

**Telomere length in Neuroblastoma -- a novel prognostic factor?** *G.M. Lundberg[1], I. Øra[2], D. Gisselsson Nord[1, 3].* 1) Clinical Gentetics, Lund University Hospital, Lund, Sweden; 2) Department of Pediatric oncology, Lund University Hospital; 3) Department of Pathology, Lund University Hospital.

Aim: To assess possible correlations between telomere lengths in neuroblastoma (NB) and clinical outcome. Background: NBs are tumours of the sympathetic nervous system, occurring predominantly in early childhood and accounting for 8-10% of all paediatric cancers. Multiple studies have shown that NB has a heterogeneous pattern of somatic chromosome changes. Previously we have found abnormally short telomeres in five NB cell lines, concurrent with chromosome segregation disturbances such as anaphase bridging and mitotic multipolarity. Materials and Methods: Quantitative fluorescence in situ hybridisation was carried out on 34 NB-biopsies. The fluorescence intensity in NB cell nuclei was compared to that of non-neoplastic cell nuclei, mainly endothelium, to obtain a relative measure of telomere length. The results were correlated with histopathological data, cytogenetic abnormalities, relapses and survival. Result: Of the 34 tumours, 10 had longer, 14 shorter and 10 had the same median telomere length as that of the endothelium. Patients whose tumours had longer telomeres showed a higher frequency (60 % vs. 35 %) of stage 4 disease and a worse clinical outcome (20 % disease free survival vs. 80 %) than those having tumours with shorter telomeres (P= 0.02 log-rank test). Unchanged telomere length did not influence survival. Neither 1-p, 11-q status nor MYCN amplification correlated to disease free survival in the present study. Conclusion: Tumor telomere length could be a future prognostic parameter in NB patients, being a better predictor of disease-free survival than MYCN status in the present study. Studies of the relation between telomere length and the expression of telomere-regulating molecules and neuroblastic differentiation markers are ongoing.

## 1280/W/Poster Board #938

**Characterization of myelodysplastic syndromes and acute myeloid leukemia with isodicentric X chromosome.** *K. Paulsson[1], C. Haferlach[2], C. Fonatsch[3], A. Hagemeijer[4], M.K. Andersen[5], M. Slovak[6], B. Johansson[1] on behalf of the MDS Foundation.* 1) Department of Clinical Genetics, Lund University Hospital, Lund, Sweden; 2) Munich Leukemia Laboratory, Munich, Germany; 3) Department of Medical Genetics, Medical University of Vienna, Vienna, Austria; 4) Centre for Human Genetics, University of Leuven, Leuven, Belgium; 5) The Cytogenetic Laboratory, The University Hospital Rigshospitalet, Copenhagen, Denmark; 6) Department of Cytogenetics, City of Hope Comprehensive Cancer Center, Duarte, CA.

An isodicentric X chromosome [idic(X)] with breakpoints in Xq13 is a rare but recurrent finding in myelodysplastic syndromes (MDS) and acute myeloid leukemia (AML) in elderly women. The molecular mechanism leading to formation of idic(X) is not known, but may involve either crossing over between sister chromatids at the G2 phase of the cell cycle or initial trisomy X with subsequent translocation between two of the three homologues. It is also unclear whether the active or the inactive X chromosome is involved in the aberration, although published data from two cases suggest the latter. We have utilized the Illumina 1M-duo single nucleotide polymorphism (SNP) array platform, comprising 1,000,000 SNPs genome-wide, to investigate the Xq13 breakpoints and identify additional clonal abnormalities in 14 cases of idic(X)-positive MDS or AML. The idic(X) breakpoints could be mapped in 12 of the cases, showing that the breakpoints clustered in two different Xq13 regions at approximately 70.9 and 72.1 Mb, respectively. Interestingly, both of these regions contain segmental duplications, suggesting a possible mechanism for sister chromatid recombination. Furthermore, methylation analyses of the *AR* gene at Xq12 revealed that six cases had gain of the inactive X chromosome and three had gain of the active X chromosome, corresponding to the isodicentric X. This suggests that idic(X) may be formed either from the active or the inactive X chromosome. In none of the cases was the breakpoint within a gene, showing that no fusion gene results from the rearrangement. The SNP array analyses also detected two recurrent regions of partial uniparental isodisomy, i.e., copy-neutral loss of heterozygosity; a phenomenon frequently associated with gene mutations. Taken together, our findings show that isodicentric X chromosomes in MDS and AML most likely arise by a crossing over between sister chromatids facilitated by the presence of segmental duplications, that there is no preference for the active or inactive X chromosome when the idic(X) is formed, that no fusion gene results from the rearrangement, and that additional gene mutations may be present.

## 1281/W/Poster Board #939

**The spatial dynamics of ATM at sites of DNA damage differ from those of other DNA damage response proteins.** *P.S. Bradshaw[1,2], M.S. Meyn[1,2,3].* 1) Program in Genetics & Genome Biology, Hospital for Sick Children, Toronto, ON, Canada; 2) Dept of Molecular Genetics, University of Toronto, Toronto, ON, Canada; 3) Dept of Paediatrics, University of Toronto, Toronto, ON, Canada.

ATM, the protein kinase defective in the cancer predisposition syndrome Ataxia-Telangiectasia, is critical for activating cellular responses to DNA Double Strand Breaks (DSBs). Accumulation of ATM at DSB sites, along with ATM phosphorylation of nearby target proteins, is thought to promote DSB repair by establishing a megabase region of modified chromatin that serves to recruit ancillary repair proteins. To better understand the role played by ATM in this process we have studied ATM behavior in human fibroblasts following induction of localized DNA damage by a laser microbeam. We find endogenous ATM forms foci at sites of DNA damage within 1 minute after photo-induction of DNA damage equivalent to ~10 Gy of γ-radiation. While maximal ATM accumulation occurs between 10 and 30 minutes post damage, some foci remain at 4 hours. Damage-associated ATM foci are small, discrete, and, unlike foci of the DNA damage response proteins Mre11, γH2AX, 53BP1 and BRCA1, do not enlarge and diffuse with time. Like ATM, the homologous recombination (HR) proteins RPA, Rad51 and FANCD2 form small, discrete damage-induced foci. However, at 1-hour post damage ATM foci do not colocalize with these HR protein foci. Consistent with our observations on endogenous ATM, FRAP data indicates that a GFP-tagged ATM stably associates with photo-induced DNA damage sites. Accumulation of both endogenous ATM and GFP-ATM at sites of photo-induced damage is dependent upon the MRN complex. In contrast, mutating the ATM 1981 phosphorylation site from serine to alanine impairs but does not completely block accumulation of GFP-ATM. Over-expression of the telomeric protein TRF2, an ATM kinase inhibitor whose binding encompasses the S1981 residue, also attenuates GFP-ATM accumulation at sites of DNA damage, while over-expression of the related protein, TRF1, does not.

Our data indicates that ATM rapidly associates with photo-induced DNA damage in an MRN-dependent dependent manner; whilst optimal accumulation requires ATM S1981 phosphorylation and may be regulated by TRF2. The spatial dynamics of ATM foci suggest that ATM is not a major component of the megabase protein platform domain. Our results are consistent with a model in which ATM rapidly accumulates at DNA break sites, then is displaced as breaks are either repaired by non-homologous end joining or processed for subsequently repair by homologous recombination.

## 1282/W/Poster Board #940

**Characterization of different *MLL* fusion genes in 40 leukemias and molecular studies of some rare *MLL* fusions.** *H. Chaker, J. Hébert.* Quebec Leukemia Cell Bank and Hematology-Oncology Division, Maisonneuve-Rosemont Hospital, Montreal, Quebec, Canada.

The mixed-lineage leukemia gene *MLL*, located at chromosomal band 11q23, is one of the most common genes involved in chromosomal abnormalities in leukemia. *MLL* rearrangements are associated with pediatric, adult and therapy-related acute leukemias of both myeloid and lymphoid lineages. In these different fusions, the N-terminal part of the MLL protein is fused to one of more than 50 partner proteins. A limited number of studies with frequent MLL fusions including MLL-MLLT1, MLL-MLLT3 and MLL-EEN, have shown a critical contribution of the partner protein to leukemogenesis. We have analyzed leukemic samples obtained from 40 adults with *MLL* rearrangements collected at the Quebec Leukemia Cell Bank, associated with different types of acute leukemia (myeloid, lymphoid, biphenotypic, therapy-related) and with chronic myelomonocytic leukemia (CMML). Cytogenetic findings were correlated with morphological, immunophenotypic and clinical data. We have investigated MLL fusions by conventional cytogenetics and FISH (Fluorescence in situ hybridization) using *MLL* and BACs (Bacterial Artificial Chromosomes) probes. Spectral karyotyping was used to define complex chromosomal rearrangements. Translocation breakpoints were studied by sequencing chimeric transcripts in less frequent and complex *MLL* fusions. Our results showed that 71.5% of analyzed *MLL* cases account for the most frequent partner genes: *MLLT3*(*AF9*), *AFF1*(*AF4*), *MLLT4*(*AF6*), *MLLT1*(*ENL*), *ELL* whereas 14.5% involve less common *MLL* fusion partners including *MLLT6*(*AF17*), *MLLT10*(*AF10*) and *SEPT9*. Other *MLL* fusions (14%) involved rare partners, such as *GAS7* and *CASC5*(*AF15q14*). Sequence analysis of a complex translocation involving chromosomes 11, 14 and 19 confirmed a *MLL-ELL* fusion in CMML. To date, only one case of CMML with a *MLL-ELL* has been reported. The two *MLL-GAS7* fusion transcripts detected in our case fused *MLL* exon 7 and exon 8 to *GAS7* exon 2. A rearrangement of the *CASC5* gene was detected by FISH using BAC clone RP11-451F21 covering the entire gene. One *MLL-CASC5* fusion transcript was confirmed by reverse transcriptase PCR using primers specific for *MLL* exon 10 and *CASC5* exon 11. Molecular characterization of rare *MLL* translocations may offer some insights regarding the role of the different *MLL* partner genes in these fusions and lead to a better understanding of their clinical impact.

## 1283/W/Poster Board #941

**Identification of cryptic and novel *RUNX1* fusions in acute leukemia.** *A. Giguère, J. Hébert.* Quebec Leukemia Cell Bank and Hematology-Oncology Division, Maisonneuve-Rosemont Hospital, Montreal, Quebec, Canada.

Cytogenetic analysis is an essential tool in the management of patients with acute leukemia. Chromosomal translocations are an important prognostic factor in this disease and often disrupt genes encoding transcription factors such as *RUNX1*. The *RUNX1* gene, located at chromosomal band 21q22, is involved in the establishment of definitive hematopoiesis and is a key regulator of myeloid differentiation. *RUNX1* is one of the most frequent rearranged genes in leukemia and is fused to more than 40 partner genes in different chromosomal translocations. *RUNX1T1* and *ETV6* are common partners of *RUNX1*, but a significant number of partners remains to be identified. In this study, we present the molecular cloning of the recurrent t(1;21)(p22;q22) translocation and the characterization of two cryptic *RUNX1* translocations using fluorescent in situ hybridization (FISH). A reciprocal translocation t(1;21) was detected in an adult patient with acute myeloid leukemia (AML) in relapse. FISH analysis with bacterial artificial chromosome (BAC) clone RP11-299D9 confirmed a rearrangement of *RUNX1* with chromosomal band 1p22. Using BACs targeting candidate genes on chromosome 1, the breakpoint was identified in a 100 kb region of band 1p22.3. Reverse transcriptase PCR and sequencing allowed the identification of the new *RUNX1* partner gene in this recurrent translocation and revealed at least three alternative *RUNX1* fusion transcripts but no reciprocal fusion. We also discovered a novel cryptic t(15;21)(q26;q22) in an adult case of biphenotypic acute leukemia. Using FISH analysis, a split signal was obtained with BAC clone RP11-17O20, suggesting that the breakpoint is within *RUNX1* intron 1. This specific breakpoint is highly associated with the t(12;21) in precursor B-cell acute lymphoblastic leukemia. Using BAC clone RP11-357H12 located at chromosomal band 15q26.1, a breakpoint region distal to the *POLG* gene was also defined. Finally, we describe a second case of adult AML with the cryptic t(9;21)(q34;q22). *RUNX1* rearrangement with chromosomal band 9q34 was confirmed by FISH using BAC clone RP11-299D9. Unfortunately, lack of sufficient material did not allow us to further identify the *RUNX1* partner gene in this case. Characterization of different *RUNX1* translocations is essential to better understand the oncogenic mechanisms associated with these rearrangements. In addition, these studies might help to identify new genes that are potential therapeutic targets in acute leukemia.

## 1284/W/Poster Board #942

**Human Multiple Myeloma Cell Lines: Molecular characterization by genome-wide profiling identifies alterations involving key enzymatic proteins.** *P.E. Leone[1], C. Elosua[1], P. Catalina[1], C. Palma[1], B.A. Walker[2], N.J. Dickens[2], A. Avramidou[2], L. Brito[2], E. Davenport[2], M.W. Jenner[2], D. Gonzalez[2], F.E. Davies[2], G.J. Morgan[2].* 1) Cytogenetics and Molecular Biology, Andalusian Stem Cell Bank, Granada, Spain; 2) Section of Haemato-Oncology, The Institute of Cancer Research, London, United Kingdom.

Multiple Myeloma (MM) is a malignancy depicted by clonal expansion of plasma cells in the bone marrow. There are two broad genetic subtypes of MM as defined as hyperdiploid MM, and nonhyperdiploid MM. These two subtypes of MM have different molecular pathogenesis. In order to contribute to the understanding of this malignancy and to unveil the different molecular pathogenesis, our interest is focused on Human MM Cell lines (HMCLs) as a model, and on a broad but specific group of enzymatic proteins: the Kinases. Kinase hyperactivity or lack of it often results in deregulation of cellular pathways involved in proliferation and survival. In our study, we describe the patterns of genetic lesions and molecular pathogenesis of 12 HMCLs with SNP-based mapping arrays from Affymetrix Human Mapping 500K array set. This technique allows the examination and identification of copy number changes, bi-allelic deletions (DAB) and the identification of loss of heterozygosity (LOH) due to loss and uniparental disomy (UPD), as well as gene localization and identification. The 12 HMCLs utilized are characterized for their structural alterations and not by hyperdiploidy. In addition, so as to fulfill the selection criteria, a minimum of 3 cell lines must present the alterations cited below. The most frequently identified alterations were located as follows: gains were observed in 1q, 4q, 7q, 8, 11q, 18, 19, and 20q.The DAB were ascertained on 3p. Similarly, we identified the regions of hemizygotic deletions on 1, 2q, 6q, 8q, 9p, 11q, 12, 13q, 14q, 17p, and 20p. In addition, regions of homozygous deletions were detected on 1p, 2q, 3, 4q, 6q, 8p, 9, 10q, 12p, 13q, 16q, 20p and 22q. Finally, the UPD obtained were traced on 1q, 4q, 8q, 10q, and 22q. These identified alterations are affecting a series of enzymatic genes belonging to targeted pathways: (1) PI3K/AKT pathway, which affect to a number of intracellular and extracellular myeloma growth cytokines; (2) Cyclin-Dependent Kinases, critical regulators of cell cycle progression and RNA transcription; (3) NFKB pathway, key regulator of the immune response; and (4) Aurora and related kinases, as another family of cell cycle regulators and often aberrantly activated in human tumor cells. These altered kinases may be potential targets for therapeutics. Our data demonstrates the genomic complexity of MM, enhancing the understanding of the molecular pathogenesis of the disease and the importance of the HMCLs as a model.

## 1285/W/Poster Board #943

**Frequency and Complexity of 10;11 Chromosomal Rearrangements in Pediatric and Adult AML.** *B.J. Dave, M.L. Wiggins, C.M. Higgins, W.G. Sanger.* Human Genetics Laboratory, Munroe Meyer Institute for Genetics and Rehabilitation, University of Nebraska Medical Center, Omaha, NE.

Acute myeloid leukemia (AML) is the most common type of acute leukemia in adults, accounting for nearly 80% of all cases; however, AML represents only 20% of all pediatric acute leukemia cases. Chromosomal rearrangements of 11q23, involving the *MLL* gene region, are common in AML and its frequency peaks in infancy. Aberrations of 11q23 exhibit high heterogeneity and are associated with poor prognosis. Multiple translocation partners are involved in 11q23 rearrangements; one of these is chromosome 10. The 10;11 abnormality is often a consequence of a complex rearrangement including inversions, insertions, and translocations with a diversity of breakpoints on 10p. The majority of the 10;11 abnormalities result in the *MLL-MLLT10* (*AF10*) fusion, however, two other fusion transcripts, the *CALM-MLLT10* and the *MLL-ABI1*, have also been described. We investigated the frequency and complexity of chromosome 10;11 rearrangements in pediatric and adult AML cases diagnosed during 2000-2008 at the University of Nebraska Medical Center. Of the 34 histologically confirmed AML (20 pediatric and 14 adult) cases containing 11q23 (*MLL*) rearrangements, 10 cases (10/34; 29%) revealed a translocation of 10p with 11q23. We present cytogenetic and fluorescence in situ hybridization (FISH) studies in these 10 AML cases (4 pediatric and 6 adult). Interphase and metaphase FISH studies using a dual color break-apart probe confirmed a disruption of the *MLL* (11q23) gene region in each of these cases. Six cases (1 pediatric; 5 adult) revealed a t(10;11)(p12;q23), three cases (2 pediatric; 1 adult) had a t(10;11)(p11.2;q23) and one case (pediatric) had a t(10;11)(p13;q23). In 4 cases (4/10; 40%) the t(10;11) appeared as the sole abnormality. Three cases (3/10; 30%) contained trisomy 8 in addition to the t(10;11), and three other cases revealed complex rearrangements of chromosomes 10 and 11 which were resolved using multiple metaphase FISH studies. Thus, a high frequency of 10p;11q abnormalities were evident among both pediatric and adult AML cases with 11q23 (*MLL*) abnormalities. The rearrangement involving *MLLT10* (*AF10*) at 10p12 was predominantly seen in adults while the rearrangement of *ABI1* at 10p11.2 was more frequent in pediatric cases. Metaphase FISH studies are imperative to resolve the many complexities noted in the chromosome 10;11 abnormality and to determine the exact breakpoints and the genes disrupted as a consequence of the rearrangements.

## 1286/W/Poster Board #944

**ArrayCGH as a Tool for Interrogating Recurrent Genomic Rearrangements in Leukemias: Proof of Concept Study.** *F.B. David[1], W. Tang[1,3], D.F. Saxe[2], K. Mann[2], S. Sunay[3], H.J. Khoury[3], B. Leyland-Jones[1], M.M. Bouzyk[1,4].* 1) Winship Cancer Institute, Emory University, Atlanta, GA; 2) Department of Pathology and Laboratory Medicine, Emory University, Atlanta, GA; 3) Department of Hematology and Medical Oncology, Emory University, Atlanta, GA; 4) Department of Human Genetics, Emory University, Atlanta, GA.

The Philadelphia chromosome [Ph, t(9;22)] is a hallmark of chronic myelogenous leukemia (CML) and is present in up to 30% of adult B-lymphoblastic leukemia (ALL). This translocation is detected clinically by chromosome analysis, FISH and RT-PCR. These methods, however, do not have sufficient resolution to identify the precise base pair location of breakpoints. In addition, both FISH and RT-PCR will not detect additional abnormalities many of which are clinically significant. We report results of a proof-of-concept study using a custom 385K mixed density array comparative genomic hybridization chip (aCGH) from NimbleGen to detect the presence of the Ph chromosome with precise location of breakpoints as well as identifying other known genomic abnormalities in leukemias. The BCR-ABL regions of the breakpoint sites of the Ph chromosome translocation were tiled at an average of 1 probe every 2bp. Other key leukemia-related regions were tiled less densely at 100 to 2500bp. Samples analyzed were from 3 reference cell lines (2 CML and 1 ALL) and 5 patients [2 CML, 1 Ph+ ALL, 1 Ph-negative (Ph-) myeloproliferative neoplasm, 1 Ph- ALL] and 1 control. The M-BCR breakpoint of the two CML cell lines, K-562 and Meg-01, were found in introns 14-15 and 13-14, respectively. This agreed with published results, and was further confirmed by RT-PCR. The breakpoints of the two CML cell lines were characterized by relatively large deletions/duplications. The candidate breakpoint for Sup-B15 on chromosome 22 was characterized by microdeletions. In addition, our custom aCGH clearly differentiated between Ph+ CML and Ph+ ALL by resolving deletions in the IKZF1 region for both Ph+ ALL cell line and patient. Some of the other regions, including CDKN2A, PAX5, 1p36, ERCC8 (5q12), and 17q12, were found to have possible duplications or deletions in some of the leukemia patients and may have clinical significance. Although the aCGH data on the patient t(9;22) breakpoints were inconclusive, our results illustrate the feasibility of utilizing aCGH as a tool in screening for not just one but for multiple types of recurrent leukemic abnormalities on one chip. *F.B. David and W. Tang contributed equally.

## 1287/W/Poster Board #945

**Application of array Comparative Genomic Hybridization to the cytogenetic analysis of pediatric Acute Lymphoblastic Leukemia.** *A. Dawson[1,2,3,5,8], R. Yanofsky[3,5,7,8], S. Mai[6,7,2,4,8].* 1) Cytogenetics Laboratory, Diagnostic Services Manitoba; 2) Dept. Biochemistry and Medical Genetics; 3) Dept. Pediatrics and Child Health; 4) Dept. of Cell Biology & Physiology; 5) Health Sciences Centre; 6) Genomic Centre for Cancer Research and Diagnostics; 7) Cancer Care Manitoba, Winnipeg, MB, Canada; 8) University of Manitoba, Winnipeg, MB, Canada.

Current detection of cytogenetic abnormalities in leukemias is based primarily on karyotype and/or FISH analysis; whereas array comparative genomic hybridization (aCGH), or cytogenetic microarray, has revolutionized conventional cytogenetics because of its increased resolution and independance from cell culture. It is well known that karyotypic analysis of haematological malignancies, although genome wide, is limited due to altered cell kinetics (mitotic rate), a propensity of leukemic blasts to apoptose in culture, overgrowth by normal cells, and poor quality chromosomes of the abnormal clone. Although FISH can be used on interphase cells upon culture failure or normal karyotype, FISH is not genome wide and is limited to analysis of specific loci of the abnormal clone. Acute lymphoblastic leukemia (ALL) is the most common and amongst the most curable of pediatric cancers. Today, 70-80% of children with newly diagnosed ALL treated with contemporary intensive state-of-the-art protocols can be cured. Clonal chromosomal abnormalities can be identified in approximately 90% of cases of childhood ALL and many have association with specific clinical, biological, and prognostic features. However, ~ 30% of pediatric (and 50% of adult ALL) do not have cytogenetic abnormalities of clinical significance. Despite significant improvements in outcome for pediatric ALL, ~ 25% of patients fail therapy, and often these failures occur unpredictably in patients with a favorable prognosis and 'good' cytogenetics at diagnosis. Thus far, aCGH has not been extensively used in haematological malignancies to look for acquired chromosome abnormalities as research has concentrated on gene expression microarrays to search for novel oncogenic pathways, prognostic factors, or mechanisms of drug resistance. In the present study, BAC and/or oligonucleotide aCGH (HemeScan, Combimatrix Molecular Diagnostics) was applied to 10 retrospective cases of pediatric ALL with a poor clinical outcome and either no chromosome abnormality identified or a chromosome abnormality not generally associated with a poor outcome. The HemeScan arrays both detected previously unidentified chromosome abnormalities and corrected previous conventional karyotypes. The use of aCGH in the clinical study of leukemias is recommended, as this will allow for more sensitive and accurate analysis of the underlying genetic profiles, which will ultimately lead to improved prognosis and treatment.

## 1288/W/Poster Board #946

**Breakpoint Mapping with Chromosome Microdissection-Derived Microarray Probes.** *T. Dennis[1], M. Bittner[2].* 1) Genetics Department, Shodair Children's Hospital, Helena, MT; 2) Computational Biology Division, The Translational Genomics Research Institute, Phoenix, AZ.

Molecular mapping of breakpoints involved in chromosomal rearrangements is problematic for many clinical tumor samples. Typically, insufficient numbers of metaphases are available for multiple FISH probe analyses. Chromosome microdissection has proven to be a valuable tool for the elucidation of cryptic chromosome rearrangements and for translocation breakpoint analysis at cytogenetic resolution. Microdissection involves physically scraping off any part of a chromosome from G-banded metaphase preparations using microneedles. Recovered DNA can then be DOP-PCR amplified and subsequently labeled for FISH or used for other molecular genetic applications. Microdissected DNA can be successfully used as a direct probe for microarray analysis providing breakpoint characterization at array resolution in a single hybridization. The analysis is based on two expectations that are met with these probes. First, the probes complementary to the region of microdissected chromosome have a strong signal. Second, the coverage of probes complementary to the microdissected chromosome region are high. Thus, microdissected regions are indicated by sets of probes that have strong signals and are found on probes close to each other on chromosomal regions.

## 1289/W/Poster Board #947

**Primary Large B-Cell Lymphoma Rearrangement of the *c-MYC* Gene.** *D. Juroske, P. Hu, M. Littlejohn, W. Im, C. Yin, P. Lin, A. Lennon.* Molecular Genetic Technology, School of Health Professions and Department of Hematopathology, University of Texas M.D. Anderson Cancer Center, Houston, Texas 77030.

Diffuse large B-cell lymphoma (DLBCL) is the most common Non-Hodgkin's lymphoma and is a heterogeneous disease with variable genetic aberrations. Rearrangements of c-MYC (at chromosome 8q24) are reported in approximately 16% of DLBCL in the western population, and have been associated with a poor clinical outcome. Using fluorescence in situ hybridization (FISH) and a break-apart probe, we examined c-MYC rearrangements in 63 DLBCL cases from China. The DLBCL were subclassified as germinal center B-cell (GCB) type (1/8, 12.5%) and non-GCB type (7/19, 36.8%), respectively, based on immunohistochemical studies using antibodies specific for CD10, BCL-6 and MUM-1 on a tissue microarray. Seven of 34 (20.5%) cases analyzable by FISH were positive for c-MYC rearrangements (Fig. 3). The percentage of cells with c-MYC rearrangements per positive sample ranged from 19-84%. When these cases were subdivided into GCB and non-GCB types, c-MYC rearrangements were found in 1 of 8 (12.5%) of GCB cases and 7 of 19 (36.8%) of non-GCB cases. We conclude that c-MYC rearrangements occur at a similar frequency in Chinese and western populations. More cases need to be assessed to determine a significant difference in c-MYC rearrangement between GCB and non-GCB types. To our knowledge, this is one of the largest studies to assess the occurrence of c-MYC rearrangements in different types of DLBCL from China.

## 1290/W/Poster Board #948

**Comparison of bone marrow cytogenetics, FISH and Agilent 244K microarray results on 25 patients with AML, MDS or MPD; evidence for the utility of each methodology for the detection of unique genetic abnormalities. Rhett P. Ketterling, Troy J. Gliem, Gary A. Hicks, Anne E. Wiktor, Margot A. Cousin, Cindy Williamson, Erik C. Thorland. Department of Laboratory Medicine and Pathology, Division of Laboratory Genetics, Mayo Clinic, Rochester, MN, 55905.** *R.P. Ketterling, T.J. Gliem, G.A. Hicks, A.E. Wiktor, M.A. Cousin, C. Williamson, E.C. Thorland.* Dept Lab & Med, Mayo Clinic, Rochester, MN.

Introduction: Primary bone marrow (e.g., myeloid) malignancies encompass the spectrum of chronic myeloid neoplasms, both proliferative (MPD) and dysplastic (MDS) and the aggressive acute myeloid leukemias (AML). Interrogation of the tumor genome in myeloid cells has historically been performed by conventional chromosome studies or FISH. The advent of array comparative genomic hybridization (aCGH) testing should allow a new level of exploration into the myeloid tumor genome and has the potential to identify many novel and presently undetected genetic abnormalities associated with these neoplasms. Materials and Methods: Following IRB approval, bone marrow specimens from 25 patients diagnosed at Mayo Clinic with a myeloid malignancy were evaluated by conventional chromosome studies and Agilent 244K aCGH studies. Specific FISH studies were performed on a subset of cases. Results: The 25 patients included 8 patients with AML, 5 with MDS and 12 with MPD. Chromosome studies were abnormal in 23 of 25 cases with 25-100% abnormal metaphases demonstrating either single clonal chromosome abnormalities or complex clonal karyotypes. FISH studies verified the presence of classic translocations and inversions associated with myeloid leukemias in 5 patients, including inv(16), t(10;11), t(8;21), t(9;22) and t(3;21). aCGH identified 955 chromosomal gains or losses, approximately 40 per patient, each involving at least 4 consecutive probes. Of these 955 abnormalities, at least 591 (62%) were deemed to be benign copy number changes. Excluding all aCGH abnormalities <1 MB in size, the comparison of array results with chromosome studies indicates at least 26 abnormalities were identified only by aCGH while up to 29 were rearrangements identified only by chromosome studies, including the five classic translocations or inversions also verified by FISH testing. Conclusions: The combined data indicate each method offers the potential for identification of novel genetic abnormalities in myeloid malignancies. The integration of aCGH into the clinical genetic algorithm for myeloid malignancies is yet to be established, although the additional abnormalities uncovered by this powerful methodology have the potential to identify new genomic regions with both diagnostic and prognostic implications.

## 1291/W/Poster Board #949

**An unusual case of ovarian undifferentiated carcinoma.** *M.J. Macera[1,2], W. Thelmo[3], A. Abdu[3], F. Zarghami[4], F. Cohen[1,2], J. Breshin[1,2], P. Chandra[2], A. Babu[1,2].* 1) Div Molecular Medicine & Genetics; 2) Dept of Medicine; 3) Dept of Pathology; 4) Dept of OB/GYN, Wyckoff Heights Medical Center, Brooklyn, NY.

A 50 year old woman came to the hospital complaining of abdominal pain and diarrhea. A CAT scan revealed a pelvic mass that was obscuring her ovaries and uterus. She also had a pleural effusion on the right side that was drained and showed negative cytology. EMA was positive and she underwent surgery. Both ovaries and the uterine wall were infiltrated by undifferentiated carcinoma. The tumor invaded omental adipose tissue and mesoappendix. Lymph nodes also demonstrated extensive metastases. A segment of sigmoid/rectal colon was densely infiltrated by tumor. Clinically the tumor was well confined within the abdomen. Cytogenetic analysis of tumor cells showed normal cells and a near tetraploid cell line ranging from 90 to 104 chromosomes. Ovarian cancers with chromosome involvement are grouped into two categories: those near diploid tumors having the lowest numerical changes with numerous structural changes and those near tetraploid tumors that possess abnormal centromeres with fewer structural rearrangements. This case had near tetraploid numbers and numerous structural rearrangements with at least 16 marker chromosomes. Based on GTG banding results, FISH analysis was performed with various probes to help elucidate the rearrangements and marker chromosomes. The results are cep1[Sat 11/111]x8 (1q12), D11Z1x4 (11p11.1q11), CCND1x4 (11q13), ATMx4 (11q22.3) MLLx4 (11q23), TELx2 (12q13), D12Z3x5 (12p11.1-q11), IGHx5 (14q32), p53x3 (17p13), D1721x5 (17p11.1-q11.1), HER2/neux6 (17q11.21-12), BCL2x4 (18q21), AML1x2 (21q21). The most distinctive marker, seen in every abnormal cell, was a chromosome approximately twice the size of chromosome 1. This derivative chromosome by FISH analysis was (cep1x1, wcp12+, TEL-, D12Z3x1). G-banding suggested one breakpoint at 1p31, while loss of TEL suggests a second break point at 12p13. Abnormalities frequently associated with ovarian cancers include additional copies of 1q, 3q and 20q, with loss of 4p, 4q, 18p, 18q and 19q. This case has eight copies of 1q12, including four copies of structurally normal 1's, one highly rearranged marker involving at least two additional chromosomes and three markers that appear to contain at least the entire 1q. There are four copies of BCL2 in two isochromosomes 18q, with no normal 18. Tumors with diploid and near diploid numbers contribute to a better prognosis and greater survival over those that are near tetraploid.

**Intracystic papillary carcinoma of breast harbors significant genomic alteration compared with intracystic papilloma: Genome-wide copy number and LOH analysis using high-density single-nucleotide polymorphism arrays.** *M. Oikawa[1,2], T. Nagayasu[1], H. Yano[1], T. Hayashi[3], K. Abe[3], N. Niikawa[4,5], K. Yoshiura[2,5]*. 1) Surgical Oncology, Nagasaki University Graduate School, Nagasaki, Japan; 2) Human Genetics, Nagasaki University Graduate School, Nagasaki, Japan; 3) Department of Pathology, Nagasaki University Hospital, Nagasaki, Japan; 4) Research Institute of Personalized Health Sciences, Health Sciences University of Hokkaido, Tobetsu, Japan; 5) Solution Oriented Research for Science and Technology (SORST), Japan Science and Technology Agency (JST), Tokyo, Japan.

**Purpose**: Intracystic papillary tumors of breast consist of benign papilloma, carcinoma in situ and carcinoma with invasion, which account for approximately 10% of benign breast tumors and less than 3% of malignant. The problem for the clinical management of these lesions is difficult to discern benign lesions from malignant preoperatively. Although the observation from genome-wide copy number and LOH analysis in these lesions may be helpful for resolving this problem, this kind of study has been scarcely conducted. By using high-density single-nucleotide polymorphism arrays, this study aimed to reveal the profile of genomic alteration in these lesions and search for the possibility of novel diagnostic method. **Method**: Eight samples of intracystic papillary tumors from Nagasaki University Hospital pathology archives that contained three pailloma (Pap), three papillary carcinoma in situ (PC) and two papillary carcinoma with invasion (IDC) were identified. Areas of tumor and normal tissue, which were identified by guide slide stained with hematoxylin and eosin, were microdissected from same formalin fixed paraffin embedded (FFPE) blocks respectively followed by three days of proteinase K treatment and DNA extraction with Qiagen DNA Mini Kit. Using probe intensity and genotype data from GeneChip Genome-wide Human 5.0 (Affymetrix), paired copy number and LOH analysis was performed by Partek Genomic Suite Software. Statistical analyses were calculated by R (version 2.8.0).**Result**: QC call rate, which is one of the indices measuring the quality of SNP microarray's experiment, were from 70.75% to 86.5%, mean 78.4%. The mean of total genomic alteration, which expressed as percent of the genome that is aberrant (sum of gains, losses and copy-neutral LOH), were 0.85%, 15.4% and 35.3% in Pap, PC and IDC respectively. Compared with benign tumors (Pap), malignant tumors (PC + IDC) had significantly more changes in their genome (Wilcoxon's rank sum test, p=0.035). Though they had a tendency to increase genomic alteration along with malignant phenotype, it wasn't statically significant among three diagnostic category (Kruskal-Wallis chi-squared test, p=0.062). **Conclusion**: Among intracystic papillary tumors of breast, malignant tumors even in non-invasive harbor significant genomic alteration, albeit with difficulty in diagnosis by histopathological method. Our finding may be helpful for clinical management of them.

## 1293/W/Poster Board #951

**Novel translocations (2;13)(p21;q14.11) and (6;17)(q23.3;p13.3) associated with genomic disturbance in two patients with myeloid neoplasms.** *J.L. Poitras[1], D. Costa[2], M.J. Kluk[3,5], P.C. Amrein[3,5], R.M. Stone[4,5], C. Lee[1,5], P. Dal Cin[1,5], C.C. Morton[1,2,5]*. 1) Pathology, Brigham and Women's Hospital, Boston, MA; 2) Obstetrics, Gynecology and Reproductive Biology, Brigham and Women's Hospital, Boston, MA; 3) Hematology/Oncology Unit, Massachusetts General Hospital, Boston, MA; 4) Department of Medical Oncology, Dana-Farber Cancer Institute, Boston, MA; 5) Harvard Medical School, Boston, MA.

Gross chromosomal rearrangements, particularly translocations, have proven a valuable tool in patient management through use in prognosis, diagnosis, and therapeutic intervention. Although many cancer genes have been illuminated by cytogenetic aberrations, hundreds of chromosomal rearrangements remain to be explored. The Tumor Genome Anatomy Project (TGAP) seeks to enhance annotation of the cancer genome through exploiting novel, uncharacterized rearrangements in diagnostic samples referred to the clinical cytogenetics laboratory. Using a systematic approach including FISH mapping, RT-PCR and sequencing, we have identified several candidate genes and novel gene fusions. Breakpoint mapping of two apparently balanced translocations, t(2;13)(p21;q14.11) and t(6;17)(q23.3;p13.3) in patients with myeloid neoplasms, detected concomitant deletions at or adjacent to all breakpoints. Array CGH on the 244K Agilent platform refined the deletion boundaries, revealing a 195 kb deletion at 2p21, a 1.4 Mb deletion distal to the 13q breakpoint at 13q14.3, a 1.7 Mb deletion directly adjacent to the 6q23.3 breakpoint, and a 562 kb deletion at 17p13.3. Additionally, a 133 kb deletion within the breakpoint region at 13q14.11 and a 265 kb deletion proximal to the breakpoint were discovered, neither of which were detected by FISH. While no obvious gene fusion resulting from either novel rearrangement can be determined from these data, possible formation of a fusion transcript cannot be ruled out because the levels of resolution of techniques used compromises delineation of the precise location of the breakpoints. Although the clinical relevance of these focal imbalances remains to be evaluated, cases presented here support high resolution evaluation of presumably balanced rearrangements in neoplasms. Such imbalances may portend important hitherto unrecognized prognostic and diagnostic categories.

## 1294/W/Poster Board #952

**High-resolution array-based comparative genomic hybridization detection of copy number changes in desmoplastic melanoma and malignant peripheral nerve sheath tumor.** *J.G. Pryor[1], B.A. Brown-Kipphut[1], G.A. Scott[2], M.A. Iqbal[1]*. 1) Pathology, University of Rochester Medical Center, Rochester, NY; 2) Dermatology, University of Rochester Medical Center, Rochester, NY.

Desmoplastic melanoma and malignant peripheral nerve sheath tumor (MPNST) can appear morphologically similar, posing diagnostic difficulties even with use of immunohistochemical stains. We attempted to determine whether whole genome microarray comparative genomic hybridization (aCGH) analysis could be used to detect copy number differences between these two tumors and potentially aid in diagnosis. Immunohistochemistry with antibodies directed against the S-100 protein was performed on 5 cases of desmoplastic melanoma, 8 cases of MPNST, and 1 normal lymph node control using formalin-fixed, paraffin-embedded archival specimens. Genomic DNA was extracted from microdissected tumor cells and lymphocytes. To obtain adequate quantities of DNA for performance of aCGH, whole genome amplification (WGA) was required for 5/5 desmoplastic melanoma cases and 6/8 MPNST cases. A portion of DNA from the lymph node control was also amplified to assess for amplification bias. A gel-based 5-primer multiplex PCR assay was used to determine the quality of the DNA samples, with the amplified and unamplified lymph node control, 5/5 desmoplastic melanomas and 5/8 MPNSTs (3 amplified and 2 unamplified) considered of adequate quality for aCGH. DNA samples were fluorometrically quantitated then run on PerkinElmer's SpectralChip 2600 BAC array platform, scanned on a GenePix 4000B scanner, then analyzed using Spectralware BAC array analysis software. Cytogenetic abnormalities present in the amplified but not the unamplified lymph node control were considered amplification bias and not reported for the test samples. Desmoplastic melanoma and MPNST exhibited karyotypic complexity and shared a number of cytogenetic abnormalities, including gains of 4p11-4q11, 4q32, 7p23-pter, 7q31-32, and 12q13, and losses of 4q28, 6q26-qter, 9p21-p22, 9p23-pter, chromosome 10, 11q23-qter, and 15q13-14. Changes present in some cases of desmoplastic melanoma but not MPNST included gains of 1p12-p34, 9q21-31, and 12p13, and losses of 5p14-pter, 11p, 13q14-21, 15q22-qter, and 17q11-12. Selective validation with fluorescence in-situ hybridization (FISH) was performed. We conclude that desmoplastic melanoma and MPNST share both morphologic and cytogenetic similarities. Genetic loci that may be involved in the tumorigenesis of these tumors will be presented.

## 1295/W/Poster Board #953

**A novel unknown translocation partner on chromosome 2 or chromosome 5 for the EWSR1 gene in Ewing Sarcoma.** *S. Shetty[1], N. Uddin[1,2], K.B. Geiersbach[1], S.T. South[1,2]*. 1) University of Utah, School of Medicine, Department of Pathology, Salt lake City, Utah and Cytogenetics/Molecular Cytogenetics, ARUP Laboratories, Salt Lake City, UT; 2) University of Utah, School of Medicine, Department of Pediatrics, Salt lake City, Utah and Cytogenetics/Molecular Cytogenetics, ARUP Laboratories, Salt Lake City, UT.

Ewing sarcoma is a common malignant round cell tumor of childhood and adolescence. Cytogenetic analysis to identify a common t(11;22)(q23;q12) or less frequently a t(21;22)(q22;q12) or t(7;22)(p22;q12) plays an important role in confirmation of the clinical diagnosis. The genetic mechanism, in majority of the cases, involves fusion of EWSR1 gene on 22q12 with a member of the ETS family of transcription factors. We report a case of a 20-year-old male who had a soft tissue tumor on the left scapula. Conventional cytogenetic analysis on unstimulated suspension culture revealed a complex karyotype with numerical and structural abnormalities. No chromosomal rearrangement involving the EWSR1 region was recognized and all cells from the monolayer culture were karyotypically normal. However, the biopsy results were consistent with the diagnosis of Ewing Sarcoma. Immunohistochemistry was positive for CD99 and vimentin and negative for AE1/3, CAM 5.2, CD45 and Fli1. To identify a cryptic rearrangement, fluorescence in situ hybridization (FISH) on interphase cells was performed utilizing the LSI EWSR1, dual-color break-apart rearrangement probe. FISH findings revealed two normal fusion signals and an extra signal for the 5' EWSR1 region suggestive of a rearrangement and deletion of the 3' EWSR1. FISH on G banded metaphases from unstimulated suspension culture identified that the extra 5' EWSR1 signal was on chromosome 2. Based on G-banding and FISH findings, the derivative chromosome 2 was shown to consist of a translocation between 2q and 5q with an insertion of the long arm of the 22q12 (approximately between bands 2q12~13 and 5q13. These findings suggest that an insertion event involving the EWSR1 locus on chromosome 22 is another mechanism that could lead to EWSR1-unknown partner gene fusion. To our knowledge, this is the first case report of an insertion of a segment of the EWSR1 region with a possible novel translocation partner on either chromosome 2q12~13 or 5q13 in Ewing sarcoma. This case also highlights the importance of chromosome studies in addition to FISH to understand the genetic mechanism and aid in identifying new partners for the EWSR1 gene on unstimulated suspension cultures in round cell tumors. Based on FISH findings alone, rearrangement of EWSR1 in this case would have been just a postulate and the rearrangements would have been missed if only monolayer culture was analyzed.

### 1296/W/Poster Board #954

**Acute myeloid leukemia with inv(16), 3'*CBFB* deletion, variant t(9;22) & del(7)(q) in a pediatric patient, a case report.** *N. Uddin[1], W. Chen[2], A. Arbini[2], L. Klesse[3], N. Karandikar[2], M. Almiski[2], I. VIllalobos[1], CA. Tirado[1].* 1) Clinical Cytogenetics, Department of Pathology, University of Texas Southwestern Medical Center at Dallas, Dallas, TX; 2) Hematopathology, Department of Pathology, University of Texas Southwestern Medical Center at Dallas, Dallas, TX; 3) Hematology/Oncology, Department of Pediatrics, University of Texas Southwestern Medical Center at Dallas / Children's Medical Center, Dallas, TX.

Coexistence of inv(16) and t(9;22) has been described, rarely in chronic myelogenous leukemia (CML) and in *de-novo* acute myeloid leukemia (AML) (~7 case reports, only one pediatric case). To the best of our knowledge, we describe the first pediatric case of AML with inv(16) and variant t(9;22) along with 3'*CBFB* deletion and del(7)(q). The patient was a -13-year old male who presented with a 3 month history of night sweats, weight loss and a 2 weeks history of swollen lymph nodes, fever, fatigue, and petechiae. Peripheral blood showed circulating blasts. Bone marrow biopsy revealed a predominant population of large blasts with variably irregular nuclei, dispersed chromatin, variably prominent nucleoli and scant to moderate amounts of cytoplasm. Some of the immature cells had features of promonocytes. Eosinophilia was largely absent. Flow cytometeric analysis showed immunophenotypically aberrant myeloblasts with a small population of mildly aberrant monocytes. Conventional and molecular cytogenetic analysis on blood showed three related abnormal clones, with a stem line showing inv(16), and described as 46,XY,inv(16)(p13.1q22)[2]/46,idem,-del(7)(q22q32)[16]/46,idem,t(9;22;19)(q34;q11.2;p13.1). Interphase FISH with break-apart *CBFB* probe (Vysis, Inc.) showed 3'*CBFB* deletion. FISH analysis using chromosome 16 Telomere probe (Vysis, Inc.) together with *CBFB* probe on abnormal metaphases confirmed the presence of 5'*CBFB* on the short arm of inv(16) while 3'*CBFB* was deleted on the long arm. Deletion 7q was also confirmed by FISH. Metaphase FISH with dual fusion probe for *BCR/ABL* rearrangement [t(9;22)] (Vysis, Inc.) confirmed the presence of Philadelphia chromosome and involvement of chromosome 19 in the variant rearrangement. The patient was initially leukoreduced secondary to respiratory distress and then treated with standard AML chemotherapy. He also received Gemtuzumab as part of a clinical trial and is currently in remission. Limited data suggests that the prognosis in *de-novo* AML cases with both inv(16) and t(9;22) seems favorable. Found rarely, the significance of the 3'*CBFB* deletion with inv(16) is unclear. Few cases of inv(16) with this deletion have shown an aggressive behavior. Deletion 7q occurs uncommonly with inv(16) and there is no apparent prognostic difference. Due to rarity and complex chromosomal aberrations, the exact clinical behavior in this case is difficult to predict. Long-term follow-up would provide further prognostic information.

### 1297/W/Poster Board #955

**Further Evidence of Poor Prognosis For Patients With Variant BCR/ABL1 Fusion Patterns.** *A. Zaslav[1], T. Mercado[1], T. Pardee[2], S. Richard[2], S. Spitzer[3], E. Knorr[1], D. Tully[1], K. Zamkoff[4].* 1) Dept Pathology, Cytogenetics Laboratory, Stony Brook Univ Hosp, Stony Brook, NY; 2) Blood and Marrow Stem Cell Transplantatiion Program, Stony Brook University Medical Center, Stony Brook, NY; 3) Dept Pathology, Molecular Diagnostics Laboratory, Stony Brook Univ Hosp, Stony Brook, NY; 4) Hematology and Oncology, Wake Forest University Medical Center, Winston Salem, NC.

Patients with chronic myelogenous leukemia (CML) typically have the Philadelphia (Ph) chromosome. Ph results from a reciprocal translocation of chromosomes 9 and 22 [i.e., t(9;22)(q34;q11.2)]. Approximately 10% to 15% of patients with CML have an apparently normal karyotype but are Ph+ using fluorescence in situ hybridization (FISH) and or reverse transcriptase polymerase chain reaction (RT-PCR). FISH identified variant abnormal signal patterns in these patients, which have been associated with a more rapid progression to blast crisis and a shorter overall survival. Initial studies on these patients were based on protocols using allopurinol, hydroxyurea, and interferon. With the introduction of imatinib mesylate in 2001 more recent studies demonstrated that this may also be true for these patients on imatinib therapy. We previously reported on three Ph+ CML patients with variant abnormal signal patterns. Here, we present the follow-up data on these patients. The patients were evaluated multiple times during treatment. Two patients failed treatment and one patient demonstrated complete remission. Even though our patient sample was small the data corroborates that CML patients with variant abnormal signal patterns have a worse prognosis than those with typical abnormal signal patterns. Here, we discuss the clinical, cytogenetic, FISH and molecular data on three patients, the possible mechanisms involved in the formation of these variant abnormal signal patterns and the clinical significance of these findings.

### 1298/W/Poster Board #956

**High rate of genetic abnormalities of neoplastic cells in pseudofollicles of CLL.** *Z. Balogh[1], L. Reiniger[1], H. Rajnai[1], J. Csomor[1], A. Szepesi[1], A. Balogh[2], L. Deak[1], E. Gagyi[1], C. Bodor[1], A. Matolcsy[1].* 1) Ist Department of Pathology and Experimental Cancer Research, Faculty of Medicine, Semmelweis University, Budapest, Hungary; 2) TARKI Social Research Institute/ Department of Statistics, Faculty of Social Sciences, Eotvos Lorand University, Budapest, Hungary.

Several lines of evidences suggest that lymph node microenvironment is critical for survival of chronic lymphocytic leukaemia (CLL) cells. In lymph nodes neoplastic cells (prolymphocytes and paraimmunoblasts) form pseudofollicles (PFs) which are also known as proliferation centers. To reveal whether PFs play a role in generation of genetic alterations in CLL we compared deletion at p53, ATM and RB-1 loci and trisomy 12 by fluorescent in situ hybridization (FISH) technique in PFs versus surrounding small lymphocytes in 12 formalin-fixed paraffin-embedded (FFPE) lymph nodes. The FFPE sections were stained with methylene blue and PFs were marked by laser. Subsequent FISH analysis was performed relocalizing the previously defined regions. Loss of 11q was detected in 5 cases, loss of 13q in 2 cases, loss of 17p in 2 cases and trisomy 12 was found in 1 case. In 7 cases PFs contained significantly higher ratio of cells with genetic alterations than the surrounding areas. Our results revealed higher rate of genetic abnormalities in PFs suggesting that these sites play a role in the generation or accumulation of cells with genetic abnormalities. The accumulation of genetic lesions in PFs denotes that genetic progression and transformation of CLL may begin in these proliferation centers.

### 1299/W/Poster Board #957

**FISH ANALYSIS OF BCL-2 AND BCL-6 REARRANGEMENTS IN GERMINAL CENTER AND NON-GERMINAL CENTER TYPES OF DIFFUSE LARGE B-CELL LYMPHOMA IN CHINA.** *C. Simien, M. Littlejohn, P. Hu, Ph.D., A. Lennon, Ph.D., W. Im, R. Pepper, P. Lin, M.D., L. Jeffrey Medeiros, M.D., C. Cameron Yin, M.D., Ph.D.* Program in Molecular Genetic Technology, School of Health Professions and Department of Hematopathology, University of Texas M.D. Anderson Cancer Center, Houston, Texas 77030.

Fluorescence *in situ* Hybridization (FISH) can be used to visualize chromosomal rearrangements in the context of tissue biopsy specimens. Diffuse Large B-Cell Lymphoma (DLBCL) is a heterogeneous disease. In the United States and European patient populations, *BCL-2* and *BCL-6* gene rearrangements have been shown in approximately 20% and 45% of DLBCL cases, respectively. Furthermore, gene expression profiling studies have shown two major prognostic groups: germinal center B-cell-like (GCB) and non-GCB. We investigated the frequency of *BCL-2* and *BCL-6* rearrangements in 63 DLBCL cases from China using FISH break-apart probes, including 21 (33.3%) cases of GCB type and 42 (66.7%) cases of non-GCB type. The GCB and non-GCB types were defined by immunohistochemical analysis using antibodies specific for CD10, BCL-6 and MUM-1 suggested by Hans et al (Blood 2004; 103:275-282). We found that 11 of 50 (22.0%) DLBCL were positive for *BCL-2* rearrangements (range of signals, 8-56%; median 11%). Additionally, 11 of 32 (34.4.0%) DLBCL were positive for BCL-6 rearrangements (range of signals, 12-55%; median, 46%). *BCL-2* rearrangements were found in 5 of 19 (26.3%) of GCB cases and 6 of 31 (19.4%) of non-GCB cases. *BCL-6* rearrangements were found in 5 of 14 (35.7%) of GCB cases and 6 of 18 (33.3%) non-GCB cases. It is noteworthy that three cases (1 GCB, 2 non-GCB) were positive for both *BCL-2* and *BCL-6* rearrangements. The frequency of *BCL-2* rearrangements in our study is similar to what has been reported in the western world. However, *BCL-6* rearrangement appears to be less frequent in the Chinese population. There is no clear relationship between DLBCL subtypes and *BCL-2* or *BCL-6* rearrangement. To our knowledge, this is one of the largest studies to assess the prevalence of *BCL-2* and *BCL-6* rearrangements in different types of DLBCL from China.

## 1300/W/Poster Board #958

**Mono- and bi-allelic deletions of 13q14.3 in B-cell chronic lymphocytic leukemia (B-CLL): FISH vs. miRNA RT-PCR detection.** *A. Block[1], M.T. Smonskey[2], G. Deeb[3,5], A.A. Chanan-Khan[4], Z.P. Bernstein[4], K.C. Miller[4], P.K. Wallace[5], P. Starostik[2].* 1) Clinical Cytogenetics Lab, Roswell Park Cancer Inst, Buffalo, NY; 2) Molecular Diagnostics Lab, Roswell Park Cancer Inst, Buffalo, NY; 3) Department of Pathology, Roswell Park Cancer Inst, Buffalo, NY; 4) Department of Medicine, Roswell Park Cancer Inst, Buffalo, NY; 5) Laboratory of Flow Cytometry, Roswell Park Cancer Inst, Buffalo, NY.

To develop risk-adapted strategies, prognostic factors are needed to allow for the prediction of individual patient clinical course. Deletion of 13q14.3 (del13q) is the most common molecular cytogenetic abnormality in B-cell chronic lymphocytic leukemia (B-CLL) and is associated with favorable prognosis. This deletion is frequently observed as the sole abnormality in B-CLL, suggesting a pathogenic role for genes in this region. MicroRNAs (miRNA), a new class of gene regulators, have recently been implicated in B-CLL pathogenesis, with frequent deletions and down-regulation of miR-15 and miR-16 at 13q14.3. In this study, we compared fluorescence in situ hybridization (FISH) and real-time miR-15a and miR-16-1 RT-PCR as methods to detect del13q. We analyzed 26 B-CLL patients (pts) showing either mono-allelic (19 pts) or bi-allelic deletion (7 pts) of the locus specific probe D13S25 mapped at 13q14.3 and detected as a sole abnormality by FISH. Both mono-allelic (del13qx1) and bi-allelic (del13qx2) pts were remarkably homogeneous in clinical presenting features (low Rai stage, male predominance, negative ZAP-70 status), with the del13qx2 group older (median age 65 yrs) when compared with the del13qx1 group (median age 58 yrs). miR-15a and miR-16-1 expression was measured as compared to the U6 standard and quantified as a percentage of the U6 using the delta $C_t$ method. Differences in miR-15a and miR-16-1 were examined using a group of trisomy 12 pts as a control. As expected, del13q samples showed lower expression of miR-15a than trisomy 12 samples (mean of 30% vs. 44.8%, respectively); within the del13q samples, the three lowest levels of miR-15a were seen in del13qx2. In contrast, miR-16-1 expression varied widely among these three groups, with the highest levels detected in del13qx1. Due to the high variability of miR-15a levels in the 13q14.3 cases, we were not able to detect a specific cut-off in regards to miR-15a and miR-16-1 expression levels for cases with del13q. As a result, we conclude that discrimination between cases with and without the deletion is better accomplished by FISH.

## 1301/W/Poster Board #959

**IgHV Deletion Detected by Florescence in-situ Hybridization Appears to be a Marker of Poor Prognosis in Plasma Cell Myeloma.** *K. Jabbar, LJ. Medeiros, M. Wang, Lu. Gary.* Department of Hematopathology, and Department of Lymphoma and Myeloma, UT MD Anderson Cancer Center, Houston, Texas, USA.

Plasma cell myeloma (PCM) is a bone-marrow-based, multifocal neoplasm of plasma cells, usually associated with a variety of clinical laboratory findings including an M protein in serum and/or urine. It is genetically heterogeneous. Multiple genomic abnormalities can be observed in up to 90% of cases by Florescence in-situ Hybridization (FISH) during the course of disease development. About 75% of the cases demonstrate rearrangements involving IgH locus, including the unfavorable FGFR3/IgH and the fair prognostic CCND1 XT/IgH. In this study, we report a new genomic marker, IgHV deletion detected by FISH, in 7 PCM cases selected from the MD Anderson Cancer Center database dated from May 2008 to May 2009. All the 7 cases were accessed with complete ancillary studies including routine Cytogenetics, FISH, bone marrow morphologic examination, and flow cytometry. There were 5 men and 2 women, with ages ranging from 52 to 72 years (mean, 62.3). Conventional cytogenetics results were available at time of initial presentation in 5 cases, showing a diploid karyotype in 4, and multiple complex abnormalities in 1. In subsequent follow up samples, FISH showed IgHV deletion in all cases, present in 8.5-49.5% cells (mean, 24.2%), and also demonstrated none of the unfavorable prognostic markers, del(13q) and del(17p), in three cases, two of the three were positive for CCND1 XT/IgH rearrangement. Concurrent routine cytogenetics revealed clonal chromosomal abnormalities in 5 cases. Examination on bone marrow aspirate smears demonstrated increased plasma cells, ranging 29-86%, with greater than 50% replacement of biopsy specimens in 5 of 7 cases; atypical morphology was observed in 4 cases. CD56 expression, an unfavorable immunophenotypic marker, was absent in 5 cases assessed, and CD20 was expressed in 1 case. All 7 patients had increased serum $\beta$2 microglobin levels, ranging from 4.2 to 25.1 with a mean of 10.4 MG/L. Retrospective FISH studies on slides available from samples collected at patient's initial presentation were performed in 3 cases and revealed negative for the IgHV deletion. All 6 patients with adequate follow-up presented with an aggressive clinical course after detection of IgHV deletion; 3 were refractory and 3 showed partial response to high-dose chemotherapy. In conclusion, our results suggest that IgHV deletion in PCM is a marker of unfavorable prognosis and poor response to treatment.

## 1302/W/Poster Board #960

**Hyperdiploid and nonhyperdiploid multiple myeloma subtypes detected by array-based comparative genomic hybridization.** *S.R. Gunn[1,2], M.E. Gorre[1], M.S. Mohammed[1], M.C. Kinney[2], R.S. Robetorye[2].* 1) Combimatrix Molecular Diagnostics, Irvine, CA; 2) Department of Pathology, University of Texas Health Science Center, San Antonio, TX.

Multiple myeloma (MM) is a clinically heterogeneous hematological malignancy recently categorized into prognostically important major aneuploidy groups based on the total chromosomal DNA content of the tumor genome. Classification of MM as hyperdiploid or nonhyperdiploid and identification of associated genomic alterations is an important part of risk stratification and treatment planning in newly diagnosed patients. However, the potential clinical impact of MM risk stratification has been hampered by the limited ability of commonly available clinical diagnostic techniques to consistently determine ploidy status and identify genetic alterations. These limitations include the low percentage of cytogenetic abnormalities detected by conventional G-banded karyotyping, the loss of global genome perspective with targeted FISH, and lack of locus specificity when DNA is quantified by flow cytometry. Here, we describe the application of a customized comparative genomic hybridization microarray (array CGH) for classification of newly diagnosed cases of MM into hyperdiploid and nonhyperdiploid subtypes. Genomic DNA was extracted from bone marrow aspirates of three patients with a clinical diagnosis of MM but whose routine cytogenetic results were uninformative. Tumor genomic profiles were determined with customized targeted bacterial artificial chromosome (BAC) arrays designed and validated for clinical identification of global chromosomal features as well as structural abnormalities associated with specific congenital syndromes. Array CGH results successfully showed genomic imbalances consistent with major MM aneuploidy groups in all patients. Based on global tumor genome presentations, two cases were categorized as hyperdiploid and one case was nonhyperdiploid. These same whole genome profiles also enabled determinations of overall genomic instability associated with hyperdiploid MM. In addition, results revealed structural abnormalities associated with shortened survival such as losses of 1p, 17p, and rearrangements involving the IgH locus. By facilitating incorporation of information about tumor genomic aberrations into clinical decision making, array CGH has great potential to positively impact patient management and care in multiple myeloma and other hematological malignancies.

## 1303/W/Poster Board #961

**Identifying DNA copy number aberrations to predict response to neoadjuvant chemotherapy in breast cancer patients.** *J.H. Woo[1], W. Han[2,3], S.J. Yang[1], K.S. Yang[1], D.Y. Noh[2,3].* 1) Macrogen, Inc., Seoul, South Korea; 2) Department of Surgery, Seoul National University College of Medicine, Seoul, South Korea; 3) Cancer Research Institute, Seoul National University College of Medicine, Seoul, South Korea.

It has been reported that only 40%~60% percent of breast cancer patients respond to neo-adjuvant (pre-surgical) chemotherapy. Without robust criteria for predicting this response, a significant number of patients will incur unnecessary financial burden, and adverse side effects. In this study, we applied array comparative genomic hybridization (array CGH), containing over 4,000 BAC probes, evenly distributed across the human genome at 1 Mb intervals, to identify putative genomic markers associated with chemotherapy response in tumor cells from 63 breast cancer patients that have received Docetaxel and Doxorubicin before surgical treatment. Genomic imbalances were detected at eight chromosomal loci (encompassing 24 clones), and these were correlated with change of tumor size ($p<0.05$ by t-test), as measured by Magnetic Resonance Imaging (MRI) before and after neoadjuvant therapy. Excluding regions that were previously known to be frequently altered in breast cancer cells, and prioritizing regions containing candidate genes, we finally selected two regions, 17p12 and 17q21.32-33, as putative genomic markers for predicting this drug response in breast cancer. The genes located in these regions, included ABCC3, and the HOXB families, members of subfamilies involved in multi-drug resistance and associated with prognosis of breast cancer patients. Twenty-one breast cancer samples were subsequently assembled for an independent validation study to further evaluate the predictive performance of these two genomic regions. In this case, we assessed copy numbers of the two regions using multicolor FISH (fluorescence in situ hybridization) assays as a technical validation. In independent validation data sets, classification models developed through the most commonly used machine learning techniques (artificial neural network, logistic regression, and decision Tree) all showed 80.95% prediction accuracy. We have identified two genomic regions that have >80% prediction accuracy for identifying breast cancer patients that will respond to pre-surgical chemotherapy. Further studies will included identifying the minimal critical regions as well as determining the mechanisms leading to a differential response in this patient population.

**Genome-wide Association Analysis of Copy-Number Variation (CNV) in Glioblastoma.** *H. Siu[1,2], H. Dong[1,2,3], G. Peng[1], Y. Wang[1,2], R. Chen[4], M. Xiong[1,3].* 1) Laboratory of Theoretical Systems Biology, School of Life Science, Fudan University, Shanghai, 200433, China; 2) State Key Laboratory of Genetic Engineering and MOE Key Laboratory of Contemporary Anthropology, School of Life Sciences and Institutes of Biomedical Sciences, Fudan University, Shanghai, 200433, China; 3) Human Genetics Center, University of Texas School of Public Health, Houston, TX 77225; 4) Department of Molecular and Human Genetics Baylor College of Medicine Houston, TX, 77030.

Copy-number variation (CNV) constitutes a large proportion of total genomic variation and is increasingly recognized to be an extremely important risk factor for cancer. To examine the role of CNVs in glioblastoma, a genome-wide association studies of CNVs in glioblastoma was conducted by assaying 221 tumor tissues and 28 normal tissues samples from primary glioblastoma multiform patients in TCGA project. CNVs were measured by the Affymetrix Genome-Wide Human SNP Array 6.0 with 906,600 SNPs and more than 946,000 probes for the detection of copy number variation. CNVs were called by the modified hidden Markov Models (HMM) and 163024 CNV loci were detected. A total of 197 CNV loci with P-value<2.25E-7 showed significant association with glioblastoma. We also did group association tests of CNV with glioblastoma by gene and pathway. We identified 169 genes with P-values <4.77E-6, including oncogene BCAS1, tumor repress genes CAMTA1, APC and CSMD1, transcription factor ELF2, and transcription activator genes ETV1, CREB5 and ZHX3, which were significantly associated with glioblastoma. Copy number changes in these genes significantly affect the expression of 19 microRNAs and 410 genes. We also identified 19 significantly associated pathways with glioblastoma with FDR <0.05. These significant pathways include Metabolism of xenobiotics by cytochrome P450, Regulation of actin cytoskeleton, Double Stranded RNA Induced Gene Expression pathway, Regulation of eIF2 pathway, Tight junction, Skeletal muscle hypertrophy is regulated via AKT/mTOR pathway, Keratinocyte Differentiation pathway, Drug metabolism - cytochrome P450, Cell cycle, Glioma pathway. Our results provide important clues for investigation of the mechanisms and drug targets of glioblastoma.

**"A cryptic t(1;21;8)(p36.1;q22;q22): A variant involving a single *RUNX1/RUNXT1* fusion in a patient with acute myeloid leukemia (AML-M2)".** *F.J. Valdez[1], W. Chen[1], R. Collins[3], S. Henderson[1], R. Garcia[1], S. Holdridge[1], C. Chastain[1], R. Smart[1], M. Auchus[2], J. Doolitle[3], P. Horna[1], C.A. Tirado[1].* 1) Pathology, UTSouthwestern Medical Center, Dallas, TX; 2) Internal Medicine-Endocrinology, UTSouthwestern Medical Center, Dallas, TX; 3) Internal Medicine-Hematology-Oncology, UTSouthwestern Medical Center, Dallas, TX.

The t(8;21) accounts for 5-12% of AML patients, often occurring in the younger population. This translocation fuses the *RUNX1* gene (formerly *AML1*) on chromosome 21q22 to the *RUNX1T1* (formerly *ETO*) on 8q22 resulting in a *RUNX1-RUNX1T1* hybrid transcript. Under the World Health Organization (WHO) classification, the t(8;21) is distinctly characterized under AML with recurrent genetic abnormalities associated with a favorable prognosis. Variant t(8;21;var) display similar clinical manifestations compared to the classical translocation; however, they are less defined and their clinical significance remains debatable. Complex t(8;21) variants account for approximately 3-4% of all *RUNX1-RUNX1T1* fusion transcripts with approximately 100 variants described in the literature. Here, we report a 45 year-old male patient whose bone marrow revealed an abnormal myeloid blast population with morphologic and immunophentotypic features suggestive of AML with t(8;21)(q22;q22). There were no markers suggestive of a more complex cytogenetic abnormality. However, conventional cytogenetic analysis revealed an apparently balanced translocation between the short arm of chromosome 1 at 1p36 and the long arm of chromosome 8 at 8q22. Fluorescence in situ hybridization (FISH) analyses using the AML1/ETO probe showed a cryptic variant (1;21;8) translocation with a single fusion *RUNX1/RUNX1T1* on the derivative chromosome 8, a small *RUNX1T1* signal on chromosome 1, a *RUNX1T1* signal on the normal copy of chromosome 8, a *RUNX1* signal on the normal copy of chromosome 21 and a small *RUNX1* signal on the derivative chromosome 21. Additional FISH studies utilizing the 1p36 (LSI p58) probe showed that a portion of chromosome 1 at 1p36 was translocated to 21q22. This report demonstrated the existence of a three-way translocation which appeared cryptic by classical cytogenetics as well as the importance of performing FISH studies in conjunction with immunophenotypic, morphologic and clinical information to characterize a specific variant rearrangement for good patient management.

## 1306/W/Poster Board #964

**Xq Duplication in three member of a family.** *V. Catala[1], C. Garrido[1], E. Gean[2], J. Amstrong[2], E. Cuatrecasas[1], A. Seres-Santamaria[1].* 1) Prenatal Genetics SL, Barcelona, Catalonia, SPAIN; 2) Unitat de Genètica. Hospital Sant Joan de Déu, Barcelona, Catalonia, SPAIN.

Duplication of any region of the X chromosome in 46,XY males, with the exception of pseudoautosomic regions, leads to a disomy of functional genes within the duplicated region. In women, this anomaly may go unperceived because the phenotype is usually normal. The duplication Xq prevalence is unknown. We report a 21 years old patient. Clinical features: severe mental retardation, epilepsy, absence of language and loss of ambulation. His older brother died few years earlier without diagnosis. There was no chromosomal abnormality in the cytogenetic study of the patient. The study of subtelomeric regions using FISH techniques showed the existence of a Xqter duplication and a Xpter deletion (an extra Xqter signal was observed in the Xpter region, indeed an X chromosome with 2 Xqter signals)). The abnormal X chromosome has been inherited from the mother. The mother has a normal X chromosome, and the second X chromosome has a Xqter duplication and Xpter deletion (one Xqter signal in each chromosome end) (demonstrated by FISH ). The patient study using MLPA technique (SALSA MLPA KIT P015-D2 MECP2 and CDKL5 KIT P189) shows overlap in the region Xq28 and Xp22 deletion in the patient. The DNA study of the dead brother and the mother could be made both checking the duplication Xq28 and Xp22 deletion in both cases. In our patient, the application of MLPA and FISH techniques has been decisive to the diagnosis. This has led to genetic counseling and to give the family the possibility of a reliable prenatal or preimplantation diagnosis, in the case of a new pregnancy.

## 1307/W/Poster Board #965

**Prenatal diagnosis of a de novo mosaic isochromosome 18p : karyotype discordance between amniocytes and fetal/neonatal blood.** *M. Kim[1], C. Park[1], S. Park[2], M. Kim[1], B. Lee[2], M. Lee[2], D. Kim[2], H. Ryu[1].* 1) Department of Obstetrics and Gynecology, Cheil General Hospital & Women's Healthcare Center, Kwandong University, College of Medicine, Seoul, Korea; 2) Laboratoy of Medical Genetics,Cheil General Hospital & Women's Healthcare Center, Kwandong University, College of Medicine, Seoul, Korea.

Isochromosome 18p is a rare chromosome abnormality and results in tetrasomy 18p. The tetrasomy 18p syndrome most often expresses itself with moderate to severe mental impairment, very delayed speech, poor ability to self feed, much delayed ability to walk, microcephaly, congenital heart diseases. We report a case of a newborn infant prenatally diagnosed de novo mosaic isochromosome 18p. A 38 year old G4P2 pregnant woman presented at 20 weeks and 4 days due to advanced maternal age. The fetal ultrasound showed an absent cavum septum pellucidum without associated anomaly. The quantitative fluorescent PCR on uncultured amniocytes showed unusual skewed allele ratio at a single locus for short arm of chromosome 18. The conventional cytogenetic study of cultured amniocytes showed a male karyotype with an additional metacentric chromosome in 29/83 colonies . The additional metacentric chromosome was confirmed as isochromosome 18p by FISH probes specific for centromere and short arm of chromosome 18. The parental karyotypes were normal. Karyotpe of lymphocytes of fetal blood at 23 weeks and 6 days was normal 46,XY. After genetic counseling, the couple opted to continue the pregnancy. A living male baby was delivered by Cesarean section at 39 weeks, with a birth weight 2,670 gm. There was no demonstrable external and internal abnormality. The echocardiogram and abdominal ultrasonogram of newborn were normal findings. The newborn had normal reflexes and no feeding disability. The neonatal brain ultrasound confirmed the absent cavum septum but there was no any other abnormality in brain. Conventional cytogenetic study of cord blood at delivery revealed a normal karyotype. The newborn was healthy until 4 weeks after birth. However, long-term evaluation of growth and development is required.

## 1308/W/Poster Board #966

**Recurrent Aneuploidies associated with maternal and paternal non-disjunction in the same sibship.** *L. Martelli[1], C.S. Pereira[1], S.A. Santos[1], F.B. Machado[1,2], L.M. Batista[1], L.A.F. Laureano[1], J. Huber[1], L.C. Veiga-Castelli[1].* 1) Dept Genetics-FMRP, Univ Sao Paulo, Ribeirao Preto, SP, Brazil; 2) UENF, RJ, Brazil.

Chromosome aneuploidy is the major cause of pregnancy wastage. Chromosome segregation errors may arise by non-disjunction during premeiotic mitotic division in the germline of either parent, a first or second meiotic division in either parent, premature separation of sister chromatids or an early embryonic mitotic division. Increasing maternal age remains the only clear risk factor associated with aneuploidy, and has been used predictively to assess risk of meiotic non-disjunction. Genetic variations in centromeric factors, proteins involved in chromatin structure, reduced recombination in meiosis, have also been suggested to affect the chromosome segregation. Down and Turner syndromes are the most common aneuploidies among liveborns and both can be a result of maternal and paternal non-disjunction. We described a young healthy unrelated couple with three children, all of them with chromosome aneuploidies. There was no family history of congenital anomalies, mental retardation or miscarriages. Maternal and paternal ages were respectively 17 and 18 years old at the first gestation. The first child was a 12 year-old boy presenting clinical features compatible with Down syndrome and karyotype 47,XY,+21. The other two children were 7 and 8 year-old girls respectively, both diagnosed as Turner Syndrome with 45,X karyotype. GTG banding analysis revealed normal karyotypes for both parents and somatic mosaicism was excluded. The parental origin of non-disjunctional error was determinated using specific DNA polymorphisms of chromosomes 21 and X. The loci studied were the microsatellites at loci D21S226, IFNAR and D21S1411. The meiotic stage of 21 non-disjunction was assigned on the basis of the pericentromeric marker D21S11. The markers DXS996, DXS1283E, DXS981, DXS1187, HPRT and P39 were used for identification of the parental origin of the X chromosome. Interestingly, the trisomy 21 was found to have arisen by maternal non-disjunction in meiosis II, while the missing X chromosome in the two females with Turner syndrome were found to be paternal. In this family, the observed recurrent paternal origin is not in keeping with the idea that spermatogenesis is more effective in selecting against unbalanced gametes than oogenesis. Identification of parental origin in families with multiple cases of non-disjunction is highly informative for accurate genetic counseling, and provides insight into the causes of recurrent aneuploidy in humans.

## 1309/W/Poster Board #967

**A new case of Double Aneuploidy Mosaicism: 47,XX,+8 / 45,X.** *K. Enomoto[1,2], K. Iju[1], K. Kurosawa[2], M. Ohta[1].* 1) Department of Pediatrics, Toride Kyodo General Hospital, Toride, Japan; 2) Division of Medical Genetics, Kanagawa Children's Medical Center, Yokohama, Japan.

Double aneuploidy mosaicism is a rare chromosomal disorder, characterized by the presence of two different aneuploidy cell lines. The mosaicism of 45,X in combination with trisomy of chromosomes 7, 8, 10, 13, 18, or 21 has been previously reported. We report on an additional case of a Japanese girl with double aneuploidy mosaicism, consisting of a cell line with 45,X and a cell line with 47,XX,+8 without a normal karyotype line. She is a 4-year-old girl seen for the first time at Toride Kyodo General Hospital at age 3 months. She was born at term by normal spontaneous vaginal delivery to a 26-year-old mother who denied consanguinity, use of alcohol, tobacco, or drugs. Birth weight was 2526g, head circumference (OFC) was 32.0 cm, and length was 48.0 cm. She developed epilepsy, which was well controled with treatment by Phenobarbital. Cardiac defect with mitral stenosis was detected by echocardiography. Her development was mildly delayed. Frontal bossing, deep-set eyes, everted lower lip, prominent ears with thick helices, long and slender trunk, and deep creases on soles were suggestive of trisomy 8 mosaicism. She also had a short neck with slight webbing and cubitus valgus, consistent with the Turner phenotype of 45,X. She had been affected with Salmonella sepsis / enterocolitis and recurrent otitis media (acute / with effusion). Cytogenic analysis on her peripheral blood showed 47,XX,+8 [24] / 45,X [6]. Confirmatory FISH studies of lymphocytes revealed 351/500 (70.2%) disomy X with trisomy 8 cells and 149/500 (29.8%) monosomy X with disomy 8 cells. Subsequent analysis on cultured fibroblasts by GTG showed 47,XX,+8 [16] / 45,X [34], and FISH studies on buccal cells showed 26/100 disomy X with trisomy 8 cells and 74/100 monosomy X with disomy 8 cells, which is contrary to the ratio in the peripheral lymphocytes. The parental origins of the alleles in chromosome X and 8 are not yet determined. Several mechanisms have been proposed to explain the double aneuploidy mosaicism involving monosomy X and trisomy 8. Most of these reported cases have biparental alleles for the chromosome X, representing the loss of a chromosome X during an early mitotic division. Two separately arising nondisjunction are assumed to occur in prezygotic and/or postzygotic division. Further analysis of parental origin of aneuploidy cells provides insight to consideration of this rare mosaicism.

**Analysis of chromosome instability in parents of fetus with aneuploidies using cytokinesis block micronucleus test.** *J. Garcia-Sagredo, A. de Leon, M. Arias, K. Yanowsky, C. Villalon, M. Talavera, E. Garcia-Galloway, M.T. Ferro.* Dept Medical Genetics, University Hospital Ramon y Cajal, Madrid, Spain.

Objective: To analyze if parents with aneuploidic fetus diagnosed in the prenatal diagnosis clinic, have an increment in the rate of chromosomal instability. Methodology: Cytokinesis block micronucleus test (CBMN) to score micronuclei (MN) rate in 1,000 binucleated cells (BNC) and distribution of MN among FISH positive, containing whole chromosome, and FISH negative, containing chromosome fragments, using a pancentromeric probe. Material: Couples recruited in the prenatal diagnosis clinic after a diagnosis of aneuploidy in their fetus. Control couples recruited in the prenatal diagnosis clinic having a fetus with normal karyotype. Taking that a high amount of first trimester abortion are due to trisomies, we also analyzed normal karyotype couples with two or more abortions. Results: Our results did not show any significant differences among parameters analyzed with CBMN test in the three groups analyzed: MN rate $6.89 \pm 2.5$ in parents of aneuploidy, $7.85 \pm 2.6$ in couples with abortions, and $6.44 \pm 2.6$ in controls. FISH distribution using a pancentromeric probe shows slight but non-significant increase of MN FISH+ in couples with an aneuploidic fetus: 53.9% MN FISH+ in parents of aneuploidy; 53.3% MN FISH+ in abortion couples, and 47% MN FISH+ in controls. There are also no differences in buds and chromatin bridges rate in BNC: 0.53 buds and 0.35 bridges per 1,000 BNC in parents of aneuploidy; 0.56 buds and 0.32 bridges per 1,000 BNC in abortion couples, and 0.37 buds and 0.44 bridges per 1,000 BNC in controls.

### 1311/W/Poster Board #969

**LOW LEVEL CHROMOSOME MOSAICISM DETECTED BY SNP/COPY NUMBER MICROARRAY.** *I.K. GADI[1], V.L. JASWANEY[1], S. SCHWARTZ[1], R. BURNSIDE[1], H. RISHEG[1], K. CASAS[2], B. WILLIFORD[1], R. PASION[1], S. GRIFFIN[1], J.H. TEPPERBERG[1].* 1) CYTOGENETICS, LABCORP, RESEARCH TRIANGLE PARK, NC; 2) MEDICAL AND BIOCHEMICAL GENETICS, TRINITY MOTHER FRANCES HOSPITALS AND CLINICS, TYLER, TX.

Structural and numerical chromosome anomalies are considered to be the most frequent cause of unexplained non-syndromic developmental delay and mental retardation. The phenotype of low level mosaicism for chromosomes other than chromosome 13, 18, and the sex chromosomes is well documented, however involvement of other chromosomes has not been clearly established. Classical G-band analysis is limited in detecting low level mosaicism in general and although fluorescence in situ hybridization (FISH) has the sensitivity to detect and resolve low level mosaicism, a specific target chromosome is needed. Recent advances in whole genome microarrays have improved the detection of mosaicism. The Affymetrix 1.8 million SNP/copy number array has shown tremendous power in detecting low level mosaicism of various chromosomes due to copy number change and also in revealing uniparental disomy or consanguinity due to loss of heterozygosity (LOH). We report two patients with low level chromosome mosaicism detected through this SNP array analysis. Patient 1 was referred for SNP microarray at 1.4 year of age because of dysmorphia, growth delay, hypospadia, small kidney, malformed ears and language delay. Previous history included IUGR, gestational diabetes, normal karyotype and array CGH results. The SNP array revealed a low level (10-15%) increased SNP/CN dosage across the whole chromosome 22. A chromosome 22 specific FISH probe (TUPLE1) confirmed 4% mosaicism in lymphocytes. Patient 2 was sent for array analysis due to short stature, limb length asymmetry, and congenital anomalies of abdominal wall, speech and language disorder and swirling hyper pigmentation of legs and arms. The SNP array revealed a low level (~10-20%) increased SNP/CN dosage across the whole chromosome 14. FISH using specific probe for 14q32 (IgH gene) on PHA stimulated cultures from this patient showed 9.5% of cells with three signals for chromosome 14. No other gain or loss of DNA was apparent in the genome wide SNP analysis of these patients. UPD for chromosome 14 and 22 was ruled out since there was no apparent loss of heterozygosity in the SNP analysis for these chromosomes. UPD is of great clinical significance when there is a rescue from trisomy to disomy involving an imprinted chromosome. These reports demonstrate that low levels of mosaicism below levels seen using routine cytogenetic analysis can be detected by SNP microarrays.

### 1312/W/Poster Board #970

**Prenatal diagnosis of a de novo trisomy 12p by array-CGH in a fetus with normal karyotype.** *CH. Lin[1], SY. Lin[2], M. Gorre[3], J. Kim[3], YN. Su[2].* 1) Department of Obstetrics and , National Taiwan University Hospital, Taipei, Taiwan; 2) Graduate Institute of Clinical Medicine, College of Medicine, National Taiwan University, Taipei, Taiwan; 3) CMDX, Irvine, USA.

Objective: Trisomy 12p syndrome is a rare chromosome anomaly with an estimated incidence of 1/50,000. Most cases are inheritance from parental balance translocation. Here we present the prenatal sonographic findings, postnatal features, and molecular cytogenetic analysis of a new de novo case. Case report: The 29 y/o G1P0 healthy woman was pregnant at 30th gestational age. Prenatal sonography showed polyhydramnios, fetal facial dysmorphism: hypertelorism, marked prenasal thickness, broad and flat nasal bridge, cleft palate, large philtrum with thickened everted upper lip, and micrognathia, short lone bones and abnormal spine curvature. She received tocolysis for frequent uterine contraction. Serial amnioreduction with 1500ml, 750ml, and 880 ml were done every 3 days. Cord blood sampling was also performed for karyotyping and BAC array-CGH study. The G-banding chromosome report was 46, XY with no obvious anomaly. aCGH result showed arr cgh 12p13.33p11.1(RP11-28313→RP11-313F23)X3. She terminated this pregnancy at 32nd gestational week for IUFD. Postmortem pictures were similar with ultrasound findings and compatible with previous trisomy 12p syndrome report. Conclusion: Trisomy 12p was characterized by profound psychomotor and mental retardation, generalized hypotonia, seizure, and facial dysmorphism. Traditional karyotyping may be suggested when facial dysmorphism was noted by detail prenatal 2D and 3D ultrasound screening. If there is no abnormal finding of chromosome, array-CGH is an additional sensitive and effective diagnosed choice for the rare syndrome.

### 1313/W/Poster Board #971

**CHROMOSOME 10P DUPLICATION ASSOCIATED WITH CENTRAL NERVOUS SYSTEM DEFECTS AND CRANIAL ANOMALIES. A CASE REPORT AT THE HOSPITAL PARA EL NIÑO POBLANO, MÉXICO.** *J. Aparicio[1,6], H.M.L. Hurtado[2], J.B. Vazquez[3], P.S. Rodriguez[4], P.M. Barrientos[5], O.H. Chavez[6], J.G. Vega[6], M.S. Chatelain[7].* 1) Dept Genetica; 2) Cytogenetics; 3) Neurology; 4) Neurosurgery; 5) Endocrinology, Hosp para el Nino Poblano, Puebla,; 6) Estomatology, Benemérita Universidad Autónoma de Puebla; 7) Biotecnology, Universidad Autónoma Metropolitana, México.

Introduction. Distal 10q duplication is a rare chromosomal disorder that causes slow postnatal growth and severe mental retardation. Humans, like all sexually reproducing species, have somatic cells that are in diploid [2N] state, there are 23 chromosomes that are arranged according to their size, function and genes they carry, but sometimes due to mutations or malfunctions during cell division, mistakes are made that cause serious health problems. One such error is the cause of duplication that causes a trisomy 10q disorder. Among the clinical manifestations in patients with chromosome 10p duplication síndromes are defects including central nervous system disorders (SNC) as hypotonia, poor feeding, and mental retardation, cranial anomalies (CA) with small head , long head , flat back of skull, microcephaly, dolichocephaly, retrognathia, wide sutures, frontal bossing and nose malformations, skeletal deformities like clinodactyly, camptodactyly, and clubfoot, urogenital anomalies, and cardiac defects. Case report. A seven months aged patient was studied by genetics, neurology and neurosurgery. Magnetic resonance imaging (MRI), three dimensional (3D) images of scalp and skull and cytogenetic studies were peformed. Conclusions. Distal 10q duplication disorder was diagnosed by citogenetics, where distal portion of the q (long) arm of the chromosome number 10 appears to be present three times, rather than two times as it is supposed to be. Chromosome 10, distal trisomy 10q is an extremely rare chromosomal disorder in which part of the end (distal) portion of the long arm (q) of one chromosome 10 is duplicated. The severity can vary from case to case. However clinical manifestations of SNC and CA were observed in this study. Often the source of this chromosomal error is a translocation in one of the parents, in over 90 percent of reported cases. Sometimes it occurs spontaneously, in which case it is termed de novo .

Pelizaeus-Merzbacher disease (PMD; MIM#312080) is a rare X-linked recessive neurodegenerative disorder. The main cause of PMD is alterations in the proteolipid protein 1 gene (PLP1) on chromosome Xq22.2. Duplications and point mutations of PLP1 have been found in 70 % and 10-25 % of all patients with PMD, respectively, with a wide clinical spectrum. Since the underlining genomic abnormalities are heterogeneous in patients with PMD, clarification of the genotype-phenotype correlation is the object of this study. Comprehensive genetic analyses using microarray-based comparative genomic hybridization (aCGH) analysis and genomic sequencing were applied to fifteen unrelated male patients with a clinical diagnosis of PMD. Duplicated regions were further analyzed by fiber-fluorescence in situ hybridization (FISH) analysis. Four novel and one known nucleotide alterations were identified in five patients. Five microduplications including PLP1 were identified by aCGH analysis with the sizes ranging from 374-kb to 951-kb. The directions of five PLP1 duplications were further investigated by fiber-FISH analysis, and all showed tandem duplications. The common manifestations of the disease in patients with PLP1 mutations or duplications in this study were nystagmus in early infancy, dysmyelination revealed by magnetic resonance imaging (MRI), and auditory brain response abnormalities. Although the grades of dysmyelination estimated by MRI findings were well correlated to the clinical phenotypes of the patients, there is no correlation between the size of the duplications and the phenotypic severity.

## 1315/W/Poster Board #973

**Characterization of the complex 7q21.3 rearrangement in a patient with bilateral split-foot malformation and hearing loss.** *H. Saitsu[1], K. Kurosawa[2], H. Kawara[3], M. Eguchi[3], T. Mizuguchi[1], N. Harada[3], T. Kaname[4], H. Kano[5], N. Miyake[1], T. Toda[5], N. Matsumoto[1].* 1) Dept Human Gen, Grad Sch Med, Yokohama City Univ, Yokohama, Japan; 2) Div of Med Genet, Kanagawa Children's Medical Center, Yokohama, Japan; 3) Dep Molecular Cytogenetics, Kyushu Medical Science, Inc., Nagasaki, Japan; 4) Faculty of Medicine, Dep Med Genet, Univ of the Ryukyu, Okinawa, Japan; 5) Div of Clin Genet, Dep of Med Genet, Osaka Univ Grad Sch of Med, Suita, Japan.

We report on complex rearrangements of the 7q21.3 region in a female patient with bilateral split-foot malformation and hearing loss. G-banding karyotype was 46,XX,t(7;15)(q21;q15),t(9;14)(q21;q11.2)dn. By fluorescence, in situ hybridization (FISH), Southern hybridization, and inverse PCR, the 7q21.3 translocation breakpoint was determined at the nucleotide level. The breakpoint did not disrupt any genes, but was mapped to 38-kb telomeric to the *DSS1* gene, and 258- and 272-kb centromeric to the *DLX6* and *DLX5* genes, respectively. It remains possible that the translocation would disrupt the interaction between these genes and their regulatory elements. Interestingly, microarray analysis also revealed an interstitial deletion close to (but not continuous to) the 7q21.3 breakpoint, indicating complex rearrangements within the split-hand/foot malformation 1 (*SHFM1*) locus in this patient. Furthermore, a 4.6-Mb deletion at 15q21.1-q21.2 adjacent to the 15q15 breakpoint was also identified. Cloning of the deletion junction at 7q21.3 revealed that the 0.8-Mb deletion was located 750-kb telomeric to the translocation breakpoint, encompassing *TAC1*, *ASNS*, *OCM*, and a part of *LMTK2*. Because *TAC1*, *ASNS*, and *OCM* genes were located on the reported copy number variation regions, it was less likely that the three genes were related to the split-foot malformation. *LMTK2* appeared to be a potential candidate gene for SHFM1, but no *LMTK2* mutations were found in 29 individuals with SHFM. Further *LMTK2* analysis of SHFM patients together with hearing loss is warranted.

## 1316/W/Poster Board #974

**Case Report: A new born with plagiocephaly, supernumerary rib, cardiopathy and a 5q11.1q12 duplication.** *I. Briceno[1,2], G. Gordillo[2], I. Zarante[2].* 1) Bioscience, U Niversidad de La Sabana, Chia, Colombia; 2) Instituto Genética Humana, Pontificia Universidad Javeriana, Bogota, Colombia.

The 5q duplications have been well described. The phenotype of trisomy 5q31& 5qter it's well know: severe psychomotor retardation, low birth weight, microchepaly, high forehead, hypertelorism, downward slanting palpebral fissure, epicanthal folds, strabismus, large outstanding pinnae, prominent nasal bridge, long philtrum, large upper lip and micrognathia; there's also brachydactyly, preaxial polydactyly and hernias. Other well know phenotype is the one that belongs to the trisomy 5q13 q22 in with high forehead, bulbuous nose, short philtrum, large, protruding pinnae and micrognathia. Also, Trisomy 5 is found in both acute lymphoblastic leukaemia and acute myeloid leukaemia, but very rarely as the sole karyotypic abnormality. We report the case of a 2-year-old boy product of a second controlled pregnancy, without perinatal history of importance; Coarctation of aorta and persistent Ductus Arteriosus are diagnosed at 4 days of life; Estenosis of the Mitral Valve is diagnosed at 3 months of age. Later Supernumerary Rib is found in thorax X-ray and plagiocephaly in TAC of cranium. The family comes to the service for genetic evaluation because of multiple malformations. To the physical examination the weight and the height were normal for the age, but the cephalic perimeter, the external intercantical distance and the interpupilar distance were higher than the percentile 97. As positive findings he had right-posterior plagiocephaly, low nasal bridge, narinas antervertidas, flat facial profile, long filtrum, rotated ears with folded helix; right prominent thorax and systolic murmur II/VI. Genitalia with scrotal hypoplasia with right inguinal testicle and left cryptorchidism. There wasn't deficit of the nervous central system. Inside the arranged laboratories the band G karyotype reports 46, XY, dup (5) (q11.1-q12) in all studied cells. The trisomy of chromosome 5q also called duplication of 5q, does not present typical genotype - phenotype correlation, but every patient described up to the date presents a variety of personal clinical signs. The Craniosynostosis has described related to the gene MSX2, located in the locus 5q53, which is not involved in the rearrangement of our patient; this opens new questions about the genes located in this region and possibly epigenetic factors related to their expression. This one is the first case of duplication q11.1-q12 described up to the date as we checked in the literature.

## 1317/W/Poster Board #975

**Molecular Characterization of a Complex Chromosome 9p Rearrangement in an Infant with Multiple Congenital Malformations with SNP Oligoneuclotide Microarray Analysis (SOMA).** *K. Anyane-Yeboa[1,2], B. Levy[1], V. Jobanputra[1], C. Paley[2], A. Revah[2], A. Woods[1,2].* 1) Dept Pediatrics, Columbia University Medical Center,NY; 2) Depts of Pediatrics and Obstetrics, ST. Luke's-Roosevelt hospital, NY.

Microarray analysis is now the preferred method for clarification of chromosome deletions and rearrangements in situations where routine cytogenetic studies are inconclusive. We report on and infant with multiple congenital malformations and a complex chromosome 9p translocation that was resolved using SOMA. He was the 2090g SGA product of a 39-week gestation to a 32-year-old mother. He was noted at birth to have multiple anomalies including relatively large head, bulbous nose, mild micrognathia, severe peno-scrotal hypospadias, cryptorchidism, short 5th fingers, clinodactyly, and bilateral simian creases. His muscle tone was mildly increased.Follow up examination at 18 months revealed failure to thrive, relatively large but normocephalic head, broad forehead, mild hypertelorism, large floppy ears, micrognathia, and hypotonia. His hypospadias and cryptorchidism had been surgically repaired.His motor and speech development were severely delayed. He was just beginning to crawl, and his only vocabulary was"-mama". Chromosome studies revealed a dicentric chromosome 9 with a complex unbalanced translocation of 9p and an acrocentric chromosome. Additional chromosome material translocated to 9p was NOR positive, and C-band positive, but no additional details of 9p could be gleaned from cytogenetic studies. SOMA revealed a 5.67 Mb deletion of 9p24.3-p24.1 and a 31.43Mb duplication of 9p24.1-p13.2. The contribution of the acrocentric chromosome is therefore confined to the centromere and short arm while the additional euchromatic material on 9p derived from an interstitial duplication of distal 9p. There are 6 OMIM disease genes in the deleted segment and 17 in the duplicated segment. We believe that haploinsufficiency for two genes in the deleted segment: DMRT1 and DOCK8, are responsible for the phenotypic features in this infant. High DMRT1 expression is necessary for testicular diffrentiation and low levels to ovarian differentiation. Haploinsufficiency may cause sex reversal or incomplete male genital differentiation as in this infant. Haploinsufficiency or dominant mutations in DOCK8 have recently been shown to cause severe mental retardation. Other genes in this region are recessive genes that would not contribute to his phenotype. There are a large number of genes in the duplicated region, 17 of them are OMIM disease genes that are expressed as dominant or recessive traits. Effects of over expression of these genes are not known.

## 1318/W/Poster Board #976

**MECP2 duplications in five patients with complex sex chromosome rearrangements.** *A.M. Breman[1], M. Ramocki[2], S.H. Kang[1], M. Williams[3], D. Freedenberg[4], A. Patel[1], P.I. Bader[5], S.W. Cheung[1].* 1) Medical Genetics Laboratories, Dept of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Section of Pediatric Neurology and Developmental Neuroscience, Baylor College of Medicine and Texas Children's Hospital, Houston TX; 3) Vanderbilt University School of Medicine, Division of Medical Genetics, Nashville, TN; 4) Department of State Health Services, Austin, TX; 5) Northeast Indiana Genetic Counseling Center, Fort Wayne, IN.

Duplications of the Xq28 chromosome region resulting in functional disomy are associated with a distinct clinical phenotype including dysmorphic facial features, severe developmental delay and hypotonia. Increased expression of the dosage-sensitive MECP2 gene, located within this region of the X chromosome, is considered responsible for the severe neurological impairment in affected individuals. While cytogenetically visible duplications of Xq28 have been well documented in the published literature, recent advances using aCGH analysis have revealed an increasing number of cases of microduplication involving MECP2. In rare cases, the duplication results from an intrachromosomal rearrangement or translocation between the X and Y chromosomes. We report 5 cases with complex X-X or X-Y rearrangements involving duplication of MECP2. Cases 1-3 are unbalanced rearrangements involving MECP2 on chromosome Xq28 and chromosome Y. In case 1, aCGH detected a gain in copy number of at least 0.38 Mb at Xq28. FISH analysis revealed an insertional translocation of Xq28 material into the terminal region of chromosome Yp. In case 2, a loss in copy number was detected in the pseudoautosomal region of chromosomes Xp/Yp, spanning at least 0.6 Mb, as well as a gain in copy number of at least 1.5 Mb at Xq28. FISH analysis revealed a de novo unbalanced translocation between the distal segments of chromosomes Xq and Yp. In case 3, aCGH indicated a duplication of ~ 2.1 Mb on Xq28. FISH analysis showed the additional Xq28 translocated to Ypter, but in this case, with no detectable loss of Ypter material. Interestingly, the FLNA gene is also duplicated in cases 2 and 3, but not case 1. Duplications of FLNA have been associated with a more severe phenotype, consistent with the clinical features of these patients. Finally, two cases (4 and 5) were identified by aCGH to have a loss in copy number at Xp22.32, spanning at least 5 Mb, as well as a gain in copy number at Xq28 spanning at least 10 Mb involving the MECP2 and FLNA genes. In both cases, FISH analysis revealed a recombinant X chromosome deleted at Xp22.32 and containing the duplicated material from Xq28 on Xp, resulting from a maternal pericentric inversion. The cases described here add to a growing number of submicroscopic Xq duplications involving MECP2 that have been detected by aCGH. These data demonstrate the utility of aCGH analysis for the accurate delineation of breakpoints in patients with complex rearrangements.

## 1319/W/Poster Board #977

**Chromosome abnormalities in spontaneous abortuses.** *J. Choi[1], M. Woo[1], N. Song[1], H. Ko[1], S. Oh[1,2], J. Park[2], J. Jun[2], Y. Choi[1,2], S. Moon[1,2].* 1) Institute of Reproductive Medicine and Population; 2) Department of Obstetrics and Gynecology, College of Medicine, Seoul National University, Seoul, Korea.

Chromosomal aberrations usually lead to spontaneous abortions which occur in 10-15% of pregnancies. The majority of clinically recognized spontaneous abortions occur during the first trimester, and abnormal chromosome is identified in 50-80% of these early miscarriages. This study reviewed chromosomal analysis of 47 abortues referred at the Institute of Reproductive Medicine and Population, Seoul National University. The spontaneous aborted specimens were performed using conventional tissue culturing and karyotype analysis. Among 47 specimens, chromosome abnormality was detected in 13 cases (27.7%). Five cases (14.9%) were consistent with numerical abnormalities for autosome, including two cases of trisomy 21 and one case of trisomy 18, trisomy 5, and triploidy (69,XXY), respectively. Two cases (4.3%) showed X monosomy. Four cases (8.5%) were mosaicsim. Unbalanced structural rearrangements were detected in two cases (4.3%) which derived due to the unbalanced chromosome segregation from female carriers with balanced reciprocal translocations. These data showed that cytogenetic analyses of reproductive failure are necessary for an approach to determining the causes of spontaneous abortion, and should be enable to provide valuable information for genetic counseling and prenatal diagnosis.

## 1320/W/Poster Board #978

**10, 11 a novel translocation in an Indian azoospermic man.** *R. Dada[1], S. Venkatesh[1], R. Goswami[2], AC. Ammini[2], N. Tandon[2].* 1) Dept Anatomy, All India Inst Medical Sci, New Delhi, India; 2) Department of Endocrinology, AIIMS, New Delhi.

Aim: Reporting a case of novel 10, 11 translocation in an infertile man with azoospermia. Methods: Semen analysis was performed according to WHO criteria (1999). GTG banding karyotyping was done in 72 hours blood culture. Hormone estimation was done by radio-immuno assay. Results: Repeated semen analysis showed azoospermia even after centrifugation. Semen volume was found to be 1 ml and the liquefaction was incomplete even after 60 min. The pedigree analysis showed that his elder brother was also found to be infertile and unavailable for the study. Patient had late virilzation and appeared to be partial. Hormone analysis showed FSH-17.47 mIU/ml, LH-22.28 mIU/ml and testosterone -1305.86 ng/dl. Peripheral karyotype analysis revealed 46, XY t (10; 11) (q11.2; p15) chromosome complements Conclusions: To the best of our knowledge this translocation has not been previously reported in an infertile man. However, such translocation involving chromosomes 10 and 11 have been frequently observed in acute myeloid leukemia (AML) (46,XY,t (10;11)(p12;q231[9]/46,XY[31, 46, XY, t(10;11)(p13;q14), 46,XY, t(10;11)(p13;q15). However, this patient showed no symptoms of such disorder as the translocation break points are different from those reported in AML. Nil sperms in the semen and elevated testosterone levels showed completely blocked germ cell division might have resulted from impaired quadrivalent synaptic complex due to novel translocation. Also, genes that were disturbed during this translocation may also responsible for impaired fertility, which cannot be ruled out.

## 1321/W/Poster Board #979

**Array based genomic analysis reveals hidden complexity of chromosome aberrations.** *J. Gerfen[1], L.K. Conlin[1], B. Kamath[1], B. Thiel[2], L. Ernst[1], H. Hakonarson[3], N.B. Spinner[1,2].* 1) Dept of Pediatrics, The Children's Hosp Philadelphia, Philadelphia, PA; 2) Dept of Pathology, The Children's Hosp Philadelphia, Philadelphia, PA; 3) Center for Applied Genomics, The Children's Hosp Philadelphia, Philadelphia, PA.

In the course of analysis of over 1,000 patients by genome-wide SNP array, we have identified several examples of complex rearrangements that were unexpected. Here we present data on 3 patients with mosaic deletions and duplications occurring on the same chromosome, that we believe are associated with an inversion. Patient 1 was studied at 1 month of age, because of fetal death, associated with a diagnosis of a hypoplastic left heart. Array analysis revealed a 518 kb mosaic deletion in 25-30% of cells, at chromosome 14q24.2 and a 3.5 Mb mosaic duplication (also at 25-30% of cells) at chromosome 14q32. The fact that the deletion and duplication occur with similar frequency, lead us to hypothesize that they are associated with a paracentric inversion, with the breakpoints marked by the deletion and duplications. To confirm this, we carried out FISH using probes from across the putative inversion, and confirmed both the copy number alterations, and the suspected inversion. Patient 2, was known to have a 900 kb mosaic deletion of 20p12.2, including the JAG1 gene. She had been identified subsequent to the birth of her daughter, who had a non-mosaic deletion of JAG1, and clinical characteristics of Alagille syndrome. Array analysis revealed that both the proband and her mother in fact had both the deletion and a 2.4 Mb duplication within 20p11, with the mother's deletion and duplication being mosaic, again at similar levels (30-35%). Patient 3 also had a 4.8 Mb mosaic deletion of 20p12 (JAG1 deleted, with clinical features of Alagille syndrome) and a 1.8 Mb mosaic triplication of 20q13.2 in 30-35% of cells. In each of these cases, the similar mosaicism levels for the deletion and duplication provided a clue to the structural relationship. Given the large distances between the deletion and duplication in each case (27, 13 and 38 Mb respectively), we hypothesize that there is an inversion between these events. And further suggest that the inversion event has resulted in the copy number changes we observe. In each of the cases we report, the event occurred mitotically, since these events were mosaic. Array analysis allows finer detail in characterization of chromosome alterations and will result in further understanding of the mechanisms of chromosome abnormalities.

## 1322/W/Poster Board #980

**A recurrent translocation between chromosomes 4 and 18 is mediated by homologous recombination.** *K. Hermetz[1], U. Surti[2], J.D. Cody[3], K. Rudd[1]*. 1) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA; 2) Department of Pathology, University of Pittsburgh Medical Center, Pittsburgh, PA; 3) Department of Pediatrics, University of Texas Health Science Center at San Antonio, TX.

Chromosome rearrangements are a significant cause of intellectual disability as ~16% of affected individuals referred for diagnostic array comparative genome hybridization (CGH) carry a pathogenic copy number abnormality. Despite the frequency of structural rearrangements in the human genome, the mechanisms of chromosome breakage and repair are usually unknown. Recurrent chromosome abnormalities provide an opportunity to unravel mechanistic factors, as their frequency is suggestive of rearrangement-prone genomic architecture. Such is the case for the segmental duplications that flank recurrent microdeletion and microduplication loci and the palindromic AT-rich repeats that underlie the breakpoints of the common translocation between chromosomes 11 and 22. Here we report the breakpoint junction and mechanism of a recurrent translocation between chromosome arms 4q and 18q. At least 3 unrelated individuals with the apparently same unbalanced translocation have been described in the literature; FISH and array CGH studies have defined the derivative chromosome as der(18)t(4;18)(q35;q23). Subsequently, we have combined high-resolution array CGH and breakpoint cloning to resolve the breakpoints and determine the mechanism of rearrangement in two unrelated individuals carrying the derivative chromosome 18. We designed a custom oligonucleotide array targeting the 5 megabases (Mb) flanking the original 4q and 18q breakpoints with a mean probe spacing of one oligonucleotide per 100 basepairs. Array CGH revealed the same breakpoints in both individuals with a net loss of 6.96 Mb on 18q and a net gain of 7.30 Mb of 4q. Based on the array CGH data, we designed PCR primers to amplify the breakpoint junction of the derivative chromosome 18. Cloning and sequencing the junction revealed that both of the breakpoints occurred in a cluster of long terminal repeats (LTRs). The LTR clusters on 4q and 18q are ~5 kilobases in size and 95% identical. Such genomic architecture is a signature of rearrangements mediated by homologous recombination. Given the mechanism of translocation, we anticipate that other individuals carry the same imbalance, and future phenotypic studies will better inform patient outcome. Interestingly, the reciprocal unbalanced translocation [der(4)t(4;18)(q35;q23)] has not been reported in the literature, possibly do to lethality of this unbalanced product.

## 1323/W/Poster Board #981

**An SRY-deleted XXY female resulting from a paternally inherited t(Y;22).** *J. Kim[1], S. Kim[2], H. Kim[3], K. Lee[1]*. 1) Laboratory medicine, Kangnam severance hospital, Seoul, Kangnam, Korea; 2) Department of Laboratory Medicine and Genetics, Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul, Korea; 3) Department of Pediatrics, Kangnam severance hospital, Seoul, Kangnam, Korea.

The Individuals found with 47,XXY appear as males, but are rarely seen in females. Most of these females were reported to show androgen insensitivity due to mutations in androgen receptor genes. To my knowledge, there was only one case report of an SRY negative 47,XXY female resulted from an aberrant X-Y interchange leading to transfer of Yp material to one of the X chromosome. We report a case of 46,XXYp- female with unbalanced Y-22 translocation inherited from the father. A 7 year and 9 months-old girl was referred to the endocrinology department of our hospital because of fast progressing signs of precocious puberty. The girl with a birth weight of 3800 g was delivered by ceasarian section due to delayed time of delivery. The height of the father and mother were 175 cm and 153 cm. At 7 years and 9 months the height of the girl was 127.3 cm (80 percentile) and her weight was 36 kg (>97 percentile). Her body mass index was 22.21 (>95 percentile). The skeletal age was around 94 to 106 months. The ultrasonography of the abdomen and pelvis showed uterus (3.7 x 0.6 cm) and ovaries (right: 1.4 cm, left 1.5 cm) slightly small in size. There were no other abnormalities on further physical examination. The endocrinology lab results were all within the reference interval. In G-banding analysis, an enlarged short arm of one chromosome 22 consisting of heterochromatic component was detected. The additional material attached to chromosome 22p was characterized by metaphase fluorescence in situ hybridization with whole chromosome painting probes as being derived from Y chromosome. The SRY gene was not amplified in the DNA analysis showing the deletion of SRY gene. Thus, the karyotype of the patient was 46,XX,der(Y;22)(q10;q10). Her father showed 46,XY,der(Y;22)(q10;q10), which revealed that the derivative chromosome has arisen from the segregation of the paternal rearrangement. Her mother showed a normal karyotype. Although it is likely that she will be fertile since she has both X chromosome intact, close follow up of the patient is necessary for relatively small sized reproductive organs. Enlargement in acrocentric short arms should be carefully examined to clarify whether it is a normal polymorphism or whether it hides a cryptic rearrangement.

## 1324/W/Poster Board #982

**Prenatal diagnosis of a maternally derived unbalanced der(4)t(4;11) leading to an overlapping phenotype of Wolf-Hirschhorn and Russell-Silver syndromes in two siblings: novel recurrent translocation, aCGH and molecular cytogenetic analyses.** *E. Kolomietz[1], A. Smith[1], K. Chong[2].* 1) Pathology/Lab Med, Mount Sinai Hosp/Univ Toronto, Toronto, ON, Canada; 2) Prenatal Diagnosis Unit, Mount Sinai Hosp/Univ Toronto, Toronto, ON, Canada.

Constitutional reciprocal translocations were thought to arise randomly with the only exception of recurrent rearrangements being the t(11;22). Recent evidence indicates that recurrent breakpoints may be more common than previously thought and mediated by non-B DNA structures, such as cruciforms, caused by palindromic AT-rich repeats. The clinical significance of these rearrangements may be underestimated because certain rearrangements, most notably subtelomeric translocations, can be difficult to detect by conventional G-banding. We report on two siblings of same sex and apparently normal karyotypes both presented prenatally with severe intrauterine growth restriction (IUGR). The mother had an apparently balanced translocation, t(4;11)(p16.3;p15.5), and both sibs had an adjacent -1 segregation variant with loss of terminal 4p and gain of terminal 11p regions which was detected by aCGH and FISH using subtelomeric probes. Each of these rearrangements is associated with well known clinical phenotypes. Paternal duplication of 11p15 is associated with the Beckwith-Wiedemann syndrome while maternal duplication is associated with Russell-Silver syndrome. As expected both fetuses presented with severe IUGR consistent with both Wolf-Hirschhorn and Russel-Silver phenotypes. This familial case of what appears to be a novel recurrent translocation demonstrates the value of aCGH in the diagnosis of submicroscopic chromosome abnormalities in those patients for whom routine chromosome analysis does not adequately explain clinical findings. Breakpoint sequence analysis in our cases is compared to previously published cases and an analysis of the 4p and 11p regions for palindromic repeat sequences may help to elucidate mediators of this recurrent chromosomal aberration.

## 1325/W/Poster Board #983

**Identification of 3q26.3 deletion in a family with blepharophimosis/ptosis/epicanthus inversus syndrome (BPES).** *M. Kumar[1], M. Tanwar[1], B. Chawla[2], R. Dada[1]*. 1) Department of Anatomy; 2) Dr R.P. Centre for Ophthalmic Sciences, All India Institute of Medical Sciences, New Delhi, India.

Blepharophimosis-ptosis-epicanthus inversus syndrome (BPES) is an autosomal dominant disease of the eyelids that may severely impair visual function. The frequency of BPES has been estimated to be 1 in 50,000. Patients with BPES have a combination of congenital anomalies as small palpebral fissures, epicanthus inversus, low nasal bridge and congenital ptosis. Other features like microphthalmos, anophthalamos, microcornea, hypermetropia, divergent strabismus, high arched palate, cup shaped ears, mental retardation and infertility in females has been reported. Based on the presence and absence of premature ovarian failure BPES has been categorized into two types: type I with infertility in females and type II involves eye malformation in both males and females. It has been shown that penetrance is 100% in type I when the transmission is by males only and 96.5% in type II in which transmission occurs through both sexes. From reviews it has been concluded that a locus for eyelid development is situated at the interface of long arm of chromosome 3. Since blepharophimosis, ptosis and microphthalmia are consistent features in Patients with BPES an interstitial deletion of band 3q2, the location of BPES gene at this position seems highly likely. Various reports linked the deletion in 3q21, 3q22, 3q23, 3q24, 3q25 and translocations t(3:7)(q26-qter:q+), t(X:3)(p22:q21), t(3:8)(q23:p22.1) to the BPES. Thus cytogenetically different deletions and translocations of chromosome 3 have been described in patients with BPES. We report a familial case of BPES. Pedigree shows autosomal dominant pattern of inheritance. We have done the Cytogenetic analysis of the family. Standard GTG banding showed deletion of band 3q26.3 in two members. This finding may represent a severe manifestation of the disease. BPES is a heterogeneous entity, and evaluation and counseling of affected individuals should be undertaken with caution.

## 1326/W/Poster Board #984

**Complex chromosomal rearrangements in a girl with Pelizaeus-Merzbacher disease.** *K. Kurosawa[1], M. Tanaka[2], H. Osaka[1], H. Ohashi[2], S. Hamano[2], K. Enomoto[1], A. Ishikawa[1], N. Furuya[1].* 1) Kanagawa Children's Med Ctr, Yokohama, Japan; 2) Saitama Children's medical Ctr, Saitama, Japan.

Pelizaeus-Merzbacher disease (PMD) is a rare congenital dysmyelinating disorder, characterized by nystagmus, psychomotor developmental delay, spasticity, and ataxia. PMD is caused by predominantly submicroscopic duplications of Xq22.2 including the entire PLP1 gene. The duplications vary in size between the families, and are detected as a double signal using PLP1 probe in interphase FISH. Several cases have been reported in which the duplication is found in a cytogenetically distinguishable band on the X chromosome or autosomes. We report here a female patient with PMD in which complex rearrangements involving the seemingly balanced translocation t(X;6) is observed. She was born after uneventful pregnancy at term by normal delivery with a birth weight of 2660 g. At age of 7 months, she visited the neurological clinic of Saitama Children's Medical Center because of horizontal nystagmoid movements present from birth, and delayed motor development. Brain MRI showed diffuse dysmyelination, and ABR study revealed no consistent waveforms after wave II. These results were consistent with those of typical PMD, but inconsistent with the trait of inheritance of PMD. FISH analysis with a BAC clone with PLP1 detected three independent signals in interphase nuclei, of those third signal was observed in the autosome in the metaphase. Cytogenetic analysis by standard GTG revealed balanced translocation t(X;6)(q22.2;p21.2). To determine the ranges of duplication and breakpoints of both chromosomes, we used Affymetrix 250K Mapping array and detected 820 kb duplication of the Xq22.1-q22.1 including the PLP1. In addition, array analysis unexpectedly detected submicroscopic 400 kb deletion in the breakpoint of chromosome 6. Both parents had normal karyotype. A small set of PMD cases is caused by gene duplication arising by a sub-microscopic transposon, jumping gene, inversion, or translocation. Diversity of genomic rearrangements found in these PMD patients suggests the unique architecture of PLP1 region in Xq22.2.

## 1327/W/Poster Board #985

**Characterization of a Large Pericentric Inversion of Chromosome One in a Multi-Generational Pedigree: Risk for Pregnancy Loss, Recombinant Offspring and the Possibility of Meiotic Drive.** *E. McCready[1,2,3], c. Honeywell[1], S. Douglas[1], J. Allanson[1,2,4], J. McGowan-Jordan[1,2,4].* 1) Dept of Genetics, Children's Hospital of Eastern Ontario, Ottawa, ON, Canada; 2) Children's Hospital of Eastern Ontario Research Institute, Ottawa, ON, Canada; 3) Department of Pathology and Laboratory Medicine, University of Ottawa, Ottawa, ON, Canada; 4) Department of Pediatrics, University of Ottawa, Ottawa, ON, Canada.

Although generally not associated with phenotypes in carriers, pericentric chromosome inversions can be associated with increased risks for miscarriage, infertility and in some cases, the birth of children with mental and/or physical differences. We have identified a large, multi-generational family with an inversion of chromosome 1 between bands 1p36.21 and 1q42.13. To our knowledge this is the largest familial inversion ever described, comprising approximately 88% of the total chromosome 1 length. The family was ascertained through the birth of a child with multiple congenital anomalies including significant cardiac and brain abnormalities. Cytogenetic studies performed during the prenatal period showed that the proband had a duplication of chromosomal material distal to band 1q42 and loss of material distal to band 1p36.2, consistent with a recombinant chromosome from a maternal pericentric inversion. Subsequent family studies have led to the identification of fourteen inversion carriers across five generations. Miscarriages were reported or observed in 35% of pregnancies to known inversion carriers (13/37 pregnancies), indicating a substantial risk for pregnancy loss associated with this inversion. There have been no additional children, or conceptuses identified with a recombinant chromosomes, although the risk of having a child with significant health issues due to chromosomal imbalances remains a possibility for family members carrying the inversion. Surprisingly, of twenty healthy family members for whom chromosome studies have been performed, 14 (70%) had inherited the inv(1) chromosome, while only 6 (30%) had inherited the normal chromosome 1. This suggests a possible meiotic drive that favors transmission of the inverted rather than the normal chromosome 1. Specific chromosomal breakpoints have been mapped to within approximately 52 kb at 1p36.12 and 532 kb at 1q42.12. A FISH protocol has also been developed to investigate the meiotic segregation of the inversion in sperm of inversion carriers. In addition to providing valuable information about risks for adverse pregnancy outcomes in this family and other families with similar rearrangements, further characterization of the above inversion and its meiotic segregation may provide valuable information about genes that influence fertility and gametic fitness.

## 1328/W/Poster Board #986

**Ring chromosome 20 syndrome: a new case with duplications of two contiguous BAC clones in 20q11.22 without deletions of the telomeric regions, studied by Genome Array-CGH.** *A. Nucaro[1], R. Rossino[3], S. Zorco[2], N. Santini[2], F. Boscarelli[2], A. Milia[5], M. Loi[4], C. Montaldo[2].* 1) CNR, Inst Neurogen Neurofarmacolog, Monserrato, Italy; 2) Dip. Scienze Chir. Odontostomatologiche, Università, Cagliari, Italy; 3) Dip.Scienze Ped. Med Clinica, Azienda Osp-Università, Cagliari, Italy; 4) Div. Neuropsichiatria Infantile, AOB, Cagliari, Italy; 5) Dip. Biol. Sperimentale, Università, Cagliari, Italy.

Ring chromosome 20 syndrome is a rare disease characterized by refractory epilepsy, moderate mental retardation and particular electroencephalographic disorder with non-convulsive status epilepticus. Herein, we report on a new case of r(20) syndrome in a 15 year old female that presented minimal dysmorphism, generalised tonic e clonic and absence seizures refractory to medical therapy and behavioural disorders. The female was the first child of an unrelated couple, and she was born after uneventful pregnancy and delivery. Among 50 cytogenetically analyzed cells, 30 showed a 46, XX, karyotype (60%) and 20 exhibited a 46,XX,r(20)(p13q13.3)(40%). FISH using whole specific probe of chromosome 20 confirmed the presence of the ring chromosome 20. Telomeric-FISH using BAC clones RP5-1103C7, RP5-1059L7, RP5- 1005F21, RP11-476I15 revealed no deletions of telomeric regions. Genome Array- CGH using Cytochips Blue-gnome (Technogenetics - Bouty) detects the absence of any deletion in the ring chromosome 20 and the presence of an amplification of about 350 kb in 20q11.22. We think that the lack of detection of any deletion could be attributed to the mosaicism,and we hypothesize that clinical symptoms of r(20)syndrome could be attributed to telomeric partial monosomy generated by ring chromosome and causing an haplo-insufficiency of two epilepsy genes CHRNA4 and KCNQ2. To the best of our knowledge, our patient was the first case presenting the typical epilepsy disorder but no detectable deletion in the ring chromosome 20 associated with amplification of about 350 kb in 20q11.22. Further studies are in progress to better definition and characterization of the duplicated region.

**Insertional translocation detected by array-based comparative genomic hybridization (aCGH).** *Z. Ou, SH. Kang, C. Shaw, PA. Eng, ML. Cooper, AN. Pursley, T. Sahoo, CA. Bacinos, AC. Chinault, P. Stankiewicz, A. Patel, JR. Lupski, SW. Cheung.* Dept Molec & Human Gen, Baylor Col Med, Houston, TX.Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX 77030, USA.

Insertional translocations (IT) are rare events that require at least 3 breaks in the chromosomes involved and thus qualify as complex chromosomal rearrangements (CCR). In the current study, we identified 41 IT cases from approximately 18,000 clinical cases (1:500) using array comparative genomic hybridization (aCGH) in conjunction with fluorescence in situ hybridization (FISH) confirmation of the aCGH findings, and parental follow-up studies. Both submicroscopic and microscopically visible IT events were detected. There were 3 major categories; 1) simple intrachromosomal and interchromosomal IT resulting in pure segmental trisomy, 2) complex IT involving more than one abnormality, 3) deletion inherited from a parent with a balanced IT resulting in pure segmental monosomy. Interestingly, of the cases where follow-up parental studies were available, over half were inherited from a parent carrying the same unbalanced rearrangement detected in the proband, thus, decreasing the likelihood that these IT events are clinically relevant. Nevertheless, we identified six cases where small submicroscopic events were detected that involved known disease-associated genes/genomic segments and are likely to be pathogenic. We recommend that copy number gains detected by clinical aCGH analysis should be confirmed using FISH analysis whenever possible in order to determine the location of the duplicated segment. We hypothesize that the increased use of aCGH in the clinic will demonstrate that IT occur more frequently than previously predicted, but can identify many genomic rearrangements with unclear clinical significance.

## 1330/W/Poster Board #988

**Cytogenetic and SNP Microarray Analysis of a Ring Chromosome 22 with a Duplicated Segment.** *V.R. Potluri[1], J.L. Smith[1], T. Solomon[1], D.L. Rodriguez[2], S. Schwartz[3], P. Papenhausen[3].* 1) Cytogenetics, Dynagene/ LabCorp, Houston, TX; 2) Pediatric Neurology, Texas Childrens Hospital, Houston, TX; 3) Cytogenetics, LabCorp, Research Triangle Park, NC.

The utilization of SNP array technology has provided a better understanding and insight into the delineation of chromosomal abnormalities. In this study, we report a two and a half year old female referred for chromosome studies with the clinical features of developmental delay, microcephaly, pulmonary stenosis, ADHA-poor behavior and stereotypical habits. The pregnancy history was uneventful and full term; birth weight was normal. Chromosome analysis on peripheral blood revealed a female chromosome constitution with a ring chromosome 22 in every cell; breakpoints were determined to be at p12 and q13.3. Initially it was believed that there could be a small deletion in 22q13.3. Subsequent studies with a whole genome chromosome SNP microarray copy number analysis revealed an interstitial 8.04Mb duplication at 22q13.2 - q13.33. No deletions at the breakpoints, or elsewhere, on chromosome 22 were detected by microarray analysis. FISH analysis of this ring with BAC RP11-938G7 confirmed that the ring chromosome contained the duplicated segment. Further FISH studies using ARSA and chromosome 22 subtelomere probes both exhibited single copy signals showing that this duplication is interstitial. These findings are very intriguing for several reasons. To our knowledge, this is the first non-mosaic, non-supernumerary ring chromosome 22 reported with a duplicated segment rather than loss of chromosomal material. This indicates that it cannot be presumed that a ring formation results in a deletion which leads to the phenotype. More importantly, it elegantly shows the need for both cytogenetic and array analysis to clearly delineate chromosome abnormalities.

## 1331/W/Poster Board #989

**CYTOGENETIC STUDY AND CLINICAL CO-RELATION IN PREMATURE OVARIAN FAILURE.** *A. Sharma[1], A.C. Ammini[2], A. Kriplani[3], R. Dada[1].* 1) Department of Anatomy; 2) Department of Endocrinology & Metabolism; 3) Department of Obstetrics & Gynaecology, All India Institute of Medical Sciences, New Delhi-110029.

Premature Ovarian Failure (POF) is defined as the occurrence of menopause before the age of 40 years, biochemically low levels of gonadal hormones (estrogen & inhibin) and high levels of gonadotrophins (FSH & LH). POF is a heterogeneous disorder affecting approximately 1% of women <40 years, 1:10,000 women by age 20 and 1:1000 women by age of 30. Several causes of POF have been identified, including X chromosome aberrations. This study finds out the proportion of genetic causes of POF and analyze different chromosomal pattern and clinically co-related. Fifty patients of POF were referred for cytogenetic analysis. Family history, age, occupation, disease information and all other medical records were reviewed carefully. Blood was collected and lymphocyte cultures were set up. Twenty GTG banded metaphases were analysed for chromosome complement. Mean age and height was found to be 20.2 years and 150cm respectively. FSH level was found to be >40mIU/ml in all patients. 82% of cases had a normal karyotype. In 6% cases karyotype was 45,XO whereas 16% of the cases showed mosaicism with normal cell lines. Two patients had a chromosomal constitution 46,X,i(X) whereas other two had the karyotype 46,XX,del Xq(13.3-21.1) and 46,XX,delXq(22-24). Various reports suggested that X chromosome deletions associated with POF are more common than translocations. In this study X chromosome aberration are involved in all cases as reported in the earlier studies. This mosaicism could explain an accelerated loss of gametes in the ovary. Cytogenetic analysis in association with molecular techniques could allow finding the molecular pathogenesis of the ovarian failure. These POF patients most commonly clinically presented with irregular menstrual cycle with night sweats , irritability, poor concentration, vaginal drying , infertility.

## 1332/W/Poster Board #990

**Novel 1q31-32 deletion in a patient with ocular coloboma.** *H. Singh[1], M. Kumar[1], M. Tanwar[1], P. Venkatesh[2], R. Dada[1].* 1) Department of Anatomy,; 2) Dr R.P.Centre for Ophthalmic Sciences, All India Institute of Medical Sciences, New Delhi, India.

Coloboma (from the Greek koloboma, meaning ''mutilated'' or ''curtailed'') may be defined as a congenital defect in uveal tissue in a site consistent with abnormal closure of the embryonic fissure during embryogenesis. Ocular features commonly associated with coloboma are microphthalmos, microcornea, cataract, and retinal detachment. Typically, coloboma are clefts caused by absent tissue in the inferonasal quadrant of the eye, but subtype, severity, and visual prognosis vary, depending on location and associated eye defects. Iris coloboma involves the pigment epithelium and stroma giving rise to the so-called ''keyhole'' pupil, which can be unilateral or bilateral. Coloboma can be caused by genetic, environmental (teratogens) or unknown factors. Autosomal dominant (AD) inheritance is the most common mechanism reported in the literature. The genetic causes can be chromosomal or monogenic. Coloboma associated with chromosomal abnormalities is usually associated with systemic abnormalities. An extraordinary number of conditions are associated with coloboma either as Mendelian inherited traits or as chromosomal aberrations. To date, 27 genetic loci have been mapped to specific chromosomal regions and 21 of the genes have been identified. Eleven chromosomal aberrations have been documented and three of these overlap with known coloboma-associated genes (SHH, CHX10, MAF). The coloboma phenotype is therefore genetically heterogeneous. We report a case with sporadic case of iridofundal coloboma. We have done the Cytogenetic analysis of the patient. Standard GTG banding showed deletion of band 1q31-32. To the best of our knowledge this is the first report. This finding may represent Novel a severe manifestation of the disease. Karyotyping and examination by clinical geneticist should be performed to identify associated syndromes. Parents should be examined for minor forms of coloboma.

## 1333/W/Poster Board #991

**Molecular cytogenetic evaluation of a proband with 12p13.32 terminal deletion and her parent with inv(12)(p13.33p12.1).** *K. Wakui[1,2], T. Kosho[2,1], A. Nishimura[3], M. Uhara[4], K. Matsuda[4], E. Hidaka[4], R. Kawamura[1], N. Matsumoto[3], Y. Fukushima[1,2].* 1) Department of Medical Genetics, Shinshu University School of Medicine, Matsumoto, Nagano, Japan; 2) Division of Clinical and Molecular Genetics, Shinshu University Hospital, Matsumoto, Nagano, Japan; 3) Department of Human Genetics, Yokohama City University Graduate School of Medicine, Yokohama, Kanagawa, Japan; 4) Department of Laboratory Medicine, Shinshu University Hospital, Matsumoto, Nagano, Japan.

The proband, a two-year-8-month-old girl, is the first child of healthy nonconsanguineous parents. The pregnancy was uneventful. At birth at 39 weeks of gestation, the child weighed 2205g (-2.1SD), measured 44.3cm (-2.6SD) and head circumference was 29.3cm (-2.8SD). Developmental delay was pointed out at her 10 months of age. G-banded chromosomal analysis was performed, and the terminal deletion of 12p13.3 was suspected, and confirmed by 12p/12q subtelomere FISH analysis. Her parents were visited to our division to get detailed information of the chromosome abnormality of their child. At age of 2 9/12 years, the proband had obvious growth failure (weight: 8.8kg (-3.3SD), height: 77.7cm (-4SD) and head circumference: 42.2cm (-4SD)), and mild developmental delay. Microarray analysis confirmed the deletion of an approximately 4 Mb fragment from the 12p telomere region without any other abnormalities. Thus, the chromosome abnormality of the proband was the terminal deletion, and the deletion breakpoint was 12p13.32. On other hand, one of the parents was suspected as paracentric inversion of 12p, according to G-banded chromosome and 12p/12q subtelomere FISH analyses. Additional metaphase FISH analyses revealed inv(12)(p13.33p12.1). These results indicated that breakpoint identified in the proband and that of the parent were somehow different. The relationship between the 12p terminal deletion in the proband and the paracentric inversion 12p in her parent will be discussed.

## 1334/W/Poster Board #992

**Microdeletion and triplication around 17p13 including PAFAH1B/LIS1 in three patients with MR and epilepsy.**
*T. Yamamoto[1], K. Shimojima[1], C. Sugiura[2], H. Takahashi[3], Y. Kubota[3], Y. Takahashi[3], K. Saito[4].* 1) International Research and Edu, Tokyo Women's Medical University, Shinjuku-ward, Tokyo, Japan; 2) Division of Child Neurology, Institute of Neurological Sciences, Tottori University Schoold of Medicine, Yonago, Japan; 3) Department of Pediatrics, National Epilepsy Center Shizuoka Institute of Epilepsy and Neurological Disorders, Shizuoka, Japan; 4) Institute of Medical Genetics, Tokyo Women's Medical University, Shinjuku-ward, Tokyo, JAPAN.

Array-based comparative genomic hybridization (CGH) analyses enabled to identify cryptic microdeletions and/or duplications in patients with idiopathic mental retardation and epilepsies. Subtelomeric region of the short arm of chromosome 17 is well-known as the responsible region for Miller-Dieker syndrome which manifests lissencephaly and characteristic facial features. We report on three patients with epilepsy and psychomotor developmental delay in whom we identified cryptic microdeletions and/or duplications of 17p13.3. Patient 1 is 25 years old female, who started intractable seizures when she was 6 years and severely delayed with bedridden. Brain MRI is compatible with lissencephaly but there was no deletion of PAFAH1B/LIS1 by FISH analysis. Patient 2 is 11-month old girl manifesting severe psychomotor delay and West syndrome. Brain MRI showed atypical hypoplasia of the brain. Patient 3 is 22-year old male. He suffered seizures when he was 7 years old. Samples derived from the three patients were analyzed by Oligoarray CGH (Agilent Technologies). Patient 1 showed partial deletion of PAFAH1B. Patient 2 showed chromosomal triplication including PAFAH1B. Patient 3 showed small subtelomeric deletion including YWHAE but not PAFAH1B. Intra genic neucleotide mutations or deletions cause isolated lissencephaly, and the neighboring gene YWHAE is believed to be necessary for dysmorphic features. In our study, microdeletions identified in patient 1 and 3 included YWHAE and PAFAH1B, independently, and nobody showed a facial feature characteristic with Miller-Dieker syndrome. Heterozygous triplication of PAFAH1B identified in patient 2 was similar to that recently reported by Bi et al. (Nature Genet 2009).

## 1335/W/Poster Board #993

**A fetus with multiple gastro-intestinal atresias, limb defects and a de novo translocation 46,XY,t(4;9)(q27-p23).**
*M. Biervliet[1,2], J. Wouters[1,2], W. Wuyts[1,2], J. Van den Ende[1,2].* 1) Medical Genetics, University Hospital of Antwerp, Belgium; 2) Medical Genetics, University of Antwerp, Belgium.

We report on a fetus with multiple malformations and a de novo translocation 46,XY,t(4;9)(q27-p23). The family history was unremarkable: there was no consanguinity and no maternal diabetes. During the pregnancy there was no infection or drug exposure. The most striking features were the multiple gastro-intestinal atresias: the esophagus and stomach were blind ending, even so the cecum. There was no proximal, transversal and distal colon. The rectum was also blind ending with anal atresia. The right upper limb was severely dysplastic with one 'humero-radial bone', one metacarpal and one digit. At the left hand there was an oligodactyly. Further malformations were cardiac abnormalities and absence of one lung. On the microarray a microdeletion was found of about 8 Mb (4q26-4q28.1). We comment the deleted genes and the possible involvement of the FGF2 gene (and the adjacent genes NUDT6 and SPRY1) in the defective morphogenesis. The deletion of the FGF2 region does not explain all the malformations, so we suppose that (an)other missing gene(s) may play an important role during the morphogenetic period (NDST3 gene ?).

## 1336/W/Poster Board #994

**Recurrent deletions mediated by complex low-copy repeats on chromosome 10q11.21q11.23 in eight patients with variable phenotypes.**
*S. Kulkarni[1,4,8], S.S. Bhatt[2,8], Z. Xia[2], A. Pursley[2], A.R. Paciorkowski[3], M.L. Cooper[2], B.A. Kozel[4], D.K. Grange[4], M.J. Noetzel[3], P.T. Golumbek[3], P. Simons[5], M. Summar[6], J. Miles[7], A. Patel[2], S.H. Kang[2], C.A. Bacino[2], S.W. Cheung[2], P. Stankiewicz[2].* 1) Dept Path, Lab & Genomic Med, Washington Univ Sch Med, St Louis, MO; 2) Dept of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 3) Dept of Neurology, Washington Univ Sch Med, St Louis, MO; 4) Dept of Pediatrics, Washington Univ Sch Med, St Louis, MO; 5) St Louis Children's Hospital, St Louis, MO; 6) Vanderbilt University Medical Center, Nashville, TN; 7) University of Missouri School of Medicine, Columbia, MO; 8) These authors contributed equally.

Using clinical oligonucleotide array CGH analysis, we have identified recurrent deletions in a low-copy repeat (LCR)-rich chromosome region 10q11.21q11.23 in eight patients with variable phenotypes, including mild to severe developmental delay/mental retardation, autistic spectrum disorder, dysmorphic features, ataxia and multiple congenital anomalies. Custom designed high-resolution array CGH analysis allowed us to narrow the breakpoint regions. The deletions range in size from ~ 1.5 to 6 Mb. No CNV has been reported in the smallest unique sequence region of deletion overlap (between ~ 49.2 and 50.6 Mb). FISH analysis revealed that the deletion was inherited from an apparently normal parent in six cases, three from the father and three from the mother. One of the maternally inherited deletions was accompanied by a de novo ~ 12 Mb deletion in 3q13.12q13.32 and the other by a maternally inherited ~ 2 Mb duplication in 13q22.3. In two cases, no parental samples were available. More than half of the analyzed 6.5 Mb region in 10q11.21q11.23 is occupied by 13 large LCR clusters of complex structure; there are also seven genomic gaps. Four same-sized ~ 6 Mb deletions are flanked by LCRs with directly homologous subunits ~ 100 kb in size with 98.2% DNA sequence identity and the fifth similar deletion is flanked by ~ 112 kb subunits with 99% DNA sequence identity, indicating a non allelic homologous recombination (NAHR) as the mechanism of formation. The other two deletions were likely stimulated but not mediated by LCRs. In addition, we describe a 21-year-old patient with developmental delay, very limited vocabulary, and poor motor conditioning, in whom we identified an ~ 9 Mb deletion in 10q11.2q21.1 present also in his healthy father and brother. We propose that the phenotypic diversity and lack of distinct syndromic features associated with the deletion CNVs in 10q11.21q11.23 warrant further careful examination of this genomic region. Variable expression and incomplete penetrance should be considered.

## 1337/W/Poster Board #995

**Exploiting 15q11.2-q13 segmental duplication structures to distinguish different classes of chromosomal rearrangements *in situ*.**
*W.A. Khan[1], P.K. Rogan[1], J.H. Knoll[2].* 1) Biochemistry; 2) Pathology, University of Western Ontario, London, ON, Canada.

Genomic regions flanked by segmental duplications in Prader-Willi and Angelman syndromes (PWS/AS) show a great proclivity for chromosomal structural changes. The most common rearrangements in PWS/AS involve large (Class I) and small (Class II) deletions sharing a common telomeric breakpoint. Based on genomic array studies, the deletion breakpoint hotspots coincide with locations of segmental duplications. Genomic arrays have determined the approximate locations of the breakpoints of these rearrangements. Greater precision in determining breakpoints can be gained by using pre-defined, short repeat-free sequences from the reference human genome in a FISH-based assay. In the present study, we devised a strategy for breakpoint analysis by mapping approximate locations of Class I and Class II breaks to overlapping adjacent single copy or duplicated intervals. Sequences of defined copy number and context of 1500-5000 base pairs were designed and overlapped across boundaries of previously reported breaks. Of a total of 47 sequences, 8 occurred at the interfaces of greatest density of breakage activity were selected for probe development. Two of the probes, embedded within segmental duplicons, which intersect the proximal end of Class I deletions, contain paralogous sequences at the telomeric breakpoint. Two different probes embedded within duplicons that intersect proximal end of Class II deletions are not found at the telomeric breakpoint. Of the remaining 4 probes, 2 are adjacent to segmental duplicons at the proximal end of Class I deletions and two are adjacent to duplicons at the telomeric breakpoint. A positive control probe is also designed for the imprinted domain in PWS/AS specific to the *MAGEL2* locus. FISH studies using probes for the proximal ends of Class I and Class II deletions have demonstrated high specificity. Departure from the expected hybridization patterns for normal chromosomes dictates the probe combinations to be used in the subsequent hybridizations. A two-step hybridization algorithm is capable of differentiating multiple classes of breakpoints by co-hybridizing probes sequences labeled with different fluorophores to discriminate deleted from non-deleted chromosome 15 homologs. This approach will accurately determine breakpoints and the genomic structure of PWS/AS deletions. These strategies should be useful for delineation of chromosome boundaries for other disorders associated with segmental duplication.

## 1338/W/Poster Board #996

**Mosaic deletion of TCF4 in a child with Pitt-Hopkins syndrome.** *D.J. Stavropoulos[1], D.L. MacGregor[2], G. Yoon[2,3].* 1) Dept Cytogenetics; 2) Division of Neurology; 3) Division of Clinical and Metabolic Genetics, Hosp Sick Children, Toronto, ON, Canada.

We present the clinical and cytogenetic findings in an 8 year old girl with mental retardation, absent speech, acquired microcephaly, delayed motor skills and stereotypical hand movements. Craniofacial exam revealed coarse facial features, up-slanting palpebral fissures, a broad nasal bridge and tip with prominent lips held open in a Cupid's bow pattern. She experienced tonic clonic seizures since the age of 14 months, and an MRI at 17 months revealed delayed myelination of the frontal lobes as well as prominence of the ventricles. Molecular testing for Rett and Angelman syndromes was negative. Array comparative genomic hybridization identified a de novo deletion of approximately 6 Mb in chromosome region 18q21.1q21.31, resulting in the loss of one copy of the TCF4 gene as well as 21 other RefSeq genes. Fluorescence in situ hybridization (FISH) analysis of peripheral blood confirmed the deletion in approximately 50% of cells, consistent with a mosaic deletion. The deletion likely occurred early in development as this child has clinical symptoms affecting multiple organ systems, consistent with those observed in Pitt-Hopkins syndrome (PHS; OMIM 610954). PHS is a rare neurodevelopmental disorder caused by haploinsufficiency of the TCF4 gene on chromosome region 18q21.1. Individuals with a deletion or de novo heterozygous mutation of TCF4, have been described with severe mental retardation with absent or limited speech, characteristic facial gestalt, unsteady gait and hypotonia. Other features include episodes of hyperventilation followed by apnea, congenital or acquired microcephaly, seizures, stereotypic movements of the hands, and constipation. The fact that our patient does not manifest all the typical features of PHS may be due to her being haploinsufficient for TCF4 in mosaic form only. This case report represents the second known example of a mosaic deletion resulting in clinical symptoms consistent with Pitt-Hopkins syndrome.

## 1339/W/Poster Board #997

**Extra structurally abnormal chromosomes: experience of a prenatal diagnostic laboratory during 11 years.** *F. Tihy, L. Oprea, E. Lemyre.* Dept Genetics, CHU Ste-Justine, Montreal, PQ, Canada.

Extra structurally abnormal chromosomes (ESACs) are one of the challenges in prenatal diagnosis. Their identification was not evident by classical cytogenetics but has become easier with the development of fluorescent in situ hybridization and recently, of CGH micro-arrays. Nonetheless, literature is still missing precise genotype-phenotype correlation for counselling once the marker chromosome has been characterised. We report here the finding of eleven years of prenatal diagnosis, with 32015 amniocenteses in which 58 had an ESAC, 51 of them characterised. 42 ESACs were de novo, 12 were inherited and 4 were extra derivative chromosomes from a parental translocation. The incidence of ESACs in our laboratory was 1/552. Of those, twenty six were from acrocentric chromosomes, eight were isochromosomes of the short arm of chromosomes 9, 12 and 18, three were complete short arms of chromosome 4, 5 and 20, eight were ring chromosomes from chromosome 1, 2, 3, 19 and X and two were centromeres of chromosomes 2 and 12. The 7 non-characterised ESACs were mostly found in the years 1998 and 1999. 4 ESACs seemed to contain euchromatin and were associated with ultrasound abnormalities and 3 were very small without evidence of euchromatin (2 inherited). Of the 58 ESACs, 32 contained some euchromatin, all of them de novo or extra derivative from a parental translocation. Most of the pregnancies were then terminated but a few continued: two pregnancies with a derivative 22 who developed signs of cat eye syndrome, one with a derivative 15 containing the PWS region, two with a derivative 14, one with a ring chromosome 3 containing mostly part of the long arm, one with a small ring 2. These children are evaluated regularly at our clinic. For a good genotype-phenotype correlation, a CGH array analysis from a blood sample of those children can assess more precisely the euchromatin present but only when the ESACs are not at a low level of mosaicism.

## 1340/W/Poster Board #998

**A healthy birth after preimplantation genetic diagnosis in two couples of reciprocal translocations.** *M. Woo[1], J. Choi[1], H. Seol[1], S. Kim[2], M. Kang[2], H. Kim[2], S. Oh[1,2], S. Ku[2], S. Kim[2], Y. Choi[1,2], S. Moon[1,2].* 1) Institute of Reproductive Medicine and Population; 2) Department of Obstetrics and Gynecology, College of Medicine, Seoul National University, Seoul, Korea.

Balanced reciprocal translocations which lead to errors in gametogenesis are known to be an increased risk of infertility, spontaneous abortions, and abnormal offspring. The application of preimplantation genetic diagnosis (PGD) has been mostly attempted by fluorescent in situ hybridization (FISH) using specific DNA probes to reduce the risk transferring embryos with aneuploidy. The FISH analysis has been used to select a chromosomally normal or balanced segregation from blastomere of preimplantation embryos. We describe our experience on the PGD analyses using FISH for couples repeated pregnancy loss. Case A, a 32-year-old female, was a carrier of balanced reciprocal translocation, 46,XX,t(9;14)(p24;q32). Her husband had normal karyotype. The couple experienced two spontaneous abortions at the first trimester. The case A was used by FISH with two telomeric probes, 9pter and 14qter probes, and centromeric probe. We identified six embryos with a normal or balanced combination of probe signals from case A, and achieved in one pregnancy. The amniocentesis was confirmed at 16 weeks gestation and a girl with a normal karyotype was born. Case B, 36-year-old female, was a carrier of balanced translocation with karyotype 46,XX,t(18;21)(q11.2;q22). The karyotype of male partner was normal. The case B was referred due to the two pregnancy losses. The FISH analysis was studied with two telomeric probes, 18qter and 21qter probes. The case B showed two embryos derived from 3:1 segregations, one from adjacent-1segregation, and one from mosaic. No embryo transfer could be carried out because all the embryos of case B were unbalanced. In conclusion, PGD-FISH for infertile couples of reciprocal translocations should be considered as a treatment method for transfer of normal embryos after in vitro fertilization, and these results will be useful information in reproductive counseling.

## 1341/W/Poster Board #999

**Evolution of centromeric sequences in Primates: new insights from the White-cheeked Gibbon and Marmoset.** *C.R. Catacchio[1], A. Cellamare[1], C. Alkan[2], G. Giannuzzi[1], F. Antonacci[2], M.F. Cardone[1], G. Della Valle[3], M. Malig[2], M. Rocchi[1], E.E. Eichler[2], M. Ventura[1].* 1) Department of Genetics and Microbiology, University of Bari, Bari, Italy; 2) Department of Genome Sciences, Howard Hughes Medical Institute, University of Washington School of Medicine, Seattle, Washington, USA; 3) Department of Biology, University of Bologna, via Selmi 3, Bologna, Italy.

Alpha-satellite DNA is the major component of centromeric DNA and forms the centromere central domain of both human and all studied primate chromosomes, ranging in size up to 5Mb. It is the most studied repeated DNA family, is made up of a basic 171bp unit tandemly organized and was first described in the african green monkey as a 340bp repeated unit consisting of two 171 bp different monomers. Human alphoid DNA is organised into higher order structures and suprachromosomal subfamilies that hybridize to a distinct subset of chromosomes. Besides higher order repeats $\alpha$-satellite in HSA can organize into monomeric repeats which are likely to be emerged first during karyotype evolution. $\alpha$-satellite pancentromeric localization clearly suggests its functional involvement in an active centromere. These long homogenous stretches of repetitive DNA could work as a spacer to protect the centromeric locus from transposable sequences that would disrupt centromeric activity rather than having a sequence-mediated specific role. The evolutionary history of $\alpha$-satellite DNA is hardly defined because of the difficulty in its sequence assembly and its rapid evolution. By using several approaches we have cloned, sequenced and characterized $\alpha$-satellite sequences from two species of Primates: the white-cheeked gibbon and marmoset. Sequence analyses demonstrate that white-cheeked gibbon and marmoset $\alpha$-satellite sequences are formed by units of ~171 bp and ~342 bp, respectively, and they both lack high-order structure found in humans and great apes. Further, FISH characterization shows a broad dispersal of alpha-satellite in the white-cheeked gibbon genome including centromeric, telomeric and chromosomal interstitial localizations. On the other hand centromeres in marmoset appear organized in highly divergent dimers roughly of 342bp that show a similarity between monomers much lower than previously reported dimers thus representing an ancient dimeric structure. Our results shed light on the evolution of the centromeric sequences in Primates. We suggest radical differences in the organization and evolution of $\alpha$-satellite DNA among different primate species, showing that centromeric function is not linked to higher-order structure and all the centromeric sequence in Primates evolved by genomic amplification, unequal crossover and sequence homogenization using a 171bp monomer as basic seeding unit.

### 1342/W/Poster Board #1000

**Mapping of functional domains at the human chromosome 5 centromere.** *B. Grimes[1], C. Steiner[1], J. Bhavsar[1], T. Schwarz[2], S. Christan[2], M. Yoder[3], D. Schindelhauer[2], R. Slee[1].* 1) Medical & Molecular Gen, Indiana Univ Sch Medicine, Indianapolis, IN; 2) Department of Medical Genetics, Ludwig Maximilians Univ, Munich, Germany; 3) Wells Center for Pediatric Research, Indiana Univ Sch Medicine, Indianapolis, IN.

This study examines the relationship between sequence and chromatin domains at the human chromosome 5 centromere to improve our understanding of centromere specification. Alpha satellite DNA is present at all centromeres and forms chromosome specific higher order repeats (HORs). Structurally, the centromere comprises two chromatin domains: the kinetochore (mitotic spindle attachment region) characterized by deposition of the CENP-A (a histone H3 variant) and flanking pericentromeric heterochromatin important for sister chromatid cohesion. Here, the contribution of the two adjacent HOR families, D5Z1 and D5Z2 to the chromosome 5 centromere has been investigated. FISH analysis revealed deletion of all detectable D5Z1 sequence and retention of D5Z2 on a mitotically stable patient derived ring 5 chromosome (with breakpoints at 5p10-p13). Consistent with D5Z2 assembling the kinetochore, combined immunofluorescence (IF) with a CENP-A antibody and Fluorescence In Situ Hybridization on chromosome spreads from a cancer cell line (HT1080) showed overlap between CENP-A and D5Z2 but not D5Z1. To refine this analysis, chromatin immunoprecipitation (ChIP) and semi-quantitative real-time PCR (qPCR) was performed on HT1080 cells and primary human umbilical vein endothelial cells (HUVECs) with antibodies to CENP-A and H3K9me3. In all cases CENP-A was restricted to D5Z2 while D5Z1 was comparable to negative controls confirming that D5Z2 assembles the kinetochore. In contrast, H3K9me3 (a heterochromatin marker) was detected on both D5Z2 and D5Z1. In HT1080, H3K9me3 was present at a lower level on D5Z2 relative to D5Z1 while in HUVECs, similar amounts of H3K9me3 were detected on each sequence. Furthermore, amounts of H3K9me3 at the centromere in HT1080 were reduced more than five-fold relative to HUVECs indicating loss of pericentromeric heterochromatin in HT1080 cells. Support for this conclusion was obtained using IF with H3K9me3 and CENP-A antibodies on chromosome spreads. H3K9me3 was rarely detected in the region between the CENP-A double dot kinetochore signals in HT1080 cells but was detected frequently between the CENP-A signals in HUVECs. These data provide an integrated DNA and chromatin map of centromere 5 and raise the possibility that loss of pericentromeric heterochromatin in HT1080 cancer cells may contribute to aneuploidy and cancer progression.

**Phenotypic effects of a pericentric inversion of chromosome 9.** *C. Albu[1], D.F. Albu[1], A. Toma[2], E. Severin[1].* 1) Dept of Human Genetics, Carol Davila Univ Med Pharm, Bucharest, Romania; 2) Panait Sirbu Hospital, Bucharest, Romania.

Aim: Inversion of chromosome 9 is a cytogenetic abnormality quite common in the general population. Phenotypic effects often do not exist. We present a case of a premature neonate with this abnormality and a congenital malformation of the midline. Material and methods: A case of a premature neonate is presented. For examination there were used: clinical and neurological examinations, ultrasound examinations, cytogenetic tests. Results: The patient is a male newborn, delivered at 33 weeks gestational age for suspicion of hydrocephalus. The postnatal ultrasound showed a hypoechogenic formation of 1.81/1.97 cm in the posterior fossa, with no vascular supply.This image was consitent with an arachnoidal cyst. The heart and abdominal ultrasound exams showed no added malformations. There were noted dysmorphic features with wide facies and low nasal bridge. The karyotype showed a pericentric inversion of chromosome 9 [46 xy, inv (9)(p12q13)]. On follow up visits the infant showed a normal neurologic development and no modification in the dimensions of the cyst. The patient is now 6 months old. Conclusion: Posterior fossa cysts can occur in the case of pericentric inversion of chromosome 9, with some added dysmorphic features.

### 1344/W/Poster Board #1002

**Micronuclei in human lymphocytes exposed to sodium pertechnetate, in vitro.** *I. Aranha.* Inst Biol, PHLC S-525-6, Univ Estado Rio de Janeiro, Rio de Janeiro, Brazil.

Technetium-99m ($^{99m}$Tc)has become the most widely used radioisotope in the detection of inflamatory sites as well as in the diagnosis of transplanted tissues. The goal of the present work was to study the effect of sodium pertechnetate on human lymphocytes in vitro, using the micronucleus assay. Micronuclei appear during cell division as a result of acentric chromosome fragments or whole chromosomes outside the nucleus. Peripheral whole blood cells collected from healthy donors, 18 to 30 years old, were incubated at 37ºC for 48 hours in the presence of $^{99m}$Tc (3.7MBq/100µL). Cells not exposed to the radionuclide served as control for the experiment. Cytochalasin B (3µg/mL) was added to the cultures 20 hours postinitiation. After fixation, cells were stained with Giemsa Gurr (2%) and were observed under optical microscope. In the test group, 12077 binucleated cells were studied and 212 of them showed alterations (18 micronuclei and 194 nucleoplasmic bridges). Nucleoplasmic bridges are biomarkers of genomic instability and are a result of chromosome rearrangements involving more than one centromere (dicentric chromosomes). In the control group 12056 cells were obsreved and 6 micronuclei were seen. The chi-square test with Yates correction indicated that the results were extremely significant ($p<0.0001$) suggesting that sodium pertechnetate was responsible for the chromosome alterations observed.

### 1345/W/Poster Board #1003

**Effect of 99m-technetium combined to its reducing agent stannous chloride on chromosomes from human lymphocytes in vitro: Micronucleus assay.** *E.C.M. Passos, I.P. Aranha.* IBRAG, Univ. do Estado do Rio de Janeiro, Rio de Janeiro, Rio de Janeiro, Brazil.

Technetium-99m ($^{99m}$Tc) has been used in the detection of inflamatory sites as well as in the diagnosis of transplanted tissues. Its efficiency is increased by a reducing agent, stannous chloride ($SnCl_2.2H_2O$). Previous work inn our laboratory has shown that the use of the reducing agent (12µg/mL) in the culture of whole blood lymphocytes neither decreased the mitotic rate nor caused any numerical or structural chromosome abnormality. The goal of the present work was to observe if sodium pertechnetate combined to its reducing agent might cause micronuclei in human lymphocytes, in vitro. Peripheral whole blood cells, collected from healthy donors, 18 to 30 years old, were incubated at 37ºC for 48h. One sample was exposed to stannous chloride (12µg/mL), another was exposed to the radionucleide combined to its reducing agent and a third one contained cells that were not exposed to any of the agents and served as control for the experiment. Cytochalasin B (3µ/mL) was added to the cultures 20h postinitiation. After fixation, cells were stained with Giemsa Gurr (2%) and were observed under optical microscope. In the group exposed to stannous chloride 13003 cells were observed and none showed micronuclei. In the group exposed to sodium pertechnetate combined to its reducing agent 12413 cells were studied and 222 had micronuclei. In the control group 13907 cells were observed and 2 had micronuclei. The chi-square test for independence indicated that the results were extremely significant ($p<0.0001$) suggesting that sodium pertechnetate was responsible for the micronuclei observed.

### 1346/W/Poster Board #1004

**Translocation 20p to 21 q in mother and son.** *A. Toma[1], C. Albu[2], E. Severin[2], D. Albu[2].* 1) “Panait Sarbu” Obstetrics and Gynecology Hospital , Bucharest, Romania; 2) “Carol Davila” Univ Med Pharm.

Aim: The paper reports a 20p;21q translocation present in the mother and in her newborn son, affecting the neonate but not the mother. Material and method: For the description of the case there were used the clinical examination of the mother and infant, the ultrasound examinations of the infant, blood samples and the karyotype test. Results: This is the case of a term male newborn, delivered by cesarean section at 38 weeks gestational age. The clinical examination at delivery noted axial hypotonia. The baby presented at 12 hours of age with digestive bleeding . The hemorrhagic disease of the newborn was excluded and head, heart and abdomen ultrasound were performed in order to exclude other hemorrhages. The head ultrasound showed the presence of a cyst in the posterior fossa. The karyotype sampled from the baby showed the following result: 47, xy, t(20p; 21q1). The same translocation was noticed in the mother, who was asymptomatic, phenotipically normal. The evolution of the infant was unfavorable with hypotonicity, apneic spells, repeated respiratory infections. There is present a severe mental retardation. Conclusion: The particularity of the case consists in the absence of symptoms in the mother and the presence of malformations and severe mental retardation in the infant.

**Cytogenetic Alterations in Peripheral Blood Lymphocyte Cultures of Occupationally Exposed Steel Welders.** *A.R. Patel, S.S. Chettiar, M.V. Rao.* Department of Zoology, Gujarat university, Navarangpura,Ahmedabad, Gujart, India.

Purpose: More than three million workers worldwide involve in welding profession. The stainless steel welding fumes contains higher content of reactive oxides of the chromium compounds. Epidemiological studies have reported a significant elevated risk for lung cancer among the welders. The overall objective of this study is to investigate the underlying relationship between airborne exposure to welding fumes and their genotoxic effects on occupationally exposed workers. Materials and Methods The selection criteria for the welders were based on a questionnaire. The questionnaire was intended to elicit information on the subject's age, smoking habits, alcohol consumption and duration of exposure and medicine usage. Individuals in control group belonged to the same age group and socio-economic status as the welders. We ensured that the welders and the controls did not markedly differ from each other except for occupational exposure. The heparinized blood of welders was collected in sterile vials and brought to laboratory in coolant box and further procedure was done within 4 hours of collection. The blood was cultured in duplicates with equal number of age matched controls. After 69 hours of culture metaphase plates were prepared as mentioned above and subjected to analyses of several genotoxic endpoints such as Single cell gel electrophoresis and Chromosomal aberration. Blood profile of these welders was also analysed using automated cell counter (sysmax). The chromium levels were also measured in the blood and water by Inductively Coupled Plasma Atomic Emission Spectrophotometer (ICP AES). Results and Discussion: The welders are divided in the three major groups depending upon the exposure years (0-5 years, 6-10 years and exposed more than 10 years). The result revealed that there is a significant increase in the tail length and frequency of the chromatid and chromosomal breaks and gaps suggesting increased DNA damage. The blood chromium levels were significantly higher than that of the control individuals. The increase in DNA damage is correlated to the chromium levels in blood of welders and drinking water at work place. The result of this study indicates a probable human genetic risk at these work places.

## 1348/W/Poster Board #1006

**Microduplication 22q11.2 in a boy with dysmorphic features and speech delay.** *L. Telvi[1], M. Minz[1], O. Brichet[2], P. Bougneres[2].* 1) Cytogenetics Laboratory, Hosp St Vincent de Paul, Paris, France; 2) Department of Pediatric Endocrinology, Hosp St Vincent de Paul, Paris, France.

Recently, the microduplication of 22q11.2 region has been reported as a new chromosomal syndrome (Portnoi, 2009). The phenotype of these patients is extremely variable ranging from normal to behavorial abnormalities to multiple defects. We report a five-years-old boy with dysmorphic features with no intellectual disability after Denver scale testing who carrying a duplication of 22q11.2. The dysmorphic features consisted with macrocephaly, unique palmar crease, pterygium colli, pectus excavatum, small upper lip with absence of philtrum. He showed also speeching difficulties, sleeping troubles, but have not development delay, no autistic trait and no seizures. The karyotype with RHG banding of the patient was found normal, the FISH analysis showed the duplication of the region 22q11.2 after using Tuple1 probe (Cytocell). A PCRq analysis and a CGH-array confirmed the duplication. The analysis of parental karyotypes are undergoing. Compared to microdeletions, few microduplications of 22q11.2 have been identified to date. Chromosome 22, particularly the 22q11.2 region predisposed to rearrangements due to misalignements of low-copy repeats (LCRs). The described phenotypes of these patients with microduplications is extremely diverse. This diversity will make ascertainment difficult and will necessitate a rapid-screening method. A correlation between the size of the duplication and the severity of the phenotypic presentation is not well defined to date. This suggests that in addition to gene dosage other mechanisms such as genetic, environmental interactions and possibly imprinting may be important in determining the phenotypic outcome of patients with 22q11.2 microduplication.

## 1349/W/Poster Board #1007

**Complex chromosomal 3:1 segregation after a chromosome breakage and reunion within the quadrivalent formation in a balanced carrier.** *C. Yu[1], C. Thompson[1], H. Huang[1], S. Gagneaux[1], A. Bhatt[2].* 1) Dept Pathology and; 2) Dept Pediatrics, University of Mississippi Medical Center, Jackson, MS.

Balanced translocation carriers could produce unbalanced gametes when there is an adjacent or 3 to 1 segregation of a quadrivalent occurring during meiosis. We report a newborn who had a complex unbalanced chromosome constitution possibly resulting from a chromosome breakage and reunion in a quadrivalent and followed by a 3 to 1 segregation in his parents during the meiosis. A 34 5/7-week infant was born to a 32 year G4P2Ab2 mother. The birth weight was 2.55kg, length was 43cm and circumference was 32.5cm. Infant was referred for chromosome study due to multiple congenital anomalies. The Mother had polyhydramnios and ultrasound fetal anomaly during pregnancy and had underwent amniotic fluid reduction at 32 weeks of gestation. On physical examination, the newborn had small and low set ears, small eyes, prominent nose, mild micrognathia, low hair line, webbed neck, wide spaced nipples, fused 4th and 5th toes on both sides. The new born expired at 57 days with renal and respiration failure. Blood chromosome study by GTG banding method indicated that this infant had 47 chromosomes with a translocation between chromosomes 3 and 9 and an extra marker chromosome. G banding indicates that this marker chromosome is dicentric and contains segments of 9pter to 9q21.2, 9q12 to 9p22 and 3q26.2 to 3qter. FISH study confirms the presence of locus 305J7-T7 and locus D3S4560 on the 9pter and 3qter end of the marker chromosome, respectively. Parental chromosome studies are not available. Thus this infant could have inherited all the abnormal chromosomes from one of his parents who is a carrier of a balanced 3/9 translocation and has a 3:1 segregation in meiosis after a possible chromosome breakage and reunion had occurred between the normal 9 and the abnormal chromosome 9 of the quadrivalent formation. The karyotype of this infant could be described as 47,XY,t(3;9)(q26.2;p22),+der(9;9)(q21.2;q12)t(3;9)(q26.2;p22). The infant had tetrasomy of 9p22 to 9q12 and trisomy of 9pter to 9p22, 9q12 to 9q22, and 3q26.2 to 3qter.

**Performance characterization of the Affymetrix Cytogenetics Research 2.7M microarray system.** *D. Abdueva, J. Veitch, V. Huynh, P.J. Collins.* Affymetrix, Emeryville, CA.

The resolution of CNV regions that can be reliably detected in a microarray platform is formulated in terms of signal to noise ratio at any given resolution. The recently released Affymetrix Cytogenetics Research 2.7M array interrogates Copy Number state at about 2.7 million locations evenly spaced along the Human. Here we present the performance characterization using Chromosome X aneuploidy cell lines with Copy Numbers ranging from 1 through 5. We use the Signal to Noise (S/N) ratio to evaluate performance. Using the CNV calling algorithm that comes with the Affymetrix supplied software, at a 50 KB resolution for gains and losses the Affymetrix 2.7M array has a False Positive Rates substantially less than 1% at a true positive rate better than 99.9%.

**Long-range expression consequences of copy number variation suggest that chromosome gene assortment is not random.** *G. Ricard[1], N. Gheldof[1], J. Chrast[1], J. Molina[2], S. Pradervand[1], F. Schutz[1], J. Lupski[3], K. Walz[2], A. Reymond[1].* 1) Ctr Integrative Genomic, Lausanne, Switzerland; 2) Centro de Estudios Cientificos (CECS), Valdivia, Chile; 3) Molecular and Human Genetics, Baylor College of Medicine, Houston, Texas, USA.

To examine the effect of genome structural changes on gene expression, we implemented genome-wide expression arrays in genomic disorder mouse models. Both a microdeletion and its reciprocal microduplication mapping to mouse chromosome 11 (MMU11), which model the rearrangements present in patients with Smith-Magenis (SMS) and Potocki-Lupski (PTLS) syndromes, respectively, were studied. We profiled the transcriptome of five different tissues that are affected in human patients in mice with 1n (Deletion/+), 2n (+/+), 3n (Duplication/+) and balanced 2n compound heterozygous (Deletion/Duplication) copies of the same region in an otherwise identical genetic background. The most differentially expressed transcripts between the four studied genotypes were ranked. A highly significant propensity of transcriptional changes are mapping to the engineered SMS/PTLS interval in the different tissues. A statistically significant overrepresentation of the genes mapping to the flanks of the engineered interval was also found in the top-ranked differentially expressed genes; an observation robust across multiple cell lineages and that extends along the entire length of the chromosome, tens of megabases from the breakpoints. These long-range effects are uncoupled from the number of copies of the CNV genes, i.e. both the deletion and the duplication, influence expression of these flanking genes in a similar manner. Thus, our data indicate that a structural change at a given position of the human genome may cause the same perturbation in particular pathways regardless of gene dosage. Consistently, conditions affecting the central nervous system were shown to be associated with both the deletion and the duplication of the same DNA segment. The uncoupling between the number of copies of the CNV genes and the phenotype, here the effect on expression of genes outside of the rearrangement, is further illustrated by the fact that we detect the same changes in expression for these genes in the compound heterozygote in which gene copy number was restored. Consistently, not all the phenotypic manifestations observed in the SMS and PTLS mice models were rescued in these animals. Finally, our results suggest that the assortment of genes mapping to a chromosome is not random.

### 1352/W/Poster Board #1010

**Case Report: A boy with a 46XY,del(14)(p11.2) Karyotype and phenotype correlation.** *C. Duran[1], A. Lopez[1], G. Gordillo[1], O. Gutierrez[2], R.A. Lopez[1], J.C. Prieto[1,2].* 1) Instituto de Genética Humana, Universidad Javeriana, Bogotá, Colombia; 2) Hospital La Victoria, Secretaría de Salud, Bogotá, Colombia.

Deletions are chromosomal disorders characterized by loss of genetic information. Terminal deletion and interstitial deletion may be instigated by agents that cause chromosome breaks and by unequal crossover during meiosis. The phenotype and clinical characteristics of the patient show a direct relationship between the involved chromosome and the amount of genetic material lost. This abnormality can also be present without having a clinical effect. However, deletion of the short arm of the chromosome 14 is characterized by hepatocellular carcinoma, squamus cell carcinoma, and prostate cancer. We report on a 6 month old boy, a product of a first pregnancy (37 weeks), born of non consanguine teenage parents. The patient required hospitalization in the neonatal unit due to low weight, jaundice and suspected neonatal sepsis. On physical examination, thepositive findings were microtia Grade I/ II bilateral with external ear canal and right helix indent. In addition there was upslanting palpebral fissures, bilateral single palmar fold and brachydactyly. During hospitalization the patient received a Renal US, chest X-rays, neonatal TSH (all reported as normal) and the band R karyotype report: 46XY,del(14)(p11.2). Until now, there have been reports of patients with this chromosomal inbalance associated with squamus cell carcinomas and prostate cancer. Deletion of information in the short arm of those acrocentric chromosomes is usually complete and is associated with Robertsonian traslocation between 13, 14 in 75%, 14, 21 in 8% and 14, 15 in 2.5%. By contrast, deletions of the long arm of chromosome 14 have been associated with variable phenotype.

### 1353/W/Poster Board #1011

**A first case of mosaic double aneuploidy (46,X,+14/46,XX) in a patient with short stature, pigmentary abnormalities, mental retardation, dysmorphic features and hypogonadism.** *T.-J. Chen, Y. Wang, G. Steen, A. Lee, C. Tuck-Muller, H. Hobart, J.E. Martinez.* Dept Medical Genetics, Univ South Alabama, Mobile, AL.

We report the first case of a patient with an unusual mosaic double aneuploidy with phenotypic features of Turner syndrome and Trisomy 14 mosaicism syndrome. The patient is a 15 year-old Asian female. She was born prematurely, at 7 months gestation and spent about three weeks in the NICU. She was later noted to be short with failure to thrive, areas of skin depigmentation, and developmentally delayed. Physical examination revealed a short and dysmorphic female with head circumference: 53 cm (25$^{tho}$%tile); Height: 128 cm (<2$^{ndo}$%tile) and Weight: 38 kg (<2$^{ndo}$%tile). Craniofacial dysmorphism includes hypertelorism, prominent forehead, micrognathia, short philtrum, low set and small dysplastic ears with outstanding pinnae and folded helix and a short neck with low posterior hair line. Striae of skin hyperpigmentation in trunk and lower back were noted and a Tanner I stage of sexual development suggested hypogenitalism that requires further investigation. The diagnoses of Hypomelanosis of ITO and CHARGE syndrome were considered and a chromosome analysis revealed a 46, XX karyotype. Array CGH analysis was performed on a blood specimen revealing an unusual double mosaicism of both monosomy X and trisomy 14. Array CGH result suggested mosaicism of both monosomy X and trisomy 14 in roughly equal percentages (10-15%). Chromosome analysis of 100 metaphases found 4 cells that were 46,X,+14. Interphase FISH analysis on 200 nuclei yielded 6.5% of nuclei with coexistent trisomy 14 and monosomy X, confirming the patient's karyotype 46,X,+14[4]/46,XX[96].nuc ish (DXZ1x1)(IGHx3)[13/202]. To our knowledge, this chromosome abnormality has not been previously reported, though Figuera et. al. (2008) noted a patient with a similar phenotype, a combination of Turner syndrome and trisomy 14 mosaicism, but whose karyotype was 45,X[45]/47,XX,+14[5]. Genotyping using chromosome 14 STR markers demonstrated only two alleles at each locus. Thus, trisomy 14 is unlikely due to a parental meiosis I non-disjunction event. Our patient's phenotype also suggests mosaicism in tissues other than blood. The primary event resulting in this double mosaicism should occur at early post-zygotic stages. However, without additional evidence it is difficult to envision a mechanism for the two numerical, coexisting chromosome abnormalities in a cell line. Further study is needed to clarify the etiology of this unusual abnormality.

### 1354/W/Poster Board #1012

**Utility of SNP arrays in detecting, quantifying, and determining meiotic origin of tetrasomy 12p in blood from Pallister-Killian patients.** *L.K. Conlin[1], M. Kaur[1], D. Clark[1], E. Zackai[1], M.A. Deardorff[1], H. Hakonarson[1,2], N.B. Spinner[1,3], I.D. Krantz[1].* 1) Department of Pediatrics, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) The Center for Applied Genomics, The Children's Hospital of Philadelphia, Philadelphia, PA; 3) Department of Pathology, The Children's Hospital of Philadelphia, Philadelphia, PA.

Diagnosis of the isochromosome 12p (i(12p)) associated with Pallister-Killian syndrome is complicated by the low frequency of this supernumerary chromosome in PHA stimulated peripheral blood lymphocytes, and frequently requires cytogenetic analysis of fibroblast cells for diagnosis. Recently, it has been shown that array CGH techniques are able to detect tetrasomy 12p in peripheral blood, even when not identified by cytogenetics. We studied 15 patients with a clinical diagnosis of Pallister-Killian syndrome using a genome-wide SNP array to investigate the ability to identify i(12p) in blood and tissue. Tetrasomy 12p was previously identified using traditional cytogenetic techniques in 12 patients, with the average age at diagnosis less than 1 year old. For this study, patient age at the time of tissue collection was between 2 months to 6.75 years. Array analysis verified tetrasomy 12p in all 13 samples from fibroblasts. Percent mosaicism was calculated using both probe intensity and allele frequency. The percent mosaicism ranged from 35% to 100%, and patterning of allele frequencies suggested Meiosis II origin in 12 patients. Tetrasomy 12p was detected in 6 of the 13 samples from unstimulated blood, with the percent mosaicism ranging from 0% to 75%. Previous cytogenetic testing results in PHA stimulated peripheral blood did not correlate with the array results; three of four patients with previous findings in blood were verified by array (5% to 75%), while two of six patients with previous negative findings in blood were found to have detectable tetrasomy 12p by array (10% and 20%). Of the eleven patients with both blood and tissue samples, two had similar percent mosaicism in both tissues, 3 patients had evidence for tetrasomy 12p in both tissues with much lower percent in blood, and 6 patients had no evidence for the tetrasomy 12p in blood. Analysis of the percentage of abnormal cells with patient age at time of study demonstrated that the frequency of the i(12p) decreased with age in blood, but not in fibroblasts. Two patients had unusual structural findings not detectable by array, with one patient with hexasomy 12p and one patient with a derivative 12p, containing tandem copies of 12p. Taken together, these findings stress the importance of traditional cytogenetic techniques, in addition to array technology, in the diagnosis of Pallister-Killian syndrome.

## 1355/W/Poster Board #1013

**Microdeletion of the Down syndrome critical region at 21q22.** *R. Kosaki[1,2], H. Fujita[1,2], C. Tori[2], J. Kudoh[3], T. Takahashi[2], K. Kosaki[2].* 1) Department of Clinical Genetics and Molecular Medicine, National Center for Child Health and Development, Tokyo, Japan; 2) Department of Pediatrics, Keio University School of Medicine, Tokyo, Japan; 3) Department of Molecular Biology and Center for Bioinformatics, Keio University School of Medicine, Tokyo, Japan.

The concept of Down syndrome critical region implies that there exist several dosage-sensitive genes of which duplication leads to abnormal phenotype. Considering that an altered amount of expression from crucial target genes, as a result of regulatory imbalance, tends to produce phenotypic effects in both monosomics and trisomics, haploinsufficiency for the Down syndrome critical region is expected to be associated with abnormal phenotype. We report a patient with severe microcephaly, developmental delay accompanied with hypospadias and corneal opacity who had microdeletion spanning Down syndrome critical region including DYRK1A and SIM2. A Japanese boy was born by a cesarean section at 39 weeks gestation due to intrauterine growth retardation. At birth, hypospadias and corneal clouding were noted. At age 14 months, he was referred to us for evaluation of multiple congenital anomalies with developmental delay. He had arched eyebrows, upslanting and narrow palpebral fissures, corneal clouding, left preauricular pit, bifid uvula, prominent nasal root, short columella, prominent cental incisors, pegged shaped teeth, retrognatia, hypoplastic nipples, thick toenails, and hypospadias. At age 3 years, surgical correction for hypospadias was performed. He never developed petechia and his thrombocyte count was normal. He could stand without support at age 3 years and walked alone at age 5 years and his gait continued to be ataxic. At age 8 years, he had no meaningful words but understood simple commands. His G-banded karyotype was normal. Array comparative genomic hybridization using the Agilent 105K Whole Human Genome CGH array revealed a de novo deletion of 3.97Mb, extending from 34984142 to 38959902 on 21q22 (hg18; NCBI Build 36.1). Mouse gene targeting experiments of the mouse homologs of genes within the deleted interval suggest that some of the phenotype of the proband might be attributed to haploinsufficiency of these two genes: Extreme degree of microcephaly in the present case may be ascribed to haploinsufficiency of DYRK1A because brain size is severely reduced in heterozygotes for Dyrk1a null mutation. Cleft uvula, a microform of cleft palate, may be due to haploinsufficiency of SIM2 because cleft palate is observed in heterozygotes for Sim2 null mutation. Third, ataxia may be associated with haploinsufficiency of KCNJ6, an inwardly rectifying K channel because the “weaver” mice with Kcnj6 hypomorphic mutation present with ataxia.

## 1356/W/Poster Board #1014

**Small Supernumerary Marker Chromosomes characterization elucidated by array techniques.** *L. Kulikowski[1,3], F.M.S. Jehee[2], R. Pelegrino[4], D.C.B Rosolen[3], L. Antonangelo[3], M.N. Buratini[3], M.A.C. Smith[1], M.I. Melaragno[1].* 1) Morphology & Gen, Univ Federal de Sao Pa, São Paulo, Brazil; 2) Instituto de Biociências Univers de São Paulo, Brazil; 3) Divisão de Laboratório Central - HC LIM 03 - FMUSP Univ de São Paulo, Brazil; 4) Molecular Core AFIP, Brazil.

Supernumerary marker chromosomes (SMCs) are a frequent chromosome alteration, although their molecular unbalanced content and their mechanism of origin are often not precisely characterized. We reevaluated four phenotypically abnormal patients, with autosomal SMCs identified previously by G-banding. We used arrayCGH or oligo-array techniques for the chromosome characterization in order to allow a better genotype-phenotype correlation.In two patients, who presented developmental delay and SMCs derived from chromosome 15, molecular investigation revealed a duplication of about 13.8 Mb, region that contain genes associated to psychiatric diseases. One of the patients presents infantile psychosis. In another patient, the SMC was inherited from her mother who presents the extra chromosome in mosaic form. Array studies revealed the marker was originated from chromosome 19 with about 44.9 Mb duplication. This unbalance has been associated with ophthalmologic disease, as found in this family. One of the patients presents a complex SMC derived from duplication of short arms of chromosome 18 and 19 with about 10,6 Mb e 26,8, respectively. These regions are associated with neurologic disease, in accordance with psychomotor retardation present in the patient.Thus, high-resolution genome-wide analysis has greatly facilitated the characterization of SMCs and has proven to be advantageous in the detection of complex rearrangements. The increasing use of array techniques in clinical cytogenetic laboratories will allow for more accurate SMC/phenotype correlation improving the clinical diagnosis genetic counseling and risk evaluation. (Financial support: FAPESP, CAPES).

## 1357/W/Poster Board #1015

**Case Report: A girl with a 46,XX/46.XX,inv(1)(p21;q44) karyotype and a characteristic phenotype.** *J. Prieto[1,2], A. Lopez[1], G. Gordillo[1], R. Romero[2].* 1) Instituto de Genética Humana, Universidad Javeriana, Bogotá, Colombia; 2) Hospital La Victoria, Secretaría de Salud, Bogotá, Colombia.

Pericentric inversions are structural intrachromosomal rearrangements resulting from two breaks on both sides of the centromere followed by the 180° rotation of the chromatin segment between these breaks. This is not an infrequent structural chromosomal anomaly in humans, with a frequency from 0.089 to 0.34% in the general population or even from 1 to 2% depending on the type of inversion reported. Although the evidence is still too limited to allow a confident conclusion, it seems that pericentric inversions are more frequent in certain chromosomes and at certain breakpoints. It is commonly noted in chromosome 3 with breakpoints at 3p25, 3q21 or 3q25; also common is inv (18)(p11q21) and inversions of chromosomes 10-12 with breakpoint close to the centromeres. Until now, there have been reports of patients with this kind of chromosomal rearrangements associated with male infertility, multiple miscarriages, papillary carcinoma of the thyroid and Bardet-Biedl syndrome. The female patient was born of non consanguineous healthy parents, a product of a third controlled pregnancy with no pathological neonatal events referred. She has a history of left eye strabismus surgically corrected and nephritis at 4 years old. Her psychomotor development was normal. At physical examination she had normal antropometrical parameters but some characteristic findings as ocular hypertelorism, epicanthal folds, palpebral ptosis of left predominance, flat nasal bridge, flat facial profile, prominent ears with folded helix; she also presents with palmar keratoderma. The band R karyotype report: 46,XX/46.XX,inv(1)(p21;q44) in 1 metaphase of 80. In this case we report a mosaic inversion of the 1 chromosome accompanied by specific phenotype characteristics. This has been the first case described to date. We continue to check literature.

## 1358/W/Poster Board #1016

**Demonstration of recombination resulting in paternal transmission of an Xp deletion originating on the Y chromosome to multiple offspring.** *N. Hoppman-Chaney[1], W. Smith[2], D. Oglesbee[1], E. Thorland[1], S. Jalal[1], J. Keefe[1], K. Olson[1], J. Yuhas[1], G. Velagaleti[1].* 1) Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN; 2) Division of Genetics, Maine Medical Center, Portland, ME.

Subtelomeric deletions of the X and Y chromosomes are generally thought to be benign variants unless they include adjacent genes. We report a case of an 8 year-old-female with a history of developmental delay, severe autism, and short stature. G-banded chromosome analysis revealed a normal karyotype; however, subtelomere FISH studies identified a cryptic deletion of Xp. Subtelomere FISH on the parents showed mother with normal results, while father was positive for an Yp deletion with a normal X chromosome. Two of her three younger siblings were found to have a similar Xp deletion, while one of a set of fraternal twins did not. Additional follow-up using arrayCGH and BAC-FISH mapping indicated that this deletion was approximately 700-940kb in size and includes the SHOX gene, consistent with short stature observed in the individuals with this deletion. Also interesting is the occurrence of cleft palate in both the father and the twin daughter with the deletion, but not in the other affected daughters. Likewise, the features of autism are variable among the daughters ranging from severe autism requiring admission to a psychiatric facility in the proband, high functioning in another and normal development in the third; the twin without the deletion has concerning behaviors. The fact that the three affected daughters had a demonstrable Xp deletion with normal Xp in both parents and a Yp deletion in the father suggests that a crossover occurred in the pseudoautosomal region during paternal meiosis which led to the transfer of this deletion onto the paternal X chromosome. This hypothesis was supported by microsatellite genotyping of dinucleotide repeats spanning the X chromosome of both parents, 2 daughters with the deletion, and the daughter without the deletion. The observation that one daughter did not inherit this deletion, while her fraternal twin sister did, also argues against the requirement of an obligate crossover in the pseudoautosomal region during male meiosis. The heterogeneity of clinical features among the affected daughters and the father might be explained by variation in the size of deleted segment since each recombination event is independent and crossover might have occurred at different regions in the pseudoautosomal regions. Oligonucleotide arrayCGH studies are in progress to determine the extent of deletion in each of the affected daughters and the father to further explore the phenotypic variation.

## 1359/W/Poster Board #1017

**del(1)(p21p22) syndrome: a Prader Willi like phenotype.** *J.G. Pappas[1], J. Borsuk[1], P.R. Papenhausen[2].* 1) Dept Pediatrics,Human Gen, New York Univ, Sch Med, New York, NY; 2) Dept Cytogenetics, Labcorp America, Res Triangle Park, NC.

We present a 22 month old boy with poor growth, developmental delay and 46,XY,del(1)(p21.1p22.1) karyotype. There are three cases reported in the medical literature with deletion breakpoints in bands 1p21 and 1p22 (Finelli P et al, 2001; Stockton DW et al, 1997). The subband of the breakpoints is different in each case and our case. These three cases and our case share common features including cardinal features of Prader Willi syndrome (PWS). Our patient was born 2.73 kg at full term via vaginal delivery to a 33 year old gravida 7 para 7 mother. During infancy he was feeding poorly and his weight was below the 5th centile. He was diagnosed with hypotonia and laryngomalacia. He had normal echocardiography and renal ultrasound. At 16 months, he started sitting unsupported and his muscle tone and food intake started improving with physical therapies. He could not stand unsupported, he had no speech, his head circumference was below the 2nd centile, his length below the 5th and his weight between the 10th and 25th centile. He had closed fontanelles, palpable metopic ridge, micrognathia, narrow and high arched palate, bilateral epicanthal folds, green eyes (rest of family had brown eyes), light brown hair (rest of family had dark brown hair) and very light skin complexion. The deletion in our case was ascertained with chromosome microarray and subsequently with routine karyotype. Whole genome chromosome microarray utilizing 1,800,000 region specific SNP/CN targets (Affymetrix, Inc.) revealed a 9.738 MB interstitial deletion 1p21.1->p22.1 with base pair linear position from 93610986 to103348942. The parents had normal karyotypes and whole genome chromosome microarray tests. The deleted segment in our case includes 30 genes annotated in OMIM. There is no known association of haploinsufficiency of any of these genes with phenotypic characteristics of our case. The case presented by Finelli at al was an 11 year old boy with hyperphagia and similar developmental history and facial features to our case. The DNA methylation test for PWS was negative in our case and the previously reported case (Finelli et al, 2001). The del(1)(p21p22) syndrome resembles PWS because of infantile hypotonia and poor feeding that improves in childhood, microcephaly, short stature, hypopigmented hair, eyes and skin as well as hyperphagia, obesity and developmental delays in childhood. Our case provides precise breakpoints and phenotypic data to delineate the del(1)(p21p22) syndrome.

**A 7Mb terminal deletion of chromosome 3p with normal phenotype: case report and review of the literature.** *G. Tiller, S. Morton, K. Wendt.* Dept Genetics, Kaiser Permanente, Los Angeles, CA.

The advent of comparative genomic hybridization by microarray (array CGH, or aCGH) has led to the characterization of genomic deletions and duplications, some of which appear to have no clinical consequence. We report an adult male with a 7Mb terminal deletion of chromosome 3p with a normal phenotype. His wife presented for prenatal counseling due to advanced maternal age; amniocentesis revealed a 46,XX,del(3)(p26) karyotype in the fetus. The couple elected to terminate the pregnancy despite determination that the paternal karyotype demonstrated the same terminal 3p deletion. The deletion was further characterized by aCGH, and found to span 36,006-7,028,403. Fourteen genes have been identified in the region, including two (CHL1 and CRBN) which are associated with mental retardation. Takagishi et al. (2006) reported a mother and daughter with an 8.8Mb terminal deletion of 3p and normal phenotype, whereas Fernandez et al. (2008) and Dijkhuizen et al. (2006) reported patients with mental retardation and mild dysmorphic features who carried 4Mb deletions within the 7Mb region deleted in our patient. These cases demonstrate the difficulty in predicting the consequences of individual chromosomal aberrations, and underscore the importance of establishing collaborative aCGH clinical databases to assist in effective genetic counseling.

## 1361/W/Poster Board #1019

**Balanced reciprocal translocation 46,XX,t(1;4)(p13.1;q34.3) associated with severe unexplained emphysema.** *N. Jinawath[1], R. Yonescu[2], N. Rush[4], K.S. Schweitzer[4], K. Murphy[2], D.B. Pearse[3], I. Petrache[4], C.A. Griffin[1,2].* 1) Institute of Genetic Medicine, Johns Hopkins Medical Institution, Baltimore, MD; 2) Department of Pathology, Division of Molecular Pathology, Johns Hopkins Medical Institution, Baltimore, MD; 3) Department of Medicine, Johns Hopkins Medical Institution, Baltimore, MD; 4) Department of Medicine, Indiana University, Indianapolis, IN.

Emphysema is a chronic obstructive pulmonary disease leading to significant morbidity and mortality. While most cases are caused by tobacco abuse, genetic defects such as mutations of alpha-1 antitrypsin (AAT) causing decreased AAT levels underlie some cases. We report a case of unusually severe emphysema (FEV1 =0.5 L/s) in a 45 year-old woman. Her clinical history of 15 pack-year cigarette smoking and MZ AAT genotype with normal circulating A1AT levels were considered insufficient to explain the severity of her illness. We hypothesized her constitutional balanced translocation, 46,XX,t(1;4)(p13.1;q34.3) may have resulted in an increased susceptibility to her developing severe and accelerated emphysema. Under an IRB-approved protocol, we mapped the breakpoint using BAC-FISH and DNA fiber-FISH, and identified the breakpoint to be inside BAC clones RP4-686J16 and RP11-763N18 on chromosome 1p13.1 and 4q34.3, respectively. Subsequent mapping using additional BAC clones on chromosome 1p13.1 identified the breakpoint between the genomic location 116,974,711 - 117,009,114 (NCBI Build 36.1), which mapped to intron 2 of *IGSF3*, a member of immunoglobulin superfamily known to be expressed in alveolar basal epithelial cells, but with unclear function. The chromosome 4 counterpart of this breakpoint contained no known gene. Affymetrix SNP6.0 array analysis using DNA from the lymphoblastoid cell line identified no genomic gain or loss in the vicinity of the breakpoint or elsewhere in the genome. Since the coding sequence of both *IGSF3* variants 1 and 2 start from exon 2, we predict that expression of *IGSF3* in this patient should be disrupted and may lead to reduced expression of IGSF3 protein. Immunohistochemistry was performed using IGSF3 antibody (R&D Systems) on human emphysematous lung tissue sections from 4 individuals and 4 control lungs and on lung tissue from mouse models of emphysema (cigarette smoke-exposed DBA/2 and C57BL/6 mice). We found significantly reduced IGSF3 expression in the human lungs with emphysema and in the cigarette smoke-exposed mice compared to normal lung tissues. Further studies on the roles of IGSF3 in lung physiology may elucidate its involvement in the pathobiology of emphysema.

## 1362/W/Poster Board #1020

**Recurrent reciprocal 16p11.2 rearrangements associated with global developmental delay, behavioral problems, dysmorphism, epilepsy, and abnormal head size.** *M. Shinawi[1], P. Liu[1], S-H. King[1], J. Shen[2], A. Pursley[1], A. Patel[1], P. Stankiewicz[1], A.L. Beaudet[1], S.W. Cheung[1], J.R. Lupski[1], CLINICAL 16p11.2 CONSORTIUM.* 1) Dept Molec & Human Gen, Baylor Col Med, Houston, TX; 2) Children's Hospital Central California, Madera, CA.

Microdeletion and the apparent reciprocal microduplication on 16p11.2 were recently associated with autism and developmental delay. We identified 27 deletions and 18 duplications of 16p11.2 in 0.6% of all samples submitted to the Medical Genetics Laboratories at Baylor College of Medicine (BCM) for clinical array-CGH analysis. Detailed molecular and phenotypic characterizations were performed on 17 subjects with deletion and nine subjects with duplication. One subject was asymptomatic and another had a normal cognitive and behavioral phenotype. The most common clinical manifestations in our cohort were speech delay and cognitive impairment. Other phenotypes associated with deletion included motor delay (50%), seizures (~40%), behavioral problems (~40%), and congenital anomalies (~30%). The autism phenotype was observed in only ~20% of deletion cases. The phenotypes associated with duplication included motor delay (6/9), behavioral problems (especially ADHD) (5/9), congenital anomalies (4/9) and seizures (2/9). Patients with the 16p11.2 microdeletion had statistically significant ($p<0.0017$) large mean head size and 2/3 of them had absolute or relative macrocephaly. Five of the nine patients with the microduplication had microcephaly. The broad forehead, macrocephaly, and flat midface render a distinct facial gestalt to the deletion patients. The chromosomal rearrangement was *de novo* in most of the deletion cases in which parental studies were available but equal inherited and *de novo* cases were observed for the duplication. Our data expand the spectrum of phenotypes associated with the 16p11.2 rearrangements. The incomplete penetrance and variable expressivity in these rearrangements complicate the interpretation of the molecular data and the genetic counseling. *CLINICAL 16p11.2 CONSORTIUM:* ***J. Belmon[1], D. Scott[1], F. Probst[1], W. Craigen[1], B. Graham[1], G. Clark[2], J. Lee[2], M. Proud[2], A. Stocco[2], D. Rodriguez[2], S. Sparagana[3], B. A. Kozel[4], E.R. Roeder[5], S.G. ## 1363/W/Poster Board #1021

**Frequency of Cytogenetic Abnormalities and Testing in Children with Congenital Defects, Metropolitan Atlanta 1986-2005.** *J. Jackson, S.A. Rasmussen, J. Cragan, K. Crider, R. Olney.* Birth Defects & Dev Disabilities, Ctr Disease Control Prevention, Atlanta, GA.

We assessed changes in the usage of cytogenetic testing of children born with congenital defects from 1986 through 2005 using data from the Metropolitan Atlanta Congenital Defects Program (MACDP). MACDP, a population-based surveillance system covering the five central metropolitan Atlanta counties, uses active methods of ascertainment to identify infants with birth defects from birth and pediatric hospitals, and certain laboratories and physician offices. Data on cytogenetic testing were obtained from hospital records and from a local academic cytogenetic laboratory, with the addition of data from a commercial laboratory for the years 1997-2005. The frequency of cytogenetic testing in children with birth defects more than tripled from 7.6% in 1986 to 23.2% in 2005 ($p<0.001$). However, prenatal cytogenetic testing in mothers aged 35 years and older declined from 33.1% in 1996 to 19.5% in 2005 ($p<0.001$); prenatal testing in mothers less than 35 years old remained fairly constant (6.4% in 1996, 5.6% in 2005; $p=0.4$). The number of infants identified with cytogenetic abnormalities increased significantly through the years: autosomal trisomies increased from 13.0 to 18.3 per 10,000 births ($p<0.001$) and other autosomal abnormalities from 3.0 to 5.4 per 10,000 births ($p<0.001$) from 1986 to 2005, respectively. Finally, we showed the value of adding an additional data source. Inclusion of results from a commercial laboratory for the years 1997-2005 increased the number of MACDP records with recorded cytogenetic test results by approximately 2% (330 cases), of which 6.5% of these were abnormal. Our results indicate an overall increase in the use of cytogenetic studies of infants with birth defects; however, a decrease in prenatal testing in women aged 35 years and older was also observed. The reasons for this decrease are unknown, but could be related to changes in noninvasive prenatal screening technologies that might be used instead of diagnostic testing by amniocentesis or chorionic villus sampling.

## 1364/W/Poster Board #1022

**The diagnostic relevance of genotyping data derived from diagnostic SNP arrays.** *R. Pfundt[1], N. de Leeuw[1], J. Hehir-Kwa[1], L. Moruz[1], C. Ruivenkamp[2], A. Gijsbers[2], H. Yntema[1], B. de Vries[1], B. van Bon[1], N. Leijsten[1], I. Neefs[1], T. Machielsen[1], S. van Gessel[1], M. Wunderink[1], J. Veltman[1], D. Smeets[1].* 1) Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands; 2) Center for Human and Clinical Genetics, Department of Clinical Genetics, Leiden University Medical Center, Leiden, The Netherlands.

Cytogenetic centers worldwide are on the verge of a revolution since, for a number of patient groups, classical chromosome analysis by karyotyping is being replaced by molecular karyotyping using microarrays. In our diagnostic cytogenetic laboratory, array analysis was implemented for patients with mental retardation with/without multiple congenital anomalies (MR/MCA) in 2003, initially using BAC arrays and only after a normal karyotype. In 2007 we switched to the Affymetrix 250k SNP array platform and more than 2000 patients and over 500 parental samples have now been diagnostically screened. This has resulted in the identification of many (novel) relevant copy number variations (CNVs) and a diagnostic yield of more than 13%. Based on these results we decided in January 2009 to make array analysis, instead of karyotyping, the “first pass” diagnostic test for MR/MCA patients. SNP based microarrays do not only provide reliable data for CNV analysis, but also generate a genotyping profile for every individual that is hybridized. Does this additional SNP data have an added value, compared to non-SNP based array platforms, or is it a byproduct without diagnostic relevance? In this presentation we present our experience in using genotype information in the diagnostic workflow of MR/MCA patients. Firstly, SNP data of patient and parent trios are screened for Mendelian inconsistencies. Based on this analysis we can rule out sample mix-up, potential non-paternity and screen for uniparental disomies (UPD). So far we have encountered one case of non-paternity and have identified 4 cases of UPD. Secondly, SNP information can be used determine the parent-of-origin of a CNV (deletions and duplications). In a number of cases this could be used to determine the de novo occurrence of a CNV even when one of the parents was not available for genetic analysis. Thirdly, the SNP data of individual patients is screened for stretches of homozygosity, indicating consanguinity (in case of many large regions) or identity by descent (single regions ranging in size from 2 - 60 megabases). We conclude that the genotyping information from SNP based array platforms is very helpful for the practical diagnostic array workflow and increases the diagnostic yield of molecular karyotyping. In addition, this genotype information from large patient cohorts will be enormously useful in research projects aimed at identifying recessive loci and for SNP-based association studies.

## 1365/W/Poster Board #1023

**Nonrecurrent genomic rearrangements associated with CMT1A or HNPP and their underlying mechanisms.** *F. Zhang[1], M. Khajavi[1], C.F. Towne[4], S.D. Batish[4], E. De Vriendt[5], P. De Jonghe[5], A. Vandenberghe[6], F. Palau[7], L. Van Maldergem[8], V. Timmerman[5], J.R. Lupski[1,2,3].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX 77030; 2) Department of Pediatrics, Baylor College of Medicine, Houston, TX 77030; 3) Texas Children’s Hospital, Houston, TX 77030; 4) Athena Diagnositics, Inc., Worcester, MA 01605; 5) Department of Molecular Genetics, VIB and University of Antwerp, Universiteitsplein 1, 2610 Antwerpen, Belgium; 6) Unité de Neurogénétique Moléculaire, Laboratoire de Biochimie, Hôpital de l’Antiquaille, F-69005 Lyon, France; 7) Institut de Biomedicina, Consejo Superior de Investigaciones Cientificas, Valencia, Spain; 8) Centre de Génétique Humaine, Institut de Pathologie et de Génétique, Loverval, Belgium.

Genomic rearrangements involving the peripheral myelin protein gene (*PMP22*) in the human chromosome 17p12 are associated with neuropathy; duplications cause Charcot-Marie-Tooth disease type 1A (CMT1A; MIM 118220), whereas deletions can lead to hereditary neuropathy with liability to pressure palsies (HNPP; MIM 162500). Our previous studies showed that most of these rearrangements are recurrent and mediated by the mechanism of non-allelic homologous recombination (NAHR), whereas nonrecurrent rearrangements also exist and their underlying mechanisms are not well investigated. In this study, we investigated 17 CMT1A/HNPP-associated nonrecurrent rearrangements by high-resolution oligonucleotide array comparative genomic hybridization (aCGH) analysis and breakpoint sequence analyses. We identified two identical complex duplication-triplication rearrangements (of which *PMP22* is triplicated), four *PMP22* duplications (two of them are identical), two identical *PMP22* deletions from the same family, and nine deletions involving only one or several *PMP22* exons (one of them is a complex exonic deletion). Our observations suggest that various molecular mechanisms, including non-homologous end-joining (NHEJ), replication-based fork stalling and template switching (FoSTeS) and/or microhomology-mediated break-induced replication (MMBIR), are implicated in the generation of nonrecurrent rearrangements of *PMP22*. Interestingly, the identical FoSTeS/MMBIR-mediated complex exonic deletion was also identified in the patient’s affected sibling and found to be mosaic in the unaffected mother, which suggests that this complex deletion is generated mitotically, consistent with a replication-based event.

## 1366/W/Poster Board #1024

**Inherited Duplication of 22q11.2 Concomitant with Mosaic Turner Syndrome.** *S. Beiraghi[1], A. Thurmes[1], S. Holzwart[1], B. Hirsch[2].* 1) Cleft-Palate Craniofacial, Univ of Minnesota, Minneapolis, MN; 2) Lab Medicine & Pathology, Univ of Minnesota, Minneapolis, MN.

Microduplication 22q11.2 syndrome is associated with variable, often subtle phenotypic findings, that typically include cleft palate, speech and neuropsychological issues. Here we present the first report of a female infant with Mosaic Turner Syndrome and a paternally inherited 22q11.2 duplication. This infant was born at full term, to a 31-year-old ($G_1P_1ab_0$); APGAR scores were nine at 1 and 5 minutes respectively. Cleft palate, left pre-auricular pit, patent foramen ovale, hypocalcemia, and congenital hip dysplasia were noted at birth. G-banded chromosome analysis and FISH analysis for 22q11.2 were ordered. G-banding revealed mosaicism for two cell lines: one with 45,X (95% of metaphases), and one with 46,XX (5% of metaphases).. FISH revealed a duplication of the TUPLE1 locus in 50 of 50 interphase cells. A follow-up specimen, analyzed by array comparative genomic hybridization (a-CGH) using a 44K oligonucleotide platform, confirmed a 2.4 Mb duplication within 22q11.2. The boundaries of the duplication were the same as those typically seen in the deletion associated with DiGeorge/VCSF. Parental FISH studies showed paternal 22q11.2 duplication. These findings highlight the ability of a-CGH to detect and characterize genomic imbalances and further define the molecular etiology of clinical phenotype seen in microduplication 22q11.2 syndrome. Furthermore, without the input of the craniofacial team, the duplication of 22q11.2 would not have been diagnosed, as the abnormality was too subtle to be seen in the newborn G-banded chromosomal study.

### 1367/W/Poster Board #1025

**Constitutional Abnormalities of Chromosome 18: Hacettepe University Experience.** *D. Aktas, G.E. Utine, Y. Alanay, K. Boduroglu, M. Alikasifoglu.* Dept. of Genetics, Hacettepe University Medical School, Ankara, Turkey.

Clinical and cytogenetic characterizations of partial monosomy 18p and partial trisomy 18q have been well documented. Deletions involving the long arm of chromosome 18 have also been reported in many patients. Most of them are localized in distal part of the long arm. However, smaller interstitial deletion 18q12.3 is less common. Furthermore, isochromosome 18q is a rare but distinctive syndrome. The common clinical manifestations associated with i(18q) closely resemble those of trisomy 18 and 18p deletion syndrome. Moreover the paracentric inversion of the long arm of chromosome 18 is also rare and the phenotypic findings are similar to those seen in 18q deletion syndrome. Additionally, due to the formation process of the ring chromosome 18, the phenotype of the r(18) patients is similar to the features of the 18q deletion syndrome. We presented patients carrying constitutional abnormalities of chromosome 18. Eight patients recruited: one with an 18p deletion syndrome; two with an 18q deletion syndrome and one of them has an interstitial deletion; one with trisomy 18q syndrome, two with isochromosome 18q syndrome and one with inversion 18q and one with ring chromosome 18q. The clinical phenotype and cytogenetic/molecular cytogenetic findings of our patients are reviewed and discussed.

### 1368/W/Poster Board #1026

**CHROMOSOME POLYMORPHISMS ASSOCIATED WITH RECURRENT FETAL LOSS.** *C.L. Campanhol[1], S.C.S. Lima[3], E. Couto[2,4], J.K. Heinrich[1], R. Barini[2,4].* 1) Cytogenetics Core at CAISM - Women's Hospital - State University of Campinas - UNICAMP, Campinas,SP, Brazil; 2) Department of Gynecology and Obstetrics - Faculty of Medical Sciences - State University of Campinas - UNICAMP, Campinas, SP, Brazil; 3) BSL Reproduction Immunology Laboratory - Campinas, SP, Brazil; 4) Obstetrics Area at CAISM - Women's Hospital - State University of Campinas - UNICAMP, Campinas, Brazil.

Chromosomal abnormalities play an important role for the etiology of the recurrent fetal loss as well as other immunological, endrocrine, morphological and gene mutational causes. Chromosomal polymorphisms have always been considered as silent alterations with no clinical repercussion. More recently many groups have indicated that recurrent fetal loss is a frequent finding in individuals with heterochromatin length polymorphisms and pericentromeric inversions of the chromosome 9. The objective of this study was to determine the frequency and distribution of specific chromosome abnormalities in individuals with recurrent spontaneous abortion, fetal abnormality and/or fetal death in a Women's University Hospital and a private outpatient service. Samples were 60% retrospectively and 40% prospectively included in the study in an 8-year time frame. Patient data were retrieved and the karyotype was accessed using conventional G and C banding. A total number of 1236 karyotypes were analyzed. Having at least two episodes of fetal loss, fetal abnormality and/or fetal death was assigned as an inclusion criteria. The total number of cases included from the University Hospital was 202 and from the private clinics was 1034. Normal karyotypes were found in 166 (82,17%) and 964 (93,23%) individuals. Twelve (5,94%) and 17 (1,64%) displayed aneuploidy; 7 (3,46%) and 13 (1,25%) displayed sctructural chromosome abnormalities; 18 (8,91%) and 40 (3,86%) showed polymorphic variants. Among women, ages varied from 19 to 42 (average of 29,59) and from 25 to 47 (average of 33,85). Among men, ages varied from 16 to 46 (average of 31,14) and from 26 to 55 (average of 35,51). Our results corroborate with the recent hypothesis which shows a possible contribution of chromosome polymorphisms to the recurrent fetal loss and also emphasize the importance of cytogenetic evaluation for an accurate approach to elucidate the etiology of fetal loss. Genetic counseling should be offered as the individuals should be assisted to decide as to deal with future reproductive risks.

### 1369/W/Poster Board #1027

**Multiple intrachromosomal rearrangements leading to a derivative chromosome 9 detected by conventional cytogenetic analysis and characterized by array CGH.** *N. Christacos, J. Meck, J. Kelly, S. Schonberg, J. Scheerle, N. Kamara, P. Mowrey.* Cytogenetics Dept, Quest Diagnostics Nichols Institute, Chantilly, VA.

We report the cytogenetic findings on a 5-year old female with multiple congenital anomalies including microcephaly, seizures and mental retardation. Conventional cytogenetic analysis identified a structurally abnormal chromosome 9 interpreted as add(9)(q33). Fluorescence in situ hybridization (FISH) studies and array CGH (aCGH) using the ClariSure 1MB BAC array chip (Quest Diagnostics Nichols Institute) revealed a complex intrachromosomal rearrangement. Specifically, the array CGH showed five abnormal regions on the long arm of one chromosome 9, which were all FISH confirmed using the appropriate BACs as FISH probes. Briefly, there was a large region of duplication from bands 9q13 to 9q21.33 (16.65 Mb/70,459,999-87,110,000) as well as a region of deletion at band 9q33.3 (2.62 Mb/ 122,650,001-125,269,996). In between these two regions, there were two separate single clone gains and one two clone gain. The most proximal and largest duplication and the most distally located deletion, both with multiple genes involved, are considered to be causative in the abnormal phenotype and cognitive development seen in this child. The other three smaller abnormalities may be copy number variants. Parental aCGH testing has been requested and will be instrumental in making this determination. Furthermore, additional molecular testing will be performed to help further define this complex intrachromosomal abnormality and elucidate a possible mechanism for its formation. To conclude, partial trisomy of 9q is rare and, to our knowledge, cases with a similar pattern of gains and loss have not been reported.

### 1370/W/Poster Board #1028

**Characterization of Contiguous Gene Syndromes in the NIGMS Human Genetic Cell Repository by the Affymetrix GeneChip SNP 6.0.** *N. Gerry[1], L. Toji[1], C. Beiswanger[1], J. Collins[2], J. Leonard[1].* 1) Coriell Institute for Medical Research, Camden, NJ; 2) Affymetrix Inc., Santa Clara, CA.

The Affymetrix SNP Array 6.0 was used to define the chromosomal segments gained and lost in one hundred and seventy-one micro or sub-micro deletion or duplication abnormalities from twenty-two disorders that were previously characterized by FISH or PCR. Data were analyzed for copy number changes using both Affymetrix Genotyping Console Software and Partek Genomics Suite. In each case the segments detected were of the expected size and included the critical regions for the respective disorder: Deletion 1p36 syndrome, Wolf-Hirschhorn, Cri-du-chat, Williams-Beuren, Greig Cephalopolysyndactyly, Trichorhinophalangeal II, Wilms Tumor-Aniridia-Genitourinary Anomalies and Mental Retardation, Potocki-Shaffer, Angelman, Prader-Willi, Chromosome 15q11-q13 Duplication, Charcot-Marie-Tooth A1, Miller-Dieker, SmithMagenis, Deletion 18p,Deletion 18q, DiGeorge, and Velocardiofacial syndromes, X-linked Ichthyosis, Duchenne Muscular Dystrophy, Pelizaeus-Merzbacher Disease, and Azospermia. The resolution of the Affymetrix SNP Array 6.0 allowed characterization of chromosomal copy number changes in the kilobase range. Within the samples studied, the smallest change detected was a 35 kb deletion of an exon in SNRPN of a Prader-Willi sample. This result, along with many other submicroscopic changes detected on the array agreed with prior molecular mapping experiments. The high resolution of the array also provided the ability to distinguish between chromosome breakpoints in multiple samples of the same disorder that appeared nearly identical by traditional G-band analysis, but in fact were all unique. In addition, the array provided more accurate breakpoints for submicroscopic changes that had previously been identified by FISH using only one or at most a few markers in the syndromes critical region. Finally, previously unrecognized complexities such as cryptic translocations and duplications adjacent to syndrome specific deletions were identified by the array. The copy number segment data and graphic output from Affymetrix Genotyping Console are being used to upgrade the descriptions of these samples on the Coriell Cell Repositories web-site (http:// ccr.coriell.org/) to better inform users in their decisions for experimental design and choice of reference samples. Each of the samples is publicly available as a culture and many are available as DNA.

### 1371/W/Poster Board #1029

**22q12.1 deletion: a new cause of syndromic mental retardation.** *A.P Jinnah[1], C. Bacino[1], S.W Cheung[1], A. Patel[1], C.W Brown[1,2].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Pediatrics, Baylor College of Medicine, Houston, TX.

We report a six year old girl with short stature, moderate mental retardation, bradycardia, and facial dysmorphic features including hypertelorism, preauricular tags, unilateral simplified ear, broad nasal tip, and high arched palate with bifid uvula. Family history is significant for several members, including her mother, with variable severity of mental retardation, hearing loss, cleft palate, and facial dysmorphism. Although the craniofacial features were reminiscent of velocardiofacial syndrome (VCFS), chromosomal microarray analysis revealed a 2.157 Mb loss in 22q12.1 occurring between (but not including) the VCFS (22q11.2) and McDermid region (22q13) regions. The microdeletion encompasses three genes, MN1 (meningioma 1), PITNB (phosphotidylinositol transfer protein beta) and TTC 28 (tetraticopeptide repeat protein 28). Haploinsufficiency of these genes has previously been reported in at least one other unrelated patient with similar clinical features. MN1 is a transcription factor that functions in part as a nuclear receptor coactivator protein. It is expressed in fetal brain, cardiac myocytes, osteoblasts, skeletal, and smooth muscle. Expression of PITNB and TTC 28 have been identified in many tissues, including brain. Targeted homozygous deletion of MN1 mice is post-natal lethal due to severe cleft palate. In addition abnormalities of intramembranous ossification processes of craniofacial bones, lethargy and poor sucking behavior have also been described in this animal model. We propose that deletion of 22q12.1 represents a new familial mental retardation syndrome in patients presenting with VCFS-like facial features and other congenital anomalies.

### 1372/W/Poster Board #1030

**Emerging Challenges in Interpreting Microduplications 1-10 Mb in Size in a Clinical Setting.** *S.-H.L. Kang, S. Neill, C.A. Shaw, C.A. Bacino, S.R. Lalani, P. Stankiewicz, A. Patel, S.W. Cheung.* Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

The increased use of array comparative genomic hybridization (aCGH) based assays has revealed extensive structural variation in the human genome. In the clinical setting, interpretation of these variations can often present a diagnostic dilemma. We evaluated a total of 4186 patient samples on a custom designed whole-genome oligonucleotide microarray (Agilent 105K). At least one copy number variation (CNV) was detected in 1356 patients (32.4%) and a total of 1569 CNVs were detected (some patients had more than one CNV). The abnormal detection rate in our cohort of patients was 16.6% (693/4186). Of the 693 pathogenic CNVs, approximately twice as many deletions (N=356) as duplications (N=176) were identified. These CNVs included many known syndromic regions that are commonly observed or have been newly described. However, a major huddle when using microarrays with whole-genome coverage is interpreting the clinical significance of genomic imbalances with no clear disease association. In particular, determining the clinical consequence of large (>1 Mb) microduplications, including reciprocal rearrangements of disease associated regions, frequently pose a challenge. We identified 164 duplication CNVs between 1-10 Mb in size. Parental analyses were completed for 78 patients, and remain pending on 86. Of the cases with follow-up parental studies, 35 were shown to be *de novo* and interpreted as pathogenic, and 43 were inherited from a parent carrying the same genomic imbalance. Two inherited duplications were in known disease associated regions (22q11.2 microduplication and CMT1A duplication on 17p12), and also interpreted as pathogenic. Nine involved duplication in a region associated with a known microdeletion syndrome and 32 were found in regions with no clear disease association. Given the size of the CNV, one presumes that the genomic imbalance would have clinical relevance. However, this hypothesis is confounded by inheritance from a seemingly phenotypically "normal" parent. This category of aCGH results blurs the boundaries between incomplete penetrance (and therefore interpreted as abnormal) and clinically benign. Understanding the clinical consequence of these observations will require compilation of genotype-phenotype data in larger cohorts of patients and controls.

### 1373/W/Poster Board #1031

**Molecular Characterization of a Chromosome 12q Telomeric Terminal Deletion in a Patient with Dysmorphia.** *N. Kaya[1], J. Al-Zahrani[1], N. Al-Dosari[1], D. Colak[1], T. Al-Sheddi[2], O. Al-Habit[1], B. Meyer[1], P. Ozand[1], N. Sakati[1].* 1) Genetics, KFSH & RC, Riyadh, Saudi Arabia; 2) College of Science, King Saud University.

Chromosome 12q deletions are rare cases in general and only a few cases have been reported in the literature without any mosaicism. In this study we describe the first Saudi patient with a 12q telomeric terminal deletion with mosaicism. The patient is 8-years-old boy affected with varying degrees of dysmorphia, developmental delay, abnormal genitalia, growth retardation and had normal standard chromosomal karyotype. We performed high resolution aCGH assay on the patient's DNA using Agilent's 244K Human CGH Assay. The aCGH results indicated presence of a hemizygous 12q telomeric terminal deletion (46,XY,del(12)(q24.31q24.33)). Besides this large deletion one novel and seven previously reported copy number variations throughout the whole genome were also identified. Confirmatory Real Time PCR and MLPA experiments were performed and validated the aCGH results in the region. Genome-wide gene expression profiling experiments were also performed to understand the pathways involved. To further validate and physically show the deletion a FISH assay was also performed on the interphase nuclei and metaphase spreads. These results indicated presence of mosaicism in the labelled nuclei and metaphase spreads. Altogether to the best of our knowledge, this is a first study showing a mosaicism among Chr12q terminal deletions and the deletion is the largest in size (around 9.3 Mb) among the previously reported cases.

### 1374/W/Poster Board #1032

**The Low-Lands-Consortium, a collaborative approach for the identification and interpretation submicroscopic chromosomal aberrations in patients with MR/MCA.** *K. Kok[1], E. van Binsbergen[2], J. Saris[3], A.C. Knegt[4], E.A. Sistermans[5], B. Ylstra[6], G.B. van der Vries[1], M. Poot[2], H.B. Beverloo[3], A.M. Polstra[4], A.W.M. Nieuwint[5], T. Dijkhuizen[1], J.K. Ploos van Amstel[2].* 1) Genetics, UMCG, Groningen, The Netherlands; 2) Medical Genetics, university Medical Center Utrecht, The Netherlands; 3) Erasmus Medical Centre, Rotterdam, The Netherlands; 4) Clinical Genetics, Academic Medical Centre, Amsterdam, The Netherlands; 5) Clinical Genetics, VUMC, Amsterdam, The Netherlands; 6) VUMC Cancer Center, Amsterdam, The Netherlands.

Array-based comparative genomic hybridization has become an indispensable tool in the detection of submicroscopic chromosomal aberrations in patients with multiple congenital anomalies and/or idiopathic mental retardation (MCA/MR). However, the discovery of presumably neutral copy number variants complicates the interpretation of CNVs found in these patients. Thus, there is a need for procedures that efficiently distinguish between benign and pathogenic aberrations. Early 2008, five Dutch clinical genetics groups have joined forces, and formed the "Low-Lands-Consortium". One goal was to implement an oligo-based array platform (2x105K Agilent custom array, designed by L. Connell , Oxford), for the postnatal genome-screening of patients with MR/MCA for cryptic microdeletions and duplications. Consensus on the hybridization procedures, reference DNA sample and methods of data-analysis (DNA analytics, Agilent, Santa Clara, USA), have resulted in a smooth and efficient data-exchange between the groups. From May 2008 to May 2009 the consortium has analysed ~1500 patients on the 105K array. In the course of this study 500 healthy parents have also been analysed on the same array. The software package NEXUS (Biodiscovery, CA, USA) has been used to generate a database of CNVs for the Dutch population for the data obtained for the healthy parents. All CNVs consist of at least 4 consecutive oligos and are, with few exceptions, larger than 100 Kb in size. The database now contains ~3500 entries, representing ~500 CNV loci. The one-hundred CNV loci with the highest frequency, represented by 2556 entries, all contain more than two hits. Export files from this database can be visualized as custom track in the UCSC genome browser and can be uploaded into several commercial data analysis platforms, including DNA analytics (Agilent). This database has proven to be invaluable for the identification of neutral (benign) CNVs in the patients. Recently within the consortium a custom 4x180K oligo-array has been designed that replaces the 2x105K design. Results on the analysis of ~1500 patients using the 2x105K array, and preliminary data on the 4x180k array will be presented.

## 1375/W/Poster Board #1033

**Frequency and inheritance of CNVs less than 1 Mb in a clinical cohort. How do we interpret these?** *A. Patel, S-H.L. Kang, S. Neill, M. Strivens, C.A. Shaw, P. Stankiewicz, S.R. Lalani, C.A. Bacino, S.W. Cheung.* Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX.

Application of Microarray analysis for detection of copy number variation (CNV) has revealed that the human genome is awash with structural variation. The locus specific mutation rate for these structural variations is two to four orders of magnitude greater than single nucleotide changes (NG 39:S43-47,2007). An enormous amount of data has been deposited in various databases for structural variations but the basic question of what role, if any, do they play in human disease remains to be elucidated. These databases have been routinely used by clinical laboratories to guide the interpretation of CNVs less than 1 Mb in size in non-disease regions. We reviewed CNVs of less then 1 Mb in a cohort of 4186 consecutive patients examined using a custom chromosomal microarray (CMA V7 105K OLIGO) that interrogates the whole genome at an average resolution of 30 Kb with increased coverage at disease loci . Included in the CMA are probes for all the known microdeletion/duplication syndromes (>270) while excluding repetitive sequences through a combination of bioinformatics and computation. Excluding clinically significant CNVs (>1 Mb), small CNVs in clinical significant regions, and known polymorphic regions, the frequency of these CNVs was 14% (586 patients). Of these, parental analyses were available in 42% of the cases. Forty six percent of these CNVs were maternally inherited, 43% were paternally inherited and 10% were de novo. Interestingly, when the CNV was present only once (i.e. unique to that patient) in our cohort, the likelihood that the CNV contained a gene was 72%. The detailed collected data will be presented. Compiling these data may lead to a more clinically relevant interpretation of smaller CNVs and identification of new genomic syndromes.

## 1376/W/Poster Board #1034

**CHRNA7 15q13.3 Interstitial ~ 500 kb Deletion/Duplication Associated with Speech Delay, ADHD, Autism and Agressive Behavior.** *J.H. Tepperberg[1], S. Schwartz[1], R. Pasion[1], R.D. Burnside[1], V. Jaswaney[1], I.K. Gadi[1], H. Risheg[2], E. Keitges[2], C. Bullen[1], B. Williford[1], P.R. Papenhausen[1].* 1) Dept Cytogenetics, Lab Corp America, Res Triangle Pk, NC; 2) Dept Cytogenetics, Lab Corp America, Seattle, WA.

The recurrent 15q13.3 microdeletion/microduplication has been reported to cause mental impairment, autism spectrum disorder, facial dysmorphism, seizures and epilepsy. The 1.5 Mb 15q13.3 critical region (chr:15:28,719,136-30,298,264) contains 6 reference sequence genes and three OMIM annotated genes (TRPM1, KLF13 and CHRNA7). This region appears to have an unequal exchange mediated by segmental duplication breakpoints 4 and 5 (BP4 and BP5). We identified 22 individuals using the Affymetrix 6.0 SNP microarray with 15q13.3q13.3 interstitial microdeletions/duplications - 12 individuals with the commonly reported ~1.5 Mb deletion or duplication, and 11 cases with a smaller ~ 500 kb microdeletion or duplication (chr15:29,754,362-30,298,264). The latter only includes the involvement of the nicotinergic acetycholine receptor gene, CHRNA7, a neuronal ion channel gene, which has been implicated as a candidate gene associated with seizures and epilepsy. The smaller 15q deletion/duplication has, to the best of our knowledge, not been previously reported. Many of the classical clinical phenotypic features of the larger 1.5 Mb deletion and duplication were observed in some these patients, including seizures and epilepsy. The smaller 15q13.3 deletion/duplication region appears to be flanked by a 109 kb segmental duplication between BP4, (BP4a - 29,806,912-29,697,285) and the distal segmental duplication BP5 (30,540,143-30,232,699). Eight of the 11 ~500 kb CHRNA7 cases were duplications and three cases were deletions, one of which was inherited from a reportedly unaffected mother. Some of the common clinical features of the BP4a - BP5 ~500 kb deletion were speech delay, developmental delay, ADHD, aggressive behavior, ADHD, and hearing loss. None of the three deletion cases were reported to have either seizures or epilepsy. Phenotypic features of individuals with the ~500 kb duplication include growth delay, midface hypoplasia, speech delay, mild autism and one case exhibiting seizures. Further studies are needed to determine whether CHRNA7 duplications are more likely polymorphic variants with little clinical significance or possibly causative with incomplete penetrance and/or variable expressivity. These results suggest that the deletion/duplication of the CHRNA7 gene by itself may not be sufficient by itself to cause seizures and epilepsy, and may instead be a susceptibility gene related to speech delay, ADHD, autism and aggressive behavior.

## 1377/W/Poster Board #1035

**DNA array-based copy number analysis in chorionic villus samples (CVS) of spontaneous abortions with normal karyotypes.** *T. Yamada[1,3], T. Ohta[3], K. Hosoki[2,3], S. Shimada[1], M. Morikawa[1], T. Yamada[1], K. Yoshiura[4], H. Minakami[1], N. Niikawa[3], H. Yamada[5].* 1) Dept. Obstet. Gynecol., Hokkaido Univ., Sapporo, Japan; 2) Dept. Pediatr., Hokkaido Univ., Sapporo, Japan; 3) Res. Inst. Personalized Health Sci., Health Sci. Univ. Hokkaido, Tobetsu, Japan; 4) Dept. of Hum. Genet., Nagasaki Univ., Nagasaki, Japan; 5) Dept. of Obstet. Gynecol., Kobe Univ., Kobe, Japan.

A half of spontaneous abortions (SA) in the first trimester are caused by chromosome abnormalities. There is a group of patients whose pregnancies end in recurrent spontaneous abortions (RSA). Environmental factors in uterus may also contribute to RSA/SA. To investigate reasons of RSA/SA with normal karyotypes, we analyzed on whether they have a microdeletion/duplication using DNA arrays. We collected 40 chorionic villus samples (CVS) (26 from RSA and 14 from SA) with normal karyotypes. Genomic DNA from 20 CVS was directly applied to DNA arrays, while whole genome amplification (WGA) was performed in the other 20 samples before array analysis as the amount of DNA was not enough. Consequently, we detected copy-number changes at 69 loci on 22 chromosomes. Of the 69 loci, 8 and 61 were those unregistered and registered in UCSC database, respectively. As all the 8 unregistered loci contain structural genes, we focused our attention on them for further analysis, and detected two deletions in one SA sample. As one of them was also found in a parent, it is likely to be a copy-number variant (CNV), whereas the other deletion, i.e., a de novo 11-Mb deletion at 5p14 may directly contribute to SA. Although 32 of the 61 registered loci contain genes, 20 (14 registered and 6 unregistered) loci were those detected after WGA, and thus they remain inconclusive.

## 1378/W/Poster Board #1036

**The effect of large *de novo* chromosomal deletions on gene expression.** *M. Ghahramani Seno[1,2], C. Marshall[1,2], P. Hu[1,2], J. McDonald[1,2], T. Paton[1,2], G. Casallo[1,2], S. Scherer[1,2].* 1) Programme in Genetics and Genome Biology, Hospital for Sick Children, Toronto, Ontario, Canada; 2) The Centre for Applied Genomics, Hospital for Sick Children, Toronto, Ontario, Canada.

In a study of a cohort of 427 individuals with autism we identified that ~7% carried *de novo* CNVs, some of which encompassed megabase-sized genomic regions. In order to study the effect of these large *de novo* CNVs (~3-20 MB) on the expression levels of genes they encompass and also on global genes expression, we carefully selected 8 individuals with large *de novo* deletions. The criteria for selection included: 1) having *de novo* deletions confirmed by qPCR on blood DNA, 2) presence of functionally interesting genes and/or miRNAs at the CNV region, and 3) presence of ultra conserved elements with potential regulatory functions at the CNV region. Included in this study is an individual with ~2.8 Mb *de novo* deletion at chromosome 22q11.21 region. This genomic segment and the genes it harbours have been associated with Schizophrenia in a number of studies. Lymphoblstoid cell lines from the selected individuals and their available parents and siblings were cultured under controlled conditions in three biological replicates. RNA was extracted and run on Illumina gene and miRNA expression arrays. Statistic analysis of the data indicated approximately one-half reduction in gene expression of the majority of the expressed genes directly encompassed by the deletion. Moreover, several genes located distant to the deletions and on different chromosomes also showed significant variation in individuals carrying the deletions compared to their family members. For instance, in the individual with deletion of 22q11.21, genes involved in the TP53 network were found dysregulated as indicated by Ingenuity pathway analysis tool. The data is further being mined to evaluate/identify gene networks affected by these large CNV alterations.

## 1379/W/Poster Board #1037

**Microdeletion at 15q11.2 between breakpoints 1 and 2 of the PWS/AS critical region: A new genomic disorder?** *X. Hu[1,2], Y.S. Fan[3], P. Li[4], T.J. Chen[5], B. Xiang[3], M. Li[1,2].* 1) 1Hayward Genet Ctr,; 2) Louisiana Cancer Research Consortium, Tulane Univ Sch of Med, New Orleans, LA; 3) Univ of Miami Miller Sch of Med, Miami; 4) Yale Univ Sch of Med, New Haven, CT; 5) Dept Med Genet, Univ of South Alabama, Mobile, AL.

Chromosome 15q11-q13 region contains multiple low-copy repeats (LCRs). These LCRs lead to a high frequency of chromosome rearrangements including deletion, duplication, and inversion. Two typical deletions, one between breakpoint 1 (BP1) and BP3 (type I) and the other between BP2 and BP3 (type II) of the PWS/AS critical region on chromosome 15q11-q13 have been described in 70% of patients with Prader-Willi syndrome (PWS) or Angelman syndrome (AS). Here we report thirteen cases of microdeletion between the two proximal PWS/AS deletion breakpoints, BP1 and BP2, using high resolution olignucleotide microarray-based comparative genomic hybridization. The patients include eleven males and four females aged from one to twenty-one years old. Common clinical features in these patients include short stature, motor and speech developmental delay, cardiac anomalies, and behavioral and psychosocial disturbances such as attention deficit disorder, attention deficit hyperactivity disorder, and autism spectrum disorder. Nine of the thirteen patients carry a deletion of minimum 300 Kb with the proximal and distal breakpoints located at the BP1 and BP2, respectively. The remaining four cases have smaller deletions (minimum 100 to 200 Kb) with only one deletion breakpoint, proximal or distal, located in BP1 or BP2. There are four highly conserved genes, GCP5, CYFIP1, NIPA2, and NIPA1, between BP1 and BP2, which have been postulated to be responsible for the compulsive behavior and lower intellectual ability in PWS/AS patients with the type I deletion. Among the 13 cases of 15q11.2 deletion, 9 deletions include all four genes, 3 contain 3 genes (CYFIP1, NIPA2, and NIPA1), and one involves only one gene (GCP5). Although the phenotypes of these patients vary, they share some common clinical features. The most frequent features include delayed motor and speech development and behavior disturbance. These results support the hypothesis that the 15q11.2 deletion between BP1 and BP2 is a novel microdeletion syndrome. The presence of deletions inherited from apparently normal parents and deletions that are de novo in these patients implies incomplete penetrance. Further study of more patients with similar 15q11.2 deletions and detailed clinical evaluation of apparently normal parents with the same 15q11.2 deletion are essential in defining this potential novel microdeletion syndrome.

## 1380/W/Poster Board #1038

**Identification and characterization of somatic copy number variants (CNVs) in embryonic cell lineages using a novel CNV-targeted array comparative genomic hybridization (aCGH) platform.** *A.A. Ghazani[1,2], M. Blake-Kinnin[1], S. Kantarci[2,3], C. Lee[1,2].* 1) Brigham & Women's Hospital, Department of Pathology, Boston, MA; 2) Harvard Medical School, Boston, MA; 3) Beth Israel Deaconess Medical Center, Department of Pathology, Boston, MA.

The identification of widespread copy number variation in the human genome has made a significant contribution to understanding the extent of genomic diversity in the general population. As a result, it has become necessary to categorize CNVs as benign, pathogenic or unknown clinical significance, in a clinical genetic diagnostic setting. In some cases, CNVs can arise somatically and are detected when two or more distinct somatic cell lines from a single zygote / individual contain different CNV profiles. Recent published studies have shown the detection of a limited number of somatic CNVs between monozygotic twins or between different tissues in a given individual. The aim of this study is to more comprehensively investigate the occurrences of somatic CNVs by studying different tissues derived from the different embryonic cell lineages (i.e., ectoderm, endoderm and mesoderm). This investigation has been conducted using a novel custom-designed 105K CNV-targeted array-based comparative genomic hybridization (aCGH) platform. The CNV array is composed of well-annotated probes from Database of Genomic Variant, probes from Phase II studies of the Structural Genomic Variation Consortium (unpublished data), and probes covering segmental duplications - that are commonly associated with CNVs. The test samples include DNA obtained from somatic cell lineages of ectoderm (skin), mesoderm (heart, kidney) and endoderm (liver, lung, stomach and large bowl) from a cytogenetically normal fetus at 27 weeks. The test samples were compared to a reference DNA obtained from the small bowel of the same fetus. Preliminary studies showed that the skin and liver samples exhibited similar CNV profiles compare to the small bowel. The lung exhibited distinct CNV profile regions compared to the remaining tissues, most likely attributed to somatically-derived CNVs. This data supports the notion that somatically-derived CNVs are more common than previously appreciated and can account for detectable genomic imbalances between one tissue and another in the same individual.

## 1381/W/Poster Board #1039

**Characterization of "new" human genome sequences variable among individuals.** *F. Antonacci[1], J.M. Kidd[1], N. Sampas[2], N.A. Yamada[2], P. Tsang[2], A. Tsalenko[2], H.S. Hayden[3], W. Gillett[3], T. Graves[4], C. Alkan[1], I. Hajirasouliha[6], M. Ventura[5], R.K. Wilson[4], L. Bruhn[2], R. Kaul[3], E.E. Eichler[1].* 1) Department of Genome Sciences and Howard Hughes Medical Institute, University of Washington, Seattle, WA; 2) Agilent Technologies, Santa Clara, CA; 3) University of Washington Genome Center, University of Washington, Seattle, WA; 4) Washington University Genome Sequence Center, St. Louis, MO; 5) Department of Genetics and Microbiology, University of Bari, Via Amendola 165A, Bari, Italy; 6) School of Computing Science, Simon Fraser University, Burnaby, BC, Canada.

Since the human genome reference assembly is now viewed as a patchwork of structurally variant sequence, it is expected that sequencing projects of other individuals will reveal novel human euchromatic sequence. We developed an approach using a fosmid clone-based resource to identify and characterize orphan euchromatic sequences that are not represented even once within the human genome reference sequence assembly. Based on our analysis of nine human genomes, we have identified 3,944 sequence contigs (from 10,516 distinct clones) corresponding to new insertions ranging from 1 kbp to 130 kbp in size. We estimate that 497 of these correspond to uncharacterized genomic segments greater than 40 kbp in size with half not associated with known gaps in the reference genome assembly. We developed a customized (Agilent) genotyping platform to robustly genotype 2,515 of these contigs in samples from the HapMap population. We found that 40% of the contigs are polymorphic. More than 97% were found in a single chimpanzee, supporting the conclusion that these sequences represent a combination of polymorphic human deletions and artifacts in the human genome reference assembly. To date, over a 100 of these regions have been sequenced. Several of these sequences map within transcribed regions and may contain additional spliced exon structures. We systematically analyzed unmapped fosmid clones for one individual (NA15510) by clone-based analyses, arrayCGH and fluorescent in situ hybridization. FISH mapping of these contigs indicates that the majority are single-copy sequences distributed throughout the genome with a particular enrichment in subtelomeric regions. We tested by FISH 69 insertions in 9 individuals predicted to be euchromatic based on paired-end sequence placement. Surprisingly, only 42% of these sequences mapped to the predicted location, with 45% mapping to the nucleolar organizer regions (NORs) on the p arms of acrocentric chromosomes. These results suggest that a subset of our contigs correspond to euchromatic sequences which have been copied into the short arm of acrocentric chromosomes. Taking into consideration the success of this analysis we applied this approach to paired-end sequence data from NGS. Based on a 42X sequence coverage from an African genome, we identified, mapped and partially characterized 1623 new insertions in one African individual ranging in size from 500bp to 6.2 kbp.

### 1382/W/Poster Board #1040

**Copy number variations associated with developmental disorders in a Bronx minority population.** *M. Babcock[1], J. Samanich[2], R.W. Marion[2], P. Levy[2], A. Shanske[2], K. Pop[2], N. Yachelevich[2], D.T. Hsu[3], Q. Pan[4], C.K. Huang[4], L. Cannizzaro[4], K.H. Ramesh[4], C. Montagna[5], J. Flynn[6], B.E. Morrow[1].* 1) Department of Genetics, Albert Einstein College of Medicine, Bronx, NY, USA; 2) Center for Congenital Disorders, Children's Hospital at Montefiore, Bronx, NY, USA; 3) Division of Pediatric Cardiology, Children's Hospital at Montefiore, Bronx, NY, USA; 4) Department of Pathology, Montefiore Medical Center, Bronx NY, USA; 5) Department of Pathology, Albert Einstein College of Medicine, Bronx, NY, USA; 6) Clinical Research Center, Albert Einstein College of Medicine, Bronx, NY, USA.

Over the last year, a pipeline to determine the genomic basis of developmental delay and multiple congenital anomalies has been created between Albert Einstein College of Medicine, Children's Evaluation Rehabilitation Center (CERC) and the Children's Hospital at Montefiore (CHAM). The goal has been to develop translational genomics research while simultaneously providing a clinical laboratory diagnosis. A total of 222 blood or saliva specimens from 96 probands and 126 parents were collected with their informed consent over the past year. Of these, 88 had developmental delay/multiple congenital malformations and 8 had cardiovascular malformations. Six of the probands had known translocations or inversions. The DNA was isolated and a targeted Agilent 44k microarray was used for aCGH (array comparative genome hybridization) testing at CHAM. Positive findings were followed up in the research lab. Of the 96 probands, 34 showed CNVs of which, 16 occurred in regions of known benign polymorphisms and 18 were in intervals of human diseases or in novel regions. One interesting finding was from a proband with skeletal anomalies who had a karyotype 46,XY, der(2)t(2;6)(q37.3;p25). The result of aCGH determined the presence of a 4Mb terminal deletion on 2q37.3, a 6 Mb duplication on 6p25.1-25.3, and a 0.8 Mb deletion on 2q13. Multiple genes for skeletal development were located in these intervals including, HDAC4, FOXC1, and FOXF2. Another example is a proband with obesity and family history of mental illness. The child had a normal karyotype and was negative for sub-telomere FISH, but had a 3.2 Mb deletion on 1p31.3 containing genes LEPR and PDE4B important for obesity and mental health, respectively. The pipeline developed can serve as a guide to other institutions embarking on translational genomics research.

**Copy number variation in subtelomeric regions in Brazilian male patients with intellectual disability.** *D.M. Christofolini, M.A.P. Ramos, S.I.N. Belangero, F.T.S. Bellucco, A.N.X. Pacanaro, M.I. Melaragno.* Genetics Division, Morphology, UNIFESP, SAO PAULO, SAO PAULO, Brazil.

INTRODUCTION: Chromosomal rearrangements affecting subtelomeric regions of chromosomes are believed to be responsible for 5-7% of moderate to severe mental retardation cases. However, this may be an underestimation because, due to the relative complexity and high cost of the screening methods used, only preselected patient populations, including mostly the more severely affected cases, are usually screened. Moreover, the presence of a small chromosome duplication, triplication or deletion is not easy to detect by routine chromosomal analysis. Recently, multiplex ligation-dependent probe amplification (MLPA) has been adapted for use in subtelomeric rearrangement screening, and has allowed characterizing larger patient samples. METHODS: In the present study, we used MLPA for the detection of microduplications/microdeletions in 120 male patients with intellectual disability, who presented normal karyotypes and negative results for the fragile-X syndrome. RESULTS: We detected five patients with copy number aberrations (4% of the investigated cases). MLPA probes showed duplications of regions inside genes FLJ22115, SYBL1, SECTM1, triplication of gene NDN, and deletion of the FBXO25 gene. These genes are located at 20p13, Xq28, 17q25.3, 15q11.2, and 8p23.3, respectively. Two of the probes (for genes SYBL1 and FBXO25) were located in regions with previously described copy number variations (CNVs). The clinical phenotypes of these patients were unremarkable. CONCLUSION: This study underscores the value of combining conventional karyotyping with novel technologies to unravel small chromosomal alterations and help understanding genomic mechanisms leading to disease. ### 1384/W/Poster Board #1042

**A novel 1.5 Mb de novo non-recurrent deletion at 14q23 detected in Autism spectrum disorders.** *D.Q Ma[1], A. Griswold[1], R.H Chung[1], D. Salyakina[1], H.N Cukier[1], J.M Jaworski[1], I. Konidari[1], P.L Whitehead[1], D. Hedges[1], H. Wright[2], R.K Abramson[2], E.R Martin[1], J.P Hussman[3], J.R Gilbert[1], M.L Cuccaro[1], J.L Haines[4], M.A Pericak-Vance[1].* 1) Miami Inst Human Genomics, Univ Miami, Miller Sch Med, Miami, FL; 2) School of Medicine, University of South Carolina, Columbia, SC; 3) Hussman Foundation, Ellicott City, Maryland; 4) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN.

Autism spectrum disorders (ASDs) are a group of highly heritable neurodevelopmental disorders with a complex genetic architecture. Several lines of evidence have implicated the rare variants such as copy number variations (CNVs) in the etiology of ASDs. A genome-wide SNP-array mapping of CNVs was carried out on 602 ASD families genotyped on Illumina Human 1M Beadchip. Preliminary CNV detection yields 39,046 CNVs from 635 cases in 600 ASD families after sample quality control embedded in Penncnv. It includes 3767 homozygous deletions, 26703 hemizygous deletions, 8386 one-copy duplications and 190 two-copy duplications. Initial analysis identified 5276 possible de novo CNVs from 597 cases in 531 complete families using family-based CNV detection algorithm. The length of these de novo CNVs ranges from 40bp to 5Mb (the number of spanned SNPs: [3, 2427]) across 22 chromosomes. 52 of them have a size of more than 500Kb. Majority of these large CNVs falls into copy-number-rich regions. A novel 1.5 Mb-long non-recurrent deletion at 14q23.2-23.3 found in one case appears to be interesting. It completely deletes an autism candidate gene (MTFHD1) and has not been reported by any available CNV databases. In addition, we successfully replicated six previously reported autism-related CNV regions (CNVRs) (UBE3A, NRXN1, CNTN4, 22q11.21, 16p11.2 and SHANK3) and five newly reported common CNVRs over-represented in ASD patients (FBXO40, AK123120, UNQ3037, NLGN1 and GYPELOC441046). In conclusion, the novel de novo deletion at 14q23.2-23.3 disrupting MTFHD1 is implicated in ASD but warrant further validation experimentally.

### 1385/W/Poster Board #1043

**From chromosome to SNP-array, a new patient with 16p microdeletion syndrome.** *A. Perez-Juana del Casal[1], M. Artigas-López[1], A. Bengoa-Alonso[1], M. Nadal Sanchez[2], C. Harteveld[3], C. Ruivenkamp[3], A. Alonso Sanchez[1], MA. Ramos-Arroyo[1].* 1) Dept Genetics, Hosp Virgen del Camino, Pamplona, Spain; 2) Genetics, Inst Recerca Oncologica. L'Hosp, Barcelona, Spain; 3) Genetics, Clinical Molecular and Biochemical Geneticist. Leiden University,The Netherlands.

A one year-old mentally retarded boy with mild facial dysmorphism was referred to the Genetics Clinic for evaluation. The patient was the first child of a healthy, non consanguineous couple. Pregnancy was complicated by decreased fetal movements and IUGR. Delivery was at 37 weeks by C-section, birthweight 2310 g, length 45 cm and head circumference 31 cm. Microbrachycephalia, occipital cowlick, low set ears, downslanting palpebral fissures, narrow nose, small mouth, long philtrum, and tapering fingers were observed. Blood was drawn for conventional karyotype analysis and Fragile-X study. Fragile-X testing came back normal. A 16p deletion was suspected cytogenetically, but could not be demonstrated by any of the available techniques in our lab. FISH analysis (ToTelVysion, Vysis) with telomeric probes was normal. Next we tried to rule out an interstitial deletion with FISH of selected BAC clones, D16Z3, RP11-517F15 (16p13), CTD-2135D7 (16p13-12) and RP11-567P19 (16p12-11), again with normal results. Finally we contacted with an external laboratory who kindly performed a genome scan using a 250K SNP array (Affymetrix), this technique revealed a microdeletion 'popping-up' of at least 7.78 Mb (536 SNP probes) in the short arm of chromosome 16. This rearrangement has been defined as a syndrome, "microdeletion syndrome of 16p11.2p12.2", by Blake C Ballif, et al. (Nature Genetics, 2007), after screening 8789 patients with developmental disabilities and normal karyotypes. Five out of 8789 patients had different copy-number imbalances on 16p, and two of them had exactly the same microdeletion size and phenotype as the patient here presented.

## 1386/W/Poster Board #1044

**Parental Origin Bias in *de novo* CNVs Detected in Autism Probands.** *N. Shah[1], R. Regan[2], J. Conroy[2], T. Magalhaes[4], J. Casey[2], R. Anney[5], A. Green[3,2], L. Gallagher[5], M. Gill[5], DC. Shields[1], A. Vicente[4], S. Ennis[2,3].* 1) UCD Conway Institute and UCD Complex and Adaptive Systems Laboratory, School of Medicine and Medical Science, University College Dublin, Dublin, Ireland; 2) Health Science, School of Medicine and Medical Science, University College Dublin, Dublin, Ireland; 3) National Centre for Medical Genetics, Our Lady's Hospital for Sick Children, Dublin, Ireland; 4) Istituto Nacional de Saúde, Lisboa, Portugal; 5) Trinity Centre for Health Sciences, Trinity College Dublin, Dublin, Ireland.

Genetic variation occurs in humans at both individual and population level. One such variation that contributes to human genetic diversity is copy number variation (CNV) of genomic segments. In addition to contributing to common variation among healthy individuals, CNVs are associated with a number of genetic disorders and the susceptibility to complex disorders. It has also been shown that there is an association between *de novo* CNVs and complex disorders including autism spectrum disorder (ASD). Such *de novo* mutations could occur in either maternal or paternal germ line or in developing embryos.

We are investigating whether there is a parental origin bias for *de novo* CNVs in ASD probands. Three hundred and eighty Irish and Portuguese autism trios were genotyped on the Illumina 1M beadarray. *De novo* CNVs in probands were predicted using PennCNV algorithm. To minimize false positive and false negative CNVs, genotype & intensity filters were applied. In our preliminary analysis of *de novo* CNVs, we observed a bias towards paternal origin (chi-square with continuity correction; P = 0.016) for *de novo* deletions with 2 or more SNPs informative and congruent for defining parental origin from SNP genotype and intensity data (maternal: paternal origin ratio is 2:12 deletions). We also observed that there is a bias towards maternal origin (chi-square with continuity correction; P = 0.041) for *de novo* duplication CNVs (maternal: paternal origin ratio is 31:16 duplications).

One theory regarding paternal origin bias in *de novo* deletions is that there are many more germ line cell divisions in the life history of a sperm relative to that of an egg and therefore greater opportunity for mutations to occur. Further studies on the relationship between duplication and deletion *de novo* CNVs and their parent of origin may provide further insights into the molecular mechanisms during meiosis. Replication of this study in a larger dataset and experimental validation is to be followed.

## 1387/W/Poster Board #1045

**Copy number variations analysis in 13 sporadic patients with mental retardation of unknown origin and normal karyotype.** *V. Stranecky[1], R. Ivanek[1], A. Baxova[2], H. Hartmannova[1], L. Noskova[1], A. Cizkova[1], S. Kmoch[1].* 1) Institute of Metabolic Disorders, Charles University, First Faculty of Medicine, Ke Karlovu 2, Prague 2, Czech Republic; 2) Institute of Biology and Medical Genetics, First Faculty of Medicine, Charles University and General University Hospital , Albertov 4, Prague 2,Czech Republic.

Microdeletions or microduplications (eg. losses or amplifications of DNA regions smaller then 5 Mb) that can not be detected by conventional cytogenetic analysis seem to be frequent among causes of sporadic syndromes associated with mental retardation. To estimate the frequency and eventual recurrence of such changes, we used Affymetrix SNP Array 6.0 and analysed copy number changes (CNVs) in 13 sporadic patients with mental retardation of unknown etiology associated with multiple (syndromology unspecific) congenital abnormalities suggestive of genetic origin and normal karyotype. Identified CNVs larger then 30 kb were tabled for each of the patient according to its sizes, characters (loss/gain) and overlaps with Database of Genomic Variations (DGV) and Database of pathologic CNVs (DECIPHER). Genomic content for each of the unique CNVs was assessed using UCSC browser and genotype - phenotype correlation was estimated based on gene expression patterns and its likely biological relevance to mental retardation and/or associated symptoms. In 4 patients we identified unique and clearly clinically significant changes ranging from 420 kb - 20 Mb. In 7 patients we identified unique deletions ranging from 35 kb to 150 kb and affecting genes coding for brain expressed transcription factors, regulatory proteins, regulatory elements or proteins of unknown function. In 2 patients no unique and biologically relevant changes were identified. Our data demonstrate that microdeletions are probably very frequent cause of sporadic syndromes and that high resolution copy number analysis provide clinically significant and scientifically useful data.

## 1388/W/Poster Board #1046

**Single Molecule Nanoarray Analysis for Genomic Structural Variation Mapping.** *M. Xiao, S. Vijayan, S. Das, p. Deshpande, S. Gallagher, M. Austin, H. Sadowski, M. Boyce-Jacino, H. Cao.* BioNanomatrix Inc, Philadelphia, PA.

We are developing a single molecule nanoarray platform for whole genome mapping. The system uses a highly miniaturized nano-channel device that enables rapid detection of single, labeled dsDNA molecules preserved in their long native linear state. Our method starts with sequence specific fluorescent labeling of high molecular weight genomic DNA. The labeled DNA molecules are then linearized inside the nano-channel device and imaged with a high resolution fluorescence imaging station. By determining the order of the fluorescent labels on each molecule, the distribution of specific sequence motifs can be inferred with great accuracy on fragments ranging in size from 50,000 to 350,000 base pairs in length, in a manner similar to reading a bar code. The motif maps generated from each long fragment are then re-assembled into a global genome map using proprietary software. We will present DNA mapping results on human BAC and fosmid samples with known structural variations as an example of the technology and describe more specifically the utility of the system in the discovery and confirmation of genome wide structural variations. Other potential applications for the system, such as molecular haplotyping and methylation analysis, will also be discussed.

## 1389/W/Poster Board #1047

**Epilepsy as an Endophenotype of Autism for Gene Discovery.** *A. Moreno-De-Luca[1], D. Moreno-De-Luca[1], S.L. Helmers[2], D.H. Ledbetter[1], C.L. Martin[1].* 1) Emory University School of Medicine, Department of Human Genetics, Atlanta, GA; 2) Emory University School of Medicine, Department of Neurology, Atlanta, GA.

Autism is a common and heterogeneous neurodevelopmental disorder characterized by a triad of impaired verbal communication, lack of reciprocal social interaction, and restricted or stereotypical patterns of behavior. It has one of the highest demonstrated heritabilities among developmental neuropsychiatric disorders: family studies have revealed a recurrence risk of 2-8% among siblings of affected probands and twin studies have shown a concordance of 60-90% among monozygotic twins as compared to ~10% in dizygotic twins. There is a close relationship between autism and epilepsy as ~30% of autistic individuals also have a history of seizures. We are using epilepsy as an endophenotype of the broader autism spectrum, with the aim of reducing phenotypic heterogeneity, to look for copy number variations (CNV) in patients with autism plus epilepsy. By using this strategy, we expect to identify underlying genetic causes shared by both conditions. Genome-wide array analysis is being carried out using a custom-designed 44K oligonucleotide array. To date, we have tested 20 patients and identified 6 cases (30%) with a CNV that could be responsible for the observed phenotype. Two deletions and 4 duplications were identified ranging in size from 452 kb to 1.6 Mb. One of the duplications involves the previously reported region on 16p11.2 which has been suggested to be associated with an increased risk for autism. The other changes are novel and we are interrogating their gene content for candidate genes. Interestingly, one case has a 452 kb de novo deletion involving only the SLC39A10 (solute carrier family 39A10) gene at 2q32.3. The proband presented with autism, developmental delay and absence seizures. This is the first case reported to have a CNV in this gene associated with autism and epilepsy and no common, benign CNVs of this region have been reported in normal control populations. The SLC39A10 gene belongs to a subfamily of proteins that show structural characteristics of zinc transporters. Extracellular zinc can interact with many different synaptic targets, including glutamate receptors and transporters. Therefore, this gene is a strong candidate since genes in the glutamate pathway have been implicated in autism spectrum disorders. The use of such rare CNVs for gene discovery in autism and epilepsy will provide insight into the underlying molecular mechanisms of these common disorders.

## 1390/W/Poster Board #1048

**High-resolution cytogenetic analysis using customized oligonucleotide-based fluorescence *in situ* hybridization (FISH).** *N.A. Yamada[1], F. Antonacci[2], R.A. Ach[1], P. Tsang[1], E. Carr[1], A. Scheffer-Wong[1], N. Sampas[1], B. Peter[1], S. Laderman[1], J.M. Kidd[2], E.E. Eichler[2,3], L. Bruhn[1].* 1) Molecular Technology Laboratory, Agilent Laboratories, Santa Clara, CA; 2) Department of Genome Sciences, University of Washington, Seattle, WA; 3) Howard Hughes Medical Institute, University of Washington, Seattle, WA.

The comprehensive analysis of structural complexity within the human genome requires extension of cytogenetics methods to fine-scale resolution. Fluorescence *in situ* hybridization (FISH) offers unique abilities to analyze chromosome structures in the single-cell context, but current FISH methods have limitations that preclude its routine use in these studies. We have expanded FISH capabilities and utilities to meet the requirements of high-resolution cytogenetics.

We tested high complexity oligonucleotide libraries (94-194mers) to empirically determine the individual length of the oligonucleotides to be pooled. We then *in silico* selected probe sequences for the most informative elements within target loci. We maintained the downstream hybridization workflow to closely resemble those widely used for BAC-based FISH with improvements that eliminated the need for suppressive hybridization reagents.

Regions as small as 1.8 kb and as large as chromosome arms were successfully visualized in both metaphase and interphase cells without further iteration using our *in silico* probe design methodology and assay protocol. Because of the inherent flexibility in our probe design methods, we readily obtained specific and robust probes for regions rich in repeats and/or GC content. Simultaneous hybridization of probes labeled with three different fluorophores for multicolor visualization was achieved without any modifications to the assay workflow. Probe performance on interphase cells after immunocytochemistry treatment was also validated, providing evidence that protein-DNA co-detection can be achieved routinely.

We then applied our FISH technology to analyze a set of recently discovered "novel human sequences" that are absent from the current reference assembly. These sequences, identified by fosmid end-sequencing, ranged in sizes from 30 kb to 5 kb. Because we do not require physical starting template DNA for probe generation, we visualized these novel sequences and validated array-based copy number measurements using our routine workflow. Our results demonstrate that complex libraries of *in silico* selected oligonucleotides extend FISH capabilities to complement microarray- and sequencing-based discoveries and enable single-cell visualization of chromosome at fine-scale resolution to further our understanding of genome biology.

## 1391/W/Poster Board #1049

**An optimised fibre-FISH protocol for characterising genomic structural variation.** *F. Yang, N.P. Carter.* Wellcome Trust Sanger Institute, Hinxton, Cambridge, United Kingdom.

Fluorescence in situ hybridisation (FISH) on stretched chromosomal DNA fibres is an indispensable tool for defining the size of gaps and overlaps between clone contigs in a given reference genome. There are many published protocols for fiber-FISH, but a robust protocol that allows high-throughput mapping by fibre-FISH is unavailable. Most fibre-FISH protocols involved the use of dual colour FISH of probes respectively labelled with biotin- and digoxigenin-dUTP by nick translation and detected indirectly with red and green fluorochrome conjugated antibodies. While being very informative in determining the genomic gap and overlap between clones, these protocols have limited use in physical ordering of multiple contigs and characterisation of complex arrangements and rearrangements that often require the simultaneous mapping of at least three probes (two test probes plus one anchor probe, each being visualised with a distinct colour). In response to the growing need of mapping genomic structural variations (copy number variation and inversions) by fibre-FISH from international community, we have further optimised the fibre-FISH protocol that is based on alkaline lysis of live cells. The main modifications include 1) the introduction of a modified whole-genome amplification kit for rapid generation of high-quality BAC and fosmid probes, and 2) the introduction of a third hapten in probe labelling (in addition to the widely used biotin- and digoxigenin-dUTP), and 3) the development of an appropriate antibody detection system suitable for the detection of three haptens. The modified protocol allows us to visualise simultaneously three or more probes in at least three distinctive visible fluorochromes (i.e. Texas red, Cy3 and FITC). We have successfully applied this protocol to the characterisation of genomic structural variations in normal human and great apes populations as well as those associated with human diseases. Our fibre-FISH results have led to a better interpretation and understanding of genomic structural variation identified by array-CGH and next generation paired-end sequencing. Fibre-FISH has also enabled a more definitive characterisation of multiallelic copy number variation that is difficult to validate by other approaches.

## 1392/W/Poster Board #1050

**Submicroscopic structural variation analysis in patients with mental retardation using SNP 6.0 array and combined data analysis.** *M. KOHDA[1], T. Hirata[1], E. Nakagawa[2,3], K. Kurosawa[4], Y. Goto[2,3], Y. Okazaki[1].* 1) Div. of Translational Research, Saitama Medical University, Hidaka, Saitama, Japan; 2) Natl. Ctr. Hospital of Neurology and Psychiatry, NCNP, Tokyo, Japan; 3) Natl. Inst. of Neuroscience, NCNP, Tokyo, Japan; 4) Div. Med. Genet., Kanagawa Child Med. Ctr., Kanagawa, Japan.

The genetic causes of mental retardation (MR) are quite heterogeneous. Recent studies have identified a series of genes involved in MR, however, there are still many patients whose causal genes are yet to be determined. On the other hand, copy number variations (CNVs) have been raised up as important genetic risk factors for developmental disorders, including neurodevelopmental disorders, schizophrenia, autism and MR. High density oligonucleotide array has emerged as a novel technology allowing one to detect DNA copy number changes that were previously unidentified by conventional cytogenetic techniques. In this study, 50 MR patients with normal karyotype were tested for CNV using Affymetrix Genome-Wide Human SNP Array 6.0. . The structural variations identified by SNP Array 6.0 were confirmed by qPCR and/or FISH. Approximately 20 DNA copy number changes per individual were detected. In about 10% of patients, suspicious disease-related imbalances were detected, ranging from 310 kb to 1.6 Mb in size. In some cases, the regions of the variations overlapped with those reported in the DECIPHER database. To identify individual variants that are pathogenic, we then combined our data with published (rare) CNVs from several studies in patients with such as autism, schizophrenia or MR and in normal populations. We will report candidate causal genes for these MR patients, and discuss about the challenges of analysing and interpreting the data generated using high density oligonucleotide arrays.

## 1393/W/Poster Board #1051

**Detection of copy number variations (CNV) in patients with mental retardation using high density SNP microarrays.** *N. Rivera-Brugues[1], M. Hempel[2], S. Spranger[3], B. Kazmierczak[3], T. Meitinger[1,2], T.M. Strom[1,2].* 1) Institute of Human Genetics, Helmholtz Zentrum München, German Research Center for Environmental Health, Neuherberg-Munich, Germany; 2) Institute of Human Genetics, Technische Univeristät München, Munich, Germany; 3) Praxis für Humangenetik, Bremen, Germany.

Chromosomal abnormalities are a major cause of mental retardation. Whole-genome array-based technologies have increased the detection rate of cryptic aneusomies among these patients up to 10-20%. DNAs from 109 children with MR and normal G-banded chromosomes and 1 mentally retarded child with a de novo balanced reciprocal translocation were evaluated for rearrangements by Illumina Human610-Quadv1_B arrays. Data quality was assessed with standard deviation (mean SD: 0.19) and mean absolute deviation (mean MAD: 0.12) of the log2 intensity ratios. In male samples, a signal-to-noise ratio (median log2 intensity ratio of the X-chromosomal SNPs minus median log2 ratio of the autosomal SNPs divided by MAD) was calculated (mean SNR: 3.82). CNVs were called using circular binary segmentation (DNAcopy). Conspicuous CNVs were compared with known variants as provided by the Database of Genomic Variants (DGV). After excluding known structural polymorphisms and the majority of CNVs within intronic and intergenic regions, we validated the microarray data and genotyped imbalances by qPCR. A total of 3,087 CNVs (2,431 losses, 656 gains) ranging in length from 118 to 13,386,172 base pairs (mean 85,149, median 24,352) were detected. 168 out of 3,087 candidate regions were investigated. Of these, 69 (41.1%) were confirmed, 99 (58.9%) were false-positive. 77 (77.8%) of the false positive were detected in regions defined by <10 SNPs, 18 (18.2%) were indicated by 10-20 SNPs and 4 (4%) by >20 SNP. We identified 16 de novo CNVs and one maternally inherited Xq13.1 deletion in a male patient, which correspond to 14 deletions and 3 duplications ranged in size from 3kb to 13.4Mb. The inheritance of 5 CNVs could not be established because of missing parental DNA. The resolution of Illumina microarrays showed to be sufficient to detect intragenic deletions. The identification of de novo CNV affecting only a single gene permitted us to consider that particular gene as a candidate for mental retardation. Mutational screening will follow based on a candidate gene approach in a large series of unexplained MR patients. Therefore, this study will lead to the identification of genes involved in MR, thus providing insights into the pathophysiology of mental retardation and into functional networks relevant for the development of the brain.

## 1394/W/Poster Board #1052

**Analyses of 499 Cases of Multiple Congenital Anomalies with Mental Retardation using array-CGH for Investigation and Diagnosis.** *S. Hayashi[1], S. Honda[1], S. Mizuno[2], N. Okamoto[3], Y. Makita[4], A. Hata[5], I. Imoto[1], J. Inazawa[1].* 1) Dept. of Molecular Cytogenetics, Medical Resarch Institute, Tokyo Medical and Dental University; 2) Department of Pediatrics, Central Hospital, Aichi Human Service Center; 3) Department of Planning and Research, Osaka Medical Center and Research Institute for Maternal and Child Health; 4) Education Center, Asahikawa Medical College; 5) Department of Public Health, Chiba University Graduate School of Medicine.

In order to screen cryptic chromosomal copy-number aberration (CNA) in unknown congenital disorders, we performed array-CGH in patients with multiple congenital anomalies and mental retardation (MCA/MR) for four years, by using several types of in-house bacterial artificial chromosome (BAC)-based arrays. All cases showed normal karyotype by conventional cytogenetics. We first screened 499 cases using 'MCG Genome Disorder (GD) Array' containing BACs covering loci associated with known genomic disorders and subtelomeric regions of all chromosomes except short arms of acrocentric chromosomes, and detected CNAs in 51 of 499 cases (10.2%). We next performed the second screening using 'MCG Whole Genome Array-4500' harboring 4523 BACs throughout human genome in cases without any CNAs in the first screening. All detected copy-number variations (CNVs) were confirmed by FISH in patients and their parents as far as possible. Through those steps, we judged *de novo* CNVs as potentially pathogenic CNAs, and consequently we detected CNAs in 45 of 239 cases (18.8%). Among positive cases, two showed recurrent CNAs, allowing us to diagnose recently identified 1q41 and 16p11.2 microdeletion syndromes. In other two cases CNAs detected harbored genes closely associated with phenotypes in each patient; BMP4 for polysyndactyly and *CASK* for microcephaly with hypoplastic cerebellum, respectively. Subsequently, we investigated genomic aberrations of the *CASK* gene in eleven females with MR, microcephaly and hypoplastic cerebellum, and identified four mutations, two deletions and one duplication of *CASK*. Taken together, our trial could efficiently screen patients with MCA/MR to detect CNAs in about 30% in all cases showing normal karyotype by conventional cytogenetics, leading to the delineation of new syndromes and accelerating understanding of gene function.

## 1395/W/Poster Board #1053

**Genomic duplication identified by genome-wide array CGH: A multicenter study of 1,670 cases.** *M.M. Li[1], Y.S. Fan[2], P. Li[3], T.J. Chen[4], B. Xiang[2], X. Hu[1], H.C. Andersson[1], T.C. Narumanchi[1], Y. Wang[4].* 1) Hayward Gen Ctr, Tulane Univ Sch Med, New Orleans, LA; 2) Univ of Miami Miller Sch of Med, Miami, FL; 3) Yale Univ Sch of Med, New Haven, CT; 4) Dept Med Genet, Univ of South Alabama, Mobile, AL.

Genomic duplications have been well documented as the cause of many genomic disorders. However, the interpretation of genomic duplications uncovered by high resolution genome-wide array CGH (aCGH) has been a challenge due to the higher level of incomplete penetrance and variable expressivity compared to genomic deletions. We have collected and analyzed genomic duplications among 1,670 consecutive cases using Agilent 4x44K oligonucleotide arrays. Criteria for pathogenic duplications include following: 1) involvement of a region associated with a known microduplication syndrome; 2) presence of the same duplication in a similarly affected parent; 3) involvement of known dosage sensitive gene(s); or 4) association of multi-gene imbalances related to visible or cryptic cytogenetic alterations. Criteria for benign duplications include following: 1) involvement of a known copy number variation documented in multiple normal individuals; or 2) presence of the same duplication in phenotypically normal family members. Clinical indications for aCGH study include mild to severe mental retardation, multiple congenital anomalies, developmental delay, and autism spectrum disorders. A total of 613 duplications ranging from approximately 30 Kb to 61.5 Mb in size were identified. The incidence of genomic duplication in this cohort of patients was 23.7% (456/1760). Of these duplications, 17.5% (107/613) were considered pathogenic, 64.3% (394/613) were classified as benign, and 18.3% were variations of unknown significance. Among 107 pathogenic duplications, 26 were associated with described syndromes and 81 were private duplications presenting in individual families. Of the pathogenic duplications, 94% (100/107) were larger than 500 Kb, whereas the average size of benign CNVs was 270 Kb, with less than 10% larger than 500 Kb. While the majority of the pathogenic duplications were scattered across the genome, benign CNVs tended to be clustered in certain regions with known genomic variations. Our experience suggests that, with some exceptions, size and location should be used as the first-line criteria in classifying genomic duplications as pathogenic or benign. We also emphasize the importance of evaluating parental DNA samples to aid in the interpretation of novel genomic duplications.

## 1396/W/Poster Board #1054

**Multiple chromosome anomalies detected by microarray CGH, including deletion of the gene for familial adenomatous polyposis.** *M. Manning[1,2], A. Kwan[1], A. Cherry[2].* 1) Dept Peds/Div Med Gen, Stanford Univ Sch Med, Stanford, CA; 2) Dept Path, Stanford Univ Sch Med, Stanford, CA.

Microarray comparative genomic hybridization, aCGH, is a precise test at detecting submicroscopic chromosomal copy number changes and is becoming standard of care when evaluating patients with multiple congenital anomalies, dysmorphic features and developmental delay/mental retardation. Recent applications of aCGH have included evaluation of patients with autism and prenatal diagnosis of pregnancies with multiple anomalies. A new use for aCGH, that of determination of tumor susceptibility, has now been described. We highlight the latter application with the presentation of a case in which deletion of the APC gene on chromosome #5 was discovered serendipitously when aCGH was performed to further define breakpoints of a 2p deletion previously identified on conventional chromosome analysis. The patient was born at 30 weeks of gestation. A two-vessel cord, heart defect, microcephaly and polyhydramnios were detected by ultrasound in the 3rd trimester. Undescended testes and hypospadias were noted after delivery. Postnatal echocardiogram demonstrated a PDA, ASD and double aortic arch with coarctation of one of the arches. Chromosome analysis revealed an interstitial deletion of the short arm of chromosome #2 [46,XY,del(2)(p11.2p12)]. By age 3 years, the patient had developed hydrocephalus (s/p VP shunt placement), severe GE reflux and chronic lung disease. He was also growth retarded and developmentally delayed. Oligoarray was performed to clarify the deletion breakpoints. In addition to the 2p anomaly [arr 2p12(78,115,314-82,644,204)x1, at least 4.5 Mb], 2 other deletions were detected: an at least 7.4 Mb deletion of 5q [arr 5q21.3q23.1(108,464,047-115,906,031)x1] with breakpoints 5q21.3 to 5q23.1 and a 1.1 Mb deletion within 7p15.2 [arr 7p15.2(26,052,791-27,171,164)x1]. Of significance to the patient's future medical management was the 5q deletion which contained at least 21 genes, including the APC gene associated with familial adenomatous polyposis (FAP), the REEP5 (deleted in polyposis 1) gene and the MCC (mutated in colorectal cancers) gene. Literature reports of individuals with deletions of this region describe dysmorphic features and mental retardation in addition to FAP. This case illustrates the effectiveness of aCGH at precisely defining breakpoints of known chromosomal abnormalities as well as the effectiveness of uncovering tumor susceptibility genes, knowledge of which can directly affect patient management.

## 1397/W/Poster Board #1055

**Diagnosis of Cohen syndrome in twin brothers: Using array CGH to identify a deletion that unmasks a recessive condition.** *M.R. Rossi[1], E. Rooney-Riggs[1], H. Wang[2], M.P. Adam[1], P.M. Fernhoff[1], G. Richard[3], S.J. Bale[3], C.L. Martin[1], D.H. Ledbetter[1].* 1) Department of Human Genetics, Emory University, Atlanta, GA; 2) DDC Clinic for Special Needs Children, Middlefield, OH; 3) GeneDx, Gaithersburg, MD.

Cohen syndrome is a rare autosomal recessive condition characterized by moderate to severe mental retardation and typical facial features. Because the clinical features of Cohen syndrome may not be easily recognized in infancy or early childhood, many patients are diagnosed much latter in life. Here we describe the diagnosis of two year old twin boys with Cohen syndrome who carry both a heterozygous deletion and a nonsense mutation of the VPS13B (COH1) gene in trans. The diagnosis of Cohen syndrome was initiated after a clinical cytogenetic array performed by our laboratory identified a 173 kilobase (kb) interstitial deletion of chromosome 8 band q22.2 in one of the children. The heterozygous deletion removed exons 19-25 of the VPS13B gene, and was predicting to be an inactivating intragenic gene deletion. Subsequent resequencing of the entire coding region of the VPS13B gene in this same child, identified a heterozygous nonsense mutation, c.1141 C>T (p.Q381X). This heterozygous point mutation and the intragenic deletion were confirmed in the second twin. Parental testing identified that the boys' father was mosaic for the heterozygous 173 kb deletion, and their mother was a heterozygous carrier of the Q381X mutation. Although this case represents what may be a rare example of a cytogenetic array identifying a recessive disorder that was unmasked by deletion, it illustrates the imperative to interpret cytogenetic array findings within the clinical context of specific patients.

## 1398/W/Poster Board #1056

**Reciprocal duplication of Sotos syndrome region (5q35) detected by oligo-array CGH in a patient with congenital anomalies.** *J. Lee, H. Zhang, M. Sun, J. Keeth, X. Lu, J. Mulvihill, S. Li.* Dept Pediatrics, OUHSC, Oklahoma City, OK.

The haploinsufficiency of the NSD1 gene due to 5q35 microdeletions or intragenic mutations is the major cause of Sotos syndrome, an overgrowth disorder characterized by large size, large hands and feet and poor coordination. The common ~1.9 Mb deletion breakpoints in Sotos syndrome are located at two flanking low copy repeats (LCRs), implying that non-allelic homologous recombination (NAHR) between LCRs is the cause of this deletion. This is a common mechanism of the recurrent microdeletion/duplication syndromes of 7q11.2, 17p11.2 and 22q11.2 regions. Using oligo-array CGH to detect genomic imbalances (gain or loss) of chromosomal segments that are too small to be seen by G-banding analysis is becoming a routine in patients with congenital anomalies. This new technology has resulted in the identification of many new syndromes, and has expanded our knowledge and understanding of known syndromes. Oligo-array CGH was used as a whole genome screening tool to detect copy number changes in a 2- year-old boy with microcephaly, seizures, delayed bone age and failure to thrive. Oligo-array CGH detected a duplicated fragment approximately 2.1 Mb in size located at 5q35.3 including the NSD1 gene. Reviewing the genomic database in the region, it showed the duplicated region likely arose by NAHR between LCRs as a reciprocal event of Sotos syndrome. Our case suggests that the gene dosage effect of the NSD1 gene causes a reversed phenotype of Sotos syndrome, i.e. microcephaly and delayed bone age.

## 1399/W/Poster Board #1057

**Chromosomal abnormalities detected in missed abortions occurring in Korean pregnant women.** *E.Y Choi[1], E.J. Seo[1, 2], K.R. Jun[1, 2], H.W. Yoo[1, 3], H.S. Won[4], J.Y. Lee[1].* 1) Medical Genetics Laboratory, Asan Medical Center, Seoul, Korea; 2) Department of Laboratory Medicine, Asan Medical Center, University of Ulsan College of Medicine, Seoul, Korea; 3) Department of Pediatrics, Asan Medical Center, University of Ulsan College of Medicine, Seoul, Korea; 4) Department of Obstetrics and Gynecology, Asan Medical Center, University of Ulsan College of Medicine, Seoul, Korea.

Causes of missed abortion are generally the same as those causing spontaneous abortion or early pregnancy failure causes, including anembryonic gestation (blight ovum), fetal chromosomal abnormalities, maternal disease, embryonic anomalies, placental abnormalities, and uterine anomalies. In this study, we performed to analyze the fetal karyotypes detected in missed abortions occurring in Korean pregnant women and compared the incidence of chromosomal abnormalities and causes of missed abortions with reports for other populations. We collected cytogenetic results of 217 cases of products of missed abortion over a period of 9 years (Jan, 2001 ~ May, 2009) and their clinical informations, including gestational age at the time of the pregnancy loss, maternal age, and previous reproductive history. The karyotyping was done by means of G-banding techniques after tissue culture of aborted products. Of the 217 cases, chromosomal abnormalities were identified in 89 cases (41.0 %). Of the chromosomal abnormalities identified, autosomal aberrations were predominant. Especially the most common abnormalities, autosomal trisomies, were found in 48 cases (53.9 % of the abnormal cases), including trisomy 16 (12 cases), trisomy 18 (7 cases), and trisomy 22 (8 cases). Sex chromosomal abnormalities were identified in 9 cases. Two cases with both autosomal and sex chromosomal abnormalities were founded. Five cases showed double trisomies, which had frequently chromosome 21 and advanced maternal age. Triploidy was identified in 10 cases and tetraploidy were found in 3 cases. Structural rearrangements were found in 10 cases; 4 cases with balanced translocations and 6 cases with unbalanced translocation or deletion. Our results detected skewing of sex ratio(M:F = 1:3.1) and low abnormal rate of fetal karyotype. This sex ratio may be likely to reflect the overgrowth of contaminated maternal cells in placenta culture. Cases of chromosomally normal spontaneous abortion will confirm by interphase FISH and array CGH. This study in Korean population may provide the valuable informations for genetic counseling.

## 1400/W/Poster Board #1058

**Novel Chromosome Xq28 Microduplication Mediated by the Homologous int22h-1 and int22h-2 Repeats in Four Cognitively Impaired Males.** *A. El-Hattab[1], V. Sutton[1], V. Enciso[2], E. Roeder[2], D. Grange[3], P. Stankiewicz[1], SW. Cheung[1], A. Patel[1].* 1) Dept Molec & Human Gen, Baylor Col Medicine, Houston, TX; 2) Genetics and Pediatrics, The University of Texas Health Science Center at San Antonio, San Antonio, TX; 3) Division of Genetics and Genomic Medicine, St. Louis Children's Hospital, St. Louis, MO.

During the last decade, about 80 genes on the X chromosome have been associated with X-linked mental retardation (XLMR). The recent expanded use of high resolution genome analysis by array comparative genomic hybridization (array CGH) has led to the identification of many cryptic microdeletions associated with XLMR. Chromosome X duplications has also been associated with XLMR with duplications including MECP2 gene being the most frequent. Here we report four cognitively impaired males with a novel ~ 0.5 Mb microduplication in Xq28 identified by array-CGH. Two male siblings aged 5.5 and 2.5 years who presented with developmental delayed and aggressive behavior. The older brother has minor facial features including broad forehead, down-slanting palpebral fissures, and broad nasal bridge. In addition, he has clinodactyly and tapered index fingers. The younger brother has failure to thrive, microcephaly, tapered distal fingertips, umbilical hernia, myopia and astigmatism, and minor facial features including, short forehead, poorly formed anterior helix, and broad nasal bridge. Their mother was found to carry the same Xq28 duplication. An 18-year-old male who presented at the age of 6 years with difficulties in walking that progressed to spastic diplegia with white matter hypomyelination noted in the brain MRI. In addition, he has scoliosis, bilateral syndactyly, and learning difficulties. A 12-month-old male infant presented with global developmental delay, microcephaly, and minor facial features including broad nasal bridge and deep seated eyes. Family history was significant for two maternal uncles with mental retardation. The proximal and distal breakpoints mapped to the directly oriented homologous low-copy repeat clusters known as int22h-1 and int22h-2 which, most likely, are responsible for mediating this duplication via non-allelic homologous recombination. The int22h-1 and int22h-2 in addition to int22h-3, mediate factor 8 gene inversion in about 50% of hemophilic patients. To our knowledge, similar duplications in this region have not been reported previously. However, an apparent reciprocal deletion has been reported in a family where females had skewed X inactivation and recurrent miscarriages, suggesting that such deletions may be lethal in males. In addition to the Factor 8 gene, there are six OMIM genes in the region. We propose this is a novel XLMR microduplication syndrome.

## 1401/W/Poster Board #1059

**Parental origin of *de novo* t(11;22)(q23;q11).** *T. Ohye[1], H. Inagaki[1], H. Kogo[1], M. Tsutsumi[1], T. Kato[1], M. Tong[1], M. Macville[2], L. Medne[3], E. Zackai[3], B. Emanuel[3], H. Kurahashi[1].* 1) Div Molecular Genetics, Fujita Health Univ, Toyoake Aichi, Japan; 2) Div Clinical Genetics, Univ Hospital Maastricht, Maastricht, Netherlands; 3) Div Human Genetics, Children's Hosp Philadelphia, Philadelphia, PA.

The constitutional t(11;22)(q23;q11) is a well-known recurrent non-Robertsonian translocation in humans. While translocations generally occur in a random fashion, the breakpoints of t(11;22)s are concentrated within several hundred base pairs on 11q23 and 22q11. These regions are characterized by palindromic AT-rich repeats (PATRRs), which could cause the genomic instability. *De novo* t(11;22)s are detected in sperm from healthy males at a frequency of $1/10^4$-$10^5$, but never in lymphoblasts, fibroblasts or other human somatic cell lines, suggesting that the generation of a t(11;22) is linked to meiosis. However, female germ cells have not been tested since the number of human oocytes that can be examined is limited. To investigate whether the translocation is meiosis-specific or male germ cell specific, we attempted to determine parental origin of *de novo* t(11;22) cases. We studied 7 carriers of *de novo* t(11;22)s and their parents. The PATRRs and flanking regions on chromosome 11, 22, der(11) and der(22) were amplified by PCR and the nucleotide sequences were determined. The highly polymorphic nature of the PATRRs allowed us to determine the parental origin of the *de novo* t(11;22)s. All of the seven translocations were found to be of paternal origin. This result indicates a novel mechanism of sperm-specific generation of t(11;22)s. It is proposed that replication errors during the numerous cell divisions in pre-meiotic spermatogenic cells or conformational changes of the DNA during chromatin remodeling in the post-meiotic stages of spermatogenesis might contribute to male-specific formation of *de novo* t(11;22)s.

## 1402/W/Poster Board #1060

**Prenatal detection of a marker chromosome derived from chromosome 8 by array- CGH.** *N. Qin[1], R. Schultz[2], T. Freeman[1], T. Johnston[1], B. Huang[1].* 1) Genzyme Genetics, Orange, California; 2) Signature Genomic Laboratories, Spokane, Washington.

Marker chromosome detected during prenatal diagnosis pose a difficult situation for genetic counseling as the risk associated with different marker chromosomes varies. A precise identification of the genetic contents of the marker will therefore be helpful. We present a case a prenatally detected marker derived from chromosome 8 in a fetus with ventricular septal defect (VSD). Amniocentesis was performed on a 34-year-old, Hispanic woman due to an abnormal ultrasound finding of ventricular septal defect (VSD) and micrognathia at 19 weeks of gestational age. Cytogenetic analysis on amniocytes revealed four cell lines. Of the total 15 colonies, 5 from two independent cultures showed an extra small marker, 4 from two independent cultures showed an extra D-group size marker, 5 from two independent cultures showed both kinds of marker, and one colony had a normal 46,XX female karyotype. Fluorescence in situ hybridization (FISH) studies using probes specific for the centromeres of chromosomes 13, 14, 15, 18, 21, 22, X and Y were unable to identify the origin of both the marker chromosomes. Microarray CGH (a-CGH) was then employed and identified that both markers were derived from the peri-centromeric region of chromosome 8 with sizes of 2.3 and 12.4 MB respectively, containing both short arm and long arm material. FISH with chromosome 8 specific probes detected four cell lines, which was consistent with the cytogenetic findings. Maternal cytogenetic analysis showed a normal karyotype. Paternal chromosome study was not available. The pregnancy was then terminated. This study demonstrates that a-CGH is a powerful technique in identifying the origin of the unknown marker chromosome, which enables better karyotype-phenotype association.

## 1403/W/Poster Board #1061

**Efficacy of an Automated Metaphase Scanner in the Clinical Cytogenetics Laboratory.** *C.M. Higgins, W.G. Sanger, M.M. Hess, B.J. Dave.* Human Genetics Lab, Munroe Meyer Institute for Genetics and Rehabilitation, University of Nebraska Medical Center, Omaha, NE.

In the cytogenetics lab, microscopy has historically been a time-consuming part of chromosome analysis. Automated digital karyotyping systems have curtailed the cumbersome dark room tasks and replaced manual karyotyping with computerized digital versions. However, long, physically demanding hours are still required at the microscope to locate and analyze metaphases. More recently, automation has found its place in metaphase scanning to decrease the hours required at the microscope. An automated metaphase scanner locates the metaphases and captures digital images into specific case files which are then organized with a fully automated bar coding system. These cases can then be analyzed and karyotyped at individual computers. We have integrated the Genetix GSL 120® automated scanner into our laboratory work flow. To determine the efficacy of the system, we performed comparisons of work hours, abnormality rates, and turn-around times (TAT) for a period of 60 days before and after introducing the automated system. In the 60 days prior to the use of automated scanner, cytogenetic analysis of 173 consecutive bone marrow specimens from hematologic cancer patients, including diagnostic and follow-up studies, required 2,640 work hours from 5.5 cytogenetic technologists. The TAT was 2.9 days with an abnormality rate of 22%. In the 60 days after the implementation of the scanner, a total of 2,160 work hours from 4.5 technologists were used to analyze 169 bone marrow specimens with a reduced TAT of 2.57 days and the abnormality rate was maintained at 22.2%. With a work force reduction of 480 hours, the TAT was reduced by 0.3 days without compromising the abnormality rate. The integration of this system has thus increased the number of cases analyzed per technologist while organizing an entire study in the computer. This information can be easily accessed for a full review of the metaphases without the use of the microscope. The software has highly visual case summary capabilities that encapsulate the pertinent information for each case thus facilitating our goals for a “paperless” file. Most significantly, the system increases the learning capabilities and allows for cytogenetic analysis by technologists-in-training to be reviewed by experts. With the ever-increasing workload in the cytogenetics laboratory and smaller experienced workforce, the automated metaphase scanner is a welcome addition as an efficient system for timely reporting of cytogenetics results.

## 1404/W/Poster Board #1062

**Wide spectrum of Peters and Axenfeld-Rieger anomalies secundary to a 4q25 microdeletion encompassing the PITX2 gene.** *A. Hazard[1], M. Mathieu[1], G. Morin[1], B. Demeer[1], J. Andrieux[2], M.C. Vincent[3], A. Receveur[4], S. Kanafani[4], H. Copin[4], B. Devauchelle[5].* 1) Clinical Genetics, Amiens Unversity Hospital, Amiens, France; 2) Molecular Laboratory, Jeanne de Flandre Hospital, Lille, France; 3) Molecular Genetics, Toulouse University Hospital, Toulouse, France; 4) Cytogenetics, Amiens Unversity Hospital, Amiens, France; 5) Stomatology, Amiens Unversity Hospital, Amiens, France.

Many genes are involved in the ocular development. The alterations of some of them are responsible of the Peters or the Axenfeld-Rieger anomalies (PITX2, FOXC1, PAX6 ...). In theses conditions, angle anomalies are responsible of glaucoma in 50% of cases, usually congenital and difficult to manage. When they are associated with extra-ocular symptoms, the name of Rieger or Peter + syndrome can be used. In these entities, the mode of inheritance is usually autosomal dominant. We report a 21-year-old patient, third child of healthy non-consanguinous parents with a negative familial history. He presented a Peters anomaly of the right eye requiring an iridectomy at 3 months of age, and an Axenfeld-Rieger anomaly of the left eye associated with a glaucoma at the age of 10. During childhood, he beneficiated of several surgical interventions that concerned umbilical hernia, Meckel diverticulum, bifid uvula, posterior sub-mucous cleft palate, pharyngoplasty and tympanoplasty. He developed dysmorphic features including flat malar region and retrognathia requiring surgical repair at the age of 16. He also presented hypodontia and persistence of lacteal teeth. He had a normal mental development, a normal puberty and a normal stature (1m80), but secondary to his visual impairment, he studied in a special school. Genetic investigations were negative for the standard karyotype and the sequencing of the genes PITX2, FOXC1 and PAX6. The array-CGH exhibited a de novo 1.7 Mb deletion at the locus 4q25 encompassing 13 genes including PITX2.

## 1405/W/Poster Board #1063

**Exploration of genes related to X-linked mental retardation (XLMR) by BAC-based X-tiling array.** *S. Honda[1], S. Hayashi[1], I. Imoto[1], J. Toyama[2], N. Okamoto[3], K. Kurosawa[4], E. Nakagawa[5], Y. Goto[6], J. Inazawa[1].* 1) Dept Molec Cytogenetics, Medical Research Inst, Tokyo, Japan; 2) Okinawa Child Development Center, Department of Pediatrics, Okinawa, Japan; 3) Department of Medical Genetics, Osaka Medical Center and Research Institute for Maternal and Child Health, Osaka, Japan; 4) Division of Medical Genetics, Kanagawa Children’s Medical Center, Kanagawa, Japan; 5) Div. of Child Neurol. Musashi Hosp., Natl. Center of Neurol. and Psychiat., Tokyo Japan; 6) Dept. of Mental Retardation and Birth Defect Res., Natl. Inst. of Neurosci., Natl. Center of Neurol. and Psychiat., Tokyo Japan.

An estimated 10-12% of mental retardation (MR) is caused by mutation on the chromosome X. Although 82 X-linked mental retardation (XLMR) genes have been identified so far, many other XLMR genes have not been identified. We constructed a BAC-based X-tiling array which contains a total of 1001 BACs throughout chromosome X except pseudoautosomal regions. In order to identify novel XLMR-associated genes, we performed array-CGH in 147 families with XLMR or probable XLMR using ou X-tiling array. CNAs relevant to MR were judged when copy number changes detected were involved known XLMR genes or have not been registered as copy number variations (CNVs) in Database of Genomic Variants (http://projects.tcag.ca/variation/). As a result, CNAs were detected in 10 families (7%). Among them, 5 had CNAs in regions involved in known XLMR-associated genes. Dup(Xq28) including *MECP2* was detected in 3 families and this frequency (3/147=2.04%) is almost same in Europe and the United States. Each patient in the 3 families shows common phenotypes such as severe MR, muscular hypotonia, absent speech, recurrent respiratory infection and cerebral atrophy. Del(Xp11.22) including *SHROOM4* was detected in a boy with moderate MR in one family. Dup(Xp11.23) harboring *FTSJ1* and *PQBP1* was detected in a boy and his younger sister in another family. On the other hand, other CNAs in residual 5 families are novel.

## 1406/W/Poster Board #1064

**Characterization of regulatory sequences essential for homologous pairing of chromosome 15q11-13.** *S. Horike[1], M. Meguro-Horike[1], M. Oshimura[2].* 1) Frontier Science Organization, Kanazawa University, Kanazawa,Ishikawa, Japan; 2) Department of Biomedical Science, Institute of Regenerative Medicine, Tottori University, Yonago, Tottori, Japan.

Autism is a common neurodevelopmental disorder characterized by abnormalities in social, communicative, and behavioral functioning. Although the etiology of autism remains largely unknown, cytogenetic and genetic studies have suggested that autism may be influenced by genomic imprinting of 15q11-13, through copy number gains of 15q11-13 occurring in 1-3% of autism cases. We focused on the homologous pairing of 15q11-13 in human neuronal cells, previously observed by Dr. Janine M. LaSalle (University of California, Davis). In addition, Dr. LaSalle observed that homologous pairing of 15q11-13 was deficient in Rett Syndrome (RTT), Angelmann Syndrome (AS), and autism brain. To model 15q11-13 maternal duplication in a neuronal cell line, we develop a systematic *in vitro* approach for studying the epigenetic consequences of cytogenetic disruptions to 15q11-13 using monochromosomal hybrids containing individual human chromosomes 15 of defined parental origin with and without targeted deletions of regulatory sequences. Modified paternal or maternal copy of human chromosome 15 will be transferred into the human SH-SY5Y neuronal cells by microcell fusion. Then, FISH analysis will be performed to compare how the homologous alleles of 15q11-13 are organized in human neuronal cells with and without modified human chromosome 15 copy number or sequence changes. The results of these studies are expected to be highly significant in 1) understanding how the homologous alleles of 15q11-13 are organized in the mammalian brain, and 2) designing better diagnostic tests and treatments for autism-spectrum disorders.

## 1407/W/Poster Board #1065

**Triplication of the *MECP2* gene causing a severe neurodevelopmental phenotype can be induced by the presence of low copy repeats (LCRs).** *C.M.B. Carvalho[1], M.B. Ramocki[2,3], L. Seaver[4,5], E. White[4], L. Friehling[6], P. Liu[1], S.W. Cheung[1], H. Zoghbi[1,2,3], J.R. Lupski[1,2,3].* 1) Dept Molecular Human Genetics, Baylor Col Medicine, Houston, TX; 2) Pediatrics, Baylor College of Medicine, Houston, TX; 3) Texas Children's Hospital, Houston, TX; 4) Kapiolani Medical Specialists; 5) Departments of Pediatrics, John A. Burns School of Medicine, Honolulu, HI; 6) Children's Medical Associates, Alexandria, VA.

Duplication involving the *MECP2* gene is one of the most common genomic rearrangements identified in neurodevelopmentally delayed males. We recently published the molecular characterization study of 30 patients carrying *MECP2* duplications using a custom 4-Mb tiling-path oligonucleotide array in which we detected six patients with complex rearrangements characterized by a triplicated segment embedded within the duplication. We extended our cohort to 32 patients and identified one additional patient with a triplication, totaling 32 patients and seven triplications (22%). The complex rearrangements vary in size from ~430 kb to ~653 kb, whereas the triplicated regions range in size from ~33 kb to ~537 kb. Interestingly, despite the fact that the proximal rearrangement breakpoints are scattered, the distal breakpoints, for both duplications and triplications, map within the same regions: either low-copy repeat (LCR) K1 or K2. The LCR K1 and K2 are positioned in inverted orientation, have 99% sequence identity and are 11.3 kb in length. The triplicated region spans the *MECP2* and *IRAK1* genes in three patients who have much more severe phenotype when compared to patients carrying *MECP2* duplications. The complex rearrangements include duplication of the *FLNA* gene in all cases, which likely contributes to their phenotype severity. The common clinical features are a history of polyhydramnios, dysmorphic facial features, hypotonia, severe global developmental delays, recurrent infections, chronic lung disease, aspiration, requirement for gastric or gastric-jejunal tube feeds, constipation, gastroesophageal reflux in 2/3, intestinal pseudo-obstruction in 1/3, epilepsy/infantile spasms in 1/3, bilateral hearing loss in 2/3, and a history of acute life-threatening events requiring resuscitation in 2/3. In six out of seven cases we determined that the complexities were inherited from the mother. In conclusion, we provide evidence that the presence of LCRs in the *MECP2* vicinity can induce DNA strand lesions, such as a collapsed fork, and facilitate a Fork Stalling and Template Switching (FoSTeS) event producing the complex rearrangements involving *MECP2* and flanking genes.

## 1408/W/Poster Board #1066

**Cytological analysis reveals striking differences in crossover interference between males and females.** *J. Gruhn[1], T. Hansen[1], E. Cheng[2], T. Naluai-Cecchini[2], C. Rubio[3], K.W. Broman[4], T. Hassold[1].* 1) School of Molecular Biosciences, Washington State University, Pullman, WA; 2) Department of OB/GYN, University of Washington, Seattle, WA; 3) Instituto Valenciano de Infertilidad, Valencia, Spain; 4) Department of Biostatistics & Medical Informatics, University of Wisconsin-Madison, Madison, WI.

The number and placement of meiotic exchanges are highly controlled, with virtually all species exhibiting at least one crossover per chromosome and with the spacing of adjacent crossovers dependent on interference. Despite these tight controls, there are remarkable sex-specific differences in recombination in humans: linkage analysis indicates that females have over 1.5 fold as many exchanges as males, and the chromosomal location of exchanges varies between the sexes. In the present study, we used cytological methodology to visualize meiotic recombination events as they occur in human oocytes and spermatocytes, allowing us - for the first time - to directly compare crossover patterns and crossover interference in meiocytes of males and females. Specifically, antibodies against the meiotic crossover protein MLH1, the synaptonemal complex protein SYCP3, and centromere associated CREST, were utilized to identify the chromosomal location of recombination sites. Subsequently, fluorescence in-situ hybridization (FISH) was used to identify ten individual chromosomes (1, 6, 9, 13, 14, 15, 16, 18, 21 and 22), allowing us to generate chromosome-specific maps for each sex. Similarly, chromosome-specific interference levels were calculated by measuring distances between adjacent MLH1 foci and determining the deviation from the gamma distribution. Our analysis has identified striking differences between the sexes. Consistent with linkage studies, MLH1 foci were significantly elevated in females by comparison with males, and were more likely to be interstitially located. Especially remarkable was the difference in spacing of adjacent MLH1 foci. For each chromosome examined, females displayed narrower inter-focus distances, correlating with weaker levels of interference. These observations provide the first cytological insights into sex-specific differences in cross-over control and suggest that differences in interference underlie the variation in recombination levels between human males and females.

## 1409/W/Poster Board #1067

**High Levels of Meiotic Recombination in the Absence of Synapsis and Homolog Pairing in Drosophila Oocytes.** *H.E. Hall[1], J.P. Blumenstiel[2], J.K. Jeffress[3], S.L. Page[4], R.S. Hawley[1,5].* 1) Stowers Institute for Medical Research, Kansas City, MO; 2) Department of Ecology & Evolutionary Biology, The University of Kansas, Lawrence, KS; 3) Institute of Molecular Biology, University of Oregon, Eugene, OR; 4) Comparative Genomics Centre and School of Pharmacy and Molecular Sciences, James Cook University, Townsville, Australia; 5) Department of Physiology, Kansas University Medical Center, Kansas City, KS.

In Drosophila melanogaster oocytes, the synaptonemal complex (SC) forms between homologous chromosomes and facilitates both the maintenance of euchromatic pairing and the formation of reciprocal crossovers. The C(3)G protein, which composes the transverse filament of the SC, is comprised of a central coiled-coil domain flanked by N- and C-terminal globular domains. Null mutants in C(3)G display a failure to produce mature SC, a near complete absence of crossingover, and failure to maintain euchromatic pairing. These data have supported a model where long regions of synapsis and/or pairing are required for reciprocal crossingover. To identify functional domains of C(3)G, we have constructed in-frame deletion constructs that remove both a small region of the coiled-coil domain and the entire coiled-coil region. We expressed these constructs both by using the nanos-GAL4::VP16 over-expression system and by using the genomic promoter (via generation of site-directed transgenic flies). Preliminary studies of oocytes using the over-expression construct missing a small region of the coiled-coil domain as their only source of C(3)G display near-normal levels of meiotic recombination. However, these same oocytes show defects in synaptonemal complex formation, homologous chromosome pairing, and exchange distribution. This implies that neither complete homolog pairing nor synapsis are required for high levels of meiotic recombination, though they may be required for proper exchange distribution (interference). These data suggest that the role of C(3)G in crossover formation is functionally separate from its role in pairing and synapsis.

**Regulation of Polo kinase by Matrimony is critical for faithful segregation of non-exchange homologs and cell cycle progression in *Drosophila* female meiosis.** *S. Smith[1,2], Y. Xiang[1], J. Griffiths[1], R. Hawley[1,2].* 1) Stowers Institute for Medical Research, Kansas City, MO USA; 2) University of Kansas Medical Center, Kansas City, KS USA.

Recent studies by Oliver et al., 2008 estimate that chromosome 21 is non-exchange in approximately 20% of human euploid oocytes, suggesting that a system exists to ensure faithful segregation of non-exchange homologs in human female meiosis. One model for such a system is segregation of non-exchange homologs in *Drosophila melanogaster* females. Utilizing this model, we have identified a gene called *matrimony (mtrm)*, which is essential for faithful segregation of non-exchange homologs and for proper timing of nuclear envelope breakdown (NEB) during *Drosophila* female meiosis. Moreover, a series of genetic and biochemical studies have shown that the Mtrm protein specifically regulates Polo kinase (Polo) in order to properly execute both of the meiotic processes mentioned above. Polo-like kinases are increasingly recognized as universal regulators of many meiotic and mitotic events, thus, a close examination of the mechanism by which Mtrm regulates Polo is essential. Here we utilize the site-specific ϕC31 integrase system to generate a series of transgenic *Drosophila* lines expressing mutant versions of the Mtrm protein. We examine the ability of mutant versions of Mtrm to rescue meiotic defects observed in oocytes containing compromised levels of the endogenous *mtrm* (and thus, mis-regulated Polo). Furthermore, we examine the ability of these mutant versions of Mtrm to physically bind Polo. We find that several mutant versions of the Mtrm protein including mutations that convert two evolutionarily conserved serines to alanine (MtrmS48A and MtrmS52A) are unable to rescue the meiotic defects observed in oocytes containing compromised levels of endogenous *mtrm*. While further work is necessary to confirm whether these residues are critical for the direct interaction of Mtrm and Polo in the fly, initial yeast two-hybrid analysis of these interactions suggests that this is the case. Overall, our work utilizing *Drosophila* as a model provides new insights into the mechanism by which Mtrm regulates Polo kinase to ensure faithful segregation of non-exchange homologs and proper cell cycle progression in female meiosis.

## 1411/W/Poster Board #1069

**Preimplantation Microarray Analysis using a SNP-based Whole Genome Platform allows for Simultaneous Screening of 24 Chromosome Aneuploidy, Unbalanced Translocations, and Single Gene Disorders in Human Embryos: First Application of Comprehensive Triple Factor PGD.** *B. Levy[1,2], X. Tao[2], J. Su[2], L. Northrop[2], M. Kamani[2], K. Miller[2], N. Treff[2,3], R.T. Scott[2,3].* 1) Dept Pathology, Columbia University Medical Center, New York, NY; 2) Reproductive Medicine Associates of New Jersey, Morristown, NJ; 3) UMDNJ-Robert Wood Johnson Medical School, New Brunswick, NJ.

Targeted aneuploidy screening, detection of unbalanced translocations (unbal-t/locations) & prevention of single gene disorders represent the major areas of PGD & simultaneous screening for all 3 disorders in human embryos has hitherto been impossible. We have previously validated a novel SNP-based microarray method for aneuploidy screening of all 24 chromosomes (24-chr-AS) & demonstrated its superiority over current FISH-based methods. Here we apply this technique together with translocation & single gene disorder screening in the 1st triple factor PGD case ever performed. First, we validated our ability to detect unbal-t/locations using microarrays by evaluating discarded IVF embryos diagnosed by FISH to have unbal-t/location derivatives. Second, the ability to accurately determine the inheritance of single gene disorders was established by evaluating single cells from embryos discarded after a PCR-based diagnosis of a single gene disorder as well as from cell lines "affected" with Mendelian disorders like Aarskog syndrome (FGD1), dwarfism (FGFR3), & cystic fibrosis (CFTR). Finally, triple factor PGD was applied to a 27 year old patient with Alagille syndrome & a "balanced" translocation - 46,XX,t(2:20)(q21;p12.2) that also included a 2.36MB microdeletion at the breakpoint region on chromosome 20, including the JAG1 locus. We established a multiplex real-time PCR assay of informative SNPs for inheritance of the microdeletion based on the parental SNP microarray profiles. Trophectoderm (TE) biopsies from 6 morphologically normal blastocysts were obtained for analysis from the Alagille patient. The embryos were cryopreserved so that genetic analysis could be performed with the intent of thawing & transferring euploid & unaffected embryos. Half of the TE biopsy was evaluated by FISH for the microdeletion, unbal-t/location derivatives, & aneuploidy of chromosome 18 & the sex chromosomes. The remaining TE was evaluated by real-time PCR for the microdeletion, & by microarray analysis for the microdeletion, unbal-t/location derivatives, & 24chr-AS. Thirteen arrested embryos were also evaluated and none of them were genetically normal. Two cryopreserved embryos were diagnosed with Alagille syndrome (carriers of the same maternal "balanced" translocation), & 4 were unbalanced &/or had aneuploidy for one or more chromosomes. Real-time PCR, microarray, & FISH based microdeletion, translocation, & aneuploidy analyses were 100% consistent.

## 1412/W/Poster Board #1070

**Comparison of genome-wide array technologies for the detection of copy-number variants.** *A. Montpetit[1], T. Tucker[2], E. Lemyre[3], S. Chenier[3], P. Eydoux[4], D. Vincent[1], A. Delaney[5], J.L. Michaud[3], J.M. Friedman[2].* 1) McGill University and Genome Quebec Innovation Centre, Montreal, PQ, Canada; 2) Department of Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 3) Division of Medical Genetics, Hôpital Sainte-Justine, Montreal, Quebec, Canada; 4) Department of Pathology and Laboratory Medicine, Children's and Women's Health Centre of British Columbia, Vancouver, BC, Canada; 5) Genome Sciences Centre, British Columbia Cancer Agency, Vancouver, BC, Canada.

Copy-number variation (CNVs) is a widespread and common phenomenon among humans and represents the majority of the sequence differences at the base level between two individuals. They also likely play a major role in phenotypic diversity, disease susceptibility and evolution. Although next-generation sequencing can provide single-base resolution for CNV identification, this method is not yet cost-effective for clinical diagnostic or for biomedical research. Many CGH- or SNP-array technologies can identify CNVs throughout the genome, but it is not well-known what are their respective experimental false positive and false negative rates and how well they compare to one another. In this study, we sought to identify pathogenic CNVs in 30 children with mental retardation by comparing the data from 4 different technologies (Agilent, NimbleGen, Affymetrix, Illumina). By using both parents as reference samples, our experimental design was specifically set-up to identify de novo CNVs. Overall we have identified an average of over 100 CNVs per child, including 5 occurring de novo. However, only 21% of the calls made with one technology did overlap with at least one other technology. Moreover, only the de novo CNVs identified by 2 or more technology could be validated by FISH or MLPA suggesting that the majority of the calls are false positives. This study demonstrates the importance of an appropriate validation method before reporting CNVs linked with diseases. An investigation of the effect of various algorithms for CNV detection will also be presented.

## 1413/W/Poster Board #1071

**Detection of two novel chromosomal deletions associated with autism using array-based comparative genomic hybridization.** *W. Chien[1,5], Y. Wu[2], S. Gau[3], Y. Huang[2], C. Chen[1,4,5].* 1) Institute of Medical Sciences, Tzu-Chi University, Hualien, Taiwan; 2) Department of Child Psychiatry, Chang-Gung Children Hospital, Kewi-Shan, Taiwan; 3) Department of Psychiatry, National Taiwan university Hospital, Taipei, Taiwan; 4) Graduate Institute of Clinical Medicine, Tzu-Chi University, Hualien, Taiwan; 5) Division of Mental Health and Addiction Medicine, Institute of Population Health Sciences, National Health Research Institutes, Zhunan, Taiwan.

Autism is a childhood-onset neurodevelopmental disorder with a strong genetic basis in its etiology. Conventional karyotype analysis has revealed that approximately 5-12% of ASD patients are associated with chromosomal structural aberrations, including translocation, inversion, deletion and duplication. Recently, several groups reported that submicroscopic deletion and duplication (collectively known as copy number variations, CNVs) are significantly associated with ASD using array-based comparative genome hybridization (aCGH) technology, suggesting genomic rearrangement is an important genetic mechanism of ASD. We screened for genomic DNA in a sample of patients with ASD using an oligonucleotide-based whole genome CGH array from Taiwan. Confirmations were performed using fluorescent in situ hybridization (FISH) and real-time quantitative PCR. Two boys were found to have a de novo subtelomeric deletion of ~ 6.8 Mb at 4q35.1-35.2 and a de novo terminal deletion of ~2.4 Mb at 8p23.2-pter, respectively. These two deletions were verified using fluorescent in situ hybridization (FISH) and real-time quantitative PCR, and they were not detected in another 282 patients with autism. To our knowledge, these two mutations have not been reported to be associated with ASD in the literature. Our data support that rare genomic variants may contribute to the genetic etiology of autism, and genes mapped to the deleted 8p and 4q regions as found in these two patients can be further considered as plausible candidate genes of autism in future study.

## 1414/W/Poster Board #1072

**CGH analysis in a cohort of 121 patients with a malformation of cortical development.** *L. Villard[1,2], C. Mignon-Ravix[1,2], P. Cacciagli[3], B. El-Waly[1,2], M. Milh[1,2,3], N. Girard[3], B. Chabrol[1,2,3], N. Philip[1,2,3].* 1) INSERM, U910, Marseille, France; 2) Aix-Marseille University, Marseille, France; 3) Marseille University Hospital, La Timone, Marseille, France.

We have collected clinical details and DNA samples for 121 patients with a malformation of cortical development in a national prospective study performed in France since 2004. The cohort is composed of the following broad categories : 36 patients with lissencephaly, 37 patients with polymicrogyria, 26 patients with grey matter heterotopia and 22 patients belonging to two different categories. All the patients were genotyped for known genetic causes allowing the identification of 15 new mutations (12%). All negative cases (n=106) were analyzed with the Agilent 44K array CGH platform. In this group of patients, we have identified 27 genomic imbalances not previously described in the database of genomic variants (25%) in addition to several hundred non pathogenic CNVs. Among these cases, 21 were confirmed using quantitative PCR (77%). In 6 cases, we were able to show that the rearrangement was inherited from one parent. These cases were not included in further analysis. In the 15 remaining cases, we found defects on chromosomes 3p24 (200kb), 5q21 (150kb), 6q14 (1Mb), 6q22 (460kb), 7q11 (2Mb), 7q33 (120kb), 9p13 (140kb), 16p13 (900kb), 17p12 (1,5Mb), 17p13 (90kb to 300kb), 17q11 (300kb) and 19p13 (350kb). Interestingly, we detected LIS1 microdeletions in three patients previously analyzed with the commercial probe designed to detect chromosome 17p13.3 deletions. In the same 17p13.3 region, we identified a patient with nodular heterotopias and a small deletion involving the YWHAE gene as the only gene expressed in the brain. An unexpected 17p12 duplication involving the PMP22 gene was detected in a patient with nodular heterotopias and cerebellar vermis hypoplasia. On chromosome 16p13, we identified a patient with periventricular nodular heterotopias and a duplication of the CBP gene. In the other genomic regions involved, we performed expression analysis in search for genes expressed in the brain. Interestingly, several microrearrangements contain one or very few genes. These genes are currently being investigated for their putative role during the development of the cerebral cortex and are screened in patients with the same clinical picture.

## 1415/W/Poster Board #1073

**Unusual Clinical Presentation of the 3q29 Microdeletion Syndrome: Autism and Psychotic Symptoms.** *F. Quintero-Rivera[1], J.A. Martinez-Agosto[2].* 1) Pathology & Lab Medicine, David Geffen Sch Med UCLA, Los Angeles, CA; 2) Department of Human Genetics and Division of Medical Genetics, Department of Pediatrics, David Geffen School of Medicine, University of California, Los Angeles, CA.

The screening of individuals with minimal dysmorphic features and mental retardation as the predominant feature has resulted in the delineation of several new microdeletion syndromes. Interstitial deletions of 3q29 have been recently described as one of these new syndromes. The clinical phenotype is variable despite an almost identical deletion size. Here, we report on a new individual to further expand the clinical presentation of this rare disorder and compare with previous reports to further define the phenotype. The proband is a 10 year-old female with a history of autism and schizophrenia versus bipolar disorder presenting with increasing suicidal ideation, and dysmorphic features including: epicanthal folds, a broad nasal bridge with a prominent metopic suture and micrognathia, asymmetric face with the right face and lips drooping, and myopathic face, almond-shaped eyes, mandibular hypoplasia, and tapered fingers. SNP array CGH detected a 1.629 Kb de novo chromosome 3q29 interstitial microdeletion, arr cgh 3q29(197194059-198823098)x1. These findings were confirmed by standard chromosome analysis (550- band resolution) and FISH with the 3p/3q subtelomere Vysis probe, 46,XX,del(3)(q29).ish 3p(TELx2),3q(TELx1). This 1.6 Mb deletion encompasses 5 known genes (PCYT1A, PAK2, MFI2, DLG1, BDH), and 17 uncharacterized transcripts. Our patient expands the phenotypic features of 3q29 deletion syndrome. The unusual clinical presentation reflects a general trend towards the classification of mental retardation syndromes associated with fine chromosomal abnormalities on the basis of similar molecular abnormalities, and not on grouping of clinical dysmorphology features alone.

## 1416/W/Poster Board #1074

**Precise identification of a unique psu dic(15;15)(q13;q13) by array cgh, FISH and classical cytogenetics.** *S.D. Batish[1], M.J. Macera[2], J. Breshin[2], F. Cohen[2], D. Thakkar[2], M. Ito[1], C. Towne[1], C. Braastad[1], J. Koch[1], A. Babu[2].* 1) Athena Diagnostic, Worcester, MA; 2) Div of Molecular Medicine and Genetics, Dept of Medicine, Wyckoff Heights Medical Center, Brooklyn, NY.

An eighteen month-old male was referred with severe developmental delay/mental retardation, encephalopathy, infantile spasms, hypotonia and dysmorphic features. Chromosome micro array analysis (CMA) revealed a gain of copy number on chromosome 15q11.2-q13.3, arr cgh 15q11.2-q13.2(20,277,049-28,157,051)x3; 15q13.2-q13.3(28,157,051-30,707,020)x3, which was detected by 988 probes. The size of the duplication is approximately 10.3 Mb and includes 35 genes. Cytogenetic analysis with GTG banding revealed the addition of a small satellited marker chromosome. FISH analysis for D15Z1 and SNRPN located at 15q13.3, confirmed chromosome 15 as the origin of the marker. These probes labeled two pericentromeric regions located at the distal ends and two copies of SNRPN, located in the interstitial section of the marker. One unique feature of this marker chromosome, as revealed by GTG banding, was the presence of two morphologically different satellites. Both stalks of the marker chromosome are positive by AgNOR staining. The karyotype is 47,XY,+psu dic(15;15)(q13;q13).ish psu dic(15;15)(D15Z1++,SNRPN++). Clinical presentation of a duplicated 15q11-q13 region, generally described as the inv dup (15) or idic (15) syndrome, is frequently of maternal origin. Features include developmental delay, central hypotonia, epilepsy, intellectual disability and autistic behavior. Microsatellite analysis on parental DNA or methylation analysis on the proband DNA can determine the parent of origin of the additional material. However, neither of these molecular methods routinely clarifies if the material is from a single chromosome or from homologous chromosomes. In this case, because of the identifiable variation in satellite/stalk of chromosome 15, we were able to determine that what would have been classified as an inv dup (15) was actually derived from two homologues and could be more correctly designated as psu dic. The phenotype of this individual case strongly suggests that the material is maternal in origin. The identifiable nature of the satellites will likely allow us to determine parental origin using classical cytogenetics karyotype analysis on the parents. This work is underway. This case emphasizes the importance of the use of all available methodologies to ensure a correct diagnosis and more precisely define the idic/inv dup (15) syndrome.

## 1417/W/Poster Board #1075

**Interstitial Deletion of 8q in a girl from Unbalanced Segregation of a Paternal Deletion/ring Karyotype.** *R.D. Burnside[1], J. Ibrahim[2], C. Flora[2], S. Schwartz[1], J.H. Tepperberg[1], P.R. Papenhausen[1].* 1) Cytogenetics, LabCorp, Durham, NC; 2) St. Joseph's Children's Hospital, Paterson, NJ.

The McClintock mechanism of chromosome breakage and centromere misdivision to create a deleted chromosome with its concomitant excised ring chromosome has been described in approximately one dozen reports. We report a case of a 6 year old girl with a prenatal history significant for IUGR and a two-vessel umbilical cord. She was diagnosed neonatally with a VSD that was surgically repaired. At 4 years of age, she was referred to genetics for short stature and noted to be developmentally delayed with dysmorphic facial features, including narrow facies, protuberant ears and a beaked nose. Her skeletal exam was significant for bilateral fifth finger clinodactyly, broad thumbs and great toes. Chromosome analysis and aCGH testing were recommended at that time, but not performed due to insurance issues. Two years later at a follow-up visit chromosome analysis and Affymetrix 6.0 SNP microarray was ordered and performed on cultured blood lymphocytes, and revealed a cytogenetically visible deletion in proximal 8q that was further defined by microarray as a 10.6 Mb deletion from 8q11.1->q12.1. Fluorescence in situ hybridization using an alpha- satellite probe demonstrated that the deletion included a significant portion of the pericentromeric repeat sequences, as well as 73 genes in the proximal q arm. The deleted chromosome 8 appeared to have a new constriction at 8p22, suggesting the formation of a neocentromere, even though some alpha-satellite sequences still appeared at the normal location. Chromosome analysis of the phenotypically normal father revealed a mosaic karyotype of 47,XY,del(8)(q11.1q12.1),+r(8)(q11.1q12.1).ish del(8)(q11.1q12.1)(D8Z2 dim),+r(8)(D8Z2+)[18]/46,XY[2]. His deleted chromosome 8 also demonstrated the presence of an apparent neocentromere at 8p22. FISH studies revealed that the majority of the chromosome 8 alpha-satellite DNA was excised from the del(8) and resided in the ring chromosome. This excision likely necessitated the formation of a neocentromere to stabilize the chromosome during mitosis. This case clearly illustrates the utilization of classic cytogenetics, FISH, and array technologies to better characterize chromosomal abnormalities and to provide the proper recurrence risks for these aberrations. It also indicates a rare case where a neocentromere can form on a chromosome even in the presence of existing alpha-satellite DNA, consistent with the "McClintock mechanism".

## 1418/W/Poster Board #1076

**Xq-Yp translocation? - Cytogenetic characterization of a rare 46,XX individual with SRY on Xq.** *M. Fang, S. O'Hara-Larrivee, J. Eck, P. Peterson, K. Starr, K. Kroeger, C. Kellum, S. Pereira.* Seattle Cancer Care Alliance, Fred Hutchinson Cancer Research Center, University of Washington, Seattle, WA.

Translocations involving the X and Y chromosomes are often associated with abnormalities of sex differentiation. Aberrant translocations between the pseudoautosomal region on the short arms of the human X and Y chromosomes (Xp-Yp translocation) is the most frequent cause of 46,XX maleness when the testis-determining SRY gene is transferred to the distal Xp. However, Xq-Yp translocations are extremely rare. To our knowledge, only one case has been reported in a 46,XX true hermaphrodite. Here, we report a possible second case of Xq-Yp translocation. A male post-bone-marrow-transplant patient with a female donor was evaluated for chimerism using short tandem repeat (STR) analysis, which demonstrated 100% donor engraftment, but the sequence at the Amelogenin locus that distinguishes the X and Y chromosomes suggested that the donor was a male. G-banding cytogenetic analysis of the bone marrow demonstrated a 46,XX female karyotype with a potential subtle Xq deletion of uncertain clinical significance. Further characterization of the X chromosome with fluorescence in situ hybridization using probes specific to the SRY gene and the X chromosome centromere revealed that the SRY sequence was located on the long arm of the X chromosome with the potential deletion. Chromosome microarray analysis is underway to determine the exact nature of the rearrangement. This is likely another rare case of Xq-Yp translocation. The SRY gene appeared to be on the inactive X-chromosome exclusively, which may explain the apparent femaleness of the donor. Additional clinical phenotypic evaluation of the donor and a molecular study of the X-inactivation pattern in this individual will provide further insight into the phenotype-genotype correlation.

## 1419/W/Poster Board #1077

**Characterization of novel copy number changes in the clinical diagnostic setting using customized targeted cytogenomic arrays.** *M.E. Gorre[1], J. Kim[1], C. McCaskill[1], R. Shah[1], D. Suciu[2], M. Caraballo[2], M.S. Mohammed[1].* 1) Combimatrix Molecular Diagnostics, Irvine, CA; 2) Combimatrix Corporation, Mukilteo, WA.

Clinical use of microarrays for assessment of genomic copy number changes is becoming increasingly common for diagnosis of mental retardation and congenital abnormalities. Although most diagnostic arrays were initially designed to target a defined set of disorders, the trend toward enhancement of these targeted arrays with additional non-disease associated probes has provided advantages such as data normalization controls and the ability to scan the patient's genome for unexpected structural changes at higher resolutions. However, as array platform probe densities increase, so too does the complexity and challenge of data interpretation, clinical reporting, and confirmatory testing of abnormal findings, particularly in light of our limited understanding of copy number variations and their pathological significance. Here we describe the development and utility of a strategy for ultra high-density characterization of copy number aberrations discovered in routine clinical array CGH testing that limits the potential liabilities of performing whole genome ultra high-density array analysis. Using completely customizable long oligonucleotide microarrays of 12,000 probes, we were able to synthesize case-specific personalized arrays with uniquely-designed probes to refine breakpoints at the various probe densities and redundancies within a turnaround time of 10 days. With this strategy, we demonstrate the ability to confirm and further characterize or "zoom in" on discovered structural abnormalities for a set of 10 patients with mental retardation of unknown etiology within a timeframe that makes clinical implementation possible. As the complexity of array-based copy number analysis technology rapidly increases, strategies that utilize these advancements while mitigating the accompanying complications will be important for broadening utilization of microarrays in routine clinical diagnostics.

## 1420/W/Poster Board #1078

**Detection of mosaicism and UPD14 in a baby with Prader-Willi like features.** *L. Jenkins[1], H. Levy[2], E. Chen[2], X. Li[1], J. Jones[3], J. Schoof[4], J. Johnson[4].* 1) Kaiser Permanente Regional Cytogenetics Laboratory, San Jose, CA; 2) Kaiser Permanente Genetics Department, Oakland, CA; 3) Molecular Diagnostic Laboratory, Greenwood Genetics Center, Greenwood, NC; 4) Department of Medical Genetics, Shodair Children's Hospital, Helena, MT.

A 12 month baby boy was referred for a genetics evaluation for congenital hypotonia, severe vomiting, anal ring requiring dilation, small penis and deceleration in growth curves for weight and more severely for height. All newborn screening tests were reported to be normal. Brain MRI revealed a normal pituitary but narrow infundibulum. At 12 months, his was just below the 5th percentile, and height was much below the 5th percentile. He had forehead bossing, small mouth, penis, and feet. There was very faint hyperpigmentation variably on the extremities. He had mild motor delays. Growth hormone (GH) deficiency was observed and he was started on GH and testosterone. He subsequently was diagnosed to have food-protein-induced-enterocolitis syndrome. Prior high resolution cytogenetics, methylation study for Prader-Willi syndrome and molecular fragile X testing all showed normal results. To rule out a possible genomic imbalance or uniparental disomy (UPD) for chromosome 14, whole genomic microarray (aCGH; Agilent 44K design) analysis and UPD 14 tests were performed. aCGH revealed a level of 40% mosaicism for a trisomy 14 cell line. Further analysis for mosaic trisomy 14 was performed counting additional metaphase cells (50) and interphase FISH analysis was performed using the IGH probe at 14q32 (Abbott; Vysis, Inc.). These analyses revealed 10 and 60% mosaicism for trisomy 14, respectively. Interphase FISH analysis of a buccal sample showed an 18% level for trisomy 14. Microsatellite UPD14 testing showed biparental inheritance for all informative loci. One informative locus showed three alleles present, 2 maternal and 1 paternal. These results supported the prior cytogenetic and aCGH findings of mosaicism for trisomy 14. The samples were assessed for maternal UPD by quantitative PCR, showing a 4:1 ratio of mat:pat alleles , consistent with presence of a paternal copy only in the trisomic cell line, with the disomic cell line showing two copies of the maternal chromosome 14, assuming roughly equal populations of the two cell lines. The observed maternal allele also showed that the disomic cell line was presumably maternally heterodisomic for chromosome 14. CONCLUSION: A diagnosis of maternal UPD14 should be considered in a young child with a clinical picture of Prader-Willi like findings including hypotonia, feeding difficulties, poor growth, micropenis, and mild delays.

## 1421/W/Poster Board #1079

**Identification of 16p13.11p13.3 duplication on amniotic fluid using arrayCGH.** *K. Jänkälä[1], M. Kaare[1], H. von Koskull[1], C. Saloranta[1,2], T. Alitalo[1,3].* 1) Dept of Clinical Genetics, Helsinki University Central Hospital, Helsinki, Finland; 2) Dept of Obstetrics and Gynaecology, Helsinki University Central Hospital, Helsinki, Finland; 3) Dept of Medical Genetics, University of Helsinki, Helsinki, Finland.

Trisomy 16 is one of the most common trisomies found in prenatal samples, but structural rearrangements of chromosome 16 are less common. A total of 42 cases of 16p duplication have been published to date, of which 41 have been detected postnatally. A 16p11.2p12.1 duplication is the only prenatally diagnosed case so far. Since euchromatic variants 16p+ have also been described, interpretation of intrachromosomal changes in 16p can be problematic in prenatal samples. A patient was referred to our clinic because increased nuchal translucency was detected in the ultrasound. Amniocentesis was performed at the 15th week of gestation. Both *in situ* and long term cell cultures were established. Cytogenetic studies on amniotic fluid presented extra material in the short arm of one chromosome 16. The karyotypes of the parents were normal, which indicated that the chromosome 16 rearrangement had arisen *de novo*. Since it was impossible to determine exactly which region of the 16p was duplicated, if any, we continued to analyze the sample using microarrays (Agilent, human 244K). Cells from one small culture bottle were used for DNA extraction. The analysis revealed a 12.4 Mb duplication, which covered the bands 16p13.11p13.3, excluding the most telomeric region of the band 16p13.3. Although no other fetal sonographic anomaly than nuchal translucency was detected, other studies had previously shown that the presence of the region 16p13.1-p13.3 in triplicate gives rise to a defined syndrome. Phenotypic features of this syndrome include mental retardation, growth retardation, microcephaly, hand anomalies and a special facial appearance. After genetic counseling, the parents decided to opt for termination of the pregnancy. The fetus had a round face and both slender shoulders and body. The autopsy results are still pending. All the results were obtained within four weeks. The aCGH method was crucial in the identification of the 16p13.11p13.3 duplication.

## 1422/W/Poster Board #1080

**Array-CGH and FISH analysis in characterization of marker chromosome.**
*F. Sheth[1], J. Andrieux[2], C. Thuilliez[2], D. Ceraso[2], A. Leurent[2], S. Romana[3], M. Lelorch[3], H. Sheth[1], J. Sheth[1].* 1) Dept. of Cytogenetics, FRIGE's Institute of Human Genetics, Jodhpur Gam Road, Satellite, Ahmedabad, India; 2) Laboratoire de Génétique Médicale, Hôpital Jeanne de Flandre CHRU de Lille, France; 3) Laboratoire d'histologie-Embryologie-Cytogénétique, Hôpital Necker-Enfants Malades, France.

Supernumerary marker chromosome [SMCs] is structurally the part of extra chromosome material that poses a major challenge of diagnostic dilemma to the geneticist for its precise nature and role in disease identification and development. Recent advancements in array-CGH have made it possible to substitute the chromosome target with DNA spotted on a glass slide. Technological progress accomplished in these last years has increased the resolution of entire genome from 1Mb to few Kilobasepair. We hereby report four different patients who were found to have SMCs during conventional cytogenetic [CC] study and investigated further by oligonucleotide based array using 44K probes. Case-1 was a young woman having Bad Obstetrical History (BOH) and array-CGH has shown 8.6 Mb duplication of 5p13.2p11 region. Case-2 also had BOH and array-CGH could not characterize de-novo marker chromosome, which has ruled out euchromatic region involved in the imbalance. Further study by multi-centric FISH confirmed the marker to be of #3 centromeric region. Case-3 was a 15yrs old girl with short stature and primary amenorrhea. Three markers of varying size were observed by CC and array-CGH has confirmed 10.9 Mb of 2q24.33, 3.5 Mb of 3p12.1p11.1 and 1.1 Mb of 7p11.21p11.1 duplication. Case-4 was 13 months old girl with MCA. Array-CGH revealed 14.9Mb 18p11.32p11.31 duplication. This shows that array-CGH enhance the identification and origin of SMC of euchromatic region that helps in providing SMC/phenotype correlation for better genetic counseling and future course of action for the affected family members. Supported by DBT-India.

**Small supernumerary marker chromosomes (sSMC) characterized by Molecular Cytogenetic technique: FISH.**
*H. Sheth[1,2], F. Sheth[2], J. Andrieux[3], A. Weise[4], E. Ewers[4], J. Sheth[2], T. Liehr[4].* 1) Dept. of Biomedical Sciences, Newcastle University, Newcastle Upon Tyne NE2 4HH, United Kingdom; 2) FRIGE's Institute of Human Genetics, FRIGE House, Satellite, Ahmedabad-380 015. Gujarat, India; 3) Laboratoire de Génétique Médicale, Hôpital Jeanne de Flandre CHRU de Lille, France; 4) Jena University Hospital, Institute of Human Genetics and Anthropology, Kollegiengasse 10, D-07743 Jena, Germany.

Small supernumerary marker chromosomes (sSMC) form a heterogeneous group of chromosomes originating from any part of the chromosome either inherited/de novo, satellited/non-satellited seen with various incidences. The incidence in general population is 0.044% that increases to 0.075% in prenatal cases to 0.125% in sub-fertile group to 0.288% in mentally challenged population. This suggests that sSMC influences the clinical manifestation and need proper characterization. Majority of the sSMC are derived from acrocentric chromosomes having satellited/bisatellited constriction and around half are derived from chromosome 15. Non-acrocentric sSMC are comparatively rare and 30% are coupled with phenotypic effects. sSMC are parentally inherited/de novo and linked with vast clinical features from normal to extremely mild to severe. We hereby report five subjects who were found to have sSMC during conventional cytogenetic study and investigated further using variety of FISH probes such as: centromeric-FISH, centromeric M-FISH, subcentromeric M-FISH, subtelomeric-FISH, multicolor banding, microdissection and reverse FISH. Marker chromosomes were de novo in all the cases. Case-1 was a prenatal study and marker chromosome was diagnosed in amnitoic fluid analysis. Microdissection and reverse FISH characterized the sSMC as a neocentromeric Y - 47,XX,+mar.ish der(Y)inv dup(Y)(pter→Yp11.2::Yp11.2→pter). Second case with MCA and FISH analysis confirmed it as tetrasomy 18p - 47,XX,+mar.ish der(18)i(18)(pter→q11.-1::q11.1→pter). For case 3 with bad obstetric history, FISH study confirmed it as a partial trisomy of 5p - 47,XX,+mar.ish der(5)min(5)(:p13.1→q11.1:). Case 4 presented with typical features of Turner syndrome and sSMC was a 46,X,+mar.ish der(14)min(14)(pter→q11.1:). The last case portrayed with Down syndrome features and FISH analysis confirmed it to be 47,XX,der(14,21)(q10;q10),+mar.ish t(14;21)(q11.1;p11.2),+21. Besides cases 2 - 3 were also characterized by array-CGH (Agilent platform). This shows presence of sSMC in various patient groups needs further precise characterization by the application of modern molecular cytogenetic techniques such as FISH which not only help to characterize quickly the sSMC with an accurate genetic diagnosis and also can further help in obtaining accurate genotype-phenotype correlation leading to better informed counselling. Supported in parts by DBT-India, Prochance 2008 and 2009 of the Friedrich Schiller University Jena.

## 1424/W/Poster Board #1082

**A Strategy For Precisely Mapping Chromosomal Translocation Breakpoints.**
*P.P. Sulima[1], P.S. Hart[2], T. Han[1], T.C. Hart[1].* 1) National Institute Of Dental And Craniofacial Research, NIH, Bethesda, MD; 2) National Human Genome Research Institute, NIH, Bethesda, MD.

Background: The identification of chromosomal translocations by conventional cytogenetics has implications for diagnosis, prognosis, and recurrence risk. For some chromosomal regions the banding pattern is repetitious, making it hard to determine with accuracy the specific segments involved. FISH analysis with BACs can help localize breakpoints, but it is time-consuming and the limit of resolution is approximately 100-200 Kb. In our study, we used PCR for mapping breakpoint regions by amplifying the isolated derivative chromosomes with primers sets specific for each chromosome. Objective: To determine the breakpoint positions in a patient with a balanced translocation between chromosomes 3 and 17. Methods: Chromosome sorting was performed at Mayo Clinic using conversion technology. Initial primer sets for chromosomes 3 and 17 were designed based on cytogenetic data. Primers were placed in low homology regions and tested using in silico PCR application with human and mouse DNA. Primers were used only if in silico testing did not give a mouse DNA product. Successive primer sets were designed to span the region between a known deleted and non-deleted region to further localize the breakpoints. Results: Cytogenetic examination localized the breaks to chromosome 3p21.1 and chromosome 17q23.3. Subsequent PCR analysis showed the der17 breakpoint between chr3:54,367,097 and chr17:65,484,251 separated by 18bp whose origin is unknown. Within this 18 bp segment are several short overlapping regions (5-9 bp) of homology to both flanking regions. The der3 breakpoint occurred between chr3:54,367,099 and chr17:65,484,249. A "CT" pair is present on both normal homologues and can not be assigned to either chromosome. The molecular data demonstrates that the breakpoint on chromosome 17 is actually in q24.3, ~6 Mb away from initial position determined cytogenetically. Conclusions: It is important to perform molecular genetic studies in patients with translocation to accurately determine the breakpoints and the corresponding genes disrupted or whose expression is altered. It is only by characterizing patients at this level that genotype-phenotype correlations will be possible. Utilizing conversion technology service to obtain chromosome sorted DNA and PCR for mapping makes this an easy, cheap and fast method that can be done in virtually every molecular biology lab. Each localization round, including primer design and PCR, takes 2-3 days.

**Utility of Array CGH for the Detection of Congenital Trisomy 8 and Trisomy 9 Mosaicism.**
*E. Thorland, T. Gliem.* Dept. of Lab Med & Pathology, Mayo Clinic, Rochester, MN.

The phenotype of patients with mosaicism for trisomy 8 or trisomy 9 is well described. However, the postnatal detection of these mosaic trisomies in peripheral blood specimens can be cytogenetically challenging. The abnormal cell line may not compete well with normal cells in the PHA-stimulated cultures necessary for conventional chromosome analysis and the trisomic cells can rapidly disappear over time. In older patients, the trisomic cells can sometimes only be detected in fibroblast cultures after skin biopsy. Herein, we describe our experience with the detection of mosaicism for trisomy 8 and trisomy 9 using array CGH. Through clinical array CGH analysis of approximately 3000 cases, 3 patients with mosaic trisomy 8 and 3 patients with mosaic trisomy 9 were detected. The age of the patients at the time of sample collection ranged from 1 day to 5 years of age. In addition to the array CGH studies, chromosome studies were performed in 3 of the cases. In two cases (trisomy 8 at age 3 and trisomy 9 at age 3 weeks), no trisomic cells were detected after the analysis of 20 metaphases and in one case (age 10 days) trisomy 8 was detected in 5 of 20 metaphases. Interphase FISH studies were performed on both unstimulated direct preparations and PHA-stimulated cultures using the appropriate centromere probe and a locus-specific probe (c-MYC and p16 for chromosomes 8 and 9, respectively) in all 6 cases. In each case, the trisomic cells were present at an equivalent or greater percentage in the unstimulated cells than in the PHA-stimulated cells. Trisomic cells ranged from 20.5% to 65% in unstimulated cultures and correlated closely with the observed deviation in the array CGH studies, indicating that array CGH has the ability to detect mosaicism for trisomy 8 or 9 down to at least 20%. Overall, these data provide evidence that array CGH is a sensitive method for the detection of mosaic trisomy 8 or trisomy 9 and may be preferable to chromosome studies on PHA-stimulated peripheral blood lymphocytes. In addition, if sufficient clinical suspicion for either of these syndromes remains following normal chromosome studies, array CGH studies should be considered before initiating chromosome studies on fibroblasts derived from an invasive skin biopsy procedure.

## 1426/W/Poster Board #1084

**Characterizing genomic imbalances of chromosome 15 by microarray-based comparative genomic hybridization(aCGH).** *S. Yu, M. Kielt, A. Stegner, S. Fiedler, D. Zwick.* pathology, Children's Mercy Hosp, Kansas City, MO.

Chromosome 15 is one of a few human chromosomes prone to structural rearrangements as the underlying causes of some genomic disorders. This chromosome is also one of a few chromosomes containing known imprinted regions. Therefore, the clinical phenotypes in individuals with chromosome 15 abnormalities depend on both genetic content and parental origin of the rearranged chromosome 15. Application of aCGH techniques has revolutionized our understanding of human genomic architecture and is becoming a new standard method for assessing genomic imbalances with high-resolution and high-throughput. In this report, we present a CNV profile of chromosome 15 derived from aCGH-244K testing to evaluate 670 consecutive pediatric patients with diverse abnormal phenotypes and 59 additional individuals with a variety of structural genomic abnormalities. In addition to 745 benign CNVs, 16 abnormal CNVs on chromosome 15 were identified in our group of 670 samples representing a 2.4% detection rate of genomic abnormalities in this cohort of patients. Four abnormal CNVs on chromosome 15 were defined in the other 59 samples. Some of the abnormal CNVs includes: 15q11.2q13.2 (18657188-26829699)x3, a 8.2 Mb duplication with BP1 as proximal breakpoints in 2 cases; 15q11.2q13.1(21246327-26208802)x1, a 4.96 Mb deletion between BP2 and BP3 in one case with PWS; 15q11.2q13.1(20249686-26365196)x1, a 6.12 Mb deletion between BP1 and BP3 in one case with AS; 15q11.2q13.3(19879461-32163873)x1, a 12.28 Mb deletion between BP2 and BP5 in one case with atypical PWS; 15q11.2q12(22,289,073-24,136,116)x1, a 1.85 Mb deletion in one case with PWS; 15q13.1q13.2(26738880-28441369)x1, a 1.7 Mb deletion between BP3 and BP4 in two cases representing a possible novel genomic disorder; 15q22.31(64430492-64542830)x1, a 112 kb deletion containing MAP2K1 gene in one case, representing a novel genetic mechanism of MAPK1 gene mutation leading to Noonan syndrome; 15q21.1q22.2 (44,586,481-57,997,910)x3, a 13.41 Mb duplication in one case. Three cases with 15q13.3 microdeletion syndrome with breakpoints between BP4 and BP5 were identified with an estimated ~1/12,000 population prevalence. Two of them have hemizygous deletions as previously reported. The remaining patient has a homozygous deletion in a boy with severe clinical phenotype, inherited from non- consanguineous parents each carrying a hemizygous deletion of the15q13.3 region.

## 1427/W/Poster Board #1085

**Case Report and Further Characterization of the 12q14 Microdeletion Syndrome.** *R.E. Pyatt[1,2], A.K. Bailes[1], A. Brock[1], C. Deeg[1], J.G. Gordon[1], A. McKinney[1], C. Astbury[1,2], S. Reshmi[1,2], K.P. Shane[4], D. Lamb Thrush[1], J.M. Gastier-Foster[1,2,3], A.M. Sommer[4].* 1) Dept. of Laboratory Medicine, Nationwide Childrens Hospital, Columbus, OH; 2) Dept. of Pathology, Ohio State Univ., Columbus, OH; 3) Dept. of Pediatrics, Ohio State Univ., Columbus, OH; 4) Dept. of Human and Molecular Genetics, Nationwide Childrens Hospital, Columbus, OH.

The 12q14 microdeletion syndrome is a rare condition characterized by pre and postnatal growth retardation, failure to thrive, developmental delay, and proportionate short stature. Osteopoikilosis, or multiple areas of dense calcification producing a mottled bone appearance, has also been identified in some children due to haploinsufficiency of the LEMD3 gene. Deletions at 12q14 range from 1.83 to 8.95 Mb and contain the LEMD3 gene in a majority of reported cases. The HMGA2 gene is deleted in all reported cases and is a candidate gene for the proportionate short stature associated with this syndrome. We describe here a case which further characterizes the features of this syndrome. The patient was born to a 22 year old primigravida mother in whom intrauterine growth retardation was noted at 5 months gestation. The child was delivered at 33 weeks by elective C-section due to oligohydramnios and was small for gestational age with a weight of 1.4 kg and a length of 40 cm (measurements below the fifth percentile). The infant was hospitalized for 3 weeks and fed by nasogastric tube. Skeletal surveys, MRI, chromosome analysis, and metabolic screens were normal. Physical examination at 5.5 years of age revealed her weight, height, and head circumference measurements below the third percentile. She was attending preschool along with speech therapy for apraxia, but otherwise had normal development and was generally healthy. A skeletal survey showed only minor, non-diagnostic findings including small iliac wings, minimally gracile long bones, and a slight flare to the distal half of the clavicles. The family history was non-contributory, and the parents and a 3 month old brother were of average height. Microarray analysis was conducted using the SignatureSelect OS 105K v1.1 oligonucleotide microarray platform which identified a 4.17 Mb deletion at chromosome 12q14.3 through 12q15 and confirmed by FISH. The deletion was confirmed by FISH and contained 25 genes which did not include the LEMD3 gene (as in most previous cases). The deleted region included the 3' coding portion of the HMGA2 gene. As a partial deletion of HMGA2 would support its role as a candidate gene for proportionate short stature, additional characterization of the HMG2A deletion will be conducted. This case refines the genotype-phenotype correlation in the 12q14 microdeletion syndrome and narrows the critical region to an approximately 1.42 Mb region at 12q14.3.

## 1428/W/Poster Board #1086

**Array CGH detection of UBE3A single gene deletion associated with Angelman syndrome.** *B. Xiang[1], PJ. Benke[2], H. Zhu[1], YS. Fan[1].* 1) University of Miami Miller School of Medicine, Miami, FL; 2) Pediatric genetics, Joe DiMaggio Children's hospital, Hollywood, FL.

Angelman syndrome (AS) occurs in about 6% of children presenting with severe mental retardation and epilepsy. UBE3A with maternal allele specific expression in brain is the critical gene of the syndrome. Approximately 70% of the patients have a ~4Mb deletion in a maternally inherited chromosome 15 at the 15q11-13 region. Paternal uniparental disomy (UPD) of chromosome 15 (3%), mutation in the imprinting center (1%) and mutation of the UBE3A gene (6%) are the other known causes of the syndrome. The remaining 20% of patients have no detectable genetic abnormality. We have recently studied 16 patients with mental retardation or developmental delay using a customized genome-wide oligonucleotide array 44K platform (Baldwin et al, Genet Med, 2008) with enriched probes for the known microdeletion syndrome regions and detected in a 2-year girl a small deletion with a size of 216 Kb that encompasses only the UBE3A gene. The deleted region is covered by 19 probes in this platform versus 4 probes by the standard Agilent 44K platform. The 2 year old female proband had development delay, speech delay, a small head, minimal epicanthic folds, borderline low set ears, and thin upper lip. The diagnosis of Angelman Syndrome was not made prior to the array CGH detection. Our case demonstrates advantages of a customized array in detection of single gene deletions associated with a known genomic disorder not detectable with other methodologies.

## 1429/W/Poster Board #1087

**18q12 deletion detected by CGH-array in a boy with inv(18) presented dysmorphia, mental retardation and epilepsy.** *M. Minz[1,3], L. Telvi[1], C. Sevin[2], P. Clement[3], P. Aubourg[2].* 1) Cytogenetics Laboratory, Hospital St Vincent de Paul, Paris, France; 2) Department of Pediatric Endocrinology, Hospital St Vincent de Paul, Paris, France; 3) Clement Laboratory, Blanc Mesnil, France.

A 5 years-old boy who presented dysmorphia and mental retardation showed a karyotype with a pericentric inversion of chromosome 18. The karyotype of the mother was normal, however the karyotype of the father with normal phenotype could not be done. The patient showed severe mental retardation, dysmorphic features and high frequency of myoclonic seizures rebel to treatment. The frequency of the myoclonic seizures is about 5 to 10 times in a day. The treatment of the seizures include Urbanyl, Valium and Epitomax. The CGH array analysis showed a large deletion at 18q12 chromosome region. The size of the deletion is large as 8.66 Mb and include many genes. Some of them are described as related to pathology of epilepsy. The FISH analysis do not detect any deletion with the Tuple1 and Shank3 probes. Epilepsy is commonly observed in patients with chromosomal aberrations. The association of seizures to chromosome 18 abnormalities was reported by many authors, and many of the loci was defined as a potential candidate susceptibility gene for epilepsy. The seizures reported with 18q-syndrome are very variable as status epilepticus (Kanazawa & al. 1989), autonomic seizures (Sturm & al. 2000, Stephenson, 2005), idiopathic generalized epilepsy (Durner & al. 2001, Lucarelli & al. 2007), febrile seizures (Baulac & al. 2001, Nakayama & al, 2003, Winawer & Hesdorffer, 2004, Nabbout & al. 2007) apneic seizures (Kumada, 2003), benign focal epilepsy (Verrotti & al. 2004), adolescent-onset idiopathic generalized epilepsy (Greenberg & al. 2005). Most of the authors suggest that the haplo-insufficiency of genes located on the chromosome 18 could be associated with epilepsy. McLin & al (2008) reported a study in inbred mouse providing the evidence that the genes of the distal part of chromosome 18 are important determinants of vulnerability to hippocampal neurodegeneration. While further EEG/clinical/genetical investigations are needed to validate these observations.

## 1430/W/Poster Board #1088

**COMPREHENSIVE PREIMPLANTATION GENETIC DIAGNOSTICS (PGD) BY SINGLE CELL SNP MICROARRAYS.** *W.G. Kearns[1], A. Benner[1], R. Pen[1], E. Widra[2], R. Leach[1].* 1) Shady Grove Center for Preimplantation Genetics, 15001 Shady Grove Rd., Ste 220, Rockville, MD 20850; 2) Shady Grove Fertility RSC, 15001 Shady Grove Rd., Ste400, Rockville, MD 20850.

We successfully amplified DNA from a single embryonic cell to perform preimplantation genetic diagnostics (PGD) and aneuploid screening (PGS) for all 23-pairs of chromosomes.

We used modified whole genome amplification (WGA) protocol on 565 single blastomeres from 61 embryos and 34 known cell lines. We used invariant DNA genomic loci to ensure the entire genome was amplified and TaqMan PCR to ensure heterozygous allele amplification. The Illumina HumanHap370 microarray was employed to determine chromosome aberrations and genotype data for 370K SNPs. Data was analyzed with deCODE genetics Disease Miner Professional and Illumina BeadStudio and KaryoStudio software.

Analyses of 565 blastomeres (n=61 embryos) and 34 cell lines showed in many cases, a genomic coverage > 98%, a heterozygous allele detection rate > 90% and a microarray detection rate and genotype call rate > 90%. Our DNA amplification protocol permits us to successfully identify ploidy in all cells without having to determine parental DNA genotypes. Sixty-nine percent (42/61) of the embryos were mosaic diploid/aneuploid, 25% (15/61) were mosaic aneuploid and 7% (4/61) were complex mosaics. Structural chromosome imbalances were identified from all cytogenetically abnormal cell lines. Genotype information was also obtained for 370K SNPs from each cell. These genome wide scans can also identify genetic disorders such as DiGeorge syndrome, some deletion forms of Prader-Willi and Angelman syndrome, uniparental disomy and some single gene disorders. By determining parental, embryonic and fetal genotypes, we can also identify which partner provided the extra chromosome in aneuploid embryos and which embryo implanted.

We successfully obtained genetic information from all chromosomes from single embryonic cells using a modified WGA protocol and microarray analyses. These types of analyses may also be successful on other cell types such as polar bodies or trophectoderm cells.

## 1431/W/Poster Board #1089

**Partial Deletion of Neuroligin 1 by aCGH in a Child with Microcephaly, Seizure Disorder and Severe Mental Retardation.** *A. Millson[1], M.J.H. Willis[2], M.E. Aston[3], S.T. South[1,4,5], E. Lyon[1,4], D.M. LaGrave[3].* 1) ARUP Institute for Clinical and Experimental Pathology, Salt Lake City, UT; 2) Clinical Genetics, Naval Medical Center, San Diego, CA; 3) Cytogenetics and Molecular Cytogenetics, ARUP Laboratories, SLC, UT; 4) Pediatrics, Univ of Utah, SLC, UT; 5) Pathology, Univ of Utah, SLC, UT.

Array CGH is used to evaluate chromosomal gains or losses in patients with mental retardation and/or dysmorphic features at a much higher resolution than is possible by standard cytogenetic means. Results of uncertain significance are not uncommon. Parental studies can clarify these results, demonstrating that the imbalance is either *de novo* or inherited, and therefore is more or less likely to be causative. However, the possibility that even inherited deletions and duplications may play a role in the phenotype of the proband cannot be excluded. NLGN1 is a member of the neuroligin gene family and may represent a candidate gene for developmental delay as members of this gene family are involved in formation and remodeling of central nervous system synapses. NLGN1 forms a heterotetramer with Nrx1. Together; they promote cell adhesion between dendrites and axons, forming a functional synapse. We present a 6.5 year-old girl born at 37 weeks gestation by C-section due to failure to progress. Developmental delay was noted at 5-6 months of age. Evaluation identified abnormal eye movements, and she was diagnosed with infantile spasms. EEG showed hypsarrhythmia. Parents report loss of milestones: that she used to smile (likely non-specific), sit in a highchair, and eat by mouth. Currently she is completely bed or wheelchair bound, has no meaningful interaction, no facial expression, and is G-tube dependent. Physical exam was significant for severe microcephaly, short stature, and unusually large fat pads on her fingers and toes. She has low central tone with increased tone and increased reflexes in lower extremities. She withdraws from stimulation, but has no other purposeful movement. Brain MRI at 9 months of age showed bilateral non-specific regions of increased T2 signal in the frontal periventricular white matter. Extensive biochemical, cytogenetic and molecular evaluations were normal. Blood was sent for aCGH and a 2.1 Mb deletion spanning 28 oligonucleotides was identified at 3q26.31. Findings were confirmed by FISH. DNA from the mother was subsequently analyzed with the same FISH probe and a deletion was detected. Quantitative real-time PCR targeting multiple exons in NLGN1 showed disruption of the gene, confirming the heterozygous loss of several coding exons in both the proband and her mother. Although the deletion is inherited, it is difficult to conclude the deletion of NLGN1 benign in consideration of its role in neural development.

## 1432/W/Poster Board #1090

**Variability in interpreting and reporting copy number changes detected by array-based technology in clinical laboratories.** *K.D. Tsuchiya[1], L.G. Shaffer[2], S. Aradhya[3], J.M. Gastier-Foster[4], A. Patel[5], K. Rudd[6], J. Sanford Biggerstaff[7], W.G. Sanger[8], S. Schwartz[9], J.H. Tepperberg[9], E.C. Thorland[10], B.A. Torchia[2], A.R. Brothman[11].* 1) Dept of Laboratories, Seattle Children's Hosp, and Dept of Lab Med, Univ of Washington Med Ctr, Seattle, WA; 2) Signature Genomic Laboratories, Spokane, WA; 3) GeneDx, Gaithersburg, MD; 4) Dept of Path and Lab Med, Nationwide Children's Hosp, and Depts of Path and Pediatrics, Ohio State Univ, Columbus, OH; 5) Dept of Molec and Hum Genet, Baylor College of Med, Houston, TX; 6) Dept of Hum Genet, Emory Univ School of Med, Atlanta, GA; 7) Idaho Cytogenet Diag Lab, Boise, ID, and PAML, Spokane, WA; 8) Dept of Pediatrics, Munroe-Meyer Inst, Univ of Nebraska Med Ctr, Omaha, NE; 9) Lab Corp of America, Research Triangle Park, NC; 10) Dept of Lab Med and Path, Mayo Clinic, Rochester, MN; 11) Depts of Pediatrics, Hum Genet and Path, University of Utah, and ARUP Laboratories, Salt Lake City, UT.

The use of microarrays for the assessment of copy number changes (CNCs) in individuals with constitutional disorders is becoming widespread in clinical cytogenetic laboratories. Although this technology has significantly increased the detection of chromosome imbalances that are known to be associated with abnormal phenotypes, the finding of CNCs in healthy individuals (also known as benign copy number variants or CNVs) has created new challenges for laboratorians and clinicians who must interpret the clinical significance of previously undescribed CNCs. The purpose of this study was to assess the variability in interpretation and reporting of copy number changes detected by array-based technology in the clinical laboratory. Thirteen copy number changes that were detected by array comparative genomic hybridization (six by BAC array and seven by oligonucleotide array) in one clinical laboratory were evaluated by directors from ten other clinical laboratories to determine how they would interpret and report the findings. The CNCs that were chosen for the study were not associated with an abnormal phenotype in the literature. The thirteen CNCs were chosen because they potentially posed an interpretive challenge in terms of their clinical significance. None of the thirteen copy number changes showed complete agreement amongst the eleven laboratories in the interpretation of the clinical significance of the change. For some cases, the interpretations ranged from normal to abnormal. Some laboratories appear to use a binary reporting system (normal vs. abnormal), whereas other laboratories utilize three or more categories for reporting. Some laboratories have absolute size cut-offs below which they do not report CNCs, whereas other laboratories will potentially report any size CNC depending on other variables. This study demonstrates the need for guidelines for interpreting and reporting copy number changes detected by array-based technology in order to clearly and more consistently communicate the clinical significance of these findings to ordering providers.

## 1433/W/Poster Board #1091

**Classification of pathogenic imbalances detected by genome-wide array CGH in patients with mental retardation and genetic counseling.** *Y.S. Fan[1], B. Xiang[1], B.L. Wu[2], Y.P. Shen[2], P. Li[3], M. Li[4], T.J. Chen[5].* 1) University of Miami Miller School of Medicine, FL; 2) Children's Hospital Boston and Harvard Medical School, MA; 3) Yale University School of Medicine, CT; 4) Tulane University School of Medicine, LA; 5) Dept Med Genet, University of South Alabama College of Medicine, AL.

We have collected the array CGH results on1499 patients with mental retardation or developmental delay from five academic diagnostic laboratories where a genome-wide oligonucleotide array, Agilent 44K has been used. We have also reviewed genome-wide array CGH results on 2501 patients published recently with different platforms used. Pathogenic imbalances have been reported in 461 of the total 4,000 patients reviewed. The diagnostic yields varied from 6.25% to 24% with an overall diagnostic yield of 11.53%. The majority of imbalances were larger than 500 Kb in size (95%) and 300Kb in size (99%). We classified the pathogenic imbalances into 6 groups according to their structures: Class 1, a deletion or duplication of a single DNA segment; Class 2, a deletion of the terminal region of one chromosome and a duplication of the terminal region of another chromosome; Class 3, a deletion in one chromosomes and a duplication in another with at least one interstitial alteration; Class 4, a deletion and a duplication involving a contiguous genomic region within the same chromosome arm; Class 5, a deletion and a duplication in different arms of the same chromosome; Class 6, other types of imbalances including complex abnormalities and mosaicism. Approximately 87% (400/461) of the abnormal cases had a simple single segment deletion or duplication whereas the remaining 13% (61/461) had a compound genomic imbalance involving two or more DNA segments. A single deletion or duplication could be the result of the segregation of a balanced insertion. A deletion and a duplication in the same patient could be derived from a balanced translocation. The finding of both a deletion and a duplication on the same chromosome can be caused by an inversion in a parent. We have recommended a conventional karyotyping for the parents to rule out a balanced translocation, inversion or insertion when an alteration was likely to be chromosomally visible or FISH when an alteration involved subtelometic regions or known microdeletion regions. Classification of the pathogenic imbalances and discussion of the possible mechanism in the report can provide useful information for genetic counseling.

## 1434/W/Poster Board #1092

**Identification of carrier status as a consequence of whole-genome microarray analysis: dilemmas regarding clinical obligation, confirmation and reporting.** *L.R. Rowe[1], A. Millson[1], J. Swenson[2, 3], E. Lyon[1, 2, 3], E. Aston[3], D. LaGrave[3], S. Shetty[3], A.R. Brothman[1,2, 3, 4, 5], S.T. South[1,2,3,4].* 1) Institute for Clinical and Experimental Pathology, ARUP Laboratories, Salt Lake City, UT; 2) Department of Pathology, University of Utah, Salt Lake City, UT; 3) ARUP Laboratories, Salt Lake City, UT; 4) Department of Pediatrics, University of Utah, Salt Lake City, UT; 5) Department of Human Genetics, University of Utah, Salt Lake City, UT.

Although carriers of mutations resulting in autosomal recessive disorders are not usually affected phenotypically, nor are they symptomatic, identifying heterozygous deletions for genes in which homozygous deletions have clinical consequences has merit. For example, identification of carrier status allows an individual to make informed decisions regarding child bearing. We discuss heterozygous findings involving three genes in which homozygotes are clinically affected. Nephronophthisis (NPH) is an autosomal recessive nephropathy with chronic tubulointerstitial involvement which represents the leading cause of end-stage renal disease in children and adolescents. The most frequent genetic abnormality found in NPH is a large homozygous deletion of the NPHP1 gene. Homozygous deletions of NPHP1 have also been identified in a subset of patients with Joubert syndrome. The most common cause of renal tubular Fanconi syndrome, cystinosis, is a lysosomal storage disorder which can be caused by homozygous deletion of the CTNS gene which encodes the lysosomal cystine carrier cystinosin. Alpha thalassemia, the most prevalent worldwide autosomal recessive disorder, is a hereditary anemia. Homozygous deletion of both HBA1and HBA2 genes results in prenatal or early neonatal death. We have identified heterozygous deletion of NPHP1, CTNS, or HBA 1 and HBA2 genes in routine clinical samples submitted for array comparative genomic hybridization (aCGH) analysis in pediatric patients referred for developmental delays and/or multiple congenital anomalies. Although these findings are likely not pertinent to the patient's indication for testing, we aim to perform confirmatory testing and include the findings of such testing in the clinical report. Using a combination of molecular tests, we have confirmed heterozygous deletions in each of these cases. While it is important to develop a robust test for confirmation and carrier status detection in heterozygous cases such as these, conveying of this information, and how it is done requires careful education and explanation. We believe these three examples are likely to be representative of multiple additional genes where clinical interpretation of aCGH results needs to be carefully presented through a health care provider such as a genetic counselor.

**Detection of Long Contiguous Stretches of Homozygosity using the Affymetrix Cytogenetics Research Solution Microarrays.** *B.M. Bolstad.* Affymetrix, Inc, Santa Clara, CA.

Affymetrix® Cytogenetics Research Solution microarrays contain both non-polymorphic markers for measuring copy number variation and markers for measuring single nucleotide polymorphisms (SNPs). On the Whole-Genome 2.7M array there are 400,103 markers for measuring SNP variability. These allow the detection of loss of heterozygosity (LOH), uniparental disomies (UPD), and regions of the genome that are identical-by-descent. The polymorphic markers were selected for the array based on performance and maximizing genomic coverage. An algorithm was developed to detect the occurrence of LOH events based on allelic intensity values rather than genotype calls. The ratio of allelic intensities can be used to summarize a single marker, and a reference set is used to improve these allelic ratios. Information from adjacent contiguous markers is combined to determine the presence of any LOH. The algorithm compensates for differences in individual marker performance by assigning each a value measuring its information content. These are used to decide how many markers should be considered at any one time in a window and weight markers appropriately. For each window a test is carried out to decide whether or not there is evidence to support the presence of underlying LOH. Windows are moved along the genome and overlapping LOH windows produce segments. Sample quality, and hence data quality can vary; to account for these differences, the algorithm dynamically selects optimal parameterization of the test statistic and window size for each sample. Using this algorithm, the Whole-Genome 2.7M array is able to robustly detect LOH events spanning 3Mb or larger and some events smaller than 3Mb.

**Development and performance of a simple assay for high resolution copy number analysis on the Affymetrix 2.7M Cytogenetics Research Array.** *Z. Hu, T. Berntsen, J. Chen, D. Flaucher, V. Huynh, S. Nautiyal, N. Ngo, D. Pankratz, D. Abdueva, B. Bolstad, V. Carlton, B. Liu, J. Veitch, J. Collins.* Affymetrix Inc, 3420 Central Expy, Santa Clara, CA.

The research field of molecular cytogenetics is transitioning from the use of classic techniques such as chromosome banding analysis and fluorescent in-situ hybridization to DNA microarray-based virtual karyotyping, which offers distinct advantages such as greatly enhanced resolution and less objective assessment of aberrations. However, broad adoption of currently available microarray tools is often hindered by laborious and complex assay workflows, an inability to detect certain aberration types, complex data analysis tools or insufficient resolution for subtle cytogenetic changes. To overcome these hurdles, we have developed a whole-genome assay that, when combined with the new high-resolution Affymetrix 2.7M Cytogenetic Research arrays and data analysis software suite, has enabled reliable detection of a broad range of chromosomal abnormalities. Starting with as little as 100 ng of genomic DNA, this assay uses a PCR-free whole genome amplification approach to amplify the sample, which is then purified, fragmented and labeled before hybridization to microarrays. The assay is fast, simple and robust, requiring less than three hours of hands-on processing time and merely 30 hours from DNA to result. The 2.7M Cytogenetic Research arrays provide the highest-available density of 2.7 million copy number markers along with 400,000 single nucleotide polymorphisms (SNPs) markers, with increased coverage of genes and regions of cytogenetic interest. Microarray data are analyzed using the Chromosome Analysis Suite software package. We present data demonstrating the successful detection of very small single copy gain and loss events (<50 kb). We also demonstrate the utility of SNP markers in enabling the reliable detection of copy number neutral loss of heterozygosity (LOH) events such as those associated with uniparental disomy (UPD) and identical-by-descent (IBD). Data are presented from a variety of clinical sample types commonly encountered in cytogenetics research, including amniotic fluid, blood, cell lines, chorionic villi, fresh frozen tissue, and saliva.

## 1437/W/Poster Board #1095

**Mosaic monosomy 7 in a male infant with ambiguous genitalia and multiple congenital anomalies.** *D.M. LaGrave[1], C.W. Booth[2], D.A. Rita[2], M.E. Aston[1], K.B. Geiersbach[1, 4], S. Shetty[1, 4], L.R. Rowe[5], S.T. South[1, 3, 4].* 1) Cytogenetics and Molecular Cytogenetics, ARUP Laboratories, Salt Lake City, UT; 2) Lutheran General Hospital, Park Ridge, Ill; 3) Department of Pediatrics, University of Utah, Salt Lake City, UT; 4) Dept of Pathology, University of Utah, Salt Lake City, UT; 5) ARUP Institute for Clinical and Experimental Pathology, Salt Lake City, UT.

Array comparative genomic hybridization (aCGH) was ordered and blood received on a three-month old, premature Hispanic male infant (corrected age 3 weeks) for the indication of ambiguous genitalia and multiple congenital anomalies, including bilateral club feet, small kidneys with pelviectasis, and hyperpigmentation. Chromosomes were normal, 46,XY by amniocentesis and peripheral blood at birth. The infant had been delivered at 27 4/7 weeks by emergency C-section due to IUGR, decreased fetal movement, and bradycardia. Perineoscrotal hypospadias and bifid scrotum were noted at birth. Low cortisol levels were found, and treated with steroids. Growth continued to lag and there were repeated episodes of sepsis as well as frequent episodes of apnea and bradycardia. There were no cardiac anomalies other than a PDA. Chest films revealed a small thymus. Absolute lymphopenia and thrombocytopenia were persistent. Chronic anemia of unclear etiology required repeated transfusions. DEB-induced breakage studies were normal. Array CGH on uncultured blood using the Cyto6000 array platform (Human Genome build: hg 18) demonstrated a mosaic monosomy for chromosome 7. Findings were confirmed using the CEP7 FISH probe (Abbott Molecular) in both a direct, unstimulated blood smear, and in cultured interphase cells where 84% of cells demonstrated monosomy 7. Further examination of this sample demonstrated two CEP7 signals in metaphase cells and two normal-appearing chromosome sevens by karyotype analysis. FISH examination using CEP7 and D7S486 (7q31) was performed on buccal cells at another laboratory and demonstrated the presence of two signals for each probe in 200/200 cells examined. The discrepant findings between aCGH and cytogenetic studies may be partially explained by the presence of sepsis and a high neutrophil count causing an overrepresentation of myeloid lineage cell in the patient at the time of aCGH. At 5-months of age, the infant developed hypernatremia and became unresponsive. The parents elected to discontinue extraordinary measures, and the infant died. Parents declined postmortem examination. We describe the identification of mosaic monosomy 7 by aCGH in an infant with an unusual constellation of findings, compare this case to one other similar case found in the literature and suggest a possible etiology explaining clinical and cytogenetic findings.

## 1438/W/Poster Board #1096

**Analysis of a Variety of Deletions and Duplications within the Dystrophin Gene Using the Affymetrix SNP Array 6.0 and Multiplex Ligation Dependent Probe Amplification.** *L. Toji[1], L. Kalman[2], J. Tarleton[3], C. Bridges[3], N. Gerry[1], C. Beiswanger[1], J. Leonard[1].* 1) Coriell Inst Med Res, Camden, NJ; 2) Centers for Disease Control and Prevention, Atlanta, GA; 3) Fullerton Genetics Center, Asheville, NC.

Mutations in the Dystrophin gene result in muscular dystrophy varying from the severe Duchenne type to the much milder Becker type. Males affected with Duchenne muscular dystrophy (DMD) have several mutation types. Approximately 65% have deletions,10% have duplications and the remainder have point mutations. To identify and characterize the causative mutations in DMD cell lines in the National Institute of General Medical Sciences Human Genetic Cell Repository (NIGMS), we studied DNA samples from 35 DMD cell lines using two methods to assess copy number; the Affymetrix SNP Array 6.0 and Multiplex Ligation-dependent Probe Amplification (MLPA). Samples were selected in order to confirm prior DNA analysis or to identify the causative DMD mutation. The sample set included 24 different probands. Both fibroblast and lymphoblastoid cell cultures were available for 5 probands; for 3 probands samples from affected brothers were available and for 1 proband a sample was available from the carrier mother. Eighteen different deletions and duplications were detected with the Affymetrix SNP Array 6.0. The assay identified duplications or deletions of identical size and location in the paired samples. These samples were further characterized using MLPA analysis. In two samples, the array identified a deletion that was one exon smaller than was determined with the MLPA analysis. The basis for these differences is under investigation. Neither method detected copy number changes in five of the DNA samples. These samples will be sequenced to identify potential point mutations. The results from these analyses provide accurate descriptions of the DMD mutation in the samples and identified for the first time, DMD exon duplications in the NIGMS collection. These publicly available samples are described on the Coriell Cell Repositories web-site (http://ccr.coriell.org/) and provide the genetics community with highly characterized cell lines and DNA samples for use as reference materials for genetic testing or for biomedical research.

## 1439/W/Poster Board #1097

**Simulation of detection of fetal cells in the maternal blood: Evaluation of the efficiency of the automatic scanning in retrieval of rare events.** *A. Emad[1], E. Bouchard[1], K. Krabchi[1], A. Dutta[2], U. Klingbeil[2], R. Drouin[1].* 1) Div Genetics / Dept Pediatrics, Univ Sherbrooke, Sherbrooke, PQ, Canada; 2) MetaSystems, 300 Bear Hill Road, Waltham, MA 02451.

Introduction- Presence of fetal cells in the maternal blood during pregnancy provide an opportunity for developing non-invasive prenatal diagnosis. Accurate identification of fetal cells is essential due to their extreme low frequency of 2-6 cells/ml. They could be identified by targeting specific genetic marker exclusive for the fetal cells; for example, male fetal cells can be located through the unique presence of Y-sequence using XY-Fluorescence In Situ Hybridization (XY-FISH). The manual scanning process used in their retrieval in very cumbersome and time-consuming. Validation of its efficiency and automation will be required before its widespread application. Objectives- Determining the efficiency of automatic scanning to detect rare XY cells amongst thousands of XX cells using FISH technique and compare it with the efficiency of manual scanning. Hybridization efficiency was also determined. Methodology- Spreading of 1-10 XY cells was done, followed by staining with Giemsa and imaging. On top, a drop of XX cells was spread, followed by FISH using XY probes. The slides were then automatically scanned using the Y-chromosome probe serving as marker. Pictures taken of XY cells were compared with the ones taken before with Giemsa. The data were recorded. Results- Results obtained by automatic scanning shows an overall detection rate of 88% (117/133) of XY-cells distributed on 60 slides with low false positive rate of 4%. A cell was considered false positive for the Y-probe hybridization by reverse color re-FISH. By evaluating the hybridization of the Y-probe in the missed events, it was found that 1.5% (2/133) were not hybridized, 3% (4/133) were poorly hybridized and the hybridization was adequate in the remaining 7.5% (11/133). The overall efficiency of the FISH technique using the index of Youden was 0.88. Conclusion- Evaluation of the results obtained by manual and automatic scanning shows that although the average time required per slide was slightly longer in automatic scanning (4 hours vs 3 hours), the automatic scanning was more efficient in comparison to the manual one (88% vs 84%). Furthermore, it alleviates the burden required for manually scanning the slides and more productive as it can work non-stopped 24 hours per 24 hours.

## 1440/W/Poster Board #1098

**Partial Trisomy 2p Arising from Inverted Duplication of 2p with Terminal Deletion of 2pter: Cytogenetic and Molecular Characterization.** *S.A. Henderson[1], S. Iyer[1], R.H. Collins[3], E. Stewart[2], I. Ratner[2], A. Holdridge[1], J. Doolittle[1], S. Patel[1], N. Uddin[1], D. Payne[1], C.A. Tirado[1].* 1) Pathology, University of Texas Southwestern, Dallas, TX; 2) Pediatrics, Univeristy of Texas Southwestern, Dallas, TX; 3) Internal Medicine, University of Texas Southwestern, Dallas, TX.

First outlined by Francke and Jones in 1976, partial trisomy 2p is associated with multiple distinctive congenital anomalies including psychomotor delay, dysmorphic facial features, and congenital heart disease. Here we present a case of partial trisomy 2p arising from inverted duplication of 2p with terminal deletion of 2pter. Clinically, this patient had microcephaly, frontal bossing, hypertelorism, low-set ears, and a mild increase in lower extremity tone. In addition, pulmonary stenosis, atrial septal defect, nasopharyngeal reflux, and a relatively undersized right kidney were also present. At about 2 months the patient demonstrated significant growth retardation and developmental delay. Conventional cytogenetics showed a complex karyotype: 46,XX,del inv dup(2)(qter->p25.1::p25.1->p22.2:). ish del inv dup(2)(qter->p25.1::p25.1->p22.2:)(VIJyRM2052-,ALK++). FISH studies using a telomere probe specific for the terminal short arm of chromosome 2 and a DNA probe specific for the band 2p23 (VIJyR2052, ALK) revealed that the additional material on 2p is derived from chromosome 2 and that the 2p-specific telomere sequence is deleted. Comparative genomic hybridization (CGH) helped to refine the break points. The duplicated region was approximately 34 Mb in length while the deleted sub-telomere region was estimated to be 2.3 Mb. Many of these clinical findings overlap with those found in previously documented cases of partial trisomy 2p. Maternal cytogenetic evaluation was normal and chromosome studies from the father was not possible. To the best of our knowledge, this is the fourth reported case of an inverted duplication of 2p with an associated terminal deletion. The phenotypic effects of both the inverted duplication as well as the terminal deletion are discussed.

## 1441/W/Poster Board #1099

**The Orientation of Unique Genetic Sequences in the Human Genome.** *F. Ray[1,2], E. Zimmerman[2], M. Cornforth[2,3], J. Bedford[1,2], E. Goodwin[2], S. Bailey[1,2].* 1) Environmental and Radiological Health Sciences, Colorado State University, Fort Collins, CO. 80523; 2) KromaTiD Inc., 515 E. Laurel St., Fort Collins, CO 80524; 3) Department Radiation Oncology, University of Texas Medical Branch, Galveston, TX 77555.

CO-FISH is a strand-specific *in situ* fluorescence hybridization technique that allows determination of the 5'-3' orientation of DNA sequences along the length of chromosomes. The technique requires that cells be cultured through a single S phase to allow incorporation of BrdU into newly replicated DNA strands. The nascent strands are then photo-enzymatically digested, leaving complementary single stranded target sequences on each chromatid. Thus, for a single stranded probe, hybridization can occur only on one sister chromatid at the same locus. CO-FISH has been used to study the orientation of repetitive sequences associated with telomeres and paracentric DNA but, to date, it has not found application for orientation analysis of unique sequences, largely because of difficulties surrounding the preparation of single-stranded probes of adequate length. Unique single-stranded DNA probe sets were designed to be complementary to a single contig on chromosome 3q. In order to eliminate interspersed repetitive sequences, DNA sequences were entered into CENSOR (www.girinst.org) and masked. Unmasked, non repetitive sequences totaling approximately 10kb were then analyzed using tiling software. The result was an ordered series of short oligonucleotides designed to hybridize to a complementary target of ~10Kb. These oligonucleotides were synthesized and then fluorescently labeled using a conventional tailing reaction. Probes were hybridized to metaphase chromosome spreads that had been previously prepared for CO-FISH. Bright punctate fluorescent probe signals were detected at the expected target loci, and were confined to a single sister chromatid (on each of the two homologs). Additional probe sets targeted to sequences of the same orientation, but further down the same contig, also hybridized to the same chromatid. Thus, our results show that CO-FISH may be used to determine the orientation of unique sequences. We can imagine a few interesting applications for this approach. For example, consider the situation whereby many such oligo probe pools were used to effectively "paint" completely one chromatid of a metaphase chromosome. In that case small inversions would appear as a microscopic segment of labeled chromatin that "jumped" across the chromosome, from one chromatid to its sister. The ability to construct probes for all 23 pairs of chromosomes simultaneously would allow the detection of even small inversions (e.g., <0.5 Mb) on a genome-wide basis.

## 1442/W/Poster Board #1100

**Automating the Workflow of aCGH Tests.** *M. Herrler, W. Ke, J. Stanchfield.* Product Development, SciGene, Sunnyvale, CA.

The current sample preparation process for aCGH tests is tedious; leading to errors that confound clinical results and increasing re-test rates and costs. To overcome this problem, we have developed three specialized instruments that work together to automate benchwork from DNA labeling to array scanning. A robotic liquid handling and incubation system (ArrayPrep® Target Preparation System) automates the labeling and magnetic bead purification of 8 to 96 genomic DNA samples then loads them onto microarrays for hybridization using a rotating incubation system (Mai Tai® Hybridization System). Arrays are then post-processed using a robotic instrument (Little Dipper® Processor) for washing and drying. In this study, we compared the reproducibility of aCGH test results of samples prepared using the automated aCGH platform to those prepared manually. Over 100 genomic DNA samples were processed using both methods. We measured technician bench time needed for processing typical numbers of patient samples. We also measured the yield and purity of labeled DNA and the degree of fluorescent dye incorporation. Samples were then analyzed using Agilent 4x44K arrays and software. The results of this study show that the automated platform reproducibly generated labeled samples of high yield (5.3±0.6μg) and purity (OD260/280=1.83±0.03) with consistently high dye incorporation (AF-3= 2.9±0.46pmol/μl; AF-5=4.2±0.46pmol/μl). Arrays showed high signal intensities and low background noise with DLR values ≤0.2 (avg. 0.16). Compared to samples processed on the automated platform, manually prepared samples showed somewhat higher but more variable yields (6.9±1.0μg) with comparable dye incorporation and purity. Arrays showed similar signal intensities but higher background and slightly higher and more variable DLRs. Time and motion studies showed that the automated aCGH platform requires a fixed technician time (~1 hour) independent of batch size. In comparison, manual processing required a varying amount of technician time, up to 4.5 hours. In conclusion, the automated aCGH platform reproducibly provides high quality labeled genomic DNA with yields sufficient for aCGH-based tests. It provides consistently high quality microarray results with less variability than that seen with manually prepared samples. Finally, the system reduces the amount of technician hands-on time by as much as 75%, thereby reducing sample handling errors for improved overall test reliability.

## 1443/W/Poster Board #1101

**Genomic imbalances detected by array-CGH in patients with syndromic congenital eye malformations.** *A. Delahaye[1,2], E. Pipiras[1,2], N. Chassaing[3], M. Gérard-Blanluet[4], A. Toutain[5], L. Faivre[6], C. Francannet[7], L. Van Maldergem[8], C. Baumann[4], ML. Jacquemont[4], A. Verloes[2,4], A. Aboura[2,4], S. Drunat[4], C. Dupont[1,4], ML. Maurin[4], AC. Tabet[2,4], P. Gressens[2], J. Elion[4,9], B. Benzacken[1,2,4], P. Bitoun[1].* 1) Histology-Embryology-Cytogenetics Department and Medical Genetics, AP-HP-University Hospital Jean Verdier, Paris XIII, UFR SMBH, Bondy, France; 2) UMR 676 Inserm-Paris VII et Paris XIII, France; 3) Service de Génétique Médicale, Hôpital Purpan, University Hospital of Toulouse, Toulouse, France; 4) Genetics department, AP-HP-University Hospital Robert Debré, Paris VII, Paris, France; 5) Genetics department, Hôpital Bretonneau, University Hospital of Tours, Tours, France; 6) Genetic Center, University Hospital of Dijon, Dijon, France; 7) Service de Génétique Médicale, University Hospital of Clermont-Ferrand, Univ Clermont1, UFR Médecine, Clermont-Ferrand, France; 8) Genetics department, AP-HP-University Hospital Henri Mondor, Paris XIII, Créteil, France; 9) UMR 763 Inserm-Paris VII.

Genomic imbalances are a major cause of malformations, mental retardation and developmental delay. With the advent of whole genome array-CGH analysis, the number of especially interstitial genomic imbalances described increased dramatically. Hereditary diseases of the eyes are a frequent cause of blindness in early childhood with complex etiology. The exact frequency of chromosomal deletions and duplications causing congenital eye abnormalities is unknown. Considering the high frequency of genomic imbalances associated with eye disorders we hypothesize that the sensitivity of array-CGH could improve the genetic diagnosis in patients with idiopathic eye anomalies associated with mental retardation.

Fifty patients with unexplained congenital eye malformations and other malformation or mental retardation were analyzed using 105K oligonucleotide arrays (Agilent). CNV polymorphism were excluded using on line databases.

We detected 8 possibly pathogenic *de novo* imbalances (16%) among analysed patients. Seven are deletions and 1 is duplication. No recurrent abnormality was identified. FISH analyses confirmed the chromosomal abnormalities in 5 cases and real time quantitative PCR in the remaining cases. In 5 patients, the genetic imbalance was shown inherited from a phenotypically normal parent (1 deletion and 4 duplications). Further analyses to confirm chromosomal abnormalities suspected using CGH array are still under investigation in 13 cases.

These results demonstrate that array-CGH is able to provide a high diagnostic yield in patients with congenital eye malformation and mental retardation. Interestingly, only 2 of the 8 possibly pathogenic de novo imbalances encompassed genes already known to be involved in eye development (*FOXC1* and *OTX2*). Besides their importance for diagnosis and genetic counselling, these data may pave the way to the identification of genes involved in eye development.

### 1444/W/Poster Board #1102

**"Classical" Cytogenetics: Not dead yet.** *D.A.S. Batista[1,2], E.C. Lisi[3], E. Wohler[2], M. Walsh[3], A. Hoon[2], R. Cohn[3], J.E. Hoover-Fong[3,4].* 1) Dept Pathology, Johns Hopkins University, Baltimore, MD; 2) Kennedy Krieger Institute, Baltimore, MD; 3) McKusick Nathans Institute, Johns Hopkins University, Baltimore, MD; 4) Greenberg Center for Skeletal Dysplasias, Johns Hopkins University, Baltimore, MD.

Microarray CGH and SNP analysis have revolutionized cytogenetics leading to the discovery of new chromosomal abnormalities and providing mechanistic and detailed insight into previously recognized syndromes. The excitement generated by these advances prompted the thought that "classical" cytogenetics would become obsolete, substituted by microarray testing. Hundreds of clinical cases were processed by microarray in our laboratory and we share the excitement and wonder. However, much emphasis has been placed on what array detects beyond karyotype without much published data pertaining to what it misses. We summarize three cases from our laboratory in which the correct diagnosis would not be achieved without karyotype. Case 1: A newborn with features of cleidocranial dysplasia, had normal RUNX2 gene mutation analysis and high resolution BAC array CGH. Karyotype showed a de novo, presumably balanced translocation between chromosomes 2q22 and 6p12.3, the band where RUNX2 is mapped (UCSC Genome Browser, Mar 06). FISH showed that the breakpoint on 6p12.3 occurred within a 110 kb region that includes RUNX2, whereas SNP analysis showed no loss or gain. Further FISH analysis and allele-specific sequencing are underway to define the breakpoint, which most likely affects the RUNX2 protein product, creating the clinical phenotype. Case 2: Array showed gain of the short arm of chromosome 18, possibly tetrasomy, and also suggested loss of chromosome Y. Karyotype confirmed both abnormalities, however in two distinct cell lines, each one containing only one of the abnormalities. The karyotype was therefore, 47,XY,i(18)(p10)/45,X. This finding has implications for the origin of these cell lines since it was a twin pregnancy. Case 3: Karyotype showed a small ring chromosome in 10% of the cells. Software analysis of array data however, was normal. Given the karyotype result, we closely inspected the raw array data from the regions around all centromeres. Chromosome 1 had a slight increase in copy number in this region but it was well below the established cutoff for anomalies. FISH confirmed the origin of the marker from the pericentromeric region of chromosome 1 including euchromatin. This accurate diagnosis allowed for the appropriate prognostic counseling. It is therefore important to emphasize that G-banded karyotype, FISH and microarray are complementary to each other and when used together provide the most accurate diagnosis of genomic copy number variations.

### 1445/W/Poster Board #1103

**Diagnosis of recessive disorders using a genome-wide SNP microarray.** *M. Crowley[1], L. Conlin[1], M. Berman[1], B. Thiel[2], C. Haldeman-Englert[1], D. Clark[1], L. Ernst[2], J. Ganesh[1], C. Ficicioglu[1], X. Gai[3], H. Hakonarson[4], I. Krantz[1], N. Spinner[1,2].* 1) Pediatrics, CHOP, Philadelphia, PA; 2) Pathology, CHOP, Philadelphia, PA; 3) Bioinformatics Core, CHOP, Philadelphia, PA; 4) Center for Applied Genomics, CHOP, Philadelphia, PA.

Utilization of genome-wide SNP arrays has proven highly successful in the identification of disease causing genomic deletions and duplications. Commonly, heterozygous deletions are identified that include genes associated with clinical abnormalities when present in only a single copy (haploinsufficiency). We used the Illumina Quad 610 array to study over 1,000 patients with various clinical features ranging from multisystem syndromes to apparently isolated single organ involvement. In general, we consider deletions and duplications as potentially pathogenic when they involve 20 or more SNP probes, are larger than 200 kb, and contain at least one gene that is not commonly deleted or duplicated in control individuals. In some cases, smaller deletions may be considered pathogenic when they involve one or more genes that are known to be dosage sensitive. In addition, homozygous deletions can be differentiated from heterozygous deletions, allowing diagnosis of recessive disorders. To date we have identified five genes with homozygous deletions whose known disturbance results in an autosomal recessive disorder, consistent with the referring diagnosis of the patient. The homozygous deletions were all relatively small, called by 2 to 28 SNPs, and to date 4 of the 5 have been validated by an alternative technique. The first validated diagnosis was non-ketotic hyperglycinemia caused by homozygous deletion of at least 8 exons (6 SNPs) of the glycine decarboxylase gene. Cockayne syndrome was diagnosed by a 28 SNP, 203 kb deletion involving both alleles of the ERCC8 gene. A 5 SNP homozygous deletion of the otoferlin (OTOF) gene caused hearing loss in one patient, and a 4 SNP, homozygous deletion of the holocarboxylase synthetase gene (HLCS) caused multiple carboxylase deficiency. In addition, a 2-6 SNP deletion within the stereocilin (STRC) gene is associated with hearing loss, although validation has not yet been carried out for this patient. These copy number abnormalities highlight the evolving utility of high-density, genome-wide SNP microarrays to obtain diagnoses in patients with various clinical features. Additionally, we identified heterozygous deletions of several genes associated with recessive disease, and sequencing of the non-deleted allele resulted in molecular diagnosis of the associated disorder. This data highlights the importance of evaluating each copy number abnormality in relation to patient phenotype and gene content.

### 1446/W/Poster Board #1104

**UPD detection by homozygosity profiling using a SNP based microarray.** *P.R Papenhausen, S. Schwartz, R. Burnside, V. Jaswaney, H. Risheg, I.K. Gadi, R. Pasion, K. Friedman, J.H. Tepperberg.* Dept Cytogenetics, Labcorp America, Res Triangle Park, NC.

Polymorphic SNP targeting in the Affymetrix 6.0 microarray easily provides sufficient allele differentiation (>900,000 SNPs) to study patterns of homozygosity (HZ). Specific HZ patterns can be seen for consanguinity, reduced gene pools and uniparental disomy (UPD). Targeting a primarily DD/MR patient base (6,000 cases), we have now prospectively ascertained and molecularly confirmed 16 cases of UPD that in addition to nine retrospectively studied cases, allow an improved HZ pattern correlation with UPD. Ten of the 25 cases showed complete chromosomal HZ consistent with de facto isoUPD and a post zygotic derivation. The remaining 15 cases showed single chromosomal LCSH (long contiguous stretches of HZ) that varied in length from 13.5-76 Mb, consistent with meiotic recombination in the homologues of the disomic gamete preceding post-zygotic trisomy rescue. Since the smallest LCSH found in UPD retrospective analysis was 13.5 Mb (4 times the average longest LCSH in our control study), we used that size for all reporting of potential UPD. In all, fifty-eight cases showed LCSH of 13.5 Mb or greater in a single chromosome. Using cases that only contained a single chromosome with LCSH, eliminated >100 cases of identity by descent which show multiple chromosomal LCSH delineating regions of recessive gene risk. Molecular follow-up of the 58 cases was obtained in 21 cases of which 15 were confirmed as hetero/isoUPD and one segmental isoUPD. Most of the cases molecularly pursued involved imprinted chromosomes, although the risk of occult trisomy effects from incomplete rescue in UPD cases may be considerable. In the five false positive cases there were no terminal LCSH found while 11 of the 16 confirmed UPD cases (including the segmental case) had at least one terminal block, a finding that fits well with UPD origin. The loci of the five false positive LCSH appear to cluster near recombinational cold spots, suggesting the need to account for these to improve predictive values. True segmental UPD secondary to mitotic recombination as a cause of a positive (done in three of the five cases) should be investigated in molecular follow-up studies. Although all retrospective cases of UPD were LCSH "positive" in these studies, clearly more need to be studied to determine whether this signature evidence of recombination is present in all cases.

**Customized oligonucleotide FISH probes offer increased sensitivity in characterizing abnormalities detected by array CGH.** *L.S. Rector[1], N.A Yamada[2], M.E. Aston[1], R.A. Ach[2], P. Tsang[2], E. Carr[2], A. Scheffer-Wong[2], N. Sampas[2], B. Peter[2], S. Laderman[2], L. Bruhn[2], A.R. Brothman[1,3].* 1) ARUP Laboratories, Salt Lake City, UT; 2) Agilent Laboratories, Agilent Technologies, Santa Clara, CA; 3) Deparments of Pediatrics, Human genetics and Pathology, University of Utah School of Medicine, Salt Lake City, UT.

Array comparative genomic hybridization (aCGH) is now an accepted methodology for detection of genomic copy number changes. FISH is often used to confirm and further characterize abnormalities detected by aCGH. It is not unusual for abnormalities detected by aCGH to be in a genomic region or of a genomic size which prohibits traditional FISH using large probes such as bacterial artificial chromosome (BAC) vectors. Our goal was to establish a robust method for visualizing FISH probes on metaphase chromosomes to further characterize small abnormalities which would not be readily seen by conventional FISH techniques. Oligonucleotide FISH (oFISH) is an alternative to BAC FISH because it allows for higher resolution visualization of smaller loci. In this study, libraries of long oligonucleotides (194mers) with high complexity (~>150 oligonucleotides per locus) were chemically synthesized. Probe generation involved PCR amplification, followed by the introduction of fluorescent labels by chemical modification. By directing oFISH probes at the most informative elements of the region under investigation, we achieved high specificity and eliminated the need for Cot-1 or other suppressive hybridization reagents. Upon the initial evaluation of 14 oFISH probes, 12 of these (86%) gave strong signals with good specificity and sensitivity. The two oFISH probes which did not hybridize well initially included regions at distal 4p and Xq which both contain a high frequency of repeat sequences. When a modified *in silico* oligo selection method was used to enhance signal while maintaining specificity, easily detectable signal was achieved at the expected sites in the 4p and Xq regions even though as little as 10% (6.5 Kb) of the initial region was included in the probe sequences. Ongoing evaluation of additional oFISH probes indicates that this method will be powerful for routine analysis of previously difficult genomic regions. The ease, reproducibility and high level accuracy of this technique suggest that it may prove invaluable to the human genetics community.

### 1448/W/Poster Board #1106

**Two Mosaic Ring Cases with Evidence of Structural Evolution Determined by SNP Microarray.** *H. Risheg[1], W. Chung[2], I. Gadi[3], R. Pasion[3], S. Schwartz[3], J. Tepperberg[3], P. Papenhausen[3].* 1) Laboratory Corporation of America, Seattle, WA; 2) Childrens Hospital of New York, New York, NY; 3) Laboratory Corporation of America, Research Triangle Park, NC.

We report two cases with supernumerary mosaic ring chromosomes identified by SNP microarray. Case 1 is a 6 month old female with mild dysmorphic features, severe congenital microcephaly and constant ataxic movements. Case 2 is a newborn male with a prominent forehead, plagiocephaly, hypertelorism and low set ears. Chromosome analysis in Case 1 revealed a 45,X karyotype in 24/ 30 cells and 6/30 with 46,X,+r. High resolution SNP analysis revealed the presence of 1.2 copy dosage from Xp11.2 to q25 (bp: 54,908,000-128,500,000) consistent with approximately 20% mosaicism of the apparent *XIST* (Xq13) bearing ring X. Furthermore, the X chromosome copy dosage was 1.1 at the long arm distal extent of the dosage gain, suggesting that the ring reduced in size to the Xq24 (bp: 117,400,000) in about half of the cells with the ring. The reason for the apparent severity of the phenotype was not clear in a case that should have an inactivated X ring, however there could have been a problem with the function of the *XIST* gene. Microarray analysis consistent with a supernumerary ring chromosome in Case 2 again showed different size and dosage gains of chromosome 8. Cytogenetic/FISH analysis showed two supernumerary ring chromosomes which included the 8 centromere. The array showed different distal q11.22 dosage gain and are 4.44 Mb and 4.8 Mb in size. This agrees with the cytogenetics studies which showed mosaicism of the different sized supernumerary rings. Eight of 20 cells demonstrated one extra ring chromosome, while the remaining 12 showed two ring chromosomes. An extended region of allele homozygosity observed on chromosome 8 was also noted, suggestive of UPD. Subsequent chromosome 8 microsatellite analysis confirmed UPD8 of maternal origin and an apparent partial rescue from zygotic trisomy. Although there have been no confirmed imprinted genes reported for chromosome 8, the homozygotic stretch of genes may be subject to disorders due to pairing of recessive genes. There may also be residual effects of an early developmental presence of trisomy during the usual rescue etiology to UPD. Determining the exact structure of supernumerary ring chromosomes has always been problematic. These cases demonstrate the precision of high resolution SNP array in identifying small mosaic supernumerary chromosomes and the mechanistic insights of supernumerary ring formation which would not have been recognized by conventional cytogenetics.

### 1449/W/Poster Board #1107

**De novo 21q22.1q22.2 deletion including RUNX1 mimicking a congenital infection.** *L. Faivre[1], P. Callier[1], C. Tauvin-Robinet[1], I. Desguerres[2], A. Masurel-Paulet[1], N. Mejean[3], S. Falcon-Eicher[4], S. Bidot[5], F. Huet[1], M. Beri-Dexheimer[6], P. Jonveaux[6], F. Mugneret[1].* 1) Département de Génétique et Centre de Référence Anomalies du Développement et Syndromes Malformatifs, Hôpital d'Enfants, CHU Dijon, Frances, Dijon, France; 2) Neurologie Pédiatrique, Hôpital Necker-Enfants Malades, Paris, France; 3) Radiologie Pédiatrique, Hôpital d'Enfants, Dijon, France; 4) Cardiologie Pédiatrique, Hôpital d'Enfants, Dijon, France; 5) Ophtalmologie, CHU Dijon, France; 6) Génétique moléculaire et cytogénétique, Nancy, France.

Patients with partial monosomy 21 exhibit various phenotypes dominated by prenatal and postnatal growth restriction, severe developmental delay, abnormal muscle tone, a variety of dysmorphic facial features, and heart defects. Patients with deletions encompassing the RUNX1 gene on 21q22.12 can also present thrombocytopenia and a predisposition to acute myeloid leukemia. To date, molecular cytogenetic characterisation has been reported in only 4 patients with this syndromic thrombocytopenia. Here we report on a sporadic case of a 7-year-old boy who presented at birth with growth retardation, thrombocytopenia, atrial septal defect with non-obstructive, hypokinetic, hypertrophic cardiomyopathy, facial dysmorphic features and poor eye-contact. There was no history of infection during pregnancy and analyses for infection and immune cells were normal. Investigations revealed normal bone marrow, normal cytogenetic and metabolic investigations. Corpus callosum dysgenesis was evidenced, with absence of the central region, in favour of a clastic origin. At 4 months of age, the cardiomyopathy regressed and the platelet count spontaneously improved but he still needed nasogatric feeding. At one year of age, he could not sit and had poor eye contact. Hypermetropia microcornea, goniodysgenesis of the left eye with iridocapsular synechies and astigmatism were diagnosed. At 2 years of age, enamel dysplasia was evidenced. He walked at 6 years of age, but had no speech. Epilepsy was diagnosed. Growth hormone therapy was started but stopped because of unsatisfactory results on growth. The association of ocular synechies, central corpus callosum agenesis, enamel dysplasia, transient cardiomyopathy and fluctuating thrombocytopenia with normal results for infection analysis led to the conclusion that an undiagnosed congenital infection was the most likely diagnosis. Nevertheless, array-CGH 105K was performed and revealed a 2.8 Mb deletion on chromosome 21q22.1-q22.2 encompassing the RUNX1 gene. This finding correlates well with the presence of thrombocytopenia, facial dysmorphism, growth retardation and psychomotor delay, but the additional clinical and imaging features contribute further to the description of this new syndrome. This observation further emphasizes that the 21q22 microdeletion could be a novel cause of mental retardation, in which a platelet disorder would be a distinctive phenotypic manifestation.

### 1450/W/Poster Board #1108

**Determining X Chromosome Inactivation Patterns.** *B. Bertelsen, Z. Tümer, K. Ravn.* Kennedy Center, Glostrup, Denmark.

In X-linked recessive inherited disorders, only males manifest the disease features, whereas the female relatives are usually asymptomatic carriers. However, it is known that female carriers may also display clinical symptoms. In these cases, skewed X chromosome inactivation (XCI) has been considered to correlate with the manifestation of the symptoms. It is therefore important to investigate the XCI patterns in these females for clinical assessment and genetic counselling. To define the XCI pattern usually the androgen receptor (*AR*) gene residing at the Xq12 is used as a genetic marker. In this approach, a region within the first exon of the *AR* locus, containing two methylation sensitive *Hpa*II sites and a highly polymorphic CAG repeat, is used. The two X chromosomes are differentiated by the polymorphic CAG repeat, and their inactivation status is determined by their methylation difference at the *Hpa*II sites.This simple, fast and elegant method has been used successfully since 1992 to determine the XCI status of many females. However, the method has its limitations, as some females are not informative for the CAG repeat. In these cases, another polymorphic locus located at Xq28 (*FMR1*) can be used for investigation as it exhibits the same features as the *AR* in regards to methylation. The aim of the present study is thus to identify other differentially methylated polymorphic loci across the X chromosome. Through in silico screening of the Xchromosome we have identified several polymorphic loci with nearby sequences, which may be differentially methylated. These loci are currently being investigated for their methylation status in active and inactive X chromosomes. The most appropriate sites will be validated in families with known X-linked disorders where the female carriers are protected from the disease due to full inactivation of the mutated X-linked gene.

### 1451/W/Poster Board #1109

**Chracterization of SRY deletions in female horses with a 64,XY karyotype.** *T. Lear, R. McGee, E. Bailey.* Veterinary Sci, Univ Kentucky, Lexington, KY.

Disorders of sexual development afflict horses, as well as humans and other mammals. Although no cases of XY sex-reversal have been reported in dogs and cats, it is the most common form of sex-reversal reported in the horse. The phenotype of affected horses ranges from a feminine female (mare) with a reproductive tract within normal limits to a masculine mare that is large in stature. Affected horses have normal female genitalia but hypoplastic ovaries and uterus and are infertile. This condition has been found in many horse breeds and can occur sporadically or within families. Four mares, three Thoroughbred and one Standardbred, were presented for cytogenetic analysis due to the lack of estrous cycles and small, inactive ovaries. All four mares had a 64,XY karyotype. Subsequent FISH studies with a horse BAC containing the SRY gene were positive for three mares while PCR for SRY was negative in all four mares. Further studies by PCR determined the entire SRY gene was deleted from the Y chromosome in all four horses. The deletion encompassed approximately 33 Kb and occurred in a similar but not identical position on each horse Y chromosome. Sequencing across the deletion was unsuccessful suggesting a structural rearrangement had occurred on the Y chromosome. Since the deletions were similar in all four horses it is possible this region may be a hotspot for mutation leading to the deletion of the SRY gene. One thousand female horses under two years of age are being assessed to determine how prevalent this SRY deletion may be in the Thoroughbred horse population and if it has a familial component.

## 1452/T/Poster Board #1

**"Universal" Carrier Screening of Recessive Genetic Disorders by Next Generation Sequencing.** *S. Kingsmore, D. Dinwiddie, C. Bell, N. Miller, J. Crow, E. Ganusova.* Natl Ctr Genome Resources, Santa Fe, NM.

While individually quite rare, recessive genetic diseases together are a major medical burden and cause significant morbidity and mortality. 20-30% of infant deaths and 11% of pediatric hospital admissions are related to genetic disorders. Widespread carrier screening was first adopted for Tay-Sachs disease (TSD, #272800), resulting in greater than 90% decrease in incidence in North American Jewish populations. In collaboration with the Beyond Batten Disease Foundation, we are developing a carrier screening test for approximately four hundred autosomal and X-linked recessive (XLR) disorders causing high morbidity or mortality in childhood, such as Juvenile Batten Disease (#204200). Proof-of-principle studies of this "universal" carrier test have demonstrated accurate identification of XLR mutations: Genomic DNA samples from 18 patients with Pelizaeus-Merzbacher disease (#312080), Lesch-Nyhan syndrome (#300322), and Menkes disease (#309400), comprising different mutations, were evaluated. The mutation spectrum consisted of SNPs, nucleotide indels, and deletions of entire exons. Illumina sequencing libraries from the 18 samples were multiplexed, enriched for chromosome X exons and sequenced. Overall, 50 +/- 9% of sequences aligned to chromosome X exons, reflecting an average enrichment of 379-fold. A median of 627 megabases of sequence corresponded to at least 20-fold coverage of 61% of target sequences; depth of target coverage varied with depth of sequence (r2 0.96). Bioinformatic analysis using the Alpheus software system correctly identified the mutations and discovered two new mutations previously mischaracterized. A prototype "universal" carrier screening test is anticipated to be available in 2010 and to be available at similar cost to current molecular tests for single disorders.

## 1453/T/Poster Board #2

**Health Technology Assessment of Ashkenazi Jewish Carrier Screening Panels.** *D.J. Allingham-Hawkins, A.P. Lea, S. Levine.* Hayes Inc, Lansdale, PA.

Objectives: Carrier screening is performed to identify couples in which both members are carriers of alleles that cause a specific disorder so that affected couples can make informed reproductive choices. Several genetic laboratories currently offer genetic testing to screen for carriers of up to 12 autosomal recessive disorders known to occur in the Ashkenazi Jewish (AJ) population. This health technology assessment focused on defining an evidence-based set of criteria for inclusion of a test for a disorder in an AJ carrier screening panel (AJCSP) and determining which disorder tests meet these criteria. Methods: A literature search was performed to identify studies of genetic tests for disorders appropriate for successful screening in the AJ population. This evidence base was reviewed to identify characteristics associated with clinical utility of the screening tests using the ACCE model that was developed by the Centers for Disease Control and Prevention (CDC) specifically to evaluate genetic tests. Fifteen autosomal recessive disorders were evaluated with this approach. Results: The minimal criteria found to be most relevant to determining if inclusion of a test for a disorder in an AJCSP is warranted were: disorder causes significant mortality and/or morbidity; an allele frequency of 1:70 or greater; a relatively clear relationship between genotype and phenotype with high penetrance; and a screening test that detects at least 90% of alleles that cause the disorder. Tests for only 4 of the 15 disorders were found to meet all of these criteria: Canavan disease, cystic fibrosis, familial dysautonomia, and Tay-Sachs disease. Several societal and ethical factors were also found to be necessary in order for an AJCSP to be successfully implemented: voluntary participation of the AJ population; adequate access to educational materials and genetic counseling; and an informed consent process that allows couples to opt out of testing for any individual disorder based on personal beliefs. Conclusions: Although several genetic laboratories provide AJCSPs that include tests for up to 12 disorders, there is currently sufficient evidence of clinical utility to support the inclusion of testing for only 4 of these disorders. Furthermore, because of the ethical requirement of allowing couples to opt out of testing for individual disorders, genetic laboratories must be able to specifically select the tests to be performed based on patient request.

## 1454/T/Poster Board #3

**Early pregnancy hemoglobinopathy diagnostics in the Dutch city of The Hague. Provisional results and a new hemoglobin variant : Hb Den Haag [β45 CD4 (Phe →Tyr)].** *J.O. Kaufmann[1], C.L. Harteveld[1], M. Bakker-Verweij[1], A. Selles[2], S.G.J. Arkesteijn[1], P.W. Wijermans[3], J.L. Kerkhoffs[3], P.C. Giordano[1].* 1) Clinical Genetics, Leiden University Medical Center, Leiden, Zuid-Holland, Netherlands; 2) Midwife practice Anno, The Hague, The Netherlands; 3) Dept. of Hematology HAGA city Hospital, The Hague, The Netherlands.

To implement country wide carrier diagnostics for hemoglobinopathy in The Netherlands at the early pregnancy level a universal pilot is ongoing in the Dutch city of The Hague. We report here the provisional figures and a new abnormal hemoglobin found in 3 members of a family of Scandinavian origin. During the first pregnancy control HPLC based Hemoglobinopathy carrier diagnostics is offered in additional to the regular test for anemia analysis. Hb separations are done on Variant 2 and when needed molecular analyses is done by Gap-PCR, by direct sequencing and or MLPA. Carriers of frequent abnormal Hb (S, C, E, D) and β-thalassemia are regularly found in the immigrant population at risk and partner analysis follows rapidly to exclude or confirm risk and to offer prevention. Thus far of the 436 women included in this study, 6 were found to be carriers of HbS, 5 β-thalassemia, 4 α-thalassemia, 4 δ-thalassemia and 3 of a Hbvariant. This has lead to the discovery of 2 couples at risk of a child with a hemoglobinopathy (HbSS and HbSC) who were referred to genetic counseling. In this cohort a 34 years old woman of Scandinavian descendant presented with chronic hemolytic anemia. HPLC analysis revealed a partially separated fraction following HbA. Molecular diagnostics disclosed a TTT→TAT transversion at HBB:c.137 causing a Phe→Tyr single amino acid substitution at position 45 of the beta globin gene. Similar abnormalities previously described at the same position were reported associated with mild chronic hemolysis. We describe the hematological picture of the 6 members of the family, the biochemical and molecular data and we discuss a possible risk in association with the β°-thalassemia and HbS traits, very common in this country.

## 1455/T/Poster Board #4

**Prenatal diagnosis of rare δβ-thalassaemia following successful identification of deletional mutation by Multiplex Ligation-dependent Probe Amplification (MLPA).** *H.Y. Law[1,2], Y. Zhao[3], R.S. Roch[1], Y.M. Tan[2], A.H.M. Lai[1], I.S.L. Ng[1,2].* 1) Dept Pediatrics, KK Women's & Children's Hosp, Singapore, Singapore; 2) National Thalassaemia Registry, KK Women's & Children's Hospital, Singapore; 3) Dept Clinical Research, Singapore General Hospital, Singapore.

**Purpose:** A couple with history of β-thalassaemia was referred to National Thalassaemia Registry (NTR) for risk assessment. The wife had typical β-thalassaemia indices and DNA analysis identified IVSInt5 (G→C) mutation in β-globin gene. The husband's indices (MCV=73.5%, $HbA_2$=2.4, HbF= 19.1%) were indicative of δβ-thalassaemia carrier. However, routine analysis for deletions associated with δβ-thalassaemia and hereditary persistence fetal haemolgobin (HPFH) in local population were negative. To determine if the couple was at risk for thalassaemia intermedia/major, Multiplex Ligation-dependent Probe Amplification (MLPA) analysis was carried out to establish if the husband was a carrier of a large deletion in the β-globin gene cluster. **Methods:** MLPA kit (MRC-Holland SALSA P102HBB) for detection of deletion in β-globin gene cluster was used to establish the extent of gene deletion in husband and was subsequently used for prenatal diagnosis to confirm presence of the paternal δβ-thalassaemia in the chorionic villus sample (CVS). **Results:** MLPA found deletion of exon 3 in $\gamma^G$ and δ-globin genes, and the entire β-globin gene in husband's sample. Between the 2 partially deleted $\gamma^G$ and δ-globin genes was an intact region that included the entire $\gamma^A$ and pseudo-β globin gene. Prenatal analysis using reversed dot blot analysis found presence of maternal IVSInt5 (G→C) mutation and absence of normal allele in the fetus. MLPA confirmed presence of paternal deletion. This predicted the fetus to be a thalassaemia intermedia with hemizygous IVSInt5 (G→C)genotype. PCR using published protocol confirmed the deletion to be "Asian-Indian inversion-deletion" that caused δβ-thalassaemia. **Conclusion:** The MLPA kit is useful for detection of novel/rare deletion and is thus useful for risk assessment in couples present with δβ-thalassaemia or HPFH. It is particularly useful for prenatal diagnosis in a mixed ethnic population, as prior knowledge of the breakpoint or the extent of deletion is often not available in view of the wide spectrum of deletion reported in the β-globin gene cluster.

## 1456/T/Poster Board #5

**Factors influencing uptake of cascade carrier testing for cystic fibrosis.**
*S.A. Metcalfe[1,2], B.J. McClaren[1,2], R.J. Massie[1,2,3], D.J. Amor[1,2,4], MA. Aitken[1,2].* 1) Genetics Education & Health, MCRI, Royal Children's Hosp, Melbourne, Australia; 2) Dept Paediatrics, The University of Melbourne, Melbourne, Australia; 3) Respiratory Medicine Department, Royal Children's Hospital, Melbourne, Australia; 4) Genetic Health Services Victoria, Royal Children's Hospital, Melbourne, Australia.

In Victoria, Australia, carrier testing for cystic fibrosis (CF) is performed by a state-wide laboratory and counselling service. CF carrier testing is offered free to relatives of babies diagnosed with CF through newborn screening. Although cascade testing is known to detect carriers for CF, its effectiveness has been questioned because most babies with CF are born to couples who do not have a family history. Uptake of cascade carrier testing was audited by examining pedigrees of newborns diagnosed with CF between 2000 and 2004, and performing data linkage to the laboratory database records. Uptake of carrier testing amongst adult relatives was adjusted for clustering within families; uptake was less than 20%. The majority of relatives have not had cascade carrier testing despite being at high risk. We identified factors influencing uptake of CF carrier testing by administering a multi-generational survey to family members of children with CF. The questionnaire assessed knowledge of CF and carrier testing, attitude towards carrier testing, factors that influence a decision about carrier testing, and demographic information (age, sex, education, parity, future reproductive plans). The questionnaire was sent to 284 family members, with a response rate of 79%. Respondent demographics were: male:female (40%:60%); tested:non-tested (37%:43%). Of those tested, the proportions were: 24% aunts, uncles; 23% grandparents; 20% parents; 13% second cousins; 11% great aunts, uncles; 7% first cousins; 1% siblings (≥18yr). The majority of respondents (77%) answered ≥9 knowledge questions correctly (max. score 12 correct). The tested group had a higher knowledge score and more positive attitudes compared with the non-tested group, although overall both groups were positive about having carrier testing. The most commonly cited factors that may influence a decision to have carrier testing were influences of another person (having a carrier partner, partner's wishes and doctor's suggestion) and having a person in the family with CF. There was no major reason cited for not having testing. Open-ended responses from family members other than parents indicate that the main barrier to being tested was a lack of awareness that testing was available for them through the clinical service. Findings provide insight into the characteristics of family members who are tested and those who are not and inform clinical service delivery around offering carrier testing to family members.

## 1457/T/Poster Board #6

**Is reflex testing for the CFTR 5T/7T/9T polymorphism needed in R117H heterozygous cases?**
*I. Warshawsky[1], S. Horwitz[1], A. Bacevice[2].* 1) Pathology and Laboratory Medicine Institute, Cleveland Clinic Foundation, Cleveland, OH; 2) Obstetrics and Gynecology, Westlake, OH.

In 2001, the American College of Medical Genetics and American College of Obstetrics and Gynecology recommended a panel of cystic fibrosis transmembrane conductance regulator (CFTR) gene mutations and variants be tested as a part of population screening for couples planning a pregnancy or for those already pregnant. Included in these guidelines were: 1) reflex testing for the 5T/7T/9T polymorphism should be performed in R117H positive samples and 2) the reproductive partner of a carrier should be tested for CFTR gene mutations. The purpose of this study was to determine whether the 5T/7T/9T reflex test ever changed patient management. Thirty R117H heterozygous cases submitted for pregnancy carrier screening were identified. Electronic medical records were searched for CFTR mutation results in the reproductive partner. If this information was unavailable, letters were sent to the ordering physicians. Information was obtained in 17/30 cases (11 via electronic medical records, 6 responses to letter). In 11 cases, the father tested negative. In 5 cases, the father was not tested (the father refused testing (n=1), the woman refused to have the father tested (n=2), the father could not pay (n=1), unknown (n=1)). In one case, simultaneous screening of the husband and wife was performed: the husband was R117H heterozygous and the wife was negative; 5T/7T/9T reflex testing was not done in the husband. When physicians were contacted via letters, they were asked if the 5T/7T/9T testing provided helpful information. No responses to this question were received. 5T/7T/9T testing was done in 16/17 R117H positive cases (7T/7T (n=11), 5T/7T (n=4), 7T/9T (n=1)). No cases were found where the 5T/7T/9T results altered outcome. 5T/7T/9T testing should be done only if the partner of a R117H heterozygous individual is also a carrier and if 5T/7T/9T test results would alter decisions regarding prenatal testing or pregnancy termination. Eliminating upfront 5T/7T/9T reflex testing for R117H heterozygotes would save unnecessary test charges and potential confusion in interpreting and explaining the results to patients. For cases where the reproductive partner of a known R117H (or other CFTR gene mutation) carrier refuses testing, prenatal testing can be offered.

## 1458/T/Poster Board #7

**Outcomes and Experience of Spinal Muscular Atrophy (SMA) Carrier Screening on a Semen Donor Population.**
*P. Callum[1], R.E. Falk[2], J. Iger[1], M. Ray[1], C.A. Sims[1].* 1) Genetics, California Cryobank, Inc., Los Angeles, CA; 2) Cedars Sinai Medical Center, Los Angeles, CA.

Donor eligibility at our facility is determined in part by a genetic risk assessment: 3-generation pedigree, chromosome analysis, hemoglobinopathy and cystic fibrosis carrier screening. Ashkenazi Jewish carrier testing is completed if indicated. SMA carrier screening was added to our donor screening protocol in August 2008. Testing was performed on 258 semen donors and donor applicants. We identified 5 carriers, all of Caucasian, non-Jewish ancestry, representing 3% (5/172) of this population; 7 (4%) had 3 copies of SMN1. Three copies of SMN1 were detected in 5/36, 0/17, 2/9, 2/10, and 0/14 men of Jewish, Hispanic, African American, Asian, and other ancestries, respectively. Specimens from 4 of the 5 carriers were already available for use. Clients who purchased these specimens were informed of the donors' positive test results, clinical features of SMA, risk to offspring, and option of carrier screening. Formal genetic counseling was recommended. Some clients were appreciative; others were angry that this information was not identified during the donors' genetic evaluations. Surprisingly, of those who were most upset, many had not attempted to conceive a pregnancy while some who received the news more calmly were pregnant at the time of contact. Many clients pursued carrier screening, but were upset by the high cost of testing. One client was found to be a carrier for SMA. General population carrier screening for SMA is controversial, in part due to differing guidelines published by ACMG and ACOG and the limitations of this test. Given the high carrier frequency and severity of the disorder, SMA screening on gamete donors is useful for assessing donor eligibility and reducing risks for medical problems in offspring, despite the limitations. Our sample is too small to assess allele frequencies but other data indicates that counseling about SMA may be revised based on variable allele frequencies and residual risks for individuals of different ethnicities. While concern about increased medical risks to their offspring is understandable, the clients' reactions suggest that they do not comprehend the limitations of genetic screening. This finding supports the need for preconceptual genetic counseling for clients using donor semen yet these services do not appear to be well utilized. Further studies are indicated to determine if this patient population is unaware of the availability or utility of this service or if they are resistant to seeking counseling.

## 1459/T/Poster Board #8

**Spinal muscular atrophy carrier screening in a diverse population: pitfalls and promise.**
*K. Bajaj, P. Reingold, J. Powers, S. Klugman.* Montefiore Medical Center Division of Reproductive Genetics, Bronx, NY.

**Background:** Prenatal carrier screening for cystic fibrosis has proven to be a cost-effective, widely accepted practice. Spinal muscular atrophy (SMA) is a disorder characterized by degeneration of motor neurons. With a carrier frequency of 1 in 40, SMA is the second most common fatal autosomal recessive disorder after cystic fibrosis. The American College of Medical Genetics recommends universal prenatal SMA carrier screening because the disorder is severe, has a high carrier frequency, and can be diagnosed prenatally. Recently, the American College of OB/GYN released a committee opinion contradicting the ACMG stance, stating there is not enough data on patient counseling and utility measures to support universal SMA carrier screening. **Aim:** To ascertain patient understanding of SMA carrier screening after genetic counseling. **Methods:** All English or Spanish speaking women receiving genetic counseling at two of our outpatient centers were asked to participate in a 25 question survey. The survey assessed demographic data, had 5 questions about clinical features and prenatal diagnosis of SMA, and investigated the motivation behind patient screening choices. The responses were analyzed using standard statistical software. **Results:** 70 women completed the survey. The mean age was 32 years and 57% of respondents identified themselves as African-American or Hispanic. 74% were privately insured and 39% had a college degree or higher. 60% of subjects had not heard of SMA prior to their visit. 46% of subjects answered 4 or 5 post-counseling questions correctly; two-thirds of these women had a college degree or higher. 14% of patients declined SMA carrier screening, of which 80% answered 4 or more post-counseling questions correctly. The bulk of those that declined perceived the disorder as "too rare" or "didn't want to know" their carrier status. Of those opting for screening, 50% identified the desire to know their carrier status as the main reason for testing. Another 15% chose screening because they were having their blood drawn for other reasons. **Conclusion:** After formal genetic counseling, the vast majority of patients will opt for SMA carrier screening. In our experience, only half of women have an adequate understanding of the clinical features and prenatal diagnostic options related to the disease. Regarding SMA, there is great opportunity for development of educational tools to provide patients with a complete range of reproductive options.

## 1460/T/Poster Board #9

**Managing the demands of the increasing disease burden in NF1.** *A. Bergner[1], L. Jordan[1], A. Belzberg[2], J. Blakeley[1,3].* 1) Department of Neurology, Johns Hopkins University, Baltimore, MD; 2) Department of Neurosurgery, Johns Hopkins University, Baltimore, MD; 3) Brain Cancer Program, Johns Hopkins University, Baltimore, MD.

Background: Neurofibromatosis type 1 (NF1) is one of the most common autosomal dominant conditions affecting the nervous system. NF1 is defined as a progressive condition, and the increasing burden of disease with NF1 has been demonstrated by both the objective measurement of symptom prevalence and the subjective experience of patients and care providers. However, it is not clear how this increasing burden impacts the daily care coordination for patients with NF1 or whether the current delivery of healthcare services for these patients is adequate given the well-demonstrated progressive nature of their disease. Objectives: This study aimed to quantify the disease burden of NF1 by utilizing the number of referrals to ancillary studies and medical specialists that were required by pediatric and adult patients with NF1 as an objective marker of disease burden. Methods: Chart review was undertaken for 42 pediatric and 40 adult patients with NF1 who were seen consecutively for routine annual outpatient Neurology appointments within the Johns Hopkins NF Center between January 1 and December 31, 2008. The number of referrals and the services to which patients were referred were separately tallied for pediatric and adult patients and then compared. Results: 22 (55%) adult NF1 patients required 5 or more referrals at the time of their visit, while only 6 (14%) pediatric patients required the same (Chi square 13.6, p=0.0006). The mean number of referrals for a pediatric patient was 3.4 (SD=1.17) and for an adult patient was 5.13 (SD=1.81) (Student's test, t=5.1, p<0.0001). Conclusions: On average, adult patients with NF1 required significantly more ancillary studies and medical specialists to manage complications related to their diagnosis than pediatric patients. These results provide further support for the understanding that the burden of disease with NF1 increases over time. Medical providers that work with adult patients with NF1 are likely to experience the increasing burden of this disease through the greater need for ancillary studies, procedures and medical management. This information can assist medical providers in planning for the comprehensive medical care that is needed by the majority of adult patients with NF1. It also has further implications for health systems utilization and costs, and is important to recognize as new technologies are developed to better diagnose and treat patients with NF1.

## 1461/T/Poster Board #10

**Expanding the Multidisciplinary Care of CDH1 Carriers.** *D. Patel, K.M. Shannon, M. Jacobs Gabree, G. Chan-Smutko.* CCRA, MGH, Boston, MA.

Hereditary diffuse gastric cancer (HDGC) syndrome is a genetic disorder that increases an individual's risk of developing diffuse gastric cancer and female breast cancer. Approximately one third of families with a clinical diagnosis of HDGC harbor germline mutations in the E-cadherin gene, also known as CDH1. Females with CDH1 mutations have an 83% risk of developing diffuse gastric cancer as well as a 39-52% risk of developing lobular breast cancer. Male carriers are at a 68% risk for diffuse gastric cancer. Given the limited effectiveness of screening, prophylactic total gastrectomy is considered to be the only definitive intervention to prevent death from gastric cancer. Our experience at Massachusetts General Hospital is that the majority (4/6) of unaffected individuals who tested positive for a familial mutation in CDH1 have undergone prophylactic gastrectomy. Through post-operative genetic counseling we have identified various issues that extend beyond genetic testing and risk assessment for the family and require additional specialty services outside of the MGH Center for Cancer Risk Assessment. We have developed a multidisciplinary, comprehensive care program to address the needs of individuals with CDH1 mutations. Female carriers are referred to a breast cancer genetics specialist to discuss the options of increased breast screening and risk-reducing bilateral mastectomy. Parents are referred to the MGH PACT (Parenting at a Challenging Time) team who has been helpful in assessing parents' motivation for testing minors and has been able to discuss with parents ways to approach the topic of genetic testing with their children. To address the issue of behavioral management with respect to eating post-gastrectomy, individuals are referred to the MGH Weight Center. The Weight Center is comprised of experts including physicians, nutritionists, and psychologists who understand weight problems and eating habits and can offer guidance to patients with respect to nutrition, meal planning, and expected behavioral changes post-gastrectomy. Given their experience in treating patients with food dependency, this team will be better equipped to offer long-term strategies for emotional adjustment after surgery. We expect that the integration of breast health care services, child psychiatry, and weight center clinicians will provide the necessary comprehensive approach to the longitudinal care of CDH1 carriers.

## 1462/T/Poster Board #11

**Cost Savings through Molecular Diagnosis for HHT.** *R.E. Pyeritz[1], D. Asch[2], C. Zayac[1], S. Keddem[1], B. Bernhardt[1].* 1) Penn Center for the Integration of Genetic Healthcare Technologies, University of Pennsylvania, Philadelphia, PA; 2) Leonard Davis Institute of Health Economics, University of Pennsylvania, Philadelphia, PA.

Hereditary hemorrhagic telangiectasia (HHT) is an age-dependent, autosomal dominant disorder that can cause major morbidity and premature death. Early diagnosis enables preventive measures that greatly improve outcomes. Mutations in at least six genes can cause HHT, but clinical testing is available for only 3. Patients with clinically verified HHT have a detectable mutation in ENG or ALK1 in ~80% of cases. We have found mutation analysis useful for confirmation of diagnosis and screening relatives who are at 50-50 risk. However, patients, providers and insurers often question the need for DNA testing. One previous study found a cost-savings of 1915 Canadian dollars per HHT family by pursuing mutation detection; however, the cost structure of many aspects of health care is different from the U.S. We conducted a cost-minimization analysis comparing the costs of screening at-risk relatives by accepted clinical methods (clinical evaluation for signs of HHT, brain MRI and contrast echocardiogram followed by chest CT if positive) vs. determining the proband's mutation followed by testing at-risk relatives for the proband's mutation if found, and then performing clinical screening only on relatives who have the mutation. We modeled 100 probands with 400 relatives and assumed full compliance. Costs were actual Blue Cross/Blue Shield reimbursements for 2009 in our region. We assumed the relatives were young, which means that negative or equivocal clinical testing requires periodic follow-up until either the diagnosis is established, or the person reaches young adulthood and is likely to be truly unaffected because of lack of clinical involvement. We assumed that genetic testing would detect a pathogenic mutation in 80% of probands. The clinical model resulted in total costs of $8,426,920, while the molecular diagnosis model resulted in total costs of $3,556,228. Because of the assumptions made, we are conducting sensitivity analyses to set upper and lower bounds on these costs. Nonetheless, the more than two-fold cost savings of mutation detection of probands provides strong evidence for cost savings through DNA testing.

## 1463/T/Poster Board #12

**Closing the Loop and Opening Vistas: A Conference to Explore the Genetic Counseling Needs and Experiences of *BRCA* Carriers and Their Families.** *C.R. Huizenga[1], D.J. MacDonald[1], S.R. Sand[1], K.R. Blazer[1], K. Hurley[2], J.O. Culver[1], K.C. Banks[3], J.N. Weitzel[1].* 1) Clinical Cancer Genetics, City Hope Comprehensive Cancer Ctr, Duarte, CA; 2) Clinical Genetics Service, Memorial Sloan-Kettering Cancer Ctr, New York, NY; 3) Cancer Genetics Program, St. Joseph Hospital, Orange, CA.

Patients seen for genetic cancer risk assessment services (GCRA) in our institution indicated on long-term follow-up surveys a need for ongoing information and support after testing is complete. A key challenge is that dissemination of updates through a newsletter or other media would not provide opportunities for questions or support, and limited resources preclude additional visits. To address this challenge, we invited patients back for an all-day conference. Information was delivered through podium presentations, expert and patient panel discussions and interactive breakout sessions to: 1) explore GCRA-related experiences and needs and 2) share medical advances in risk assessment, management and treatment, current research, and information and resources for individuals genetically predisposed to breast and ovarian cancer. Invitees were individuals who completed GCRA at City of Hope or collaborating regional facilities between 1998-2008 and carried a *BRCA1/2* mutation or variant of uncertain significance (VUS), and their family members. Mixed methods research (surveys and discussion directed by Audience Response System (ARS) interaction) was used to explore participant GCRA experiences and needs. All 79 participants answered ARS questions and 70 (89%) completed a voluntary survey. Most survey responders were female (84%; mean age, 48 years); 64% were *BRCA* positive, 4% had a VUS, and 32% were non-carrier relatives, spouses, or friends. Fifty-seven percent had a personal history of cancer, primarily breast (86%) and ovarian cancer (20%). The majority of participants expressed that at least some information provided during GCRA was overwhelming (68%) and that the GCRA process evoked anxiety or worry (59%), particularly regarding unexpected parental transmission guilt and concern for relatives. Needs for an additional appointment (62%) and updates on cancer risk (71%), screening and prevention (74%), and cancer genetics (60%) were expressed. Participant ideas for GCRA process improvement included: 1) sending more information prior to the appointment; 2) placing more emphasis on bringing a spouse or significant other to the appointment; and 3) allowing more time to digest test results before discussing risk management. Ongoing information needs beyond *BRCA* result disclosure and risk management recommendations can be effectively met through large group format. Clearly, the Closing the Loop conference concept is an effective way to improve the GCRA process.

### 1464/T/Poster Board #13

**Use of X-linked Short Tandem Repeats Loci to Confirm Mutations in Parentage Caseworks.** *D.P. CHEN[1,2], C.P. TSENG[2,3], S.H. TSAI[1], M.C. WANG[1], S.C. LU[1], T.L. WU[1], P.Y. CHANG[1], C.F. SUN[1,4].* 1) Department of Laboratory Medicine, Chang Gung Memorial Hospital, Tao-Yuan, Taiwan; 2) Department of Medical Biotechnology and Laboratory Science, Chang Gung University, Taoyuan County, Taiwan; 3) Graduate Institute of Medical Biotechnology, Chang Gung University, Taoyuan County, Taiwan; 4) Department of Pathology, School of Medicine, Chang Gung University, Taoyuan County, Taiwan.

Background: Analysis of short tandem repeat (STR) has become widespread in routine for parentage test. However, the accuracy of STR is sometimes interfered by the presence of microsatellite mutations. Analysis of other DNA markers such as the HV1 and HV2 hypervariable regions of mitochondrial DNA or the Y-STR becomes essential to settle the noncongruence. Owing to the limited polymorphism of mitochondrial DNA and the time-consuming nature of the test, we investigated here the use of X-chromosome STR (X-STR) to resolve the maternity disputes. Methods: At first, the STR mutation frequencies among 4758 Taiwanese individuals were analyzed. Population data were obtained from randomly selected 99 females and 101 males to setup the X-STR database. Two families with a mismatch of one allele in autosomal STR analysis were subjected to the X-STR test to explore its clinical application. Results: The STR mutations occurred in all 15 autosomal STR loci with the exception of TH01 and TPOX. The mutation rates could reach as high as 0.106% for the D8S1179 and D18S51 loci. As to the X-STR frequencies, the p-values for DXS7132, DXS981, DXS6789, DXS101, and HPRTB were 0.1471, 0.0019, 0.0025, 0.1427, and 0.1167, respectively. By linkage analysis, 33 and 34 different haplotypes were revealed for DXS101-DXS6789 and DXS7132-DXS981, respectively. Furthermore, two cases with one allele mismatch in routine parentage test were resolved by performing X-STR analysis. Conclusion: Typing of X-STR markers is recommended for parentage test when one or two alleles mismatch is present or when the samples are difficult to be analyzed.

### 1465/T/Poster Board #14

**The impact of 'uninformative' BRCA1/2 genetic test results on health professionals, caring for affected and unaffected women with a significant breast cancer family history.** *A. Ardern-Jones[1], R. Kenen (joint first author)[2], E. Lynch[3], R. Doherty[4], R. Eeles[1,4].* 1) Dept Genetics, Royal Marsden NHS Trust, Sutton Surrey, United Kingdom; 2) The College of New Jersey, Department of Sociology and Anthropology, New Jersey, USA; 3) The Royal Melbourne Hospital, Melbourne, Australia; 4) The Institute of Cancer Research, Cotswold Rd, Surrey, UK.

The professional specialists who care for breast cancer patients with uninformative BRCA genetic test results, as well as their unaffected high risk female relatives - geneticists, genetic counsellor/nurses, oncologists, gynaecologists and breast surgeons, are an understudied group. We conducted a small qualitative study that investigated women who had developed breast cancer under the age of 45 and who had received the information that their BRCA1/2 genetic test results were inconclusive, thus no pathogenic mutation had been identified despite a significant family history of breast cancer. We interviewed 12 health professionals who were involved in the care of such women and their families. We conducted three focus groups with thirteen women - those affected with breast cancer who had undergone testing, as well as their unaffected sisters/daughter who had not had any testing. We asked them questions regarding their understanding and reactions to the inconclusive test result of their affected sister/mother. The majority of the women had a good grasp of the meaning of their own, or a sister's inconclusive result, but a few indicated some misunderstanding. A difficult issue for professionals caring for such families relates to prophylactic surgery, mainly for the unaffected women, but also for the affected women. Affected women have an increased risk of contralateral breast cancer as well as ovarian cancer, if ovarian cancer is present in the family. The unaffected women in this study were mostly concerned about breast cancer risk and options. The professionals were sensitive to the difficulties in explaining an inconclusive result to the cancer patient who has had the test. Some felt frustrated that technology had not as yet provided them with a better tool for prediction of risk. For the most part, the professionals believed that they should support the women in whatever management decisions they consider, provided these decisions were based on a complete and accurate understanding of the current limitations of the genetic test. The Hospital's Clinical Research Committee and Local Regional Ethics Committee approved the study.

### 1466/T/Poster Board #15

**A different key mutation among their family members in Familiar Neurofibromatosis Type1.** *Y. Jo[1], H. Kim[1], H. Song[2], K. Yoon[1].* 1) Dept. of Biochemistry and Mol.biology(BK21 project),School of Medicine, kyungHee univ.,; 2) Dept. of Orthopedics, Korea Univ.,Guro hospital, Seoul, Korea.

Neurofibromatosis Type1 (NF1) is a one of the most common autosomal dominantly inherited disorder, and NF1 (MIN162200) gene maps to chromosome 17q11.2. The main clinical features od the disease are café-au-lait spots, cutaneous neurofibromas, hamartomas of the iris (Lisch nodules), optic or chiasma glioma, and pseudoarthrosis. Almost everyone who inherits the NF1 gene has clinical features of the disease by the age of five years. The majority of sporadic mutations in neurofibromatosis type1 arise in paternally inherited alleles. The aim of this study was to investigate the pathogenic genes related to NF1 in 15 families with typical NF1 patients. We have analyzed 15 families, as 37 samples. RNA samples from these families' peripheral blood ware analyzed using RT-PCR and nucleotide sequencing with 12 primer sets including whole coding region. All patients had the premature termination codon involved premature formed protein. About 46% patients, 17 of 37, had multi site deletions or both deletion and insertion mutations. , 10 families' mutations had same pattern mutations but almost had multi site mutation have not identity. In these families, some progeny has more deletion site (2 cases) or larger deletion (2 cases) and others had fewer deletions (8 cases) than their proband. 1 family, members are 2 sons and mother, has not shown the inheritance, but brothers are same mutation site. 1 family, members are 2 sons and father, has not shown the irregular inheritance, one has spontaneous mutation, another has inheritance from the father and same mutation, spontaneous mutation, form his brother. Interestingly, many family members (10 of 15 families) are little difference mutation site, and their key mutations, as the shortest premature formed mutation, are different between progeny and parents. In this series of familiar studies, we reported the novel mutation and different key mutation in the family members. Some inheritance genetic mutation diseases are not from their parents or probands, because NF1 genes have very high rates (50%) of spontaneous mutation. These mutations caused abnormal transcript and premature termination of the mutation alleles. And we find many exon skipping appearance for splicing errors. Then we provide new information for pathogenesis of NF1 patients and assist in identifying the NF1 mutations in NF families.

### 1467/T/Poster Board #16

**Real World Experience with Cancer Genetic Counseling via Telephone.** *R. Sutphen[1,2], B. Davila[1], H. Shappell[2], T. Holtje[1], S. Vadaparampil[1], S. Friedman[1,4], M. Toscano[3], J. Armstrong[3].* 1) Dept Med Gen, H Lee Moffitt Cancer Ctr, Tampa, FL; 2) Informed Medical Decisions, Inc; 3) Aetna, Inc; 4) FORCE: Facing Our Risk of Cancer Empowered.

**Purpose:** One barrier to cancer genetic counseling and testing is the lack of access to genetic counselors. Recent studies suggest that telephone genetic counseling may be an effective delivery model, but published experience to date is largely confined to research in academic centers. We provided cancer genetic counseling via telephone, through a pilot project for employees of Aetna, Inc., a national insurer with approximately 35,000 employees nationwide. Knowledge transfer, behavioral intentions, and patient satisfaction were assessed by survey after genetic counseling.

**Methods:** All Aetna employees received email notification of availability of cancer genetic counseling via telephone as a covered benefit and were provided a link to a brief online hereditary cancer questionnaire. Individuals identified as having potential risk for inherited cancer based on the screening questionnaire were invited to schedule a telephonic genetic counseling session conducted by board-certified genetic counselors employed by Informed Medical Decisions, Inc., a national genetic services provider. After the session, respondents were asked to complete an online survey.

**Results:** 397 individuals completed the questionnaire. 39 proceeded with telephone genetic counseling, and 22 completed the follow-up survey. One third reported prior discussion about inherited cancer risk with their primary care provider (PCP). Twenty percent had an accurate perception of their personal cancer risk at baseline. After counseling, 94% reported understanding of their risk for cancer and 87% were aware of available risk-reduction strategies. Among high-risk respondents, 87% intended to engage in risk-management interventions. 93% reported high satisfaction with the service provided. 66% indicated they would not have pursued genetic counseling if it was not available by phone.

**Conclusion:** Results suggest telephone counseling is a viable option for increasing access to genetic experts. Telephone counseling increases knowledge of cancer risk, motivates intention to change relevant health-related behaviors, and elicits a high satisfaction level. Consequently, Aetna now offers telephone cancer genetic counseling to its 16 million members nationwide as a covered benefit.

## 1468/T/Poster Board #17

**Integration of genetic counseling and testing into a Parkinson disease clinic: Assessment of patient knowledge, attitudes, and interest.** *D. Clay Falcone[1], E. McCarty Wood[1], P. Ahimaz[2], V. Van Deerlin[1].* 1) Center for Neurodegenerative Disease Research, University of Pennsylvania, Philadelphia, PA; 2) Genetic Counseling Program, Arcadia University, Glenside, PA.

Parkinson disease (PD) is a neurodegenerative condition characterized by tremor, rigidity, postural instability, and bradykinesia. The most common genetic contributor to both familial and sporadic late-onset PD is the leucine-rich repeat kinase 2 (*LRRK2*) gene. The discovery of *LRRK2* has significantly changed the landscape for PD genetics and clinical *LRRK2* genetic testing is available. In order to effectively integrate *LRRK2* genetic testing into clinical practice, an effective strategy tailored to the PD population must be developed. We assessed 126 individuals with Parkinson disease for baseline knowledge of basic genetics principles and PD genetics, interest and opinions regarding genetic counseling and testing options, as well as levels of concern regarding a possible familial risk. A structured patient interview was developed after a literature review of previously published tools in the field of adult-onset genetic conditions and was administered to patients seen at the Parkinson Disease and Movement Disorders Clinic at Pennsylvania Hospital, Philadelphia, PA. Knowledge responses were graded based on both the correct response and demonstration of concept understanding. Participants had an average knowledge score of 58% (range 32%-92%). For concept understanding, the majority of participants demonstrated understanding of Parkinson disease, gene functions and mutations, and risk factor genes, but did not demonstrate an understanding of Parkinson disease genetics, such as *LRRK2*, and genetic testing concepts. Only 11% of respondents had heard of *LRRK2*; 32% had heard of genetic testing for PD. While 71% of respondents thought it was likely they had inherited a PD gene, only 41% thought it was likely other family members would develop PD. The majority (64%) of respondents did not have any concerns about genetic testing and 88% believed genetic testing for PD would be useful. Fifty-seven percent of respondents were interested in obtaining genetic testing for PD and 51% were interested in a genetic counseling program for PD. These results indicate that there is a significant level of interest in genetics and genetic testing options within the PD patient population, but also highlight a considerable deficit in genetics knowledge as well as an over-estimation of gene carrier status. Genetic education and counseling tools to address these needs were developed to provide PD patients with the ability to make informed and knowledge genetic testing decisions.

## 1469/T/Poster Board #18

**Effectiveness of a visual media presentation as a decision aid tool for pregnant women considering early prenatal screening tests.** *S. Demsey[1], D. Rada[2].* 1) Dept. of Genetics, Kaiser Permanente Med Ctr, Bellflower, CA; 2) Dept. of Genetics, Kaiser Permanente Med Ctr, Fontana, CA.

Pregnant women are faced with multiple complex choices for prenatal screening and diagnosis. Providers of prenatal care have only limited time to discuss the options with their patients. For this reason, an alternative method for educating patients was considered. A narrated and animated PowerPoint presentation (video) was created to give prenatal patients complex information about options of early screening and testing for birth defects. In addition to factual information regarding timing, methods and accuracy of the screening options, the video posed questions intended to allow the viewers to consider their personal values regarding diagnostic testing and risk factors to aid in their decision process. METHODS: The subject population was composed of women over 18 years of age who presented for prenatal care in the first trimester to two different OB clinics at our institution. The women who participated in the study were English speaking between the ages of 20-44 years, half of whom were over 35 years of age. Subjects were given a questionnaire to assess knowledge before and after viewing the video. Data was analyzed with paired t-test. RESULTS: 16/44 (36%) of respondents answered all questions correctly or answered only one question incorrectly prior to the presentation, indicating a high baseline level of knowledge. The average score of correct answers before watching the media presentation was 77%; the average score of correct answers after watching the video was 85% which represents a significant improvement (p=0.02). Before watching the video, 98% (43/44) of subjects could correctly identify that there is an increased risk of chromosome anomalies in pregnancies of women over 35 years of age. However, even with this knowledge, 75% of the women over age 35 considered themselves "low risk" for chromosome defects prior to the educational video. 5/18 (28%) women over age 35 changed their perception of risk to "high risk" after the informational presentation. Questions regarding the timing and risks of diagnostic testing were answered incorrectly most often both before and after watching the video.-CONCLUSIONS: Participants stated the content, tone and organization of the presentation was "helpful, clear and thought provoking". Clients present for prenatal screening with predetermined values and assumptions. Additional studies could assess how these values affect client choices and learning about prenatal screening and diagnostic testing.

## 1470/T/Poster Board #19

**The telephone clinic model facilitates rapid BRCA genetic testing for patients with advanced cancer who are eligible for PARP-inhibitor clinical trials.** *K. Kohut[1,2], K. Myhill[1], S. Thomas[1], E. Bancroft[1,3], P. Fong[1,3], S. Kaye[1,3], J. de Bono[1,3], T. Yap[1,3], R. Eeles[1,3], S. Shanley[1,3].* 1) Clinical Academic Cancer Genetics Unit, The Royal Marsden NHS Foundation Trust, London, United Kingdom, SM2 5PT; 2) Barts and The London School of Medicine, London, United Kingdom, EC1M 6BQ; 3) Drug Development Unit, Institute of Cancer Research, Royal Marsden Hospital, Sutton, SM2 5PT.

Introduction: Genetic testing can have a vital impact on cancer patient management with respect to surgical decision-making and, more recently, targeted chemotherapy options. The telephone clinic model was initially a pilot study to triage all new GP referrals to Cancer Genetics with the aim of offering a more flexible and efficient service in a setting and time span to best suit patient needs. This model has been adapted for urgent clinical care of patients eligible for a new form of chemotherapy in the context of a clinical trial. The PARP inhibitors are a class of drugs that specifically target DNA repair-deficient tumours such as those caused by an inherited mutation in the BRCA1 or BRCA2 gene. In such trials, there is a need to provide genetic testing and advice quickly for patients with advanced cancer who may benefit from targeted treatment. Alternative methods of counseling and testing need to be explored in order to meet the changing needs of cancer patients. Methods: New referrals were reviewed by senior staff and appointments for a telephone clinic consultation were arranged where appropriate. Results: Eighteen patients were referred to the Cancer Genetics Unit for genetic assessment as part of eligibility evaluation for for a Phase I trial of PARP inhbitors in advanced cancer. Seventeen were eligible for BRCA mutation analysis and of these, six were found to have a mutation and one to have a variant of uncertain significance. Results were provided within three weeks of referral, and generally, result provision was by telephone. Conclusions: Rapid genetic testing of the BRCA1 and BRCA2 genes is facilitated by the use of a telephone clinic and fast turn-around time from the laboratory. Rapid entry into a PARP inhibitor clinical trial was made possible. Patients were relieved to have access to a fast test and appreciated not having to attend additional in-person appointments when dealing with an advanced cancer diagnosis.

## 1471/T/Poster Board #20

**An internet-based approach to enhance genetic data discovery in ALS.** *C.A. Brownstein, T.E. Vaughan, M.P. Massagli, P. Wicks, J. Heywood.* Research and Development, PatientsLikeMe, Cambridge, MA.

Purpose: Patients with familial ALS (FALS) have a strong need to understand their illness and the impact of genetics on their outcomes. To meet this need, a novel disease-focused social network (PatientsLikeMe.com) was used to investigate the variability in clinical phenotype and disease progression due to different ALS-causing mutations, with the aim of sharing this information with patients. Methods: Genetic data-capture capabilities were added to PatientsLikeMe.com, and all active members of the ALS community were asked to submit their genetic mutation, if known. A genetics search engine was launched on the site so patients could identify others with the same mutation. Clinical features of the mutation-carrying cases were summarized and compared with the published literature. Results: Fifty percent of Familial ALS (N=227) patients responded to a request to tell PatientsLikeMe any genetic information they had on their disease, including "no mutations found". Eighteen community members with 12 different mutations submitted their genetic mutations and self-report clinical outcome scores. The most frequently reported mutations were SOD1 A4V (N=4), SOD1 D90A (N=4), and the VAPB mutation P56S (N=3). Preliminary analysis indicate that D90A patients lost 0.22 points per month on the self-report Amyotrophic Lateral Sclerosis Functional Rating Scale, Revised (ALSFRS-R)(SE 0.06, CI95%: -0.40, -0.05), SOD1 A4V patients lost an average of 1.2 points per month (SE 0.5, CI95%: -2.5, 0), and VAPB P56S mutation patients had an average loss of 0.30 points per month (SE 0.16, CI95%: -0.82, 0). By comparison, Sporadic ALS patients with no genetic information (N=1727) had a mean loss of 0.68 points per month (SE 0.01, CI95%: -0.71, -0.66). Conclusions: Even with a small sample size, trends rapidly become visible in ALS progression rates due to different mutations. Our hope is that sharing this information with patients who want it will help them plan for and anticipate future disease progression. Using the internet to aggregate groups of patients by specific mutation criteria allows for the international sharing of predictive outcomes based on historical data. This presents the possibility of real time distribution of new information to improve clinical understanding and communication. Making patients the driver of this communication medium means that they become educated and engaged, and can more effectively contribute to research and their own clinical management.

## 1472/T/Poster Board #21

**The psychosocial impact on healthcare professionals managing fetal abnormality.** *M.A. Menezes[1,2], M. Sahhar[2,3], J. Hodgson[1,2], S.A. Metcalfe[1,2].* 1) Genetics Education & Health Research, Murdoch Childrens Research Institute Parkville, Victoria, Australia; 2) Department of Paediatrics, University of Melbourne Parkville, Victoria, Australia; 3) Genetic Health Services Victoria, Royal Children's Hospital Parkville, Victoria, Australia.

Approximately 4% of pregnancies in Victoria, Australia each year are diagnosed with a fetal abnormality. Healthcare professionals working in prenatal settings are often involved in the diagnosis and/or counseling of patients at risk of fetal abnormality who are facing a decision as to whether or not to continue their pregnancy. This potentially raises professional, ethical, moral and legal issues for healthcare professionals working in this field, and could lead to feelings of stress and/or 'burnout'. This study aims to explore the experiences of healthcare professionals who work with fetal abnormality and to identify any support systems currently used and/or needed. A qualitative approach was used in this study. Over 40 semi-structured, in-depth interviews have been conducted with healthcare professionals who work with fetal abnormality including clinical geneticists, genetic counselors, obstetricians, maternal fetal medicine specialists, midwives etc. Interviews were audiotaped, transcribed verbatim and analyzed using thematic analysis. Participants identified a range of challenging situations they encounter in their work. Most participants believe that working with fetal anomaly has an impact on their daily lives, particularly when pregnant themselves. Pregnancy presented a unique challenge for healthcare professionals and many reported an increased risk perception resulting in their being worried about their own pregnancy fairly early on. Participants reported breaking bad news to be one of the most difficult areas of their work. They found the act of breaking bad news to be difficult and reported that unprepared patients complicated this process. Genetic healthcare professionals were more comfortable with breaking bad news and reported having more formal training in this area. Many participants discussed at length the emotional nature of working with patients in crisis. Working with fetal abnormality appears to have a substantial impact on healthcare professionals, both personally and for the workforce as a whole. This study identifies that additional training on breaking bad news would be beneficial to healthcare professionals working with fetal abnormality. The training received by genetic healthcare professionals could be used as a model for non-genetic trained healthcare professionals working with fetal abnormality and support could be put in place, particularly when healthcare professionals are pregnant themselves.

## 1473/T/Poster Board #22

**HUNTER: Development of a mnemonic screening tool for Hunter Syndrome using data derived from the Hunter Outcome Survey (HOS).** *G.M. Cohn[1], I. Morin[2], D.A.H. Whiteman[1] on behalf of the HOS Investigators.* 1) Shire, HGT Cambridge, MA; 2) Global Outcome Surveys, Shire HGT, Cambridge, MA.

**Introduction**: Hunter syndrome (mucopolysaccharidosis II, MPS II) is a rare, X-linked multisystem disorder that is caused by a deficiency in the activity of the lysosomal enzyme, iduronate-2-sulfatase (I2S) that leads to the lysosomal accumulation of dermatan sulfate and heparan sulfate in affected organs. Signs and symptoms of Hunter syndrome generally develop during the first decade of life, though age of onset and rate of clinical progression are variable. A recent publication of Hunter Outcome Survey data suggests that the median age of diagnosis of MPS II is 3.5 years and that a 1.4-year median lag exists between the initial onset of signs and symptoms and eventual diagnosis. As newborn screening for MPSII is lacking, this delay in diagnosis may reflect a decreased awareness of this rare condition among primary care providers as well as the challenge of diagnosing this complex disease of diverse signs and symptoms. **Objectives**: To address the issue of delayed diagnosis we have developed a screening tool, HUNTER: H (Hernia, Hearing) U (Unusual facies) N (Nasal obstruction) T (Tongue & Tonsils enlarged) E (Enlarged liver & spleen) R (Respiratory compromise, Range of motion decreased) that is a weighted mnemonic score (score 0-16) based on prevalence data of the most common signs and symptoms found at diagnosis and recorded in HOS. **Results**: This screening tool was initially applied to data derived from a random sample of 25 patients enrolled in HOS, and following modification, was applied to data from a second random sample of 25 HOS patients. The modified screening tool correctly identified over 95% of the MPS II patients at a score (six) unlikely to identify individuals unaffected by a mucopolysaccharidosis. The modified tool was then applied to data of a larger cohort of 237 HOS patients. Over 95% of patients were again correctly identified using a score of six. The median (P10-P90) score for patients $< 2$, 2 to 4, and $\geq 4$ years old at diagnosis was 12 (7-16), 13 (8-16), and 13 (7-16), respectively. **Conclusion**: The HUNTER mnemonic had a sensitivity of over 95% at a score unlikely to identify individuals unaffected by MPS. Validation in a clinical setting is required to determine its utility as a reliable clinical screen for MPS II. This approach highlights the potential benefit of utilizing patient registry data in the development of tools that may assist physicians in the diagnosis and management of rare genetic disorders.

## 1474/T/Poster Board #23

**Two new bioinformatics tools to help in distinguish neutral variations from pathogenic mutations.** *G. Collod-Beroud[1,2], F-O. Desmet[1,2], M. Lalande[1,2], M.Y. Frederic[1,2], D. Hamroun[3], M. Claustres[1,2,3], C. Beroud[1,2,3].* 1) INSERM, U827, Montpellier, F-34000 France; 2) Université MONTPELLIER1, UFR Médecine, Montpellier, F-34000 France; 3) CHU Montpellier, Hôpital Arnaud de Villeneuve, Laboratoire de Génétique Moléculaire, Montpellier, F-34000 France.

Approximately, half of gene lesions responsible for human inherited diseases are due to an amino acid substitution, showing that this mutational mechanism plays a large role in diseases. In another hand, if these mutations usually have a direct impact on proteins, an increasing proportion is now believed to impact mRNA splicing and to be responsible for genetic diseases. They mostly involved donor or acceptor splice sites but synonymous, non-synonymous or even nonsense mutations can also create and/or disrupt splice sites or auxiliary splicing sequences. Being able to distinguish neutral sequence variations from those responsible for the phenotype is of major interest in human genetics. Since in vitro validation of mutations is not always possible in diagnostic settings, indirect arguments must be accumulated to define if an exonic or intronic variation is causative. To further differentiate harmless variants from pathogenic nucleotide substitutions, we developed two new tools: 1) The **UMD-predictor® tool** provides a combinatorial approach that includes: localization at the protein level, conservation, biochemical properties of the mutant and wild type residues and the potential impact of the variation on mRNA (http://www.umd.be). 2) The **Human Splicing Finder (HSF) web resource** is dedicated to the prediction of mutation's impact on splicing signals and/or the identification of these motifs in any human sequence. It contains all available matrices for auxiliary sequences prediction, new Position Weight Matrices to evaluate the strength of 5' and 3' splice sites as well as branch point sequences (http://www.umd.be/HSF/ ). These tools have been extensively tested on a thousand of exonic and intronic mutations from more than 15 genes and have given very accurate predictions (99.4% positive predictive value, 95.4% sensitivity and 92.2% specificity for exonic mutations; accurate predictions of 93% of branch point inactivating mutations; accurate prediction of all pathogenic mutations affecting donor or acceptor splice sites including +3 and +4 positions; accurate identification of auxiliary splicing motifs when available). These two tools could therefore help to rapidly scan for pathogenic mutations both for clinical and research purposes. They could be used to filter the numerous variations produced by large scale sequencing research programs such as the new solid sequencing technologies.

## 1475/T/Poster Board #24

**The inbred Bedouin population of southern Israel: from disease gene identification to massive carrier screening.** *O.S. Birk[1,2].* 1) Genetics Inst, Soroka Med Ctr, Beer-Sheva, Israel; 2) Morris Kahn Laboratory of Human Genetics, National Institute for Biotechnology in the Negev, Ben Gurion University, Beer-sheva, Israel.

The Bedouin population of southern Israel (~170,000) is unique in its combination of extreme inbreeding within tribes (~60% first or second cousin marriages) and an average of 8-9 children per couple, with many males having two or three wives. As a consequence, there is an extremely high incidence of both common and novel autosomal recessive diseases, taking a dramatic toll on this community. We have embarked on a massive research initiative leading to the discovery of 10 novel disease genes over the past 5 years, as well as several dozen mutations in previously known disease genes. The research is done in-house using cutting edge technology, with a major part of the team designing our own software for SNP data analysis as well as for selection of candidate genes from within a disease-associated genomic locus. Some of the severe neurological diseases whose molecular basis we have recently deciphered include lethal congenital contractural syndrome (arthrogryposis) types II and III, mitochondrial complex 3 deficiency, infantile neuroaxonal dystrophy and the novel genomic-imprinting Birk Barel syndrome. Based on our findings, we initiated a government-financed free carrier testing operation, making use of the existing network of maternity clinics. A significant effort has been made also in educational programs from highschool through adulthood. The combination of the massive research initiative leading to the massive free carrier testing had a major impact, with a dramatic fall in infant mortality in this community from 17/1000 to 8/1000 over the past 3 years. As the mutations we find are often common to other Arab populations, we are now seeking collaborative projects to share our experience with others to the benefit of Arab communities elsewhere.

## 1476/T/Poster Board #25

**Manchester Project to Eradicate Sickle Cell Disease.** *I.H. Ejebe[1], F. Gibson1[1], K. Mason[1], G. Serjeant[1, 2].* 1) Sickle Cell Trust Kingston, Jamaica; 2) Southern Regional Health Authority Ministry of Health.

Sickle cell disease (SCD) results from the inheritance of abnormal hemoglobin genes from both parents, and its frequency at birth is determined by the frequency of these genes in the population. In Jamaica, these abnormal genes are the sickle cell (HbS) trait in 10%, the HbC trait in 3.5% and the beta thalassaemia trait in 1.5%. Therefore 15% or 375,000 Jamaican are at risk of having a child with a type of SCD which occurs once in every 150 births. Can any of these births be prevented? In Bahrain, a programme of voluntary screening in place for the last 10 years, has halved the frequency of births with SS disease. The Manchester Project is a 5-year pilot project of school education and student screening coupled with newborn screening in the Manchester Parish of Jamaica. Gel electrophoresis and HPLC are used to detect abnormal hemoglobin. The newborn screening project began in August 2008 in three different Manchester hospitals and has screened over 2,700 babies (91% coverage) and detected 20 babies with sickle cell disease. A survey of 100 mothers at the Mandeville Hospital maternity ward revealed over 95% of the mothers felt that this free service was important for their child. The student-screening program couples sickle cell disease education with optional screening and genetic counseling. The program has screened 5th and 6th form students in 15 different secondary schools in the Manchester Parish. In the 2007-2009 school years 4,748 students have been screened (75% coverage) with the detection of 691 abnormal hemoglobin types. A survey of students that opted out of the test showed that fear of the pain of the needle was a significant reason opting out of testing.

## 1477/T/Poster Board #26

**Development of a Rapid Genetic Screening Panel for the Southern Californian Persian Jewish Community.** *C.A. Riley-Portuges[1], J.R. Lopategui[1], M.M. Kaback[3], D.L. Rimoin[2].* 1) Pathology, Cedars-Sinai Medical Center, Los Angeles, CA; 2) Medical Genetics Institute, Cedars-Sinai Medical Center, Los Angeles, CA; 3) Department of Pediatrics, University of California, San Diego, San Diego, CA.

Introduction: Genetic screening for mutations common in the Ashkenazi Jewish population is widely accepted, but has not been developed for Persian Jews (PJ), despite their having a number of unique prevalent founder mutations. We developed SNP detection assays for 3 common PJ diseases with known founder mutations. : Hereditary Inclusion Body Myopathy (HIBM, mutation: M712T); Autoimmune Polyendocrinopathy Syndrome Type I (AIRE, mutation: Y85C); and Pseudocholinesterase deficiency (BCHE, mutation: D70G). These conditions are considered appropriate as potential candidates for community- based screening as each of these conditions is either avoidable (BCHE), treatable (AIRE) or preventable (HIBM). In Israel, carrier frequencies among PJ are reported as: 1:12 for HIBM; 1:50 for AIRE; and 1:9 for BCHE. PJ residing in the United States may have slightly different frequencies due to differences in migration patterns. To verify the presence of these mutations in the Southern California PJ community, and to evaluate the feasibility of targeted community-based screening, we genotyped a group of 86 asymptomatic persons of Middle Eastern Jewish descent referred for Tay Sachs carrier testing and 111 individuals previously electing HIBM carrier screening. Methods: 86 anonymous patients of Middle Eastern Jewish descent had genomic DNA isolated using Qiagen QIAamp kit. An additional 111 DNA specimens were provided by HIBM Research Group (HRG, Encino, CA), 11 of who were homozygous for HIBM. DNA was quantitated by spectrophotometry and normalized to 25 ng/μl. Each SNP was analyzed using a single primer pair and wild type and mutant allele specific probes in Quantitect Probe master mix (Qiagen, Valencia, CA). Results: All samples yielded interpretable genotypes for the 3 SNPs tested. Of 197 total samples tested, 18/197 were identified as heterozygotes (het) for HIBM; (2/86 and 16/111 in the 2 sample sets); 5/197 were het for AIRE (2/86 and 3/111 in the 2 groups); and 17/197 were mutation positive for BCHE (8/86 and 9/111 in the 2 groups). Conclusions: Our results demonstrate the feasibility of PJ carrier screening for HIBM, AIRE and BCHE in the Southern California PJ community. We are planning a large population survey, which will allow a more accurate determination of the heterozygote frequencies of these and other conditions in this population, without ascertainment bias, and where interventions are feasible.

## 1478/T/Poster Board #27

**Susceptibility mutations and aminoglycoside-induced deafness in high-risk newborns.** *E. Sartorato[1], P. Andrade[1], J. Bergmann[1], V. Moraes[1], M. Azevedo[3], M. Câmara[2].* 1) CBMEG, Universidade Estadual de Campinas, Campinas, SP, Brazil; 2) Departamento de Fonoaudiologa, Universidade de Fortaleza, UNIFOR, Fortaleza, CE, Brazil; 3) Departamento de Fonoaudiologia, Universidade Federal de São Paulo, SP, Brazil.

An early diagnosis has been a priority in the audiological practice. Identifying the hearing loss until 3 months old and make an intervention before 6 months old minimizes the impact of auditory loss in the health and communication development of these children. Nonsyndromic sensorioneural hearing loss (NSHL) affects 1 in 1000 births. The prevalence of profound bilateral deafness elevates from 1 per 1000 newborns to 20-40 per 1000 when neonatal intensive care unit (NICU) newborns are considered. Mutations in the mitochondrial DNA have also been found to be associated with NSHL and some of them with aminoglycoside-induced deafness. The aims of this work were to determine the etiology of the hearing loss in children admitted into Neonatal Intensive Care Unit (NICU) and compare with other factors, mainly ototoxic medication. The subjects were divided in four groups in order to elucidate the etiology of their hearing impairment and the bases of aminoglycoside ototoxicity. Group A - 25 newborns at risk with aminoglycoside-induced and sensorineural non-syndromic hearing impairment. Group B - 25 newborns at risk with aminoglycoside-induced and normal hearing. Group C - 25 full term newborns with sensorineural non-syndromic deafness and no history of ototoxy medication. Group D - 25 full term newborns with normal hearing and no history of ototoxy medication. All groups were screened for A7445G, G7444A, A1555G, C1494T, A827G, T961G and 961delT/insC mitochondrial mutations, del(GJB6-D13S1830) and del(GJB6-D13S1854) in the GJB6 gene, and mutations in the GJB2 gene. Our findings suggest that in these cases the deafness is not related to susceptibility mutations and ototoxy medication in NICU pre-term newborns.

## 1479/T/Poster Board #28

**Screening Hemoglobinopathies by High Performance Liquid Chromatography in a Filipino population.** *C.L.T. Silao[1,2], M.L.T. Naranjo[3], M.L.E. Leporgo[3], C.D. Padilla[1,2], E.dJ. Yuson[3].* 1) Institute of Human Genetics, National Institutes of Health Philippines, University of the Philippines Manila; 2) Department of Pediatrics, College of Medicine-Philippine General Hospital, University of the Philippines Manila; 3) Thalassemia Center of the Philippines, Dr. Fe Del Mundo Medical Center, Manila, Philippines.

Background: The hemoglobinopathies are a heterogeneous group of congenital hemolytic anemias, which include hemoglobin (Hb) variants, thalassemia and hereditary persistence of fetal hemoglobin. Thalassemias and hemoglobinopathies, a group of autosomal recessive inherited human disorders, are prevalent in many parts of the world. The automated cation-exchange High Performance Liquid Chromatography (HPLC) system is a sensitive and precise method for detecting thalassemia and abnormal Hbs. A pilot study using this system was conducted to determine the prevalence of hemoglobinopathies in the Philippines. Methods: Blood samples from two hundred eighty-five (285) randomly selected healthy individuals and individuals suspected to have thalassemia or a particular hemoglobinopathy, irrespective of age and gender, were collected during the local celebration of World Thalassemia Day in May 2008 and were subsequently screened for thalassemias and hemoglobinopathies using the HPLC system (VARIANT TM, BioRad). Results: Of the 285 samples, 35 (12.3%) were shown to have beta thalassemia with high A2, 19 (6.6%) had beta thalassemia with normal A2, and 14 (4.9%) had beta thalassemia with E interacting. Four (4) subjects were found to be heterozygous E and one (1) subject was found to be homozygous E. Interestingly, 3% of the samples yielded results suggestive of alpha thalassemia. Conclusion: A significant proportion of thalassemias among randomly selected Filipino subjects were noted. The HPLC method was found to essential for rapid screening of beta thalassemia and hemoglobinopathies. This is important for proper clinical management/counseling and for early and precise diagnosis.

## 1480/T/Poster Board #29

**Combination of SMN2 copy number and NAIP deletion predicts disease severity of spinal muscular atrophy in Northern China.** *Y. Zhang, Y. Luo, L. Cao, S. Wang.* Medical Genomics, China Medical University, Shenyang, Liaoning, China.

OBJECTIVE: Spinal muscular atrophy (SMA) is an autosomal recessive neuromuscular disorder caused by decreased levels of survival motor neuron protein (SMN). In the majority of cases, this decrease is due to absence of the SMN1 gene. The SMN2 gene is highly homologous to SMN1 and has been reported to be correlated with severity of the disease. The clinical presentation of SMA varies from severe to mild, with four clinical subtypes (type I, type II, type III and type IV) that are assigned according to age of onset and severity of the disease. In this study, we aim to investigate the potential association between the number of copies of SMN2 and the deletion in the NAIP gene with the clinical severity of SMA in patients of Northern Chinese origin. METHODS: Multiplex ligation-dependent probe amplification (MLPA) is a modern quantitative molecular method. Applied in SMA cases, it improves diagnostics by simultaneously identifying the number of copies of several target sequences in the SMN1 gene and in nearby genes. Forty-one probable SMA cases were examined by MLPA and those carrying deletions of the SMN1 gene were enrolled in the study. Altogether thirty-one SMA patients (3 of type I, 24 type II, 3 type III and 1 type IV) were selected. SMN2 and NAIP copy number were determined by MLPA. RESULTS: One type I patient carried one copy of SMN2, while the other two carried 1.5 copies. Among the type II SMA patients, 8 percent (2/24) of cases carried 1.5 copies of the gene, while 92 percent (22/24) carried 2 or 2.5 copies of SMN2. All the type III patients carried three copies and the asymptomatic type IV patient carried four copies. Deletion analysis of NAIP showed that two type I SMA patients had a homozygous deletion of this gene, while the other one had a heterozygous deletion. Only one out of 24 type II SMA cases carried a homozygous deletion, while all the other type II patients had a heterozygous deletion. All type III patients carried intact copies of the NAIP gene. CONCLUSION: There exists a close relationship between SMN2 copy number and SMA disease severity, suggesting that the determination of SMN2 copy number may be a good predictor of SMA disease type. Furthermore, NAIP gene deletion was found to be associated with SMA severity. In conclusion, combining the analysis of deletion of NAIP with the assessment of SMN2 copy number increases the value of this tool in predicting the severity of SMA.

## 1481/T/Poster Board #30

**Mutation analysis of ATP7B gene in Korean patients with Wilson disease.** *B.Y Kim[1,2], C.H. Lee[2], E.S. Park[2], J.S. Lee[2].* 1) BK 21 Project for Medcal Sci, Graduate Sch Yonsei Univ, Seoul, Korea; 2) Dept Clinical Genetics, Yonsei Univ Col Medicine, Seoul, Korea.

Wilson disease is an autosomal recessive disorder of copper transport that results in accumulation of copper primarily in the liver, the brain and the cornea. The incidence of the disease is between 1 in 35,000 and 1 in 100,000 live births, and caused by mutations in the ATP7B gene. The ATP7B gene encodes for a membrane copper transport protein. In this study, we examined the ATP7B gene in 61 Korean patients with Wilson disease. Genomic DNA was obtained from peripheral leukocytes and coding regions of the ATP7B gene were amplified using PCR followed by direct sequencing. We have identified 11 different mutations in 28 Wilson disease patients: Gln717Term, Arg778Leu, Ala874Val, Thr1029Ile, Gly1035Val, Leu1083-Phe, Val1216Met, Asn1270Ser, c.2304dupC, c.2695_2721del27bp, IVS13+5G>C. The Arg778Leu mutation is the most common mutation in Korean patients with Wilson disease. Eleven different mutations were detected in exon 8 (Gln717Term, c.2304dupC, Arg778Leu), exon11 (c.2695_2721del27bp, Ala874Val), exon14 (Thr1029Ile, Gly1035Val), exon15 (Leu1083Phe), exon17 (Val1216Met), exon18 (Asn1270Ser) and intron 13.

## 1482/T/Poster Board #31

**Bloodspot based genetic testing identifies a high prevalence of bi-allelic *GJB2* mutations from infants who fail newborn hearing screening.** *L.A. Schimmenti[1], B. Warman[1], A.M. Jurek[2], K.A. Daly[3], M.R. Schleiss[2], J.A. Ross[2], S.A. Berry[1], M. McCann[4].* 1) Department of Pediatrics, Institute of Human Genetics, University of MInnesota, Minneapolis, MN; 2) Department of Pediatrics, University of MInnesota, Minneapolis, MN; 3) Department of Otolaryngology, University of Minnesota, Minneapolis, MN; 4) Minnesota Department of Public Health, St. Paul, MN.

**Background:** Newborn Hearing Screening (NHS) is performed at the infants's bedside with automated devices that test functional hearing. Despite nearly universal screening, about half of all infants who fail NHS do not return for follow-up evaluation. To determine the prevalence of bi-allelic *GJB2* mutations in bloodspots from infants who fail and pass NHS, we performed a pilot study using anonymous residual newborn screening bloodspots. We tested the hypothesis that genetic screening would detect a greater prevalence of bi-allelic *GJB2* mutations in bloodspots from infants who fail than in a control group of bloodspots from infants who pass NHS. We also tested the hypothesis that we would identify bloodspots from infants with bi-allelic mutations in *GJB2* that escape detection by NHS. **Methods:** We performed a case-control study comparing the prevalence *GJB2* mutations from anonymized bloodspots. Over a 22-month period, we analyzed 1177 bloodspots from infants who failed NHS in both ears and 1177 contemporaneously selected control bloodspots from infants who passed NHS. Mutation analysis was performed by allele specific melt curve analysis for common mutations 35delG, 167delT, 235delC, and V37I. Bi-directional sequencing of *GJB2* exon 2 was performed on samples identified to have one mutant allele by melt curve analysis, an abnormal melt curve, or samples from ethnic groups where common mutations are not typically identified. This study was performed with the approval of the Institutional Review Boards of both the University of Minnesota and the Minnesota Department of Health. **Results:** The prevalence of bi-allelic *GJB2* mutations in a cohort of bloodspots from infants who failed NHS was 22 in 1177 while the prevalence of bi-allelic *GJB2* mutations from a control group of spots was 2 in 1177 ($p<0.0001$). **Conclusions:** There are a significant number of bloodspots from infants who fail NHS harboring bi-allelic *GJB2* mutations. This high prevalence emphasizes the need for follow-up of all infants who fail NHS as nearly 1 in 50 will have bi-allelic mutations in *GJB2*. Bi-allelic *GJB2* mutations were identified in bloodspots from infants who pass NHS. These results demonstrate that infants who pass NHS could still be at risk for hearing loss and that molecular screening approaches may be preferable to functional NHS for identification of genetic etiologies of hearing loss. *Funding: March of Dimes.*

## 1483/T/Poster Board #32

**Molecular Results and Deaf Community Identification in GJB2-Associated Deafness: Relationship Between DNA and Culture.** *J.L. Deignan[1], P. Boudreault[2], E. Baldwin[3], M. Fox[4], Y. Kobayashi[2], J.J. Zhou[5], J.S. Sinsheimer[5], W.W. Grody[4,5,6], C.G.S. Palmer[3,5].* 1) Medical Genetics Institute, Cedars-Sinai, Los Angeles, CA; 2) Deaf Studies Department, CSU Northridge, Northridge, CA; 3) Department of Psychiatry and Biobehavioral Sciences, UCLA, Los Angeles, CA; 4) Department of Pediatrics, UCLA, Los Angeles, CA; 5) Department of Human Genetics, UCLA, Los Angeles, CA; 6) Department of Pathology, UCLA, Los Angeles, CA.

The most common genetic cause of nonsyndromic sensorineural deafness worldwide is sequence variation in the GJB2 gene, encoding the protein connexin 26. Around 100 protein truncating (T) and non-protein truncating (NT) GJB2 variants have been described, with truncating variants more likely to result in audiograms in the severe-profound range compared to non-truncating variants. The recent availability of genetic testing for deafness has caused some concern within the Deaf Community since deafness is not considered a disability but is one component that defines themselves, their families, and their culture. An affiliation with either the Hearing or Deaf Community is an important aspect of cultural identity, and many factors participate in shaping this affiliation. One aspect that has not been previously analyzed is how genetic variants for deafness relate to a deaf individual's affiliated community. In our cohort of 202 deaf and hard-of-hearing adults drawn from regions of California, we sequenced exons 1 and 2 of GJB2, tested for a common deletion in the GJB6 gene, and assessed cultural affiliation using questionnaires. A majority (55%) of our subjects reported an affiliation with the Deaf Community, 9% with the Hearing Community, and 34% with both communities; 85% self-identified as deaf, 10% as hard-of-hearing, and 5% as hearing impaired. The frequency of truncating alleles was 38%, with 35delG being seen in 30% of Caucasians (78% of our sample), 9% in Hispanics, and 0% in other ethnic groups, while each of the other allele frequencies fell below 8%. We identified two novel variants (delF141, -3177C>T), and the GJB6 deletion was rarely observed (0.5% of alleles). Biallelic GJB2 variants were found in 40% of our subjects; the most common genotype was 35delG homozygosity (18%). The genotypes of those with biallelic GJB2 variants were categorized based on protein truncation [T/T (87%), T/NT (9%), NT/NT (4%)], and a homozygous truncating genotype was found to be significantly correlated with both a self identification as deaf (FE $p=0.006$, $n=79$) and a preferential identification with the Deaf Community (FE $p<0.001$, $n=79$). This is the first study to empirically associate the functional nature of an individual's deafness-causing variants as a factor related to both self identification and community affiliation, which underscores the importance of fully examining the ethical and social issues raised by genetic testing for deafness.

## 1484/T/Poster Board #33

**Prenatal genetic counseling in fetuses with mosaic 45,X/isodicentric Y. Is this Turner syndrome?** *C.L. Blout[1], S.E. Hickey[1], B.D. Rink[1,2], J.F. Atkin[1,2].* 1) Dept Gen, Nationwide Children's Hosp, Columbus, OH; 2) The Ohio State University, Columbus, OH.

Isodicentric Y is a common structural abnormality of the Y chromosome. Individuals with this condition often have a 45,X (Turner syndrome) cell line in addition to their isodicentric Y due to the unstable nature of an isodicentric chromosome. Depending on the nature of the structural abnormality and the level of mosaicism individuals can present as normal males, normal females, or ambiguous genitalia with or without a Turner-like phenotype.

We present three families with isodicentric Y mosaicism, including monozygotic twins, who were prenatally ascertained with ultrasound abnormalities. Their prenatal diagnosis and postnatal outcomes illustrate the complexity of counseling patients with this condition.

Family 1: Baby prenatally diagnosed with hypoplastic left heart syndrome (HLHS). Amniocentesis revealed an abnormal karyotype ultimately confirmed to be mosaic 45,X/isodicentric Y. Clinical evaluation confirmed female gender with absence of other Turner stigmata. Family 2: Monochorionic, diamniotic twin gestation with both fetuses appearing female by ultrasound at 18 weeks gestation. Twin A presented with a cystic hygroma, heart defect, club feet and developed hydrops with intrauterine fetal demise around 28 weeks. Twin B had no known prenatal anomalies detected until the labia appeared edematous during a 33 week ultrasound. Postnatally the neonate demonstrated ambiguous genitalia with palpable but undescended gonads and hypospadias. Karyotype revealed mosaic 45,X/isodicentric Y. The parents identified Twin A as female and elected male gender assignment for twin B. Family 3: Baby prenatally diagnosed with HLHS, mitral valve stenosis, and ambiguous genitalia. Amniocentesis revealed an abnormal karyotype of mosaic 45,X/isodicentric Y. Neonatal exam confirmed male gender with bilateral cryptorchidism.

Our families represent the gender spectrum associated with this complex karyotype which makes prenatal genetic counseling difficult. Presentation may be consistent with clinical Turner syndrome, but gender assignment should not be made until the baby is evaluated after birth with the help of an experienced team of subspecialist physicians.

## 1485/T/Poster Board #34

**Array CGH characterizes abnormal prenatal karyotypes and identifies chromosome imbalances missed by conventional cytogenetics.** *J. Coppinger, B.A. Bejjani, R. Schultz, L.G. Shaffer, B.A. Torchia, A.N. Lamb.* Signature Genomic Lab, Spokane, WA.

Microarray-based CGH (aCGH) has become a routine test in the neonatal/postnatal setting for the characterization of suspected genetic disorders. The use of this technology in a prenatal setting, however, has been limited. We performed aCGH on 68 prenatal cases that had previous findings of either abnormal karyotype or abnormal FISH. Sample types included 54 cultured amniotic fluids (79.4%), nine cultured CVSs (13.2%), four direct amniotic fluids (5.9%), and one DNA specimen from cultured CVS (1.4%). aCGH characterized all 20 cases submitted with previous findings of aneuploidy, suspected deletions or additions, suspected variant 16p or unbalanced translocations detected by karyotyping and/or FISH. In addition, aCGH identified unexpected clinically significant imbalances in three of these cases. Nearly half of the specimens were submitted because of full or mosaic marker chromosomes (45.6%). Of these, aCGH identified and further characterized the marker chromosome in 7/13 non-mosaic cases, and in 7/18 mosaic cases. The marker chromosome cases not identified are interpreted as composed of heterochromatin, regions not represented on the array or undetectable due to the low level of mosaicism. Benign CNVs (7.4%) and results of unclear significance (2.9%) were found with equal frequencies on the BAC-based and oligo-based platforms. Our data demonstrate that array CGH is an important diagnostic tool to further characterize chromosome imbalances identified prenatally by karyotyping or FISH, and to identify clinically significant imbalances that conventional cytogenetics did not detect. In many circumstances, such as cases with non-mosaic marker chromosomes, a normal aCGH result can provide added reassurance that the abnormality is either balanced or composed of heterochromatic material. Pre-test genetic counseling is critical to prepare parents for the possibility of normal aCGH results, or for abnormal clinically significant results that may or may not be related to the chromosome abnormality detected by karyotyping or FISH, or for results of unclear clinical significance. In some cases pregnancy outcome may be difficult to predict even if aCGH further characterizes the chromosome abnormality.

## 1486/T/Poster Board #35

**A severe congenital brain disorder explained by microarray.** *R. Forbes[1], R. Leventer[3,2], G. McGillivray[1,2].* 1) Genetic Health Services, Royal Children's Hospital, Victoria, Australia; 2) Murdoch Children's Research Instiute, Royal Children's Hospital, Melbourne, Aust; 3) Dept Neurology, Royal Children's Hospital, Melbourne, Aust.

We describe the clinical phenotype and genetic counselling issues in a female patient with a del(5)(q31.2q31.3) microdeletion. She presented in the neonatal period after term delivery with marked central hypotonia, poor suck, abnormal movements, hiccough and an encephalopathy with altered level of consciousness. She has mild dysmorphic features, profound motor and intellectual disability, visual impairment with enlarged optic discs and dystonic movements and posturing. The initial MRI brain scan showed immature frontal gyration and abnormal white matter. Subsequent scans showed cystic lesions of the basal ganglia and internal capsule, delayed myelination and cerebral atrophy. Developmental assessment at two years was consistent with profound motor and intellectual disability, but not regression. Multiple metabolic investigations including mitochondrial biopsies were normal. SNP microarray (Affymetrix SNP 6.0) subsequently diagnosed a 3.36 Mb microdeletion of 5q containing 89 known genes. We discuss family issues and psychosocial impact of this diagnostic information.

## 1487/T/Poster Board #36

**Novel and recurrent mutations in the *NF1* gene in 44 Korean patients with neurofibromatosis type 1.** *H. Kim[1,2], J.M. Ko[1,2], G.N. Baek[1], Y.C. Kim[3], L.M. Messiaen[4].* 1) Ctr Gen Disease, Ajou Univ Hosp, Suwon, Korea; 2) Dept of Medical Genetics, Ajou Univ Hosp, Suwon, Korea; 3) Dept of Dermatology, Ajou Univ Hosp, Suwon, Korea; 4) Dept of Medical Genetics, University of Alabama at Birmingham, Birmingham, Alabama, USA.

Neurofibromatosis type 1 (NF1) is one of the most common autosomal dominant disorders in humans. NF1 is caused by mutations in the *NF1* gene. Mutation detection is complex due to the large size of *NF1* gene, the presence of pseudogenes and the great variety of lesions. Numerous studies have looked at genotype-phenotype correlation, however, there was no obvious genotype-phenotype correlation has been found in NF1. In order to assess the *NF1* mutation spectrum and genotype-phenotype relationship in Korean NF1 patients, we screened 48 (16 for familial and 32 for sporadic cases) unrelated Korean patients for mutations in the *NF1* gene. The mean age of diagnosis was 22.5 yr (range; 2 - 45 yr) in familial cases and 14.7 yr (range 0.2-58 yr) in sporadic cases. Mutation analysis of the entire coding region and flanking splice sites was carried out, and included the use of a combination of FISH and MLPA. Thirty nine distinct *NF1* mutations were identified in 44 (91.7%) patients. Causative mutations were detected in all patients having positive family history, and we could not find any mutations in 4 of 32 patients without family history. The mutations included 22 single base substitutions (9 missense and 13 nonsense), 10 splice site mutations, 3 small deletions, 2 small insertions, and 2 large deletions. Twenty (51.3%) mutations have been previously reported in other studies and 19 (48.7%) mutations were novel. c.6792C>A was found in three patients, and c.2033_2034insC, c.4537C>T, c.5546G>A were identified in each two patients. These four recurrent mutations were already reported mutations. The mutations are evenly distributed across exon 3 through intron 47 of the *NF1* gene and no mutational hot spots were found. The mutation spectrum shown in our study was similar to those of other reports performed in different ethnic background. This analysis revealed a wide spectrum of *NF1* mutations in Korean patients. A genotype-phenotype correlation analysis suggests that there is no clear relationship between specific *NF1* mutations and clinical features of the disease. As technologies advance in molecular genetics, mutation detection rate will become higher. Considering that about 50% of detected mutations were novel, exhaustive mutation analysis of the *NF1* seems to be one of the important tools in early diagnosis and genetic counseling, especially in young NF1 patients without family history.

## 1488/T/Poster Board #37

**Identification of a putative region associated with primary microcephaly through SNP array analysis in a consanguineous family.** *J. Wiszniewska, S-H.L. Kang, R. Pace, C.M. Eng, A. Patel, C.A. Bacino.* Dept Molecular & Human Genetics, Baylor College of Medicine, Houston, TX.

Chromosomal Microarray Analysis (CMA) is a sensitive method for the detection of genomic gains and losses, and a widely available clinical tool to help establish a diagnosis. Recent implementation of SNP arrays in clinical diagnostics allows not only for the detection of copy number changes but also enables identification of copy neutral changes such as uniparental disomy, and absence of heterozygosity (AOH) that occur through identity by descent. It may also help elucidate rare genetic syndromes due to recessive conditions in consanguineous families. Here we describe two male siblings, from a consanguineous family who presented with identical phenotypes including congenital microcephaly. The two brothers were evaluated because of severe microcephaly and moderate to severe developmental delay. The family history reveals that both parents were consanguineous, first cousins once removed. The 8 yr old has a head circumference (FOC) of 45.5 cm (below the 3rd centile, 50th centile for 9 months). He can follow simple commands, but has few words and is not toilet trained. The 5yr old brother had an FOC at 16 months of age of 39.5 cm (less than 3rd centile, 50th centile for 2 1/2 months). He has moderate developmental delay. Extensive genetic and metabolic testing was undertaken and failed to identify an underlying genetic condition. Subsequently, both siblings were analyzed by a SNP array (Illumina 610Quad) in order to identify common regions of absence of heterozygosity. SNP array did not detect any abnormalities in copy number however continuous regions of copy neutral AOH were present on several chromosomes in both children and were consistent with parental consanguinity. Only two regions of AOH showed overlap in both siblings, approximately 14Mb on 9q12-q21.21 and approximately 15Mb on 19q12-q13.31. Interestingly, the region of AOH on chromosome19 includes a previously mapped primary microcephaly (MCPH2) locus. Primary microcephaly (MCPH) is a genetically heterogeneous autosomal recessive neurodevelopmental disorder that is linked to at least 7 loci of which four MCPH genes have been identified thus far. Given the AOH was found in both siblings, it is possible that both are homozygous for a mutation in yet unidentified MCPH2 gene mapping to this region. These results demonstrate that analysis by SNP arrays is a useful clinical tool to narrow the region of interest and can be potentially valuable for gene discovery.

## 1489/T/Poster Board #38

**Pena-Shokeir syndrome : uncommon ins/del mutation in RAPSN gene.** *V. Benoit[1], U. Ullmann[2], C. Verellen-Dumoulin[1], P. Hilbert[1].* 1) Human Genetic Center, Inst Pathology & Gen, Charleroi, Belgium; 2) Centrum Medische Genetica, Universitair Ziekenhuis, Brussel, Belgium.

Pena-Shokeir syndrome is a rare early lethal autosomal recessive disorder mainly characterized by neurogenic arthrogryposis, facial and brain anomalies, polyhydramnios and lung hypoplasia. This syndrome was first described to be a deformation sequence caused by a reduction of foetal movements in the uterus (FADS, foetal akinesia deformation sequence). These manifestations are usually severe, and death occurs during pregnancy, at birth or in the neonatal period of life. Mutations in the RAPSN gene are usually associated with congenital myasthenic syndrome but reports also underlined RAPSN mutations in Pena-Shokeir syndrome We reported on the identification of a new causing mutation in the RASPN gene for two Pena-Shokeir affected male foetuses from consanguineous parents (first cousins). The first foetus died in utero at 29 weeks of gestation. He had generalized oedema, overlapping fingers, bilateral pulmonary hypoplasia and bilateral pleural effusion. An amniocentesis was performed and the karyotype results were normal. DNA material was kept for additional tests. During a second pregnancy, male foetus presented at 23 weeks similar signs. This second gestation was terminated and the couple refused any sampling. Having a suspicious diagnosis of Pena-Shokeir syndrome, we collected DNA samples from the parents and we sequenced the RAPSN gene. We were able to identify an heterozygous c.149-153del ins24 (p.Val50fs) mutation for both samples. We then tested the DNA extracted from the amniocytes collected during the first pregnancy and found a homozygous c.149-153del ins24 mutation resulting in a truncated protein along with maternal DNA contamination. This strongly suggested that this Pena-Shokeir syndrome was the result of a very severe form of congenital myasthenic syndrome. The mutation we found is very uncommon and, to our knowledge, it is the first time that an ins/del mutation is described in the RAPSN gene. Moreover, our data clearly confirm that sequencing of the RAPSN gene must be considered in case of Pena-Shokeir syndrome.

## 1490/T/Poster Board #39

**A NOVEL QF-PCR BASED ASSAY FOR DETECTION OF MECP2 GENE DELETIONS AND DUPLICATIONS.** *S.P. Rivera, M. Peng, R. Owen, A. Buller, F. Quan, A. Rebuyon, W. Sun, C. Strom.* Molecular Genetics, Quest Diagnostics, Nichols Institute, San Juan Capistrano, CA.

PURPOSE Rett syndrome (RTT) is an X-linked dominant, progressive neurological disorder caused by mutations in the gene for methyl-CpG-binding protein 2 (MECP2). Deletions/duplications account for approximately 16% of classic RTT and 7% non-classical RTT female patients. Males with MECP2 deletion are rare but duplications have been found in males with severe mental retardation. Direct sequence analysis of the MECP2 gene has been offered at Quest Diagnostics Nichols Institute to aide the diagnosis of RTT. In order to offer a comprehensive MECP2 gene test for classic and non-classic RTT, and nonsyndromic X-linked mental retardation disorders as well as for the recently defined MECP2 duplication syndrome a MECP2 gene dosage test has been created. Methods: Fragments sampling the four exons and proximal promoter of the MECP2 gene, Amelogenin and two autosomal gene fragments are amplified in a single multiplex polymerase chain reaction (PCR) in the presence of fluorescently-labeled primers. Products of the amplification reactions are analyzed on an automated capillary DNA sequencer. Dosage analysis is carried out using SeqPilotTM software. Summary We have created a QF-PCR based dosage assay to detect MECP2 gene deletions/duplications. We have examined two hundred specimens submitted for RTT sequencing analysis with this assay and detected a partial deletion of exon 4 in a female Rett syndrome case with negative sequencing result. We have also confirmed a large full gene duplication in a case originally identified by CGH array in a male patient with behavior problem, speech and motor delay, and learning disability.

## 1491/T/Poster Board #40

**DNA diagnostic testing for nephrogenic diabetes insipidus: novel mutations in the AVPR2 and AQP2 gene.** *M. Nagel, S. Nagorka, M. Brzeska.* Laboratory for Molecular Diagnostics, Center for Nephrology and Metabolic Disorders, Weisswasser, Germany.

Hereditary nephrogenic diabetes insipidus (NDI) is a chronic disease that occurs soon after birth or in childhood. Affected patients have incongruous polydipsia, polyuria, dehydration, vomiting, and hypernatraemia. The disease can result in brain damage followed by permanent mental retardation or retarded physical growth. Hereditary NDI is caused by mutations in the AVPR2 (X-linked) or AQP2 (autosomal recessive or dominant) genes. In this study, we performed direct sequencing of entire coding regions of the AVPR2 and AQP2 genes in 50 unrelated individuals referred to our laboratory with a clinical diagnosis of NDI. The patients were from different ethnic backgrounds. Overall, 70% of these patients were male and 36% of them were 1-5 years old. Since most NDI is caused by AVPR2 mutations, we started the analysis with AVPR2 sequencing. If no mutation found, AQP2 sequencing was performed. The goal was to identify the mutation in order to confirm the clinical diagnosis of NDI. Thirty one different mutations were identified with an overall detection rate of 62%. There were 23 mutations identified with the AVPR2 gene and 8 with the AQP2 gene. Notably, many mutations were novel (17 of the 23 AVPR2 mutations and 6 of the 8 AQP2 mutations). We found 9 novel hemizygous missense mutations: S54I, Y117H, I130N, P173T, Q174E, W200C, L211P, A216P, and C283Y, 2 novel hemizygous nonsense mutations: W208X and Q291X, 4 novel hemizygous deletions (c.823_834del, c.832_834del, c.415_447, c.783delC), 1 novel hemizygous insertion (c.573insCAG), and 1 novel splicing mutation (IVS1+3G>A) in the AVPR2 gene. Additionally, we identified 2 novel heterozygous missense mutations: L18R and T125R, 2 novel splicing mutations (IVS1+3G>A and IVS2+3A>G), and 2 novel heterozygous deletions (c.754_772del and c.727_736del) that affected the AQP2 gene. Missense mutations were the most common mutation identified in the AVPR2 gene and account for 56% of all identified mutations in this gene. 6 out of 8 mutations identified in AQP2 gene were involved in autosomal recessive NDI. In conclusion, this study is an update on mutations in the AVPR2 and AQP2 genes. All identified mutations confirm the clinical diagnosis of NDI. There are no differences in clinical symptoms in patients with X-linked and autosomal NDI, thus if no mutation are found in AVPR2 gene, the analysis should be followed by AQP2 sequencing.

## 1492/T/Poster Board #41

**Identification and prenatal diagnosis of a novel G→A splicing mutation at position +1 of intron 7 of PHEX gene in a large Han Chinese family affected with vitamin D resistant rickets.** *G.R. Qiu[1,2], J. Wang[1], J. Li-Ling[1,2,3], Y.Y. Zhao[1,2], C.L. Jin[1,2], K.L. Sun[2], C.X. Liu[1].* 1) Liaoning Center for Prenatal Diagnosis, Department of Gynecology and Obstetrics, Shengjing Hospital of China Medical University, Shenyang 110003, China; 2) Department of Medical Genetics, China Medical University, Shenyang 110001, China; 3) Sino-Dutch Biomedical and Information Engineering School, Northeastern University, Shenyang 110003, China.

Short stature comprises a group of heterogeneous disorders featuring retarded development and reduced adult height, among which X-linked hypophosphatemia has been characterized by growth retardation, rachitic and osteomalacic bone disease, hypophosphatemia, and renal defects in phosphate reabsorption and vitamin D metabolism. The causative gene of the latter, i.e., phosphate-regulating endopeptidase (PHEX) gene, has been mapped at Xp22.2-p22.1. Here we report on a large Chinese family having at least 11 members (3 males and 8 females) affected with the disease. Pedigree inspection was consistent with X-linked dominant inheritance. The proband was a healthy pregnant woman querying for prenatal testing. Medical history revealed that her husband and 10 of his relatives have features including short stature (adult males < 160 cm in height, adult females < 150 cm in height), chest wall deformity, scoliosis and curving of lower limbs, with males to be more pronounced affected. Blood and urine analysis indicated hypophosphatemia in conjunct with increased urine phosphate, whilst blood and urine calcium were both normal. At the request of the family and with the consent from the Ethics Committee of Shengjing Hospital, China Medical University, genetic testing and prenatal diagnosis were provided. With 29 pairs of primers designed, the 22 exons of the PHEX gene, in addition with all exon-intron junctions were screened with PCR and DNA sequencing. As revealed by the result, all patients from the family have carried a novel G→A splicing mutation at position +1 of intron 7 of the gene, with male and female patients being, respectively, hemizygous and heterozygous for the mutation. The same mutation was found in none of the unaffected members from the family and 100 non-related normal controls. Bioinformatics analysis has suggested above mutation has abolished the corresponding splicing site, whilst a potential splicing site at 517 bp downstream may have been activated (to be verified by experiment). Prenatal testing suggested that the fetus did not carry the same mutation, and a healthy boy was born at full term. Conclusion: a novel G→A splicing mutation at position +1 of intron 7 of the PHEX gene may be pathogenic in the reported family. Prenatal testing may also be extended to a 34-year relative of the family, who has also been affected and is planning for pregnancy.

## 1493/T/Poster Board #42

**Hispanic Male with Invasive Breast Cancer Is Negative for a Known Deleterious Family BRCA 1 Mutation : Complex Genetic Counseling Issues and Possible Explanations.** *J. Wetzel[1], S. Demsey[2].* 1) Genetics, Kaiser Permanente, Anaheim, CA; 2) Genetics, Kaiser Permanente, Bellflower, CA.

Breast cancer affects more than 10% of women during their lifetime. Approximately 1% of breast cancer occurs in males. This is a report of genetic counseling for a 49 year old male affected with invasive ductal carcinoma who is negative for a familial deleterious BRCA1 mutation. BRCA1 mutation K654X results in the premature truncation of the BRCA1 protein at amino acid position 654. This mutation was previously noted in his affected sister. Site-specific analysis with reflex to comprehensive BRCA analysis (including large rearrangements; "BART" analysis) was performed and failed to reveal any known mutation in BRCA1 or 2. Site-specific analysis was repeated on a second blood specimen and was again negative. Counseling issues addressed included: a Mexican American male with a "female cancer", cultural issues, reluctance to inform his family of his diagnosis, initial refusal to request family assistance regarding necessary medical records, personal concern regarding risk for other cancers, and concern for his daughter's risk to inherit a cancer susceptibility. Counseling was further complicated by an unexpected negative result and the implications of not identifying a mutation in a very high risk individual. The negative result caused the counselor to challenge assumptions about the testing process, the presence of a cancer susceptibility mutation in an affected male and family dynamics. It required the client to reconsider his desire for confidentiality versus divulging personal information in order to obtain family cooperation with the testing process. Medical information from multiple affected family members was considered necessary to interpret his results. The patient's negative results could indicate that: a) there are two BRCA mutations in the family and the patient carries a BRCA mutation that is not detectable with current technology, b) there are two mutations in the family and the patient developed cancer due to a mutation in a more rare cancer susceptibility gene, possibly one which has not yet been identified or one for which testing is not available, c) the patient's cancer is due to a somatic mutation. Counseling a male with breast cancer poses a much higher initial level of suspicion regarding a cancer susceptibility mutation. When there is a known deleterious BRCA family mutation, a negative result is usually a true negative. This case demonstrates the complexity of genetic counseling and test result interpretation.

## 1494/T/Poster Board #43

**The application of next generation sequencing technology for the diagnostics and study of mental retardation.** *J. Brezo[1], M. Domanus[2], D. Antonopoulos[2], S. Das[1].* 1) Human Genetics, University of Chicago, Chicago, IL; 2) Institute for Genomics and Systems Biology, Argonne National Laboratory, Argonne, IL.

Nonsyndromic mental retardation(MR) presents a formidable challenge for molecular diagnostics because of the high number of implicated genes and low throughput of traditional Sanger sequencing. Next generation sequencing (NGS) is a promising new technology capable of simultaneous sequencing of hundreds of potential gene candidates in patients in whom clinical diagnosis is difficult. This capability can be used in sequencing entire pathways rather than a small panel of established genes. We are evaluating the potential of NGS for the analysis of patients with non-syndromic MR. To this end, we have compiled a panel of 100 genes implicated in MR that will be sequenced and analyzed on the Roche Genome Sequencer FLX. An important aspect for the use of this technology is the selection of a robust high-performance amplification method for downstream NGS. We are in the process of evaluating and comparing two amplification methods, array-based capture by hybridization (Nimblegen's 385K array) and microdroplet-based amplification by PCR (Raindance's RDT 1000). We selected five samples with known genotypes based on Sanger sequencing that have been amplified using both methods. An approximate coverage of 96.8% was obtained using the sequence capture array platform and approximately 96.9% coverage was obtained using the Raindance platform. The Roche Genome Sequencer FLX will be used to compare the two amplification methods, investigate the performance of multiple identification tags for multiplexing, and assess the depth of coverage that yields the best-read accuracy. Using the Genome Sequencer, we will further analyze a series of twenty patients collected through our diagnostic laboratory with a suspicion of Rett syndrome that were negative for testing for the MECP2, CDKL5 and FOXG1 genes. These samples will be re-sequenced for additional pathway genes that have been empirically, evolutionarily, or theoretically linked to these three established Rett syndrome genes. Additional pathway genes have been selected using the Search Tool for the Retrieval of Interacting Genes/Proteins (STRING) interaction database and have been included in our panel of MR genes. This study will provide useful information on the comparison and performance of currently available amplification/enrichment platforms for NGS and the application of NGS to the study of MR genes. The applicability of this technology to the diagnostics of MR will be evaluated and our results presented.

## 1495/T/Poster Board #44

**Williams-Beuren syndrome microdeletion diagnosis: the use of MLPA.** *R.S. Honjo[1], R.L. Dutra[1], C.C. Rebelo[1], I.M. Furquim[1], D.R. Bertola[1], L.M.J. Albano[1], P.C. Pieri[1], J.F.M. Araújo[2], C.A. Kim[1].* 1) Unidade de Genética, Instituto da Crianca, Universidade de São Paulo, São Paulo, SP, Brazil; 2) Departamento de Genética e Biologia Evolutiva - Instituto de Biociências - Universidade de São Paulo, São Paulo, SP, Brazil.

Introduction: Williams-Beuren syndrome (WBS) is MR/MCA syndrome caused by microdeletion of 1.5 to 1.8Mb in 7q11.23 region. Patients usually present with typical facies, congenital heart disease (particularly supravalvar aortic stenosis), mental retardation, arterial hypertension and peculiar hypersociable behaviour. Most cases are sporadic and the gold-standard method for diagnosis is FISH. Objectives: to evaluate MLPA (Multiple Ligation-dependent Probe Amplification) as a reliable alternative method for the diagnosis of WBS. Material and Methods: 23 patients with clinical suspicion of WBS were tested for the presence of 7q11.23 microdeletion using MLPA kit SALSA P029 (MRC-Holland). Results: Twenty-three patients with clinical suspicion of WBS were tested by MLPA and 21 were positive (91%). Among them, eight had also FISH with positive results and nine had a positive analysis using polymorphic genetic markers. One patient had MLPA negative for WBS but FISH and polymorphic markers confirmed the clinical diagnosis. Conclusion: MLPA was able to confirm the diagnosis of WBS in 91% of the patients. It failed to diagnose one patient, who has FISH and polymorphic markers positive for WBS microdeletion. In general, MLPA seems to be a reliable and cost-effective alternative to FISH for WBS diagnosis.

## 1496/T/Poster Board #45

**Molecular Diagnosis of Wolman/CESD Disease: Mutation Detection and Genotype-Phenotype Correlations.** *Y. Yang[1], P.H. Fernandes[1], I. Miloslavskaya[1], P. Orchard[2], S.J. Schwarzenberg[2], M. Grimley[3], W.E. O'Brien[1], C.M. Eng[1].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Pediatrics, University of Minnesota, Minneapolis, MN; 3) Texas Transplant Institute, San Antonio, TX.

Lysosomal acid lipase (LAL, gene: *LIPA*) deficiencies associated with two allelic autosomal recessive disorders: Wolman disease, which is characterized by complete absence of LAL activity, and the milder cholesteryl ester storage disease (CESD) which has residual LAL activity. Until recently, biochemical testing for LAL activity was the only method to confirm Wolman/CESD suspected by clinical criteria. We have recently developed LIPA gene sequencing for confirmatory and carrier testing for Wolman/CESD.

Since offering clinical DNA sequencing of the *LIPA* gene, we have analyzed five Wolman/CESD patients by sequencing the entire coding region of the gene. All the patients had deficient LAL activity by clinical biochemical analysis. A 27 day old patient with calcified adrenal glands was found to be homozygous for the p.G66V mutation. The p.G66V mutation in the heterozygous state was previously reported in a CESD patient as well as a Wolman patient, in trans with heterozygous c.894G>A and p.G5R mutations respectively. A 39 year old patient with microvesicular steatosis was heterozygous for p.G266X and c.894G>A mutations; the same genotype was previously reported in a CESD patient. The third patient was 4 months old and heterozygous for p.G266X and a novel c.822+1G>A mutation. A 6 year old patient with deficient activity had only one mutant allele of c.894G>A detected. The second unidentified mutation may be outside our standard region of sequence analysis or may be a large deletion or duplication. Finally, a four-month-old with calcified adrenal glands, elevated triglycerides and hepatosplenomegaly had two unclassified variants, c.894G>C and p.D345N. While in silico predictions showed conflicting results on the deleterious effects of the p.D345N unclassified variant, the c.894G>C unclassified variant, which affects the last nucleotide of exon 8, is predicted to cause exon 8 skipping at mRNA level, the same effect as the common c.894G>A mutation. The availability of clinical molecular testing and the identification of acid lipase sequence variants may help determine genotype-phenotype relationships in Wolman/CESD patients and provide information for enhanced genetic counseling.

## 1497/T/Poster Board #46

**Diagnostic method validation : High resolution melting (HRM) analysis for mutation screening of the ACVRL1, Endoglin and CFTR genes using the 7500- Fast system.** *S. PATRI, D. HAYE, A.M. DELVAUX, D. HAYE, B. GILBERT-DUSSARDIER, A. KITZIS.* SERVICE DE GENETIQUE, CHU LA MILETRIE, POITIERS, France.

We describe here optimized conditions for HRM analysis using the 7500 Fast Real Time PCR System (Applied Biosystem). We tested 3 genes which were routinely studied in our laboratory : ACVRL1, ENG and CFTR. The aim of this work was to perform all the studies with a unique condition (reaction mixture and cycling profile). Genomic DNA was extracted from whole blood using Magtration system 12GC instrument (PSS Co.Ltd) according to the manufacturer's instructions and diluted to 10 ng/μl. Genomic DNA samples from patients with previously characterized genetic variants and from normal control were used to determine the sensitivity of this analysis. Primers were designed to amplified entire exons and their flanking regions. Amplicon length was kept relatively short (< 400 bp) to improve genotype discrimination. Some larger exons were covered by 2 or 3 overlapping amplicons. Amplifications were performed in a final volume of 20 μl containing 30 ng of genomic DNA, 0.3 μM of each primer and 10 μl of Master Mix 2X (Applied Biosystem) containing the SYTO-9 dye (Invitrogen). The cycling profile was 10 min denaturation at 95°C, followed by 40 cycles of denaturation at 95°C for 15 sec and annealing/extend at 59°C for 1 min. High resolution melting was carried out after PCR denaturation at 95°C and renaturation at 50°C for 1 min followed by a slow (rate 1%) denaturation from 50°C to 95°C. This method does not require processing, reagent addition or separation after PCR. Amplification and melting curve analysis are performed in the same tube or plate which avoid the risk of contamination. All the known nucleotide variations were detected with the HRM analysis, point mutations as well as deletions. In complement we studied several patients and we detected some abnormal HRM profile. Each PCR product with abnormal profile was directly sequenced after ExoSAP (USB) treatment. The sensitivity was excellent with a very few number of false positive. For the polymorphism c.314-35A>G in the intron 3 of the ACVRL1 gene, we were able to distinguish the 3 genotypes (homozygote AA or GG and heterozygote AG). For all the samples, heterozygotes were easely discriminated from wild type, however mutations within the same exon were not necessary distinguishable one from the other. On a unique plate and with the same mixture reaction (except primers) and the same cycling profile, it was possible to genotype 5 patients for 12 amplicons or 9 patients for 8 amplicons.

## 1498/T/Poster Board #47

**Novel Neurofibromatosis 1 mutation in a patient with neurocutaneous and optic nerve lesions.** *F. Bolduc.* Dept Pediatrics, University of Alberta, Edmonton, Canada.

NF1 is the most common autosomal dominant disorder. Some of the major features are cutaneous, cerebral and neoplastic manifestations. Several mutations in neurofibromin have been described so far, affecting various regions of the protein. Neurofibromin contains a Ras-GAP domain involved in the regulation of the Ras-GTPase activity and CRAL-TRIO domain. We identified a 2 years old right-handed male with 9 cafe-au-lait macules and macrocephaly. He had normal psychomotor development. His MRI of the brain revealed the presence of a gadolinium-enhancing region in the right optic nerve, suggestive of optic nerve glioma. His father, as well as multiple members of his family, had clinical diagnosis of NF1. Multiplex ligation-dependent probe amplification (MLPA) analysis detected no whole-exon deletion or duplication. Sequencing of the NF1 gene revealed a point mutation in exon 8 resulting in a heterozygous L247P alteration that has not been previously reported. Based on alignment analysis, PolyPhen preditcs this to be damaging with a score of 2.110. Our case expands the range of mutation associated with NF1 and underline the need for sequence analysis in cases where MLPA may be negative.

**A Comparison of 23andMe and Navigenics Predictions for Five Individuals.** *P.C. Ng[1], S.S. Murray[2], S. Levy[1], J.C. Venter[1].* 1) Genomic Medicine, J. Craig Venter Institute, San Diego, CA; 2) Scripps Genomic Medicine, Scripps Health and The Scripps Research Institute, San Diego, CA.

Direct-to-consumer (DTC) companies such as 23andMe, Navigenics, and deCODE provide disease risk predictions to customers who have their DNA genotyped. We compare the predictions between two DTC companies, 23andMe and Navigenics, for five individuals. We find that on average, approximately a third of the predictions do not match between the two companies. The primary reason for differences in disease prediction is determined by whether the companies used the same markers with moderate to high odds ratio (OR). This indicates that markers with high OR should only be included if there is strong evidence to suggest that they are real, and that these markers have been verified in replication studies. While consensus among which markers to include will cause prediction agreement between the DTC companies, the markers that are currently used may not have good predictability because their effect size is still small. This may be improved by sequencing in the future, when rare variants with large effects might be identified.

## 1500/T/Poster Board #49

**Analysis of large genomic rearrangements of BRCA1 genes in Korean breast cancer patients.** *D.Y. Cho[1], S.Y. Choi[1], S.Y. Moon[1], S.J. Hwang[1], E.J. Park[1], H.M. Cheon[1], B.H. Son[2,3], B.K. Koo[2,3], S.H. Ahn[2,3].* 1) Clinical Research Institute, LabGenomics, Seoul, Korea; 2) Dept of Surgery, Asan Medical Center, Seoul, Korea; 3) Dept of Surgery, College of Medicine, University of Ulsan, Seoul, Korea.

Background : The BRCA1 and BRCA2 genes are associated with inherited susceptibility to breast and ovarian cancer. Most of disease-causing mutations in BRCA1/BRCA2 are point mutations and small insertion/deletions, but recently increasing number of large genomic rearrangements in BRCA genes have been reported in different populations with various prevalence. However, little is known about the prevalence and types of genomic rearrangements of BRCA genes in the Korean population. In this study, we have analyzed for the presence of BRCA1 large genomic rearrangements in Korean breast cancer patients. Methods : Multiplex ligation-dependent probe amplification (MLPA) was used to screen BRCA1 large genomic rearrangements in 249 Korean breast cancer patients at a priori risk of BRCA1/2 mutations due to known risk factors. The patients have been comprehensively analyzed for germline mutation in the entire regions of the BRCA1 and BRCA2 genes, using a combination of fluorescent-conformation sensitive capillary electrophoresis (F-CSCE) and direct sequencing, and were found negative. Positive MLPA result was confirmed and located by long-range PCR and sequencing. Results : We identified one large deletion in BRCA1, deleting exon 13-15, in one patient with family history of breast cancer. Breakpoints of this deletion are novel. Conclusion : Our results suggest that the large genomic rearrangements in BRCA1 gene are not a major cause for increased breast cancer susceptibility in Korean population.

## 1501/T/Poster Board #50

**Awareness and Utilization of *BRCA1/2* Testing and the US Preventive Services Task Force Guidelines among US Primary Care Physicians, 2007.** *C. Bellcross[1], K. Kolor[1], K. Goddard[2], R. Coates[1], M. Khoury[1].* 1) Office of Public Health Genomics, Centers for Disease Control and Prevention, Atlanta, GA; 2) The Center for Health Research, Kaiser Permanente, Portland, OR.

**Purpose:** While commercial testing for mutations in the breast/ovarian cancer susceptibility genes *BRCA1* and *BRCA2* (*BRCA*) has been available since 1996, there remains limited information regarding application in primary care. The United States Preventive Services Task Force (USPSTF) and other organizations have published guidelines regarding *BRCA* counseling and/or testing. However, there is a paucity of data regarding adherence to these recommendations in clinical practice. In addition, recent direct-to-consumer (DTC) advertising efforts may influence both awareness and utilization of *BRCA* testing. **Methods:** We assessed awareness and use of *BRCA* testing among physicians in the 2007 DocStyles national survey (1500 respondents: 515 family practitioners, 485 internists, 250 pediatricians, 250 obstetricians/gynecologists). **Results:** Overall, 87% of physicians were aware of *BRCA* testing, while 25% reported having ordered testing for at least one patient in the last year. Obstetricians/gynecologists were the most likely to be aware of (100%) and to have ordered (62%) testing, while pediatricians were the least likely (53% aware, 1.2% ordered). In multivariate logistic regression analyses, predictors of having ordered testing included physician specialty, higher patient socioeconomic status, and more than 10 years of practice. Physicians were asked to select indications for *BRCA* testing from seven different clinical scenarios representing increased (4) or low risk (3) situations. Of the increased risk scenarios, three were specifically identified by the USPSTF as considerations for genetic counseling referral. Among ordering physicians, 45% selected at least one low risk scenario as an indication for *BRCA* testing. In contrast, 19% chose none of the low risk, but all four increased risk scenarios. The “all correct” response rate rose to 31% when the analysis excluded the one increased risk scenario that was consistent with, but not directly addressed by, the USPSTF guidelines. **Conclusions:** While the substantial majority of primary care physicians are aware of *BRCA* testing and many have ordered it, a minority appear to consistently recognize the indications for counseling and testing set forth in the USPSTF guidelines. As the USPSTF concluded that potential harms outweigh benefits for women at low risk, these results suggest the need for improved provider awareness of existing guidelines, particularly in this era of increased *BRCA* DTC marketing and testing.

## 1502/T/Poster Board #51

**Utilization of genetic counselors to disclose clinically relevant genetic information obtained through research.** *L.L. Cheng[1], L. Le Marchand[2], N.M. Lindor[3], T.L. Burnett[2].* 1) Comprehensive Genetics Center, The Queen’s Medical Center, Honolulu, HI USA; 2) Epidemiology Program, University of Hawaii Cancer Research Center, Honolulu, HI USA; 3) Medical Genetics, Mayo Clinic, Rochester, MN USA.

The return of results generated in research laboratories has generally been discouraged; however, there are circumstances in which available medical management is of sufficient recognized value that the risk-benefit ratio may lean toward diagnosis disclosure. The Colon Cancer Family Registry (CCFR) is an international consortium dedicated to interdisciplinary studies in the genetics and genetic epidemiology of colorectal cancer. The six registries including the University of Hawaii Cancer Research Center (UHCRC) recruited population-based families at various risk for the disease and collected family history, epidemiological and clinical data, screening behavior, tumor blocks and blood samples from probands and their relatives. Samples were tested for DNA mismatch repair deficiency. When a deleterious germline mutation was identified in a proband, samples from consented relatives were also tested. Given the potential impact of these research test results on the subjects’ medical management, the CCFR recognized an ethical obligation to disclose these results. Statement of Purpose: To describe the collaboration between UHCRC researchers and clinical genetic counselors to develop a protocol for disclosure of test results. Methods: 1) Subjects whose blood was tested for deleterious mutations in MLH1, MSH2 and MSH6 were provided the option to receive test results; 2) Willing subjects were scheduled for an appointment with a genetic counselor; 3) Informed consent was obtained prior to results disclosure; 4) Confirmation of test results in a clinical laboratory was recommended; 5) Follow-up genetic counseling in a clinical setting was offered to all subjects; 6) A written summary of the counseling session was provided to the subject and optionally to their physician; and 7) Participants were encouraged to contact at-risk family members to share their genetic test results, inform relatives of the opportunity for testing through participation in the CCFR or community services, and options for genetic counseling. Summary: The protocol for subject notification of test results was approved by the University of Hawaii Committee on Human Subjects and The Queen’s Medical Center Research and Institutional Review Committee. This protocol is expected to increase enrollment of relatives into the Hawaii CCFR, identify new carriers of deleterious mutations and improve the medical management of participants. To date, 19 Hawaii CCFR participants have been counseled.

## 1503/T/Poster Board #52

**Predictive Testing for Inflammatory Bowel Diseases: The Views of Unaffected Siblings.** *A.M. Mindlin[1], C. Shuman[1], T. Walters[2], D. Chitayat[1], C. Popalis[2], S. Reif[3], K. Frost[2], M. Wright[2], A. Griffiths[2].* 1) Clinical & Metabolic Genetics, Hospital for Sick Children, Toronto, Ontario, Canada; 2) Gastroenterology, Hepatology, and Nutrition, Hospital for Sick Children, Toronto, Ontario, Canada; 3) Pediartric GI unit, Dana Children's Hospital, Tel Aviv, Israel.

Inflammatory bowel diseases (IBD), including Crohn's disease (CD) and ulcerative colitis (UC), are chronic inflammatory conditions of the colon and small intestine with an incidence of around 10 cases per 100,000 in the United States. Both CD and UC exhibit a multifactorial mode of inheritance with well recognized genetic, immunological, and environmental contributions to disease susceptibility. Although genetic testing for IBD is not currently utilized to predict disease, research in the genetic etiology of CD and UC suggests that such testing will likely become available. First degree relatives and especially siblings are at the highest risk of developing IBD and thus they are the ones that could potentially benefit the most by understanding their individualized risk. The objective of this exploratory study was to investigate factors considered important in adolescents' and young adults' decisions to participate in predictive testing for IBD. Unaffected individuals aged 13 to 25 years with at least one sibling with IBD were invited to participate. Recruitment took place through the IBD clinics at The Hospital for Sick Children in Toronto, through online sources including Facebook and the Crohn's & Colitis Foundation of Canada, and through the Dana Children's Hospital in Tel Aviv. Participants were asked to complete a 15 minute online questionnaire developed from constructs of the Health Belief Model. Data analysis was performed on 130 questionnaires of which 70% of respondents were female and 30% were male. 88% of participants expressed interest in predictive testing for IBD and this did not significantly differ by gender or age of participant. This is consistent with previous studies looking at patients with IBD and their interest in genetic testing for themselves and for their children. Perception of severity of ulcerative colitis correlated with interest in testing. The top two reasons cited in favor of testing included: to watch for early symptoms of the disease and to help science. However, 45% of the individuals felt that a positive test result would make them feel anxious with females being significantly more likely to worry about developing IBD than males. The results of this study provide insight into the perceptions of adolescents and young adults regarding potential genetic testing for IBD; this data is important to consider in the development and implementation of testing for common, complex disorders.

## 1504/T/Poster Board #53

**Comparing emotions and cancer screening behavior between family members who do or don't receive genetics services for Lynch syndrome.** *D. Hadley, S. Ashida, A. Giroux, H. Devlin, C. McBride, L. Koehly.* Social & Behavioral Research Branch, National Human Genome Research Institute / NIH, Bethesda, MD.

Purpose: Uptake of genetics services in families with inherited, adult onset diseases with preventive strategies range from 23 to 45%. This leaves a majority of at risk family members without the benefits of genetics education, counseling and risk assessment. Little is known about the psychological wellbeing and preventive health practices of those not receiving genetics services. In families with Lynch syndrome, relatives at risk to inherit mismatch repair mutations but not pursuing molecular testing are recommended to follow cancer-screening guidelines for mutation carriers. The aim of this study was to compare mood and use of colonoscopy between at risk family members receiving and not receiving genetic services in families with Lynch syndrome. Methods: One hundred sixty-three (163) family members (20 families) at risk to inherit a deleterious mutation completed questionnaires assessing the variables of interest prior to their receipt of genetics counseling and the offer of genetic testing. Family members at risk of inheriting the identified mutation, but not receiving genetic services (GS) (n= 49), were recruited through relatives receiving GS to complete a questionnaire assessing the variables of interest. Linear and logistic regression models were used to test for differences in 1) the number of depressive symptoms reported and 2) colonoscopy use between family members who went on to pursue GS as compared to those who did not, respectively. Analyses adjusted for the within family clustering and relevant covariates. Results: Mean scores for the number of depressive symptoms reported was significantly higher for at risk family members not receiving GS than for at risk family members presenting for GS. Colonoscopy use by relatives who did not receive GS was significantly lower than relatives receiving GS and identified as mutation carriers. Conclusions: Research to identify effective clinical and family based interventions that promotes cancer screening in at risk relatives not receiving genetic services is needed to facilitate prevention and early diagnosis of colon cancer. Higher numbers of depressive symptoms in family members not receiving genetics services may play a role in limiting uptake. Genetics counseling should include discussions that help family members who receive genetics services encourage those who don't to undergo cancer screening and offer support.

## 1505/T/Poster Board #54

**Support for patients with multiple endocrine neoplasia type 1 and their spouses: what do they want?** *S. Maruyama, A. Sakurai, Y. Fukushima.* Department of Medical Genetics, Shinshu University, Matsumoto, Japan.

Multiple endocrine neoplasia type 1 (MEN1) is a relatively rare autosomal dominantly inherited disorder characterized by hyperplastic and neoplastic disorder of endocrine organs such as parathyroid, anterior pituitary and gastroenteropancreatic endocrine tissues. Less frequent manifestations include adrenal cortex adenoma, thymic/bronchial neuroendocrine tumor and cutaneous tumors including facial angiofibroma, collagenoma and lipoma. Most subjects with MEN1 carry a heterozygous germline mutation in the MEN1 gene which localizes to chromosome 11q13 and encodes 615 amino-acid nuclear protein menin. Patients with MEN1 need to have various medical managements including periodic biochemical- and imaging studies, medication for various symptoms and surgery which usually need to have more than once. Genetic testing of patients and family members can cause them significant psychological distress. To know what they have felt when they were diagnosed as having MEN1 and what kind of supports they needed, we carried out a written questionnaire-based survey for affected patients and their spouses. Twenty-nine patients and 22 their spouses completed questionnaires and those were analyzed. Age of respondents varied from twenties to seventies, and ratio of males and females were nearly equal. More than three fourths and more than half of patients, respectively, were diagnosed based on results of genetic testing and family history. At the time of diagnosis, with surprise and uneasiness, many respondents concerned "inheritance of the disease to their children" as well as their own future health problems. As time passes after the diagnosis, majority of patients reported a relief from anxiety, but some reported further increase of anxiety, probably related to aggravation of the diseases and concern about genetic testing for their children. At the time of diagnosis, medical information was on the top of the list they wanted, but as time passed, they asked more social- and physical support. In addition to an appropriate medical management, sustained assistance which meets variety of needs of patients and family members is necessary to achieve better quality of life for them, and establishment of an appropriate administration system is desired for that purpose.

## 1506/T/Poster Board #55

**Recurrence risk of severe osteogenesis imperfecta (OI): parsing the risk due to parental mosaicism for dominant inheritance and recessive mutations.** *S. Pyott, U. Schwarze, M. Pepin, P. Byers.* University of Washington, Seattle, WA.

About 95% of individuals with lethal forms of OI have dominant mutations in type I collagen genes and the remainder have recessive mutations in two known (CRTAP and LEPRE1) and additional genes that remain to be identified. Measured recurrence risk in families with unaffected parents range from 2% to about 7% and depends on the methods of ascertainment of the sample. Recurrence risks are at the lower end with samples comprised by only those with one affected. The risk of recurrence after a second infant is substantially increased and is likely the result of a mixture of recessive inheritance and parental mosaicism, but the contribution of the two is unknown. To determine the relative contributions of the two mechanisms, we identified 45 families in which two or more infants with lethal and severe forms of OI were born to unaffected parents (a total of 146 children with 102 affected). We sequenced genomic DNA or cDNA from cultured cells, or from DNA provided from affected infants, to identify mutations in COL1A1, COL1A2, CRTAP, LEPRE1, PPIB, and SERPINH1 until we identified causative alterations. In 56% of these families (66 children with 52 affected) we found dominant mutations in the type I collagen genes, COL1A1 (16) and COL1A2 (9). In 27% of the families (43 children with 29 affected) we found homozygosity or compound heterozygosity for mutations in CRTAP (6), LEPRE1 (5), or PPIB (1). We failed to find mutations in the remaining 18% of the families (8) (37 children with 21 affected). Accounting for ascertainment by two affecteds, the overall recurrence risk was 21%; in families with recessive mutations it was 26% (5 of 19); in families with parental mosaicism for dominant mutations it was 13% (2 of 16), and in families with no mutation identified it was 24% (5 of 21). This last group is consistent with additional genes in which recessive mutations account for recurrence in these families. The rate of recurrence in mosaic families depends on the proportion of primordial germ cells that contain the mutant allele. The recurrence risk (13%) is compatible with 1 in 4 cells allocated to the germ line containing the mutant allele and argues for a relatively small pool of cells destined for the germline. These data support the contention that mutation identification is important in the assessment of recurrence risk and provides the basis for prenatal and preimplantation diagnosis when requested by the family. Supported by grants from USPHS and OI Foundation.

## 1507/T/Poster Board #56

**Incorporating locus heterogeneity into recurrence risk estimates in Bardet-Biedl syndrome.** *J.C. Sapp[1], D. Nishimura[2], J.J. Johnston[1], E. Stone[4], E. Heon[3], V. Sheffield[2], L.G. Biesecker[1].* 1) National Human Genome Research Institute, National Institutes of Health, Bethesda, MD, USA; 2) University of Iowa Hospitals and Clinics, Department of Pediatrics, Iowa City, IA, USA; 3) Hospital for Sick Children, Department of Ophthalmology and Vision Sciences, Toronto, ON, Canada; 4) University of Iowa Hospitals and Clinics, Department of Ophthalmology, Iowa City, IA, USA.

Bardet-Biedl syndrome (BBS) is a pleiotropic multiple anomaly syndrome inherited in an autosomal recessive pattern. Prior to genetic analysis, this disorder was assumed to be a unitary clinical and genetic entity. Recurrence risk calculations based on these assumptions estimate the risk for an offspring of a sibling of an affected individual who reproduces with an unrelated person to be approximately 1/950. It is now known that this disorder has remarkable locus heterogeneity, with causative mutations identified in as many as 14 genes. While the risk for a subsequent pregnancy for parents of an affected child is 1/4 regardless of which gene is mutated in that family, the risks for other relatives can vary substantially because of this locus heterogeneity. Clinical practitioners are increasingly called on to evaluate, molecularly diagnose, and counsel individuals and families affected by BBS, and risks to unaffected siblings and the affected probands themselves are among families' primary concerns. Thus, we set out estimates that can be used for recurrence risk counseling based on locus heterogeneity and a large cohort of families with mutations in BBS genes. To estimate these risks, we counted the relative proportion of families with mutations at each of 10 loci (BBS1-7, 9, 10, & 12) from a cohort of 182 families with one or more members who have two mutant alleles in any BBS gene. We estimated the carrier rate for mutations at each locus using Hardy-Weinberg principles and an aggregate population frequency of 1/100,000 for the phenotype. Taking into account locus heterogeneity, the risks for an offspring of the sibling of an affected individual actually range from ~1/1,500 to ~ 1/13,000, compared to ~1/950. As there is substantial phenotypic variation in BBS, locus-specific risk calculations may also be relevant for affected patients themselves. For the two common loci (BBS1 and BBS10) the magnitude of the difference between locus-specific and aggregate estimates is modest, yet for rare loci this difference is large and likely to be clinically relevant. Variation of recurrence risks using a locus-specific model is likely to have implications for genetic counseling about prenatal testing and other reproductive options.

## 1508/T/Poster Board #57

**Early Experience with a Prognostic Test for Adolescent Idiopathic Scoliosis.** *L. Nelson, M. Singleton, R. Chettier, K. Ward.* Axial Biotech, Inc, Salt Lake City, UT.

Introduction: We recently developed and validated a prognostic test for prediction of curve progression in adolescent idiopathic scoliosis (AIS) (Submitted). AIS affects 2-3 % of the pediatric population and 10% of patients will require bracing or fusion surgery. Although mandated in 26 states, school screening, to provide early identification of AIS patients, is controversial since 90% of AIS patients have non-progressive disease. Our test was designed to address problems in school screening such as cost, patient and parent anxiety, serial X-ray exposure and missed school and work. We report our initial experience with this test. Methods: The initial indications for testing includes female Caucasians age 9-13 that had been identified as having mild AIS. AIS is diagnosed using the Cobb method (radiographic measurement of the angle of intersection from the start to the end of the curve; angle of at least 10 degrees). Angles greater than 25 degrees are typically treated. The AIS-PT uses a panel of 53 DNA markers and current Cobb angle to assign a risk progression score (1-200). Risk scores correlate with the patient's risk of progressing to a severe curve (progression to a curve >40° in a skeletally immature individual or progression to a curve >50° in an adult). Low risk patients (<1% risk of progression to a surgical curve) are those with scores ≤ 40 and high risk patients are those with scores between 181-200. A follow-up survey after testing assessed how the test is used in clinical practice. Results: 316 patients with initial Cobb angles <20 degrees were tested during the first 5 months of use. 49% had "low-risk" scores, 50% had "intermediate risk", and 1% had a "high-risk" In the subset of patients with Cobb angles of 10-14 degrees there were 146 patients. 72% of them had low-risk scores, 28% had intermediate scores and 0% had high scores. Surveys were returned on approximately a third of the patients. Conclusions: The first patients tested appear to represent a population with a more severe prognosis (older patients with more severe Cobb angles) compared to typical mild patients. In research and validation populations from similar practices approximately 68% of patients were identified as low risk. Surgeons report that the AIS-PT helps in making management decisions especially in low and high-risk patients.

## 1509/T/Poster Board #58

**Collection and use of family history information in the primary care setting.** *S.E. Hahn[1,4], K.L. Powell[2], S.H. Blanton[1,4], A.H. Buchanan[3], C.A. Christianson[2], V.C. Henrich[2], A. Agbaje[5], J.M. Vance[1,4], M.A. Pericak-Vance[1,4].* 1) Miami Inst for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 2) The Center for Biotechnology, Genomics, and Health Research, The University of North Carolina at Greensboro, Greensboro, NC; 3) Cancer Center, Duke University, Durham, NC, United States; 4) Dr. John T. Macdonald Foundation Department of Human Genetics, Miller School of Medicine, University of Miami, Miami, FL; 5) Moses Cone Health System, Greensboro, NC.

Healthcare infrastructure does not support appropriate disease-related risk assessment. Family history (FH) is our most powerful tool to identify patients at risk for complex disorders, but it is underused. One goal of The Genomedical Connection is to determine the feasibility of using a computer-based self-administered family history and genetic risk assessment tool to facilitate the practice of genomic medicine in primary care. To determine the effectiveness of the tool we plan to measure primary care providers' (PCPs) practices regarding the collection of family history, genetic risk assessment and management strategies at baseline and subsequent intervals. Here we report the results of the baseline chart review conducted in two pilot practices. A modified version of the chart checklist developed by the Michigan Department of Community Health was used. A list of patients age 18 or older seen for a new patient- or a well-visit in the 6 months preceding 11/1/2007 was generated. 264 patient charts were randomly pulled and analyzed; at least 23 for each of 11 clinicians (except one in transition). 50% were for female patients. 98% included FH information (none in pedigree form). Parents were most frequently reported in FH (91%), followed by siblings (69%), children (20%), grandparents (8%); aunts/uncles (7%); and cousins (0.5%). Age of onset for diseases in relatives was rarely reported ("never" 90% of time). When relevant (e.g. cousins), maternal vs. paternal side of the family was missing 31% of the time. No patients had been referred to a genetic specialist. Two patients had genetic testing - one for hemochromatosis (not by PCP) and one for factor V. Five were referred to a non-genetics specialist based on family history - three to a cardiologist; one to an oncologist; and one to a gastroenterologist. Eleven (4%) were referred for cancer surveillance (e.g., colonoscopy at early age, breast MRI) and 2 (1%) were referred for EKG due to FH. While PCPs collect FH information, they are frequently missing critical pieces that would aid risk assessment, such as 2nd and 3rd degree relatives, age of onset, and side of family. Also, only a very small proportion of patients had recommendations based on FH. By comparing baseline results with the data collected at subsequent points in this study we will be able to assess the effectiveness of the model and secondary effects on overall physician practice.

## 1510/T/Poster Board #59

**Family HealthLink: A Unique, Online, Automated Risk Assessment Tool for Cancer and Coronary Heart Disease.** *A. Sturm[1], C. Craven[1], P. Coss[2], B. Bennett[2], S. Nottingham[2], K. Sweet[1].* 1) Dept Internal Med/Div Human Gen, Ohio State Univ, Columbus, OH; 2) Chronic Disease & Behavioral Epidemiology, Center for Public Health Statistics and Informatics, ODH, Columbus, OH.

Even with Human Genome Project advances and related efforts, family history (FH) remains the "gold standard" for assessment of the interaction of familial and environmental risk factors. This is especially so for common diseases such as cancer and coronary heart disease (CHD), the top two causes of death in the developed world. We previously demonstrated the rate of FH collection (69%) and assessment of high risk cancer status (14%) was inadequate at a Comprehensive Cancer Center. In 2008, we added FH questions to the Ohio Behavioral Risk Factor Surveillance System survey, n= 6,079. While 86% surveyed indicated their physician or health care professional (HCP) asked them about FH, 36% did not receive adequate risk assessment and 38% did not receive recommendations based on FH. Importantly, most (95%) were willing to spend at least 15 minutes completing FH, either on their own or at their HCP's office, and most were very likely (66%) or somewhat likely (30%) to make prevention and lifestyle changes based on increased risk. To address this need, we developed an automated tool known as Family HealthLink (FHL), https://familyhealthlink.osumc.edu, which is unique in providing assessment for all known hereditary cancer syndromes and CHD. The FHL consists of branched-point decision-making screens that guide the user through the program, mimicking face-to-face FH collection and distinguishing this interactive media from a paper-based FH questionnaire. The user enters demographic information, personal cancer and CHD history including age at diagnosis, and the cancer and CHD history of first- and second-degree relatives, in both the maternal and paternal lineages. This takes the average user less than 15 minutes. The individual's familial risk (average, moderate, or high) for cancer and CHD is then computed based on published algorithms. A qualitative risk assessment with recommendations for prevention is provided in PDF format. Since October 2008, the FHL public access website has had 722 users (590 females, 132 males). 57% of users were assessed as high risk, most for one criterion, although 67 (9.3%) were at high risk for both cancer and CHD; 28% of users had moderate risk for at least one disease. Regarding CHD risk specifically, 35% were at high risk and 14% were at moderate risk. Local marketing initiatives on the importance of FH for cancer and CHD risk correspond with tool usage, and higher risk individuals may be seeking such services on the Internet.

## 1511/T/Poster Board #60

**Combining genotypes and family history for prediction of complex disease.** *E. Ziv[1], S. Rosset[2].* 1) Dept Medicine, Dept of Epidemiology and Biostatistics, Institute for Human Genetics, Helen Diller Family Comprehensive Cancer Center, Univ California, San Francisco, San Francisco, CA; 2) Department of Statistics, Tel Aviv University, Tel Aviv, Israel.

As the number of associations discovered by genome wide association studies increases, the results from these studies are often considered in the context of predictive tests. Such predictive testing can be used to risk stratify individuals and consider preventive interventions. However, genome wide association studies often identify only a fraction of the causative variants which account for only a fraction of the heritability. Thus, family history will continue to be a useful predictor of complex disease in the near future. In addition, family history may continue to remain an important factor in individual risk assessment since it may also capture shared environmental factors. Therefore, properly combining information from genotypes and family history is important to maximize the utility of individualized risk prediction. We demonstrate how to combine information from genotypes and sibling relative risk for a complex trait to estimate individual risk. In particular, we demonstrate how to partition sibling relative risk into the proportion that has been accounted for by the genotypes measured and the proportion that remains unaccounted for, or the residual sibling relative risk. Combining information from the genotypes and the residual sibling relative risk gives the optimal risk assessment from the available data. We illustrate our approach with recent results from genome wide association studies of breast and prostate cancer.

## 1512/T/Poster Board #61

**A computational approach to predict the pathogenic effect of missense mutations in genetic diagnostics of hypertrophic cardiomyopathy (HCM).** *D.M. Jordan[1,2], B.H. Funke[3], R.C. Green[4,5], S. Sunyaev[2].* 1) Program in Biophysics, Harvard University, Cambridge, MA; 2) Division of Genetics, Department of Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, MA; 3) Laboratory for Molecular Medicine, Harvard-Partners Center for Genetics and Genomics, Cambridge, MA; 4) Department of Genetics, Harvard Medical School, Boston, MA; 5) Departments of Neurology, Genetics, and Epidemiology, Boston University Schools of Medicine and Public Health, Boston, MA.

Many mutations identified by sequencing in clinical diagnostic labs are not clearly correlated with the disease phenotype. These mutations are considered variants of unknown significance (VUS) and are difficult to interpret clinically. A reliable *in silico* method to assess these variants would be a valuable tool to assist in their classification. However, current methods are considered too unreliable for clinical use, and have not been validated to the standard required by physicians.

Using the PolyPhen software, we have designed a new tool to identify missense variants that cause hypertrophic cardiomyopathy (HCM), a genetic heart disease that affects approximately 1/500 individuals in the general population and is thought to be the most common cause of sudden death in the young (including trained athletes). Our goals were to improve on the native performance of PolyPhen, and to assign a confidence to our predictions, which is required for clinical use. HCM is caused mainly by variants affecting contractile proteins of the cardiac sarcomere. We focused on ten of these genes (ACTC, LAMP2, MYBPC3, MYH7, MYL2, MYL3, PRKAG2, TNNI3, TNNT2, and TPM1). This enabled us to improve performance by incorporating new statistics that rely on specific prior knowledge of the phylogenies, structures, and functions of these genes. The small number of patient sequences to be analyzed in a clinical setting also allowed us to use more computationally expensive algorithms.

We assigned confidence to our predictions based on a set of 106 missense variants that had been previously classified using a variety of traditional genetics criteria, relying heavily on frequency in controls and segregation with disease in families. We used a jackknife validation method to identify which variants we could classify confidently, and chose classification thresholds that allow us to claim a confidence of ~90%. Out of 137 missense variants classified as VUS from the same data set, we were able to classify ~50% of them at this level.

In addition to producing a tool that may assist in classification of VUSs for HCM, this methodology is also widely applicable to other genetic diseases. This work suggests new avenues for the clinical application of computational genetic diagnostics.

**ABO Genotyping by Capillary Electrophoresis.** *A.A Pradhan[1], S.R. Berosik[1], A. Chhibber[1], C.J. Davidson[1], Y. Doi[4], R.N. Fish[1], S.C. Hung[1], B.F. Johnson[1], M. Kondo[3], J. Lee[1], R.A. Padilla[1], D. Rodriguez[1], A.C. Felton[1], Y. Yamamoto[5], M. Yamazaki[2], L.K. Joe[1].* 1) Life Technologies Corporation, Foster City CA USA; 2) Hitachi High Technologies, Naka, Ibaraki, Japan; 3) Life Technologies, Tokyo, Japan; 4) Criminal Investigation Laboratory, Okayama Prefectural Police Headquarters, 1-3-2 Tonda-Cho, Okayama City, Okayama 700-0816, Japan; 5) Department of Legal Medicine, Okayama University Graduate School of Medicine, Dentistry and Pharmaceutical Sciences.

Identification of specific combinations of SNPs in the ABO locus on chromosome 9 can be used to determine ABO blood type, and this method is often used in identification of suspects, victims, or missing persons in criminal investigations. ABO blood-group identification by genotyping can also be a valuable tool in medical applications where routine serological typing is either not feasible or inconclusive, or where greater detail about precise allele composition is required. However, standard methods of ABO genotyping are either too time consuming (e.g. PCR-restriction fragment length polymorphism (PCR-RFLP)) or too complex (e.g. single-stranded conformational polymorphism (SSCP)) for routine laboratory use in forensic or clinical settings. Furthermore, sensitivity is an important consideration, with ABO typing in forensic cases often relying on very small quantities of genomic DNA. A simple and rapid procedure for a multiplex single-base primer extension reaction for ABO typing using six SNP sites within the ABO gene has been described in the literature. We present a method for capillary electrophoresis of such multiplex primer extension reactions. This method allows for sensitivity capable of accurate genotyping down to 0.05 ng of genomic DNA and improved consistency across instruments and laboratories. In addition, we demonstrate a robust and rapid secondary analysis workflow that minimizes the need for manual data interpretation of each sample.

## 1514/T/Poster Board #63

**Human Stem Cell Research; the State of the Art: Scientific and Ethical Challenges.** *A.I. Al-Aqeel[1,2], A.A. Alaiya[2], S. Coskun[3], C.N. Adra[2].* 1) Deptartement of Pediatrics, Riyadh Military Hospital, PO Box 7897-W951, Riyadh 11159, Kingdom of Saudi Arabia; 2) Stem Cell Therapy Program, Research Centre, King Faisal Specialist Hospital and Research Centre, MBC-03, P.O. Box 3354, Riyadh 11211, Kingdom of Saudi Arabia; 3) Assisted Reproductive Technology, King Faisal Specialist Hospital and Research Center, P.O. Box 3354 MBC 10, Riyadh, 11211, Kingdom of Saudi Arabia.

Stem cells are unspecialized cells able to divide and produce copies of themselves and having the potential to differentiate, i.e. to produce other cell types in the body. Because of the latter ability, the scientists investigate their possible use in regenerative medicine. Especially embryonic stem cells (ESCs) have huge therapeutic potential because they can give rise to every cell type in the body (pluripotentency) as compared to stem cells from certain adult tissues which can only differentiate into a limited range of cell types. For this reason scientists stress the importance of embryonic stem cell research. However, this research raises sensitive ethical and religious arguments, which are balanced against possible great benefit of such research for the patients suffering from so far incurable diseases. Serious questions remain about safety. The main technical problems are the control of cell differentiation in vitro and in vivo, the correct targeting of the desired tissue and the control of proliferation. Only when the processes of proliferation and differentiation are fully understood can stem-cell therapy become a viable option for treatment. The integration of stem cells into the target tissue is not yet fully understood. Research must also find efficient methods for controlling differentiation into tissue cells of the liver, nervous system, bones or heart and prevent uncontrolled proliferation after insertion. The difficulties of culturing these cells to maintain their pluripotencyas can be done for mouse ESCs has made the manipulation of hESCs an even more highly skilled art and one that few scientists have yet mastered. A major limitation on the field of hESC research is, therefore, a shortage of human research skill that can only be overcome slowly. Recent advances in the field of cloning and stem cell research has raised many complex questions. It is rare that a field of science causes debate and challenge not only among scientists but also among ethicists, religious scholars, governments and politicians. There is no consensus on the morality of human cloning, even within specific religious traditions. In countries in which religion has a strong influence on political decision making, the moral status of the human embryo is at the center of the debate. We will discuss our experience; how Islamic teachings make this very promising research and therapeutic technique, and modality of treatment permissible; and the Islamic perspectives about reproductive/therapeutic cloning. In conclusion, it is still unclear which human stem cellswhether embryonic or adultwill be developed and for which conditions. Qualities of the ideal stem cell in a clinical setting are expected to be extensive and far reaching. The ability for stem cells to be expanded in culture without genetic and epigenetic abnormalities, their ability to form functional cell types in vitro and in vivo, and their immuno-compatibility with the patient need to be studied. Given this, the focus of research community, should be on developing human research capacity in both ASCs and ESCs. Each type of research will take time to mature. The ethical debate will need to produce acceptable policy and regulatory compromises so that the regulatory burden can be reduced and investors' risk aversion can be overcome. If these things happen, the major remaining barrier to realizing the medical benefits of stem-cell research might be the lack of skilled scientists in the field.

## 1515/T/Poster Board #64

**When the Findings are Not Certain: Dissemination and Disclosure Options for Ecogenetics Research.** *K.M. Beima-Sofie[1], J. Hofmann[4], C. Jansen[5], R. Cunningham[3], M. Negrete[6], P. Palmandez[6], M. Keifer[3], K. Fryer-Edwards[1,2].* 1) Institute for Public Health Genetics, University of Washington, Seattle, WA; 2) Bioethics and Humanities, Univeristy of Washington, Seattle, WA; 3) Department of Environmental and Occupational Health Sciences, University of Washington, Seattle, WA; 4) Department of Epidemiology, University of Washington, Seattle WA; 5) School of Public Health, University of Washington, Seattle, WA; 6) Pacific Northwest Agricultural Safety and Health Center, Yakima, WA.

Increasingly, we need to understand how ambiguous research findings impact the translation and distribution of research results. Incomplete understanding of direct correlations between genetic polymorphisms and disease risk make it difficult to translate research results into clinical and public health practices. In addition, the ethical, legal and societal implications arising from the disclosure of uncertain or unclear genetic information are not well understood. Because of these uncertainties, current guidelines advise against returning results to individuals unless they are valid, reliable, and have clinical utility. These recommendations create a dilemma for researchers who believe results should be returned to study subjects regardless of whether they meet these criteria. We build on an existing study at the University of Washington Pacific Northwest Agricultural Safety and Health Center that provided pesticide handlers with individual results regarding their paraoxonase (PON1) status and information on cholinesterase (ChE) inhibition and personal protective behaviors. Our project utilized various outreach methods to disseminate information about genetic susceptibility, environmental exposures, and individual genetic test results. Study subjects received information by letter, phone call, and/or informational video. Preliminary interviews show that workers who received individual genetic results by letter did not understand genetics or what their results meant. However, because of previous education efforts, participants were aware of ChE monitoring programs and were more interested in obtaining individual ChE levels than genetic susceptibility information. Current projects are evaluating the effectiveness of video risk communication strategies. The goal of this poster is to review guidelines for returning results, to demonstrate where genetics creates ambiguity, and to share successful outreach methods with other researchers in order to ethically and effectively communicate research results to study participants. We point to education and research practices that preserve trust and ensure that study participants understand the results they receive and are motivated to engage in healthy behaviors. By better understanding how one particular cohort of study participants reacts to results with ambiguous implications, we hope to contribute to emerging best practices for future research and outreach projects in ecogenetics and environmental health.

## 1516/T/Poster Board #65

**Bioethics and socioethics: The paradoxes associated with non-invasive prenatal diagnosis performed on fetal cells obtained from maternal blood.** *C. Bouffard, A. Ducos, K. Krabchi, R. Drouin.* Dept Ped, Fac Med Hlth Sci, Univ Sherbrooke, Sherbrooke, PQ, Canada.

Pregnant women may one day be able, merely by providing a blood specimen, to obtain non-invasive prenatal diagnoses (NIPDs) on fetal cells circulating in their blood. This form of prenatal diagnosis is performed during the first trimester and makes it possible to determine, without recourse to such invasive methods as amniocentesis or chorionic villi sampling, whether a fetus presents with chromosomal or genetic anomalies. Testing on fetal cells from the mother's bloodstream is deemed non-invasive and non-threatening to the pregnancy. It thus offers undeniable bioethical benefits. Nevertheless, it presents significant socioethical problems. Our paper deals with the ethical paradoxes raised by NIPD. Method: Comparative discourse analysis of the scientific and bioethical literature on NIPD. Results: On one hand, NIPD would allow for solving numerous bioethical problems raised by prenatal diagnosis. Its non-invasive nature; its freedom from risks to the pregnancy; the earliness of the diagnosis, allowing more time for decision-making or for earlier and thus less distressing recourse to abortion; the overall lessening of parental anxiety in connection with prenatal diagnostic testing; greater equity among pregnant women in terms of access to such testing; reliable results; low cost: these are among the benefits that NIPD would bring. On the other hand, the technique gives rise to some fundamental socioethical concerns. For example, in democratic countries, NIPD could allow, under the banner of liberal individualist values, for recourse to genetic testing (and consequent decisions about interrupting a pregnancy or not) based on individual or non-medical social criteria (family balancing, paternity, social sex selection). Conclusion: We can easily imagine that any diagnostic method that reveals the fetus's state of health without threatening either the mother's health or the pregnancy would be well received by most women and couples at risk of transmitting a genetic disorder. The introduction of NIPD into clinical service delivery brings with it the obligation to develop empirical knowledge about: 1) our societies' response to intellectual handicaps and to individuals with trisomy 21; 2) social pressures exerted both by and on pregnant women; 3) support structures for parents who continue a pregnancy when the fetus is known to present with a disorder; 4) the impact of informed consent and informed choice; and 5) the effects of direct-to-consumer tests.

## 1517/T/Poster Board #66

**Consent given from the desire to please versus the exercise of free will: The involvement of adolescents with neurofibromatosis in social science research, viewed from an ethical standpoint.** *C. Legendre, R. Drouin, C. Bouffard.* Dept Ped, Fac Med Hlth Sci, Univ de Sherbrooke, Sherbrooke, PQ, Canada.

Although the individual's free will in relation to consent is a key concern in the ethics of genetics research, several factors continue to represent obstacles to the genuine exercise of free will. Despite the existence of numerous statements of principle, laws, and guidelines designed to ensure that all are in a position to give free and informed consent, the influence exerted by those in a position of authority still plays a preponderant role in the dynamics of consent. In Canada, children may refuse to take part in a study protocol. Minors aged fourteen and over also have the right to refuse to take part in a non-medical study without their parents' permission. These measures do not, however, protect adolescents with genetic disorders, who may wish to consent, from their parents' perhaps well-meaning influence. Our research on neurofibromatosis (NF) shows that parental influence is an especially significant factor in the case of adolescents with that disorder. While they may be able to act independently as regards consent, certain aspects of NF make them particularly vulnerable to the influence of those closest to them. Methodology: Ethnographic methodology (analysis of the literature on research ethics; interviews and participant observations with members of Canadian NF associations). Results: Since participants in social science studies are in effect subject to little or no physical risks, parents' desire to see their children's lives improve often leads to the over-riding of their adolescents' right to exercise free will in granting consent When it comes to NF, this problem is exacerbated by the scarcity of psychosocial research and the importance of such studies for the intellectual and psychosocial development of children with the condition. In these circumstances, we must be concerned about the nature of the children's consent. Added to this is the known fact that children with NF are inclined to want to please and tend to have a more highly developed capacity for empathy than usual. Conclusion: Ethically speaking, it is important to take into account that, even if adolescents are unlikely to suffer parental sanctions for refusing to take part in a study, the parent-child relationship is hierarchical, with parents in a position of authority. This we must wonder about the real benefits of the right to free and informed consent when consent may be subject o the desire to please.

## 1518/T/Poster Board #67

**Direct-to-consumer genetic testing: An overview of regulatory aspects in Europe.** *P. Borry, H.C. Howard.* Biomedical Ethics and Law, Katholieke Universiteit Leuven, Leuven, Belgium.

There has been a recent rise in companies offering genetic testing services directly-to-consumers and bypassing the traditional face-to-face consultation with a health care professional from the established health care system. The presence of these services, mostly concentrated in North America, but also present in Europe and Asia, have generated a lot of debate regarding their potential benefits and harms. Supporters of direct-to-consumer genetic testing point to, among others, increased access and empowerment for consumers, and enhanced confidentiality of results as potential benefits. Meanwhile, detractors have many concerns, including, but not limited to, issues regarding tests' analytical and clinical validity, as well as clinical utility; issues related to the quality of pre- and post-test counselling; and the lack of an adequate legal framework. Through a systematic review of the literature, we present a summary of important existing European legal and ethical documents framing the sale of genetic tests sold directly to consumers. Among others, we will discuss the European IVD Directive, the Additional Protocol to the Convention on Human Rights and Biomedicine concerning Genetic testing for Health Purposes, as well as specific national initiatives to regulate these services.

## 1519/T/Poster Board #68

**The Emerging Language of Genetic Biobanking: A Contest for Transparency, Control, and Power.** *J.M. Conley[1], A.M. Davis[2], J. Cadigan[2].* 1) University of North Carolina School of Law, Chapel HIll, NC; 2) Department of Social Medicine, University of North Carolina, Chapel Hill, NC.

The Emerging Language of Genetic Biobanking: A Contest for Transparency, Control, and Power John M. Conley University of North Carolina School of Law CB#3380, Chapel Hill, NC 27599 USA This paper will report early results from a sociolinguistic study of the discourse taking place in and around the creation and maintenance of research-focused DNA repositories, or biobanks. Health researchers around the world are accelerating their efforts to develop large-scale repositories of human DNA, with an ultimate goal of deciphering the relationship between genetic variation and health outcomes. Research biobanks are being created at every level, including comprehensive, state-sponsored projects like Biobank UK and the samples being collected by numerous university-based projects in the United States and elsewhere. The latter depend on enrolling large numbers of volunteer subjects, a reality that has already provoked a vigorous ethical and legal debate (sometimes waged in court) over such issues as informed consent, the relationship between researcher and subject, and log-term control over samples and the genetic information derived from them. Strikingly, the various participants have yet to arrive at a taken-for-granted vocabulary. In each instance, the variants that are in play convey strong messagesoften with legal implications--about transparency, control and power. For example, is the subject (itself a heavily laden term) a "donor," a "participant," a "patient," or something else? Is the contribution of a sample a "gift," a "donation," a "transfer," a "loan," or even a "license"? Is the researcher a "fiduciary," a "trustee," a "custodian," or an "owner"? Even the ubiquitous "biobanking" assumes many conclusions. This paper is based on the qualitative discourse analysis of lengthy, semi-structured interviews of both research subjects and researchers. This method has previously been used to study various aspects of science and medicine, as well as such domains as law and business. The analysis reveals that the two groups (subjects and researchers) often have strikingly different ways of speaking about themselves and their relationship. Moreover, the subjects frequently voice their concerns and fears about biobanking in a vocabulary and idiom that has yet to be represented in the "official" discourses of law and medical ethics. The authors argue that these "native" concerns deserve more serious attention in law and policy debates.

## 1520/T/Poster Board #69

**Attitudes toward human research protections in genetic research among ASHG members: Results from the Genetics Research Review and Issues Project (GRRIP).** *K.L. Edwards[1], A.A. Lemke[2], H. Starks[1], G.L. Wiesner[3], "GRRIP" Team.* 1) University of Washington, Seattle, WA; 2) Northwestern University, Chicago, IL; 3) Case Western Reserve University, Cleveland, OH.

**Background:** Protocols submitted to Institutional Review Boards (IRB) for genetic research are increasing in number and complexity. A collaboration between the Univ. of Washington Center for Genomics and Healthcare Equality and Case Western Reserve Univ. Center for Genetics Research Ethics and Law, has sought to assess experiences with and attitudes toward review of genetic research. GRRIP was conducted in two phases; 1) qualitative interviews of researchers and IRB members, and 2) national surveys of the ASHG and Public Responsibility in Medicine and Research (PRIM&R) memberships. The results from the ASHG survey are presented here, while results from PRIM&R are reported separately. **Methods and Results:** An anonymous, web-based survey was sent to the ASHG membership in April 2009. The survey included questions on experience with the genetic research application and review process, views toward specific genetic research issues, and basic demographic information. To date, 360 /4,908 individuals have responded to the online survey. The majority of respondents are female (54%), U.S. based researchers (82%), and involved in research as their primary activity. Most respondents (48%) reported 15 years or more experience in conducting human genetic research studies. Issues related to consent of subjects has caused considerable discussion with their IRB (51%), followed by procedures related to protecting personal information of research participants (35%), and return of results to participants (31%). When asked about consequences of IRB review, 54% of participants indicated that an excessive delay of a project had occurred, and 27% were dissuaded from pursuing similar projects in the future. On the positive side, 25% reported improved participant protections, 23% help in planning for future research, and 12% reported identification of potential harms to subjects that were not addressed. Participants reported they would be equally or slightly less likely to experience these consequences in nongenetic studies and generally felt that review of research protocols should not be different for genetic studies. **Significance:** Findings from this study will be used to inform a consensus process aimed at proposing guidelines regarding human subjects protection in genetic research.

## 1521/T/Poster Board #70

**Association for Molecular Pathology v. USPTO: A Controversy Involving Gene Patents, Intellectual Property Law and the U.S.Constitution.** *D.L. Greenfield[1,2,3,4,5].* 1) Center for Society and Genetics, UCLA, Los Angeles, CA; 2) American Bar Association, Sub-Committee on Reproductive & Genetic Technologies (Family Law Section) 2001-2009; 3) California State Bar; 4) Los Angeles County Bar Association Bioethics Committee; 5) Center for Policy on Emerging Technologies: http:www.c-pet.org.

The recently filed case, Association for Molecular Pathology v. U.S. Patent and Trademark Office, does not simply concern a narrow issue, a rarified intersection of intricate patent law and complex science. Rather, the ACLU suit on behalf of plaintiffs including leading groups and members of the scientific and medical research communities as well as individuals affected by breast and ovarian cancer, against defendants USPTO and Myriad Genetics, has broad and historically significant implications for human genetics. The important knowledge and discoveries of the 20th Century Human Genome project nonetheless created 21st Century social, ethical, political and legal dilemmas: controversies have arisen where tensions between biotechnological achievement and civil liberties exist. One of which is whether or not human DNA and its embodied information should be subject to intellectual property regimes, specifically, patent rights; and if allowed, are Constitutional guarantees of the First Amendment, specifically freedom of speech and expression, infringed? A discussion of the legal history and societal effects of gene patenting that brought about the unique convergence of the ACLU and the plaintiffs will introduce the issue. Following which, an argument will support the conclusion that these patents are contra to the law which specifies and defines the subject matter for which patents may be obtained, as well as free speech guarantees. The specific requirements for statutory subject matter, including exceptions to what is generally considered patentable, and definitions of allowable categories will be presented, concluding that patents on human DNA and DNA sequences, are, as both products and laws of nature, exceptions to what is statutory subject matter, and exclusions to the enumerated categories: as explained and articulated in case law, human DNA is not a process; machine; manufacture; or composition of matter. When these genes are nevertheless privatized, free speech rights are implicated. Individuals, including patients, biomedical researchers, scientists and physicians cannot use their own genes to communicate something about themselves to others and are denied access to both their own information as well as the information of the human genome: freedom of thought is restricted and academic freedom is denied. In conclusion, it will be suggested that new paradigms should govern the use and control of human DNA.

## 1522/T/Poster Board #71

**Ethical implications of research on the genetic aspects of autism spectrum disorders: A qualitative study of parental opinions in Japan.** *J. Higashijima[1], K. Kato[1,2,3].* 1) Dept Biostudies, Kyoto Univ, Kyoto City, Kyoto, Japan; 2) Institute for Research in Humanities, Kyoto Univ, Kyoto City, Kyoto, Japan; 3) Institute for Integrated Cell-Material Sciences, Kyoto Univ, Kyoto City, Kyoto, Japan.

Genetic research on autism spectrum disorders (ASD) is being given much attention these days. From a historical perspective, such as eugenics and social stigma, as well as emerging practical issues, such as privacy, informed consent, and data sharing, it is necessary to consider the ethical and social aspects of ASD's genetic research (Journal of Genetic Counseling, 15, 41-50; American Journal of Medical Genetics, Part C, 142C, 52-57). In this process, a consideration of opinions of ASD patients and parents is essential. The aims of the current research are to clarify and examine Japanese parental attitudes and knowledge regarding genetic research on ASD. Participants were recruited through a nonprofit autism agency in Japan. The data were collected through a survey of parents with at least one child diagnosed with ASD. Approval was obtained from the Medical Ethics Committee of Kyoto University, Japan, and data were gathered using a semistructured interview format developed for this study on the basis of a comprehensive literature review and on the results of earlier interview studies. Questions in the survey consisted of 4 format types: "fill in the blank," "Likert response," "nominal," and "open-ended." Also, they were divided into 4 parts: (i) Demographics, (ii) Parental knowledge of gene mutation, (iii) Parental knowledge of ASD research, and (iv) Parental attitudes toward ASD research, focusing especially on genetics. Answers and comments to open-ended questions were analyzed by content analysis in relation to quantitative information, though we conducted no quantitative analyses. About 20 surveys were completed, and our results have revealed many important issues to consider and discuss for researchers, medical personnel, and genetic counselors. For example, although many parents favored a medical diagnosis at birth, some respondents considered the prediagnosis child-rearing period necessary to gradually prepare their minds for a medical diagnosis of ASD. Some respondents expressed serious concerns over research focusing on genetic differences between ASD patients and ordinary people, though many strongly supported research on the genetic mechanism of ASD. However, respondents showed negative attitudes toward research on the causes of ASD, which concerned prenatal genetic testing and abortions, and some considered direct scientific or therapeutic benefits to the subject unimportant.

## 1523/T/Poster Board #72

**Ethical issues surrounding the research activities of companies selling direct-to-consumer genetic tests.** *H.C. Howard, P. Borry.* Biomedical Ethics and Law, Katholieke Universiteit Leuven, Leuven, Belgium.

There has been a recent rise in companies offering genetic testing services directly-to-consumers and bypassing the traditional face-to-face consultation with a health care professional from the established health care system. The presence of these services, mostly concentrated in North America, but also present in Europe and Asia, have generated a lot of debate regarding their potential benefits and harms. Supporters of direct-to-consumer (DTC) genetic testing point to, among others, increased access and empowerment for consumers, and enhanced confidentiality of results as benefits. Meanwhile, detractors have many concerns, including, but not limited to, issues regarding tests' analytical and clinical validity, as well as clinical utility; issues related to the quality of pre- and post-test counselling; and the lack of an adequate legal framework. Moreover, there is evidence suggesting that consumers may be confused as to the worth and ultimate meaning of such test results for their health. Some companies are also inviting and/or recruiting consumers who choose to purchase testing to also take part in genetic research being conducted by the company. With this specific aspect in mind, we performed a content analysis of the websites of five companies offering DTC genetic testing. We described how companies present their research activities to consumers as well as their policies regarding the storing of biological samples and data. We then discussed issues surrounding informed consent including consumer understanding, company transparency, and the right to withdraw. Finally, we also address this recruitment method and what it means to be a consumer of services versus being a research subject.

## 1524/T/Poster Board #73

**Public attitudes toward genetic testing for children in Japan: A comparative study between nationwide opinion surveys in 2005 and 2008.** *I. Ishiyama[1], K. Muto[2], A. Tamakoshi[3], T. Maeda[4], A. Nagai[5], Z. Yamagata[5].* 1) Teikyo-Gakuen Junior College, Hokuto, Yamanashi, Japan; 2) The University of Tokyo, Tokyo, Japan; 3) Aichi Medical University, Nagakute, Japan; 4) The Institute of Statistical Mathematics, Tokyo, Japan; 5) University of Yamanashi, Yamanashi, Japan.

**Purpose:** Rapid developments in genetic technologies increase the ability to identify the asymptomatic children susceptible to disease. These developments confront parents and their children with ethical and legal issues. The purpose of this study was to assess public attitudes toward genetic testing for children, to examine the attitude change of Japanese general public by comparing two nationwide opinion surveys conducted in 2005 and 2008, and to explore the factors related to attitudes toward genetic testing for children. **Methods:** The participants were comprised of 4,000 people (age, 20-69) in 2005 and 3,000 people in 2008, selected from the Japanese general population by using the two-step stratified random sampling method. They were queried about the following topics in a mail survey: (1) attitudes toward genetic testing for disease susceptibilities of children on common diseases, (2) images of the genomic studies related to medicine, (3) awareness of the benefits and risks of genomic studies related to medicine, (4) level of genomic literacy, (5) demographic and socioeconomic background, and (6) knowledge and attitudes toward science in general. We examined the attitude change using $\chi^2$test and identified the factors related to the attitudes toward genetic testing using logistic regression models. **Results:** The response rate was 54.35% (2,171/4,000) in 2005, and 53.8% (1,613/3,000) in 2008. The genetic testing for disease susceptibilities of children on common diseases was favored by 55.5% people in 2005, and 66.2% people in 2008. A difference in the attitudes was observed ($p<0.001$). The negative image of 'scary' decreased ($p<0.01$), and awareness of the risks about 'discrimination' and 'unexpected harmful effect' decreased ($p<0.05$) in 2008. Multivariate analysis of 2008 survey revealed that positive attitudes toward genetic testing for children related to positive images of the genomic studies (the highest quartile of score versus the lowest: adjusted odds ratio (OR), 3.69; 95% confidence interval (CI), 2.57-5.30) and having cognition of 'scientific development has more advantages than disadvantages' (adjusted OR, 1.62; 95% CI, 1.26-2.09). By contrast, respondents of 40-49-year-old group (adjusted OR, 0.64; 95% CI, 0.41-0.99), and having a child (or children) actually (0.65; 0.46-0.91) showed negative relations. At the same time, increases of the genomic literacy score did not relate to positive attitude toward genetic testing for children.

## 1525/T/Poster Board #74

**Direct-to-consumer personal genomic services: An exploratory case study of product claims, disclaimers, and performance.** *R. Sterling[1], S. Adams[2], H. McLeod[3], J. Evans[4].* 1) Center for Genomics and Society, University of North Carolina, Chapel Hill, NC; 2) School of Medicine, University of North Carolina, Chapel Hill, NC; 3) School of Pharmacy, University of North Carolina, Chapel Hill, NC; 4) Department of Genetics, University of North Carolina, Chapel Hill, NC.

Advances in genomic research have enabled the commercialization of whole genome profiling or personal genomic services (PGS). Direct-to-consumer (DTC) marketing and sale of PGS has raised concerns among clinicians, researchers, and policy makers. In 2008, the Secretary's Advisory Committee on Genetics, Health and Society reported 29 gaps in the oversight of genetic services and New York and California issued a provisional moratorium on the DTC sale of PGS, fueling debates about whether restrictions that limit consumer choice are warranted to avoid potential harm to consumers. As policy makers work to improve oversight of genetic services, the continued DTC sale of PGS warrants examination of advertising. Although federal regulations do not specifically address advertising for genetic services, various laws and recommendations set forth basic requirements and a normative standard. In this study, we purchased two PGS kits from two companies (23andMe and deCODE) and examined: 1) whether websites provided information recommended by experts, 2) website claims and disclaimers, and adherence to Federal Trade Commission (FTC) requirements for product advertising, and 3) whether claims were supported by product performance. In our content analysis of websites, we found both PGS companies presented information on topics repeatedly recommended by experts, such as lab certifications, test limitations, and privacy. However, they did not meet FTC requirements that disclaimers be presented in close proximity to claims. FTC also requires that disclaimers qualify and not contradict claims; however, we found several examples of disclaimers that contradicted claims, particularly in regard to medical relevance. Finally, our independent genotyping of submitted specimens confirmed the accuracy of genetic profiles reported by both companies, but reported risk profiles showed significant variability. Of the 14 conditions profiled by both companies, risks for five conditions were reported in opposite directions for the same specimen. The current lack of a "gold standard" to guide the interpretation of genotypic profiles is a substantial limitation to the utility of PGS and poses a major challenge to advertisers charged with both increasing PGS sales and avoiding deceptive advertising. We encourage PGS companies in the US and abroad to adhere to FTC requirements regarding product claims and disclaimers to enable informed decision-making by consumers.

## 1526/T/Poster Board #75

**Resurrecting the Dead?: Research on Archived Samples (The ENGAGE Scenario).** *A.M. Tassé[1], I. Budin Ljøsne[2], B.M. Knoppers[3].* 1) Faculté de droit, Université de Montréal, Montréal, Québec, Canada; 2) Norwegian Institute of Public Health, Oslo, Norway; 3) Faculty of Medicine, Department of Human Genetics, McGill University, Montréal, Québec, Canada.

Human biological material has always been collected for different purposes: medical care, biopsies, pathology, research, rare disease archives, tumor banks, etc. These resources are highly coveted for research purposes that often differ from the initial objectives of the collection. Access and use of such archived samples and data raise legal and ethical issues distinct from those of prospective studies, especially when the samples come from deceased individuals. The secondary use of biological samples and data from deceased individuals is increasingly important for epidemiological and international research initiatives such as the European Network for Genetic and Genomic Epidemiology (ENGAGE). An analysis of the consent forms of 50 ENGAGE cohorts reveals that most did not anticipate the use of samples and data after the death of the participant/individual. Moreover, this secondary use is regulated quite differently between countries, especially when the biological material has been collected for clinical diagnostic purposes. A comparative analysis of the legal frameworks governing the secondary use of biological data from deceased individuals demonstrates that contradictory approaches can affect research objectives. In the USA, research is permissible on samples from deceased individuals whereas in Canada free and informed consent must be expressed in a prior directive provided at the time of the collection, or by an authorized third party. Within Europe, there is an equally broad range of possible options. But in the context of international collaborative research, distinctions in legal and ethical frameworks create hurdles which hinder (if not block) research. Perhaps a re-interpretation of ethical principles specific to this context can provide direction.

**Enabling Responsible Public Genomics.** *D.B. Vorhaus[1], J.M. Conley[2], D.J. Clark[1].* 1) Genomics and Genetics Practice Group, Robinson, Bradshaw & Hinson, P.A., Charlotte, NC; 2) School of Law, University of North Carolina, Chapel Hill, NC.

As understanding of the complex relationship between genes and traits advances, researchers require increasingly rich datasets that combine genomic, phenotypic and environmental data from increasingly large numbers of individuals. A dramatic decline in the cost of genomic sequencing has made such datasets economically feasible. The generation of individuals' genomic sequence data inescapably produces clinically actionable information even as the linkage of that data with personal and phenotypic data simultaneously precludes traditional privacy promises; features not contemplated by the established ethical, legal and social framework governing human genomic research. The researcher's duty with respect to clinically significant data, the boundary between genomic research and the practice of medicine and the challenges to privacy presented by the return of genomic dataall these issues must be addressed if the next generation of genomic research is to be pursued in a responsible fashion.

Responsible public genomics combines identifiable data contributed by an informed and fully consenting cohort of information altruists with a public domain database model, resulting in rich datasets that maximize research potential and seed a genomic commons that is freely and globally accessible, enabling ethically, legally, and socially responsible genomic research in full view of the public. This Article examines the risks and benefits of the public genomics model in the context of one of the most ambitious genetic research project currently under waythe Personal Genome Projectand (i) demonstrates that large-scale genomic projects are both inevitable and desirable, (ii) evaluates the risks and challenges presented by public genomics research, and (iii) assesses the current legal and regulatory regimes that govern public genomics research and determines that even as they fail to adequately protect research subjects they simultaneously restrict beneficial and responsible scientific inquiry. The proposed solution is a modified normative and legal framework that embraces and enables a future of responsible public genomics.

## 1528/T/Poster Board #77

**Using Genetics to Overturn The Legacy of Slavery? The Hope and the Hype of Popular Representations of Personal Genomics, U.S. African Americans and Genetic Ancestry Testing.** *E. Clay.* Zygon Center, Lutheran School of Theology at Chicago, Chicago, IL.

The hope that advances in genomic research would discredit the biological legitimacy of 'race' as an operative category in research design and practice has been tempered by misleading hype in popular media that uncritically promotes social categories of race as biologically distinct; hype initiated in part by sensationalized genetic narratives and misrepresentations or omissions within researcher statements. In recent years, media coverage of genetic genealogy, ancestry-testing estimations, and approximated ancestral origins for U.S. born African Americans or Black British persons has increased. Described in several films as a means to overturn the legacy of slavery and reclaim black identity, ancestry tests are framed as a means to achieve personal empowerment and reconcile ancestral origins. These claims go far beyond what can be supported by currently available scientific methods. Expanded media attention to personal genomics, the marketing of direct-to-consumer (DTC) genetic testing and dramatic media portrayals of race and ancestry pose social, ethical, educational, and policy challenges. This paper provides an overview of representations of genomics, race and ancestry. Examples of hype in film, radio shows, and news print media from 2003 to 2009 are examined to investigate the role that messages of personal empowerment, images of travel to homelands and genetalk of newly discovered genetic 'kin' play in the representation of African American consumption of personal genomics. Many representations inaccurately depict human genetic diversity and seldom question the utility, direction, or methods of ancestry tests Media storylines not only make grandiose claims concerning ancestry tests, they also map older social categories of race onto less than 1% of human genetic variation. Following thematic plots of reversal of fortune or a quest for heritage, popular media portrays test-takers as pioneers, geneticists as keepers of secret knowledge, and genetic tests as having the ability to predict the past and the future well being of persons with certainty. The ethics of manufactured demand for a product of limited utility and validity should be scrutinized. Serious information asymmetries between testing companies and consumers call for increased regulation of ancestry claims and commercial genetic testing. Lastly, the legal implications of using ancestry tests to grant U.S. African Americans dual citizenship in African countries are considered.

## 1529/T/Poster Board #78

**Understanding the impact of long qt syndrome in a BC First Nations community.** *L. Huisman, R. McCormick, L. Arbour.* The University of British Columbia 3800 Finnerty Road Victoria B.C. V8P 5C2.

**Background:** There is a disproportionately high rate of hereditary Long QT Syndrome (LQTS) in Northern British Columbia First Nations people, partly due to a novel missense mutation in KCNQ1 (V205M). The effect has been previously described (Arbour et al 2008) predisposing those affected to syncope, arrhythmia and sudden death. A community based participatory research approach has enabled over 200 community members to take part, identifying more than 30 carriers of the mutation. Although a great deal of previous research has been carried out on the biological aspects of LQTS, there has been little study into the impact of living with a mutation that predisposes to sudden death, and no previous studies have provided cultural insights into the issues a remote First Nations community might face. **Objectives:** 1) From a cultural context explore what facilitates and hinders resiliency and coping for individuals and families 2) To explore issues of barriers to effective physical and psychological management, 3) understand the multigenerational impact of LQTS. **Methods:** Participants were invited to partake in their choice of 1) One to one interviews 2) photovoice and 3) talking circles. Interviews and talking circles were recorded, transcribed, and analyzed qualitatively using the Systematic Text Condensation method. **Results:** Consistent with the core study, men were reluctant to participate, however ten women shared their personal experiences of living with LQTS. Five of the women had known mutations and 5 had unknown genetic status. Most had affected children. In general, learning about a LQTS diagnosis was perceived as traumatic, with gradual acceptance that lead to coping. The main factors that facilitate resiliency and coping are: 1) positive family relationships, 2) spiritual faith, and 3) knowledge about LQTS. The main factors that hinder resiliency and coping were: 1) a poor understanding of the biological or clinical aspects of LQTS, 2) conflicting medical advice, especially about necessary physical restrictions, 3) LQTS not being taken seriously by both social contacts and health care providers, and 4) concern for the wellness of the next generation. **Conclusion:** Learning to live with LQTS is an ongoing process, requiring balance and interconnectedness between all aspects of wellbeing. These issues warrant further exploration. Recommendations to enhance genetic counseling within FN communities will be presented to reflect the Medicine Wheel concept.

## 1530/T/Poster Board #79

**Genetic health attitudes and reproductive intention in college students: Implications for public health genomics.** *H.H. Honoré[1,2], L-S. Chen[3], P. Goodson[3], D.M. Latini[1,2].* 1) Michael E DeBakey VA Med Ctr, Houston VA HSR&D Center of Excellence, Houston, TX; 2) Baylor College of Medicine, Houston, TX; 3) Department of Health & Kinesiology, Texas A&M University, College Station, TX.

Purpose: Although the relationship between certain disease-specific risk perceptions and sexual/reproductive intentions has been previously studied, fewer studies have explored the relationship between individual perceptions of genetic/genomic risk and these intentions. As college students are of reproductive age, this mixed-methods study examined the relationship between genetic risk perceptions and reproductive decision-making among college students. Method: This study consisted of qualitative (8 focus groups; n=86) and quantitative (survey; n=2,576) phases. Participants were primarily young, female college students. We asked participants how genetic/genomic risk might affect their reproductive decision-making. Responses were assessed using content analysis. Later, we developed hypothetical genomic-related scenarios (i.e., individuals with unknown genotype, asymptomatic carrier status, symptomatic carrier status, genetic/genomic-related physical disabilities, genetic/genomic-related mental disorders, and any genetic/genomic disorder). We used descriptive analyses to examine reproductive intentions under each scenario. Results: Focus group participants expressed overall negative attitudes related to childbearing with individuals having personal/familial histories of mental and physical health issues. These issues were considered "genetic" and stigmatized. Survey respondents were more likely to have childbearing intentions towards unknown genotype (41.7%), asymptomatic (26.2%) and symptomatic (18.4%) carriers, or any genetic disorder (17.1%) than those perceived to have physical disabilities (13.4%) or mental disorders (8.4%). Conclusion: Our mixed data show similar patterns: negative attitudes and lower reproductive intentions towards individuals with genetic/genomic disorders. With increased genetic/genomic test availability, caution must be taken to avoid genetic/genomic stigma and discrimination. Additional research is necessary to determine psychosocial factors influencing the perceived genetic risk-intentions relationship and develop psycho-educational and stigma-reducing interventions.

## 1531/T/Poster Board #80

**Genomic Medicine: The Tip of the Iceberg.** *A. Pai.* Healthcare Practice , IBM Global Business Services, Toronto, ON, Canada.

Recent data on genomics from a number of publications and Web sites demonstrate that the role of genomics in healthcare represents the "tip of the iceberg". As genomics technologies (e.g. genomic testing) improve in sensitivity and decrease in cost, genomic medicine will reach a tipping point and become an integral part of health care delivery and a key part of a citizen's electronic health record. Healthcare stakeholders thus have a remarkable opportunity at their hands; one that promises to increase in uptake as such technologies mature. Healthcare and wellness decisions will routinely include a genomic component and change its approach to care delivery from retrospective, interventional care to prospective and preventative care which is highly personalized and pre-emptive. More specifically, in the case of chronic diseases such as diabetes, mental health disorders and cancer, such data will lead to significant pre-emptive measures to prevent the onset of disease, years in advance of symptoms appearing. Genomic data will thus influence chronic disease and prevention management strategies. Key enablers in this regard include genomic literacy, privacy and security and the role of e-health (and corresponding information technology). The impact of genomic medicine will also not occur in isolation, but will instead converge with advances in information technology (e.g. the Internet and electronic health records), communication (e.g. social networking), and other innovative areas of medicine (e.g. clinical research and regenerative medicine). Instead of debating whether genomics is really impacting healthcare or not, it will be prudent for healthcare leaders to grapple with how quickly the game will change as a result of genomics. Given the importance of success of enablers such as genomic literacy, privacy and security of genomic information and the key role that e-health and information technology will play in this regard, strong policy measures that support these enablers will be crucial for the successful incorporation of genomic medicine in healthcare.

## 1532/T/Poster Board #81

**Population Prevalence of Stratified Familial Cancer Risk and Common Hereditary Cancer Syndromes: The 2005 California Health Interview Survey.** *M. Scheuner[1,2,3], T.S. McNeel[4], A. Freedman[5].* 1) RAND Corp, Santa Monica, CA; 2) VA Greater Los Angeles Healthcare System, Los Angeles, CA; 3) Department of Health Services, UCLA School of Public Health, Los Angeles, CA; 4) Information Management Services, Inc., Silver Spring, MD; 5) National Cancer Institute, Bethesda, MD.

Background: Family history helps guide cancer screening, prevention, and referral for genetic services. Using data from the 2005 California Health Interview Survey, we estimated the population prevalence of increased familial risk for breast, ovarian, endometrial, prostate and colorectal cancers and hereditary cancer syndromes that include these cancers. Methods: For each respondent, a weak, moderate, or strong familial risk was assigned for each cancer type using rules that consider age at diagnosis, number of affected 1st and 2nd degree relatives, their relationship to each other, and occurrence of related cancers. Guidelines were applied to identify individuals with family histories suggestive of hereditary breast-ovarian cancer (HBOC) and hereditary nonpolyposis colon cancer (HNPCC). Results: Of 33,187 respondents between the ages of 18 and 64 years, 2% reported a personal history of breast, ovarian, endometrial, prostate or colorectal cancer. Among respondents without a personal history of these cancers, women had higher prevalence of both moderate and strong familial risk for each cancer, except prostate cancer. Whites had the highest prevalence, and Asians and Latinos had the lowest prevalence of moderate and strong familial risk for each cancer. Of all familial cancer, familial breast cancer was most prevalent (5% of family histories were strong and 7% moderate risk). Among women without history of breast or ovarian cancer, 3% met criteria for HBOC; 89% had a strong and 11% a moderate familial risk for breast or ovarian cancer. Of women who did not meet HBOC criteria, only 4% had a strong and 9% a moderate familial risk. Among individuals without history of colorectal, endometrial or ovarian cancer, 0.3% met criteria for HNPCC; 99% had a strong and 1% a moderate familial risk for these cancers. Of those who did not meet HNPCC criteria, only 3% had a strong and 7% a moderate familial risk. Conclusions: Based on the first large state survey of familial cancer history, we provide population-based prevalence estimates for moderate and strong familial risk for five common cancers and family histories consistent with HBOC and HNPCC. Among respondents without a personal history of cancer, 3% of the population had a family history indicative of HBOC and only 0.3% for HNPCC. Such estimates will be helpful for planning and evaluation of genetic services and prevention programs, and for assessment of cancer surveillance and prevention strategies.

## 1533/T/Poster Board #82

**A Policy to Develop Public Trust; the Discourses of Accountability and Transparency in Biobank Japan.** *S. Iwae.* Institute for Research in Humanities, Kyoto University, Japan.

It has been known that a human biobank project potentially generates a number of complex ethical and social issues. So, the necessity of establishing adequate governance framework has been emphasized in biobank researches. In particular, it can be said that the core of the governance policy is fostering public trust, which also consists of two significant components: accountability and transparency. In this research, I explored how those two factors were actually interpreted in the governance framework of Biobank Japan by interviews with several people involved in Biobank Japan project. Eventually, it seemed that solid and consistent governance policies did not exist in Biobank Japan, because people, who were involved, had many different views toward how accountability and transparency should be in the project. Such condition implied that those various views and activities in Biobank Japan were not well-organized and guided to build up the public trust. Finally, some future policy suggestions on how a biobank project may develop public trust will be discussed in this presentation.

## 1534/T/Poster Board #83

**If You Build It ... Will They Come?: Hurdles to Biobank Access.** *B. Knoppers, S. Wallace, S. Pathmasiri.* Dept CRDP, Univ de Montreal, Montreal, PQ, Canada.

In the last decade, public investment and participation in large, population genomics research studies has been constant. When such studies are harmonized, they can increase statistical power as well as serve as a resource for validation, replication or comparison (controls). The time to access such infrastructures has come. But how realistic are the possibilities for access and use by researchers? The identification of the core access elements across 21 major population genomics biobanks reveals both convergence and divergence. Not surprisingly, approaches to intellectual property vary greatly (if addressed at all!). But a myriad of other procedures might also hinder access and so thwart the "research -resource" mission of such biobanks. They include lack of clarity and transparency as to: i) the process of evaluation; ii) local requirements; iii) costs of access, and iv) necessary prior levels of ethics or security approvals. Providing an analysis of core elements and proposing a model for international sample and data access may foster their actual use for research.

## 1535/T/Poster Board #84

**Ethics in the Age of Direct-to-Consumer Personal Genomics: Evaluating Traditional Approaches towards Protecting the Public.** *S. Lee.* Dept Biomedical Ethics, Stanford Univ, Palo Alto, CA.

The rapid commercialization of cutting edge technologies often evokes challenging social and ethical questions. Over the past several years, increasingly efficient high throughput bioinformatics technology and ubiquitous internet use among the public have laid the foundation for academic and commercial efforts that provide personal genetic information directly to consumers and research participants. These developments have prompted a debate over the clinical utility of these services, focusing on questions over what information should be returned to individuals, what criteria should be used in making these decisions and who should be ultimately responsible for delivering results. As yet, there has been little empirical work that examines how the public understands, interprets and applies personal genomic information. This paper discusses initial findings from a qualitative pilot study of the attitudes, expectations and actions of consumers who have purchased personal genetic information through the internet. This paper evaluates traditional approaches to ethical issues concerning genetic testing that build on assumptions that genetic information is unique and discusses these in the context of attitudes among study participants. Building on emerging data from ongoing research of public attitudes and uses of personal genomic information, this paper addresses whether a paradigm shift is occurring in how genetic information is understood and applied by the public and discusses key social, ethical and policy issues related to this growing field.

## 1536/T/Poster Board #85

**Un-enrolled Family Member Information Collected in NIH Sponsored Family Genetic Studies - Privacy Risk?** *M.T. Quinn Griffin[1], G.L Wiesner[2], M. Flatt[3], S. Lewis[2].* 1) Frances Payne Bolton School of Nursing, Case Western Reserve University, Cleveland, OH; 2) Department of Genetics, School of Medicine, Case Western Reserve University, cleveland, OH; 3) Department of Bioethics, School of Medicine, Case Western Reserve University, Cleveland, OH.

Purpose: Family genetic studies collect information on enrolled and un-enrolled family members. While privacy concerns have been raised over the collection and use of family based data, it is not clear what type of information is gathered and how it is used by researchers. Un-enrolled family members may be at particular risk for breeches of privacy as they did not provide informed consent for the collection of their information. The purpose of this study was to describe the collection of un-enrolled family member data in family genetic studies. Methods: 211 abstracts of eligible studies were identified through the online "CRISP" (Computer Retrieval of Information on Scientific Projects) database of projects funded by NIH. An email with a link to an online survey was sent to 175 unique investigators. The survey questions addressed the recruitment of family members, collection of demographic and health data, and use of pedigree information. 17 investigators did not match the inclusion criteria or had incorrect email addresses. The response rate was 30.4% (n=52). Most of respondents held Doctoral degrees (55.8%; n=29) and were experienced. Results: Almost one-half of the respondents (48.1%; n=25) asked participants asked to provide demographic or health information about un-enrolled family members. Five (10%) collected identifiers such as address while 7 (13%) recorded telephone numbers. Of these, 22 (88%) indicated that they drew a pedigree based on the information. The majority annotated the pedigree with health and personal/demographic information. Seventeen respondents (41.5%) included the pedigree in publications and 13 of these (81.2%) modified it before publication. There was no consistent method for gathering the family member's contact information from the proband, Eleven (21%) asked the proband for family members contact information before the family member expressed interest in being contacted. Conclusions: Varying amounts of data are collected from enrolled family members about their un-enrolled relatives. These data are used in pedigrees, many that are modified and published. This poses a risk of identification of these un-enrolled family members and the potential of a breach of privacy. This suggests a need for guidelines on specific protections for un-enrolled family members that may be useful to both researchers and to committees involved in the review of human subjects' research. Supported by CGREAL and NIH grant P50-HG003390.

## 1537/T/Poster Board #86

**Protecting Privacy, Trust, and the Future of Individualized Medicine: An analysis of genomic research practices and policies that fail to account for DNA as a unique identifier, and recommendations on how to fix them...** *J.T. Wu, B. Koenig.* Program in Professionalism and Bioethics, Mayo Clinic, Rochester, MN.

The growth of bioinformatics and genetic technologies has greatly increased the availability and accessibility of individual DNA data. This creates profound challenges to conventional notions of genetic privacy protection. Current policies regulating the collection and use of DNA data rely on administrative "anonymization" or "de-identification," and individual control of genetic information to protect privacy. As genomic and bioinformatics technologies have developed, current regulatory policy has fallen behind. Current policy cannot, and does not account for most of the privacy concerns that arise with the development of large-scale genetic biobanks and genome wide association studies, such as breaches in data security, re-identification of individual DNA data, and lapses in informed consent. This paper contains policy recommendations that aim to improve regulatory policy dealing with the collection, use, and dissemination of DNA data. A unique feature of our project was the structured integration of empirical and normative analyses. First, we conducted a review of conceptual literature relevant to genetic privacy and biobanking. This paper will provide an account of the social, scientific and legislative evolution of individualized medicine research. Second, we completed a collection of descriptive data from interviews with key informants. We conducted 15 semi-structured interviews with key stake holders in the fields of privacy, forensics, data safety, personalized medicine research, and government. Based on the qualitative analysis of our interviews, we will discuss the major themes addressed by the interviewees. Finally, we organized a multidisciplinary advisory board meeting where expert consultants came together to discuss the implications of the previous steps and outlined concrete policy recommendations based on prior steps. Here we present the major finding from each step in the above process.

## 1538/T/Poster Board #87

**A Framework for the Delivery of Genetic Testing: A Foundation for Translational Genomics Research.** *T. Bentley[1,2], S. Olmsted[3], E. Eiseman[1], S. Wooding[4], B. Kim[1,5], M.T. Scheuner[1,2,6,7].* 1) RAND Corporation, Santa Monica, CA; 2) UCLA Center for Health Policy Research, Los Angeles, CA; 3) RAND Corporation, Pittsburgh, PA; 4) RAND Europe, Cambridge, UK; 5) Department of Hematology-Oncology, David Geffen School of Medicine at UCLA, Los Angeles, CA; 6) VA Greater Los Angeles Healthcare System, Los Angeles, CA; 7) Department of Health Services, UCLA School of Public Health, Los Angeles, CA.

Purpose: With increasing availability of molecular genetic tests, strategies are needed to increase access to quality genetic testing services. We have created a model for the delivery of genetic tests to understand how best to organize and strategically plan for the delivery of these services. Methods: We adopted an existing structure-process-outcome model of provider behavior to characterize the factors that might influence the delivery of genetic tests used for medical decision-making. These factors reside in four key domains: external environment, organizational structure and processes, and provider and patient characteristics. We defined the different provider types that would be involved for various genetic testing indications, outlined the steps involved in delivering genetic tests, and detailed the process and provider assumptions. We convened an advisory board to validate our approach and refine our framework. Results: Our resulting seven-step framework represents the logical and temporal sequence of the delivery of genetic testing services. The steps include: (1) selection of the individual for testing, including assessment of pre-test probabilities and post-test implications; (2) selection of the test; (3) pre-test communication, including informed consent if necessary; (4) test uptake decision; (5) [if testing chosen] ordering of test; (6) results interpretation and disclosure; and (7) provision of medical recommendations. In the absence of testing, medical recommendations follow pre-test communication. The frequencies of actions taken at each step represent the outcomes of interest, which are influenced by use of clinical decision support, genetic counselors, and clinician referrals. The framework serves as a basis upon which to model specific genetic tests for the indications of susceptibility, diagnostic, prognostic, and pharmacogenetic testing. Types of providers include primary care clinicians, geneticists, other specialists, and direct-to-consumer marketing firms. Conclusions: We have developed a framework for the delivery of genetic tests that can be used in future translational genomics research including modeling studies, implementation research, clinical trials, and comparative effectiveness studies. By identifying processes and factors that influence the delivery of these services by different types of providers, applications of this framework will guide future development, planning and evaluation of genetic testing services.

## 1539/T/Poster Board #88

**Informing evidence-based policy for expanded newborn screening: Engaging the general public about the provision and governance of newborn screening.** *Y. Bombard[1], F.A. Miller[1], J.C. Carroll[2], D. Avard[3], R.Z. Hayeems[1], J. Allanson[4], J. Bytautas[1], P. Chakraborty[4], Y. Giguere[5], J. Little[6], K. Senecal[7], B. Wilson[6].* 1) Faculty Medicine, Department of Health Policy, Management and Evaluation, University of Toronto, Canada; 2) Department of Family and Community Medicine, Mount Sinai Hospital, University of Toronto, Canada; 3) Centre for Genomics and Policy, Department of Human Genetics, McGill University, Montreal, Canada; 4) Department of Genetics, Children's Hospital of Eastern Ontario, and Department of Pediatrics, University of Ottawa, Canada; 5) Department of Medical Biology, Centre Hospitalier Universitaire de Quebec (CHUQ), University of Laval, Canada; 6) Department of Epidemiology and Community Medicine, University of Ottawa, Canada; 7) Centre de recherche en droit public, University of Montréal, Canada.

**Purpose:** Continued debate about expanded newborn screening (NBS) has led to calls for stakeholder engagement to inform policy. Research reports consumers' attitudes towards NBS, but little reflects the perspectives of the general public - important stakeholders of public health initiatives. **Methods:** We conducted a public engagement study using deliberative focus groups and pre-and post- questionnaires to assess the public's values and attitudes toward NBS. Participants were recruited through community agencies and advertisements to ensure socio-economic, ethnic, age and family life diversity. **Results:** Five focus groups were conducted (n=36). The majority supported expanded NBS that identifies serious disorders with highly effective treatment (36/36:100%), where treatment exists to reduce severity (34/36:94%) or where no treatment exists (26/36:74%). Participants reasoned that expanded NBS provides information, which even in the absence of treatment can help families plan for the future and help research. Potential harms, such as learning false positive or carrier results, were often minimized, but some respondents identified risks from stigma and unwanted knowledge. On consent, participants preferred that parents be *strongly encouraged* to have their baby screened (27/36:77%); they differentiated between highly treatable conditions where screening should be *required* (27/36:75%) and untreatable conditions where parents should be *able to choose* whether to have their baby screened (21/36:58%), but generally endorsed the need to ensure that parents were informed. The majority supported storing NBS samples for quality control (35/36:97%), diagnosis (35/36:97%) and anonymous research purposes (33/36:92%), but were ambivalent towards law enforcement or unspecified purposes (15/36:42% for both). Most preferred that parents should be s*trongly encouraged* to have their baby's sample stored (28/36:77%). The impact of deliberation on attitudes will be discussed. **Conclusions:** Most participants anticipated benefits from early disease identification through NBS, and expected few if any harms. Respondents anticipated that parents could make effective use of NBS results, and expected them to be able to make decisions about the scope of screening after being informed, ideally in the prenatal period. These findings should be considered in developing policy in this controversial domain.

## 1540/T/Poster Board #89

**Direct-to-Consumer Genetic Testing: Recommendations from the Secretary's Advisory Committee on Genetics, Health, and Society.** *S. Au, Secretary's Advisory Committee on Genetics, Health, and Society.* Genetics Program, Hawaii Dept Health, Honolulu, HI.

Advances in genetic and genomic technologies have allowed increasing amounts of genetic information to be provided to patients and consumers with declining costs. At the same time, there has been a shift toward consumer-driven health care and patient empowerment. Capitalizing on these technological and social developments, commercial entities offering genetic services directly to consumers have emerged. The unprecedented speed at which genetic technologies have been translated into commercial products, however, has raised some concerns. The Secretary's Advisory Committee on Genetics, Health, and Society (SACGHS) has developed a paper that outlines issues for consumers to consider in making an informed decision about using the services of companies that offer direct-to-consumer (DTC) genetic testing and the information they receive through testing. SACGHS was established to assist the Department of Health and Human Services (HHS) and, if requested, other Federal agencies in exploring issues raised by the development and application of genetic and genomic technologies, and the Committee makes recommendations to the HHS Secretary on how to address such issues. This presentation will describe areas of concern raised by DTC genetic testing, particularly potential issues that may arise when a consumer's personal health provider is not involved in health decisions or if government regulations do not apply to entities providing DTC testing. It will also highlight recommendations from prior SACGHS reports that address concerns about genetic testing regardless of the route in which tests are ordered (i.e., DTC or through a consumer's personal health care provider) and identify issues not adequately addressed by prior SACGHS recommendations. The scope of the paper is limited to DTC genetic testing that provides risk assessment or diagnosis of disease or health conditions, and information about drug response or other phenotypic traits. It excludes forensic analyses and paternity and ancestry testing.

## 1541/T/Poster Board #90

**The HumGen Spanish Portal Human Genetics Database of Law and Policies: A tool for the policy-making process in Latin America.** *P.F. Oliva-Sanchez[1], A. Arellano[1], C. Lara[1], R. Isasi[2], B. Knoppers[2], G. Jimenez-Sanchez[1].* 1) National Institute of Genomic Medicine, Mexico City, Distrito Federal, Mexico; 2) Research Center in Public Law (CRDP) at the University of Montreal.

Spanish is the second most-spoken language in the world, after Mandarin Chinese. Researchers, policy-makers, and the general public need accurate information to develop policy and legal regimes to inspire fruitful contributions to these debates. Due to the lack of this information in Latin America (LA), The National Institute of Genomic Medicine of Mexico (INMEGEN) and the Research Center in Public Law (CRDP) at the University of Montreal is participating in The HumGen International Project, developing it's Spanish portal. This project is an existing database of laws and policies in Human Genetics. The database is available in English and French to. HumGen includes Spanish-language sources and reach a Spanish-speaking audience. The portal is a research database of international, regional, and national instruments concerning aspects of human genetics. In the selection criteria we searching and included, documents that aim to set standards, either binding (such as laws and regulations) or non-binding (such as policies and recommendations of professional associations). We based the searching process in a list of keywords that includes important areas in like intellectual property or discrimination. The process of search and selection of documents is done by scientists to be part of the INMEGEN Team. The documents are sent to Canada Team, those who administer the portal.The Updated of the database HumGen began in August 2008. We found 252 new documents but only 46 documents in Spanish, were selected and added to the 64 documents that were available in the portal. From the documents found, 35% are laws and 65% are policies. By type of coverage for 22% of documents are national, 22% are international and 54% are regional. Documents were found belonging to 18 countries, of which 12 have Spanish as the official language. Regarding the spread of this portal, INMEGEN has conducted various academic events in institutions like the Senate of Mexico. Currently is organizing a presentation of the portal in the Pan American Health Organization. The Internet is the leading media for democratizing and disseminating knowledge and connecting providers of information with users. This portal serves for the dissemination of relevant information to policy-making in human genetics over Internet, aimed to researchers and policy-makers in the Hispanic countries, who are adapting in their cultures, new laws and policies based in a international regulatory framework.

## 1542/T/Poster Board #91

**Genome-wide genotyping linked to electronic medical records: demographics, ancestry, and other factors influencing consent in a large pediatric cohort.** *J.H. Flory[1], R. Chiavacci[1], K. Annaiah[1], W. Glaberson[1], H. Zhang[1], K. Wang[1], C. Kim[1], R. Grundmeier[2], S. Ostapenko[2], A. Thomas[1], K. Harden[1], A. Hill[1], S. Wildrick[1], C. Johnson-Honesty[1], K. Fain[1], S. Harrison[1], C. Drummond[1], D.E. Surrey[1], S.F. Grant[1], H. Hakonarson[1].* 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Center for Biomedical Informatics, Children's Hospital of Philadelphia, Philadelphia, PA.

Collection of genome-wide data is important for research and expected to become relevant to clinical practice. For the first 21,000 children recruited by the Center for Applied Genomics (CAG) at Children's Hospital of Philadelphia (CHOP), genome-wide data have been linked to their electronic medical record (EMR) for research. Data from CAG's enrollment, data security, and analytic activities can help inform debates over how genetic data can safely be used in research and ultimately clinical care.

80-95% of parents were willing to enroll their children for genome-wide genotyping at CAG from 2006-2009. This rate varied depending on enrollment site and the identity of the person obtaining informed consent. About 15% of parents only consented on the condition that there be no persistent link between the genetic data and their child's EMR or further contact with investigators. Consent to both further contact and persistent linkage to EMRs rose with time (80% in 2007 versus 90% in 2008, $P < 0.0001$). Participants' health had little effect on consent.

CAG was able to enroll a primarily African-American and Caucasian population roughly reflecting the demographics of CHOP's patient population. Multidimensional scaling to study participants' ancestry showed that self-reported race was accurate but that the African-American population in particular was highly admixed. After multivariable adjustment Caucasians were more willing than African Americans (OR=1.44, 95% CI 1.31-1.59) to consent to keeping data identifiable and Asians were less willing (OR = 0.68, 95% CI 0.54-0.85)). A history of visits to CHOP for routine care was also associated with consent to keep data identifiable (OR = 1.3, 95% CI 1.0-1.7, P=0.03).

The results show a substantial majority of Americans from diverse backgrounds in the Philadelphia area trust a large health care institution to collect their genetic information, and most are willing to have persistent linkage between that information and their identity. Several factors extrinsic to participantsnotably the year of recruitment and the identity of the recruiter who approached themhad a significant effect on willingness to give consent.

## 1543/T/Poster Board #92

**Developing an Evidence Review Process for Newborn Screening Decision-Making.** *R. Howell[1], M. Lloyd-Puryear[2].* 1) Prof & Chair Emerit, Dept Ped, Univ Miami Sch Med, Miami, FL; 2) Maternal and Child Health Bureau Health Resources and Services Administration 5600 Fishers Lane Rockville, MD 20857.

When to test? What test to order? When to treat? How to treat? Who to treat? What guides our decisions that affect patient care and the publics' health in the provision of genetic testing and services? The development and use of systematic evidence reviews, professional guidance, and expert opinion will be considered as components of the decision making process in deciding what newborn screening and genetic services should be offered, to whom, and for what purpose within State newborn screening (NBS) programs. In the US, over 4 million infants a year receive a series of NBS tests. Standard criteria for synthesizing evidence are widely accepted for the evaluation of screening tests and treatments for common conditions. However, criteria need to be adjusted for evaluating screening for rare conditions, such as those identified by NBS. The screening tests, methods of diagnosis, and treatments for many conditions that NBS identifies have not undergone the large-scale and randomized trials that are the standard for other domains. The **Advisory Committee on Heritable Disorders in Newborns and Children** was created by Congress and began its work in 2004. The Committee's charge is to advise and guide the Secretary of the federal Department of Health and Human Services regarding the most appropriate application of childhood and universal newborn screening tests, technologies, policies, guidelines and programs for effectively reducing morbidity and mortality in newborns and children having or at risk for heritable disorders. The Committee also provides advice on a specific grant program delineated in its authorizing legislation. This presentation will outline the Committee's decision and recommendation process and its implications for screening newborns and children. We will also address other relevant Committee activities.

## 1544/T/Poster Board #93

**Transforming Research Practices: Achieving Benefits through Accountability.** *K. Fryer-Edwards[1], S. Goering[2], S. Holland[3], G. Geller[4], R. Sharp[5], M. Yarborough[6].* 1) Bioethics and Humanities, University of Washington, Seattle, WA; 2) Philosophy, University of Washington, Seattle, WA; 3) Religious Studies and Bioethics, University of Puget Sound, Tacoma, WA; 4) Berman Institute of Bioethics, Johns Hopkins University, Baltimore, MD; 5) Department of Bioethics, The Cleveland Clinic, Cleveland, Ohio; 6) Center for Bioethics and Humanities University of Colorado Denver, Aurora, CO.

The promise of biomedical research depends, quite pragmatically, on the translation of basic scientific findings into therapeutic applications that improve health. The translational imperative is particularly strong for areas of research like human genetics that carry a substantial expectation of benefit, and have involved significant investment. Yet some studies suggest that only 5% of "highly promising" basic genomic science findings ever result in applications suitable for clinical use, and only 1% are used according to clinical guidelines. This state of affairs suggests significant problems of translation. In the United States, the National Institutes of Health have recognized the importance of providing incentives for researchers to attend to translational obstacles through the creation of Clinical and Translational Science Awards (CTSAs). Such awards, given to interdisciplinary teams of researchers, are designed to speed the movement of new knowledge gained through bench science to the bedside, into regular clinical practice, and ultimately to improve community health. Yet while efficiency of translation is no doubt important, more fundamental questions remain: who benefits, and is justice served? Our work has focused on examining how standard research practices can inadvertently create harms, and how transformed practices might be possible. The usual practices of open data sharing, working with anonymized samples, prioritizing discovery-based science and publications in peer-reviewed journals, have done much to advance the research enterprise while not necessarily staying in touch with public needs and interests. In 2008, we met with community-health leaders in Colorado to explore issues related to translational research, and biobanking with genetic material more specifically. We heard clear messages regarding the need for the research institution to build relationships and develop two-way lines of communication, as well as have transparent systems of accountability. For example, participants discussed: developing mechanism for shared authority; traceable samples so participants can learn who has their samples, for what purpose; appreciating need for specific opt-out or withdrawal. This abstract reports on the work from two research groups: Testing Justice (funded by Greenwall Foundation and NHGRI through the Center for Genomics and Healthcare Equality) and TIES, or Trust, Integrity, and Ethics in Science (funded in part by NHGRI).

## 1545/T/Poster Board #94

**Age-related differences in attitudes toward participation in genomic research.** *S.M. Fullerton[1], S.B. Trinidad[1], J. Bares[1], G.P. Jarvik[2], E.B. Larson[3], W. Burke[1,2,3].* 1) Bioethics & Humanities, Univ Washington, Seattle, WA; 2) Medical Genetics, Univ Washington, Seattle, WA; 3) Center for Health Studies, Group Health Cooperative, Seattle, WA.

Members of the public are increasingly being called upon to participate in a range of large-scale genomic research projects designed to advance our understanding of genetic contributions to health and disease. However, relatively little is known about prospective participants' perceptions of the benefits and risks associated with genomic research, or how these perceptions might vary according to key demographic characteristics, such as age at time of recruitment. To explore the effect of age on attitudes toward genomic research participation, we compared responses of participants in 6 focus groups with members of a non-profit health maintenance organization (HMO), Group Health Cooperative in Seattle, Washington. The study, conducted as part of a Group Health-University of Washington eMERGE (electronic Medical Records and Genomics) project, was designed to elicit the viewpoints of consumer stakeholders regarding a number of ethical issues surrounding involvement in genome-wide association studies (GWAS) including data-sharing, privacy, secondary research uses, and informed consent. Two focus groups were held with each of three categories of HMO members not currently participating in Group Health-sponsored research: (1) those aged 18-34 (average age 27), (2) those aged 35-49 (average age 42), and (3) those aged 50 and above (average age 66). In these discussions, older participants (age 50+) were more likely to express altruistic motives for research participation and trust in Group Health as both health-care provider and research institution, whereas younger participants (age 18-50) were more likely to suggest that they would not be comfortable with broad terms of consent and would expect on-going engagement with the research team. Contrary to expectation, the major age-correlated difference was in views regarding risks to genetic privacy, with younger participants unexpectedly citing many more concerns about the security of genetic and electronic medical record data than older participants. Concerns included unauthorized access to computerized data, fears of identity theft, worries about insurance discrimination, and distrust of the government. Despite these misgivings, younger focus group participants reported a similar degree of willingness to participate in GWAS and related forms of genomic research.

## 1546/T/Poster Board #95

**Genome Diner: A strategy to increase community-researcher engagement.** *J.M. O'Daniel[1], T.M. Livingston[2], L. Boles[2], M.K. Rosanbalm[3], S.B. Haga[1].* 1) Institute for Genome Sciences & Policy, Duke Univ, Durham, NC; 2) Museum of Life and Science, Durham, NC; 3) Center for Child & Family Policy, Duke Univ, Durham, NC.

Large population studies often required in genome research could greatly benefit from a public who understands and values the potential benefits of the research and who trusts the researchers themselves. Researchers, however, may have difficulty communicating to diverse, lay audiences about the importance and relevance of their work. Further, the interests and unique perspectives of the public may not always align with what researchers wish to communicate. Thus, it is critical for researchers and the public to gain a better awareness of each other's perspectives. To address this need, we developed and piloted a unique strategy which bridges the concepts of formal (public school) and informal (Museum of Life and Science) science learning, with the experiential context of family learning and public communication training for university researchers. The resulting Genome Diner program engaged student/parent groups in thoughtful dialogue about scientific and social issues side-by-side with university researchers. The small group discussions were facilitated by moderators and a fun "menu" of genome discussion topics and questions to encourage participation by all. A total of 98 student/parent participants (47 students; 51 adult parents/guardians) and 16 genome science researchers took part in one of four Genome Diner sessions conducted at a local middle school. Using a series of pre-, post- and follow-up surveys, we assessed the impact of the program on: Community a) knowledge, perceptions and interest in genome science research and b) confidence in ability to seek and interpret genome science information; and Researcher a) perceptions about public understanding and attitudes, b) opinion of public input and c) confidence and willingness to participate in public science programs. Analysis reveals that participation in Genome Diner had significantly positive effects on perceptions and attitudes for both researcher and community participants. The outcomes of this project suggest that Genome Diner is a successful approach to building awareness and positive perceptions between community members and researchers.

## 1547/T/Poster Board #96

**Community response to mental health intervention on the basis of genetic susceptibility in a large national population.** *A. Wilde[1, 3], B. Meiser[2], P.B. Mitchell[1,3,6], D. Hadzi-Pavlovic[1,3], P.R. Schofield[4,5,6].* 1) School of Psychiatry, University of New South Wales, Sydney, Australia; 2) Prince of Wales Clinical School, University of New South Wales, Sydney, Australia; 3) Black Dog Institute, Sydney, Australia; 4) Prince of Wales Medical Research Institute, Sydney, Australia; 5) School of Medical Sciences, University of New South Wales, Sydney, Australia; 6) Brain Sciences UNSW, Sydney, Australia.

Purpose. Despite an apparent high demand for predictive genetic testing, few data describe anticipated health behavior as a consequence of such testing. Using the example of the replicated association between a functional polymorphism in the serotonin transporter gene promoter and exposure to stressful life events resulting in an increased likelihood of major depression, this study aimed to evaluate anticipated community behavioral response to predictive genetic testing for depression risk. Methods. A quantitative survey of a large Australian nationally representative population sample of 1046 participants was ascertained through random digit dialing. Attitudes were assessed via structured interviews. Results. There was strong support for health-protective behaviors in the event of being identified with an increased genetic risk for major depression. Intention to start therapies (78%) was significantly and positively associated with higher self-estimation of risk for depression (p=0.001); endorsement of gene-environment interaction as a causal mechanism of mental illness (p=0.017); and endorsment of 'stressful life events' as a causal attribution for mental illness (p=<0.001). Intention to modify potential life stressors (84%) was significantly and positively associated with personal history of mental illness (p=0.032); endorsement of gene-environment interaction as a causal mechanism of mental illness (p= 0.005); and endorsment of 'abuse' as a causal attribution for mental illness (p<0.001). 'Do nothing' due to self perception of not being at risk (24%) was significantly and positively associated with being male (p=0.029), being older (p=0.001) and having no post school education (p=0.003) and significantly and negatively associated with endorsement of gene-environment interaction as a causal mechanism of mental illness (p=0.023). Conclusion. The study has identified strong community receptivity to behavioral mental health intervention in association with predictive genetic testing. In particular, we have identified target groups most likely to be motivated to engage in such interventions as those with a high risk of depression who endorse that mental illness may develop from both genetic and modifiable environmental risk factors. Our results suggest genetic risk information has potential value as an early intervention and prevention tool.

## 1548/T/Poster Board #97

**Public attitudes and knowledge regarding genetic research and participation in the establishment of a biobank in Portugal.** *M. Barreto, B. Nunes.* Department of Epidemiology, Instituto Nacional de Saúde Dr. Ricardo Jorge, Lisboa, Portugal.

Cohort studies investigating genes, environment, and lifestyle require large samples of population. To recruit and retain participants, it is important to understand the factors that influence individual's motivation to participate. In this context, the aim of this study was to evaluate the Portuguese population's basic knowledge about gene-environment interactions in disease development, and their attitude regarding participation in a genetic research project, as well as the factors that would motivate people to participate. A Computer Assisted Telephone Interview (CATI) survey of Portuguese adults (≥18 years old) was conducted in January 2009. The questionnaire, consisting on 13 questions, was applied to a member of each of the 870 households comprising our random sample. Overall, 753 interviews were completed (87% response rate). To describe the estimates of population knowledge and participation in a genetic research study, the sample was weighted by region and sex. Most respondents (87.3%) believe that genetic research significantly contributes to disease prevention and 64.4% have good or very good knowledge regarding the interaction between genes and the environment in disease development. Regarding their willingness to participate in a genetic research study that required individuals to donate blood, 64.1% of respondents would be willing to participate and 16.7% would like to contribute to the study, but can't due to advanced age or due to the presence of chronic diseases. Only 13.5% of respondents would not participate. Refusal was mainly associated with having to donate blood (35.7%). To examine factors related to participation, an ordinal logistic regression model was used. Individual characteristics that potency participation were: belonging to the age group between 25-44 years old, having a higher education, supporting biomedical research and having very good genetics knowledge. The great majority of the respondents willing to participate (88.8%), would not mind to have their samples stored for large periods of time in a biobank to be used in other studies in the future. Overall, the Portuguese population believes that genetic research has an important role in disease prevention, has reasonable knowledge regarding gene-environment interaction in the development of certain disorders and is willing to participate in a study to investigate this type of interactions.

## 1549/T/Poster Board #98

**Validation of the Brazilian Database on Orofacial Clefts.** *V.L. Gil-da-Silva-Lopes[1], P.A. Mossey[2], I.L. Monlleó[3,4].* 1) Department of Medical Genetics, State University of Campinas, ampinas, SP, Brazil, Campinas, São Paulo, Brazil; 2) University of Dundee, UK; 3) Universidade de Ciências da Saúde de Alagoas, Alagoas, Brazil; 4) Universidade Federal de Alagoas, Alagoas, Brazil.

Introduction: In 1998 the National Health Ministry of Brazil created the Reference Network for Craniofacial Treatment (Rede de Referência no Tratamento de Deformidades Craniofaciais - RRTDCF). The first evaluation of the RRTDCF was held in 2004 by our team. Regional disparities, structural and functional constraints, and lack of coordination were problems identified. To address these problems we proposed a long-term project, starting with the Brazilian Database on Orofacial Clefts (BDOC). Aim: To discuss the validation phase of the BDOC. Methods: BDOC was designed according to the Who's recommendations. The proposal was promoted at four meetings and clinical geneticists were invited to test the case record form and manual for case registration, and to assess its feasibility. Results: Seven clinical geneticists entrusted with craniofacial care engaged in a six months test. Three of them are members of multidisciplinary teams of the RRTDCF while four are from genetic centres (two in the Northeast and Southeast, and three in the South of Brazil). After six months of collection, 126 record forms and 10 assessment questionnaires were received. Average time spent to complete the record form was 15 minutes. Reliability was assessed. Problems identified were need for revision of wording and spacing. Conclusion: Record form and manual have been assessed as useful and reliable tools and reduced time spent to complete would be advantageous. Overall, however, the BDOC seems to be a useful and feasible strategy to help address the challenge of orofacial clefts in Brazil. CAPES, CNPq, FAPEAL and FAPESP.

## 1550/T/Poster Board #99

**Developing a "Social Marketing Plan" for appropriate genomic medicine -meeting the needs of a cultural and linguistic minority group: The Deaf community.** *Y. Kobayashi[1], P. Boudreault[1], E. Baldwin[2], M. Fox[3], L. Dutton[2], L. Tullis[2], W.W. Grody[3,4,5], C.G.S. Palmer[2,4].* 1) Deaf Studies Department, CSU Northridge, Northridge, CA; 2) Department of Psychiatry and Biobehavioral Science, UCLA, Los Angeles, CA; 3) Department of Pediatrics, UCLA, Los Angeles, CA; 4) Department of Human Genetics, UCLA, Los Angeles, CA; 5) Department of Pathology, UCLA, Los Angeles, CA.

In addition to existing clinical genetic services, (e.g., prenatal, pediatric) an increasing number of genetic services devoted to common adult conditions, such as heart disease and diabetes, are anticipated; with personalized genomic medicine it is expected that everyone may benefit from genetic services in their lifetime. The integration of genomic medicine into public health to optimize the impact of this scientific knowledge will likely promote a broader understanding and appreciation of individual and population variability. Hence, this expansion in genomic medicine will likely affect public policy, healthcare and social service delivery. Historically, federal, state, and local programs have provided genetic services and use of information in genomic medicine to specific target groups; however, use of general genetic services is very low among members of the Deaf community, a linguistic and cultural minority group. Several researchers have addressed the economic, political, social, moral, cultural, educational, and ethical issues faced by members of the Deaf community and these issues seemingly interact with their use of genetic services, and use of genetic information. We describe a social marketing plan, one useful tool for health promotion, to increase use of genetics services in this group. Instead of using a top-down approach, social marketing focuses on the needs of the targeted audience, which in this case is a collective group that uses networking systems. As a community-based public health campaign with media components, social marketing strives to create a plan to best approach the target group that would ensure participation in the public health activity as well as integrating primary care for both individual and community. This marketing technique includes strategic planning, culturally and linguistically sensitive message and materials development, pretesting, implementation, and program evaluation. Design of the social marketing plan for this cultural and linguistic minority group is based on experience with a current research project examining impacts of genetic testing on deaf adults. Additional research is needed to determine if tailoring a culturally competent social marketing plan for members of the Deaf community increases the group's awareness of genetics services, increases effective use of genetic information, promotes health, and improves their overall quality of life.

## 1551/T/Poster Board #100

**Using family history in primary care for predicting risk of common, complex diseases in individual patients.** *B. Wilson, Q. Hasanaj, J. Little, S. Hawken.* Epidemiology & Community Med, Univ Ottawa, Ottawa, ON, Canada.

**Background** Chronic diseases account for a large proportion of deaths, premature loss of life, and health costs. As well as known risk factors such tobacco and nutrition, unknown factors contribute substantially to risk. Family history (FH) may offer a clue to shared disease susceptibilities arising from genomic susceptibility, shared environments, and common behaviors (and do not require an understanding of molecular etiology). Including FH in risk assessment algorithms for common, complex diseases may permit better prediction of individual disease risk. FH, in isolation, is not likely to be highly predictive for complex disease risk, so it is important to examine its performance in conjunction with risk factors whose measurement is considered standard of care. **Objectives** 1. To identify how FH is incorporated into disease specific guidelines which are currently in use in North America. 2. To compare these recommendations with evidence on the predictive ability of FH information in order to identify gaps or errors. 3. To formally assess the incremental improvement in individual risk prediction which is gained by incorporating FH with other forms of clinical information recommended in the guidelines. **Methods** We performed an environmental scan of chronic disease prevention guidelines currently disseminated in North America, Europe, and Australia, using standard systematic review methods. Relevant data were extracted pertaining to the condition of interest, the specified FH items, how they are factored into recommendations, and quality of guideline development process. We compared the results with published systematic reviews of FH items as predictors of future disease and rated the original guidelines according to level of consistency with evidence. Finally, we used data from meta-analyses and secondary analyses of large datasets to calculate receiver-operator curves for 'predictive tests' based on different combinations of established risk factors and FH information for several exemplar conditions (including coronary heart disease, diabetes and cancers). **Preliminary Results** No consistency was found across guidelines for how FH was incorporated in risk assessment. A well-developed evidence base exists for FH as a risk factor (relative risk), but not for its use in individual discrimination of risk (sensitivity and specificity). Modeling of combinations of specific FH items with established risk factors is underway.

## 1552/T/Poster Board #101

**Preparing for the Next Generation of Biorepository Research: Points to Consider.** *G.F. Guzauskas[1], K. Fryer-Edwards[1,2], S.M. Fullerton[1,2], N. Anderson[3].* 1) Public Health Genetics, University of Washington, Seattle, WA; 2) Department of Bioethics and Humanities, University of Washington School of Medicine, Seattle, WA; 3) Division of Biomedical Health Informatics, University of Washington School of Medicine, Seattle, WA.

Biorepositories are invaluable resources for genetic epidemiology and genomics and are anticipated to be a key component of translational research. Researchers use samples and data stored in biorepositories to study the complex relationship of genetic and environmental factors, and wide sharing of such resources is increasingly seen as the best way to advance discovery science and its translation to clinical benefit. However, many new challenges accompany this anticipated paradigm shift. In this poster, we address these ethical and practical considerations, including issues of consent, de-identification, and data sharing. Traditional biorepositories ("first-generation") are single-institution, small-scale operations that typically use anonymized or de-identified biospecimens for a range of downstream research generally exempt from human subjects protections. In such settings, research oversight is maintained by biorepositories' investigators who control data uses according to terms defined by the initial informed consent agreement. With the advent of data sharing among biorepositories many others, not just those with whom the participants entered into direct agreement, will use the data, complicating oversight and governance. The traditional means of protection, data de-identification, is also less reliable in the face of large amounts of inherently identifying genomic data being generated by research. In response to these concerns, we propose that first-generation biorepository models must give way to a new set of ethical and practice guidelines better suited to current forms of biorepository-based data sharing ("second generation"). In such settings, we argue, the treatment of research as exempt from human subjects oversight is not tenable, nor is it feasible to broaden the terms of informed consent to permit all conceivable secondary research uses. New systems of governance must be devised which permit on-going review of research uses, based in the interests of biorepository donors, and can be dynamic and responsive to the continually evolving state of the science and technology. Rather than focus exclusively on privacy concerns, we examine systems that permit identified tracking of participants for greater accountability as well as improved follow up to expand research data and scope as needed. Such policy recommendations are guided by expert opinion, consensus development meetings, and policy analysis of existing international guidance.

## 1553/T/Poster Board #102

**Capacity Building for the Transfer of Genetic Knowledge into Practice and Prevention: Health Care Needs Assessment for Medical Genetic Services in Middle- and Low-Income Nations.** *I. Nippert[1], U. Kristoffersson[2], J. Schmidtke[3], A. Kent[4], A. Christianson[5], R. Raouf[6], C. Barreiro[7].* 1) Women's Hlth Res, Univ Muenster, Muenster, Germany; 2) Dept Clin Gen, Univ Hosp Lund, Lund, Sweden; 3) Inst Hum Gen, MHH, Hannover, Germany; 4) GIG, London, UK; 5) Div Hum Gen, Univ Witwatersrand, Johannesburg, South Africa; 6) Ain Shams University, Cairo, Egypt; 7) Hospital de Pediatria SAMIC, Buenos Aires, Argentina.

*Background:* CAPABILITY (http://www.capabilitynet.eu) is a 3-year model project developed by the European Network of Excellence: Genetic Testing in Europe - Network for test development, harmonization, validation and standardization of services (EuroGentest) (http://www.eurogentest.org) and by leading experts from emerging economies: Argentina, Egypt and South Africa, the latter being currently engaged in major development projects to integrate genetic services in primary care and prevention in their countries.

*CAPABILITY Objectives:*

identify priorities for capacity building for genetic services by a systematic health care needs assessment (HCNA) and

validate the HCNA approach by means of demonstration projects.

*Methods:* CAPABILITY has formalised a HCNA for medical genetic services that middle- and low-income nations can utilise for implementing genetic services. Key elements of the HNCA are the development of strategic aims; an evaluation of existing services and the environment in which they function; a review of epidemiology, effective interventions, opinions of consumers and professionals, available resources and possible contraints. Analysis of these elements enables the production of a HCNA. The approach is currently assessed by demonstrations projects in Argentina, Egypt and South Africa.

*In Conclusion:* A systematic HCNA will assist nations with emerging economies to marshal and allocate their limited resources when developing medical genetic services.

*Funded by:* EC Contract no.: FP6-037275.

## 1554/T/Poster Board #103

**The National Ophthalmic Disease Genotyping and Phenotyping Network: eyeGENE™ - Progress in Three Years.** *X. Wang[1], D. Blain[1,2], K. Goetz[1,3], V. NDifor[1,3], M. Reeves[1,3], S. Vitez[1,3], D. Scheim[4], C. Antolik[1], S. Tumminia[5].* 1) OGFVB/NEI, NIH, Bethesda, MD; 2) MedStar Research institute, Hyattsville, MD; 3) BioSearch/Team Placement Service Incorporated, Rockville, MD; 4) Private Systems Specialist, Blacksburg, VA; 5) OD/NEI, NIH, Bethesda, MD.

Genetic mutations are associated with many ocular diseases including glaucoma, cataracts, strabismus, corneal dystrophies, and many forms of retinal degenerative disease. As a result, gene-based therapies are actively being pursued to ameliorate genetic eye diseases that once were considered untreatable. However, molecular diagnostic testing for these diseases is not widely available to patients. The National Ophthalmic Disease Genotyping and Phenotyping Network (eyeGENE™) was created three years ago by the National Eye Institute (NEI), part of the National Institutes of Health, in partnership with research laboratories, ophthalmic clinics and CLIA-certified molecular diagnostic laboratories in the United States. The major goals of this network are to 1) broaden patient accessibility to diagnostic genetic testing, 2) facilitate research into the genetic causes of ophthalmic disease by establishing a genotype/phenotype database and a DNA repository, and 3) provide a de-identified genotype/phenotype-linked sample resource for ophthalmic disease researchers. This Network currently includes the eyeGENE™ Coordinating Center, more than 110 ophthalmic clinical organizations nationwide, and 12 clinical diagnostic laboratories. The Coordinating Center, based at NEI, manages a centralized repository for blood/DNA and a genotype/phenotype database. The Coordinating Center also manages the referral of clinical genetic testing for patients submitted from participating clinics to a Network CLIA-certified laboratory and reports the test results back to submitting physicians. To date, Network laboratories offer testing for mutations in more than 65 genes. Mutations in these genes correlate with 32 different clinical diagnoses. At the time of this submission, more than 1000 patient samples have been collected in the repository. Preliminary data analysis indicates that 40% of participants are in the Retinitis Pigmentosa or allied retinal degeneration category, 24% have a diagnosis of Stargardt Disease, and 7% are in the Cone-Rod Dystrophy category. Public access to de-identified clinical and genetic information is under development and will be available to researchers in the vision community upon NIH IRB approval. The eyeGENE™ Network will continue to serve the vision community by promoting accessibility of genetic testing to patients with ocular diseases and by promoting clinical and basic research for a better understanding and treatment of ocular diseases.

## 1555/T/Poster Board #104

**Creating interest in autism genetics research among underrepresented populations through targeted outreach.** *J.L. Robinson, M.L. Cuccaro, R.J. Martinez, M.J. Gavier, M.A. Pericak-Vance.* Miami Institute for Human Geno, University of Miami, Miami, FL.

High throughput gene discovery efforts such as genome-wide association studies (GWAS) have substantially increased efforts to detect both common and rare genetic risk variants in complex diseases such as Alzheimers disease, multiple sclerosis, and autism. While critical for gene discovery, GWAS require large numbers of participants to ensure sufficient power. Increasing enrollment must also recruit from underrepresented populations. These populations have historically been challenging to recruit in large numbers for genetic studies of various complex diseases and autism in particular and are poorly represented in such studies. Given recent discoveries of common and rare risk variants in autism, it is crucial that we ascertain individuals and families of diverse ethnic and ancestral groups to identify population specific risks for autism. In this study we describe efforts to increase interest and participation of underrepresented populations in autism genetics research through a targeted outreach approach. This approach has two components: 1) increasing community education about autism and the importance of genetic and genomic research and 2) increasing community trust in our research group. Outreach methods include creating community partnerships with established service provider groups, offering targeted information sessions in communities where underrepresented populations are served, providing personalized and/or language matched follow-up, and focused advertising to reach underrepresented populations. We will present findings demonstrating the values of specific outreach activities and events on participation rates in autism genetic research in Hispanic Americans and Blacks/African Americans in the South Florida Area.

## 1556/T/Poster Board #105

**Consideration of Molecular Technology Issues Using an Ethics Values Game.** *R. Anderson, T. Schonfeld, A. Jameton, M. Godfrey.* Univ Nebraska Medical Center, Omaha, NE.

Is choosing traits for one's children a desired outcome of current progress in molecular genetics? In a recent national survey about 10% of people seeking genetic counseling said they would prefer a child with greater intelligence, height, or athletic ability. More than 50% would use genetic testing to avert blindness and more than 75% to avert mental retardation in a child. In contrast, when we asked high school students on six Indian Reservations whether people should be allowed to choose traits for their children or let nature take its course, more than 95% of the times the student response was to let nature take its course. But these students also believed that everyone should have equal access to health care reproductive technologies.

After our survey, these students played an "Ethics Values Game" we developed that allows players to choose traits for their "offspring." The game is played by dealing five "trait" cards to each player. The player can then keep all the cards or discard up to three cards and draw new ones. In addition, the roll of a die or the spin of a wheel gives players points to buy additional traits or modify their trait cards. The more points, the greater the choices. This allows students to experience the uneven distribution of opportunity as well as inborn characteristics. (Students were later asked to explain why they chose to retain, discard, or purchase traits.)

Even though students initially said they wanted to let nature take its course, most played the game with zeal. It was rare to find a student who simply kept the initial five cards, and declined to purchase additional traits if given the opportunity. These students were the ones who really let nature takes its course. On one occasion a fifteen year old student played the game while holding her infant daughter. By chance she received a trait card for low fertility for her "offspring." The student was elated and said, "that way I would not be a grandma too soon." This hands-on exercise invites participants to consider numerous questions about the Pandora's Box opened by advances in molecular and reproductive biology.

**Assessing the Cost-Effectiveness of Genetic Testing.** *M. Bergman[1], H. Honoré[2], D. Regier[3].* 1) VA Puget Sound, Seattle, WA; 2) HCQCUS, MEDVAMC, Houston, TX; 3) National Perinatal Epidemiology Unit, University of Oxford, Oxford, England.

Background: Genetic testing has potential to advance quality and efficacy of care at many stages of disease. However, this promise does not come free; patients and doctors are presented with personal and economic choices concerning use of these tests. As these tests become more prevalent greater understanding of their cost-effectiveness is needed. Purpose: Here we systematically review studies analyzing cost-effectiveness of different human genetic tests. Data Source: PubMed search of English language papers published from 1975 to December 2008. Study Selection: Papers were included if they provided empirical results of an economic evaluation on the application of a specific genetic test, or set of genetic tests in the human population. Data Extraction: We categorized papers by type of test offered and divided tests into these categories: carrier screening, prenatal screening/diagnosis, predictive/diagnostic, prognosis, and reoccurrence. Data Synthesis: 42 of the 86 studies indicate that, for their particular test, genetic testing is cost-effective. 10 studies indicated that testing was not cost-effective, although 5 of these were analyzing tests that were found cost-effective in at least 1 other study. The remaining 5 encompassed 3 genetic tests and one method, with only 1 test having more than 1 study performed. 8 studies discussed willingness to pay rather than cost-effectiveness. 7 studies were strict cost studies, with no mention of effectiveness, or discussed technologies that are currently obsolete. 17 studies stated that cost-effectiveness depends on parameters that can change, and are changing, over time. Limitations: Each type of disease had only a limited amount of studies that included empirical economic evaluation. Conclusions: Genetic testing has been found to be cost-effective for a wide variety of test types and diseases. The majority of qualifying studies showed cost-effectiveness uniformly, or in certain circumstances. Those not found to be cost-effective represent a small portion of the populations tested, and typically have a non-genetic test to determine their presence. We can conclude then, that genetic testing can be a cost-effective method of determining health outcomes. However, each test should be analyzed on its own merits and within a specific population, because it is not possible to generalize the results of any study of an individual test.

## 1558/T/Poster Board #107

**Gaining Consent for Biobank Samples: the NW Biobank Experience.** *K. Goddard, S. Smith, C. Chen.* Ctr Hlth Res, Kaiser Permanente Northwest, Portland, OR.

Human tissues provide essential molecular data for basic and translational research. Large-scale population-based biobanks can provide large sample sizes for genomics research, and offer economies of scale, improved quality and reliability of samples, and widespread access through automated sample retrieval. However, it is challenging to adequately inform participants of the broad nature of the research and participation risks and benefits. In a pilot study to develop a biobank at Kaiser Permanente Northwest (KPNW), we wrote recruitment materials at an 8th grade reading level that were vetted by a communications team, focus groups of KPNW members, the IRB, and external advisory boards. We then surveyed 500 KPNW members to assess attitudes and response to the materials. We asked members in waiting rooms to review the recruitment materials then complete a brief survey on demographics, willingness to participate, reasons for non-participation, and knowledge of the written materials. The survey respondents were 39% male, 20% had a high school education or less, 16% minorities, and 50% over 49 years old. Overall, 69% agreed to contribute to the biobank, 20% were not sure, and 11% did not agree. Of those who agreed, 82% also agreed to have their information posted in a US government database, such as dbGaP. The primary reason for non-participation was concern about confidentiality of genetic and health-related information. Respondents who agreed to contribute were more likely to be male (75% males vs. 65% females, p=.01), older (75% highest age group vs. 62% lowest age group, p=.03), more affluent (77% highest income group vs. 58% lowest income group, p=.01), and white (70% vs. 56% of minorities, p=.005). Overall, 74% of respondents correctly answered ≥6 of 9 questions, indicating a high understanding of the information. Respondents who answered the questions correctly were white (77% vs. 58% of minorities, p=.0023), college graduates (83% vs. 52% of high school education or less, p=.0001), and more affluent (86% highest income group vs. 58% lowest income group, p=.0001). Respondents who agreed to contribute were more likely to correctly answer the knowledge questions (71% vs. 51% who did not agree or 55% who were not sure). Biobanks will be most beneficial for genomic research if they widely represent the underlying population. Our findings indicate that more communication methods may be needed to ensure the broadest participation possible.

## 1559/T/Poster Board #108

**Some Remarkable Women in Medical Genetics.** *P.S Harper.* Institute of Medical Genetics, School of Medicine, Cardiff Univ, Cardiff, United Kingdom.

A series of highly talented women have played a major role in key discoveries in human and medical genetics, dating from the beginning of the 20th Century, a time when women rarely met encouragement and the possibility of making major contributions in science. Out of a large number of possibilities, three individuals are discussed here, two of whom have not received the credit due to them. The achievements of these three are described, Julia Bell (UK), Eva Melander (Sweden) and Marthe Gautier (France), the last two having made major, but largely unrecognised contributions to early human cytogenetics. It is instructive to compare their experiences with the situation in contemporary medical genetics, where women form a majority, in both clinical practice and laboratory research.

## 1560/T/Poster Board #109

**Increased participation of African Americans in genetic studies.** *S. Hartz[1], E. Johnson[2], N. Saccone[1], J. Rice[1], L. Bierut[1], COGEND Investigators.* 1) Dept Psychiatry, Washington Univ, St Louis, MO; 2) Division of Health, Social, and Economic Research, Research Triangle Institute International, Research Triangle Park, NC.

Although investigators select samples to preserve genetic homogeneity for association studies, differing genetic structures between ethnic groups may lead to improved identification of variants related to disease. In addition, the inclusion of minority subjects in genetic studies allows for a more accurate representation of the population. Unfortunately, there is a paucity of genetic data from minority subjects. In the attempt to preserve genetic homogeneity, community samples may not have adequate numbers of minority participants to analyze separately. Also, specifically sampling minority populations is considered to be particularly difficult because minorities are thought to be less likely to consent to genetic research. In fact, increasing numbers of Caucasian-only samples may perpetuate this belief. Therefore, we used previously collected population-based genetic data to test the hypothesis that minorities (specifically African Americans) are less willing to participate in genetic studies.

The Collaborative Genetic Study of Nicotine Dependence (COGEND) screened 42,289 community subjects. Based on preliminary data, 30,557 European Americans (EA) were screened, 3713 qualified for the study and 2081 (56%) participated in the study. Conversely, 11,732 African Americans (AA) were screened, 1115 qualified for the study and 757 (68%) participated. The difference in participation rates between EA and AA was statistically significant ($p<0.0001$).

These results strongly challenge the conception that minorities are less likely to consent to genetic studies. It suggests that standard protocols for population recruitment work at least as well on AA as EA.

## 1561/T/Poster Board #110

**Beyond Race: Utilizing genetic markers instead of racial categories to characterize diversity among children participating in clinical research.** *P. Payne[1,2], R. Freishtat[2,3], F. Suer[2,3], J. Devaney[2,3], K. Panchapakesan[2,3], S. Choudhry[4], S. Teach[2,3], E. Hoffman[2,3].* 1) The George Washington University School of Public Health and Health Services, Department of Health Policy, Washington, DC; 2) Children's National Medical Center, Center for Genetic Medicine Research, Washington, DC; 3) The George Washington University School of Medicine and Health Sciences; 4) University of California San Francisco School of Medicine, San Francisco, CA.

OBJECTIVE The use of racial/ethnic Census categories to characterize diverse populations in pediatric clinical research can create misleading findings and pose safety problems, such as inappropriate diagnosis or treatment, when this information is translated into clinical practice. Herein, we offer an alternative approach for characterizing diverse populations in clinical research by using ancestry informative markers(AIMs), single nucleotide polymorphisms(SNPs) associated with certain geographic regions. This approach may provide a better way to assess risk for disease or drug response in diverse populations of children. METHODS A panel of AIMs was developed from existing literature using a number of selection factors including the existence of an allele frequency difference of 60% between one geographically defined population and two other different populations. For this preliminary study, 11 of the selected SNPs were genotyped in the AsthMaP Project cohort which contained parent-identified African American children with asthma (n=48), and a related control group (n=92). Simpson's Biodiversity Index (SBI), a measure used to quantify habitat diversity, was used as a measure of diversity for the genotypes of each AIM. Chi square tests were used to assess differences between the observed and expected genotypes using three different models of expected genotype frequencies. RESULTS Based on the SBI, cases and controls were generally more diverse than their parent-identified racial group labels, with the SBI ranging from .39 (more diverse) to .92 in cases and .33 to .69 in controls. More diversity was seen in the cases and controls for AIMs linked to regions of Africa. Chi square tests revealed significant differences between expected and observed genotype frequencies for all models of expected genotype frequencies with p-values ranging from approximately 0 to 9.5 E -12. There were a few exceptions for the case group. These exceptions were probably due to a smaller population size in the case group which will change as the cohort grows. CONCLUSIONS This preliminary study demonstrated that a cohort of parent-identified African American children are more diverse with regard to ancestry than their parent identification assumes. This finding is particularly important, given the increasing genetic diversity of American children. The current approach of using race/ethnicity alone in clinical research appears outdated and deserving of policy change.

## 1562/T/Poster Board #111

**Getting the Word Out: Genetic Medicine for the Health Care Provider through Continuing Medical Education.** *A. Gilbert[1], C. Wiener[2], D. Valle[1].* 1) Inst Genetic Medicine, Johns Hopkins Univ, Baltimore, MD; 2) The Johns Hopkins Hospital Department of Medicine Baltimore, MD.

Since the completion of the Human Genome Project (HGP) the ongoing rapid progress in genetic medicine is producing new insights and vast amounts of information that will ultimately transform the practice of medicine. Increasingly, we are identifying genetic contributions to all human diseases, and the prospect of genetic testing for predisposition to disease, molecular diagnosis, prognosis and response to treatment is thus becoming a reality. Advances in our understanding of the unique interaction between individuals and their environment as the framework for the balance between health and disease has the potential to revolutionize prevention and treatment. These advances form the basis for personalized medicine/individualized care. Medical education regarding the genetic contribution to disease varies greatly in the content and extent provided. Though primary care physicians in academic centers may have access to genetic information through a variety of venues: genetic colleagues, lectures and seminars, there is, however, no single organization responsible for delivering and assessing this information effectively. Furthermore, clinicians in private practice do not have ready access to these resources and are increasingly faced with patient's who are better informed. Addressing this need, the Johns Hopkins University (JHU), School of Medicine has developed an entirely new medical school curriculum commencing in the fall of 2009: Genes to Society. The course content is embedded in the concepts of human individuality and variability, risk, and the ability to alter disease presentation and outcomes. The Institute of Genetic Medicine at JHU is also expanding the effort to bring genetic information to the practicing healthcare provider, as well as JHU house staff, by offering a one-and-a-half day continuing medical education (CME) course titled: Genes to Society: Genetic Medicine for the Healthcare Provider. This course, the first of its kind at JHU, will be given in the fall of 2009. Registration will be free for all JHU postdoctoral trainees. This 12 credit CME course contains 13 half-hour lectures that will offer up-to-date information applicable to today's clinical practice. The course will also provide information and instruction on the effective use of the WWW for obtaining vetted genetic information. The effectiveness of the course will be measured by the uptake and CME evaluation forms. If successful, the course will be offered every year.

## 1563/T/Poster Board #112

**Lysosomal Disease Network, and WORLD Symposium 2010.** *B. Kohler[1], J. Barranger[2], J. Muenzer[3], C. Eng[4], G. Grabowski[5], M. Patterson[6], S. Walkley[7], B. Davidson[8], R. Steiner[9], W. Wilcox[10], E. Shapiro[1], C. Whitley[1], the other LDN investigators.* 1) University of Minnesota, Minneapolis, MN; 2) Genzyme Corporation, Cambridge, MA; 3) University of North Carolina, Chapel Hill, NC; 4) Baylor College of Medicine, Houston, TX; 5) Children's Hospital Research Foundation, Cincinnati, OH; 6) Mayo Clinic, Rochester, MN; 7) Albert Einstein College of Medicine of Yeshiva University, New York, NY; 8) University of Iowa, Iowa City, IA; 9) Oregon Health & Science University, Portland, OR; 10) Cedars-Sinai Medical Center, Los Angeles, CA.

The Lysosomal Disease Network (LDN) is a consortium of basic researchers, clinicians, pharmaceutical industry professionals, and patient advocates devoted to promote and facilitate basic, translational and clinical research in lysosomal diseases. The network is a scalable multi-center consortium of geographically distributed expert medical centers, patient support and corporate partners. The infrastructure, mission and charter were developed through organizational committees; the collaborating medical centers, pharmaceutical and patient support organizations will direct the activities of the network through participation in the Steering Committee. Toward meeting its goals, the LDN has launched its web site www.LysosomalDiseaseNetwork.org to facilitate professional and public education, timely network communication, and develop a data entry mechanism for research projects. The web site has announced its 6th annual research meeting, We're Organizing Research for Lysosomal Diseases "WORLD Symposium 2010" (February 10-12, 2010) in Miami, FL, USA. Through the web site, participants are able to submit abstracts (October 1, 2009 deadine), register for the meeting, and join the growing membership list to receive regular communications. The Network is currently conducting longitudinal studies to understand the natural history of lysosomal diseases and treatment outcomes. Long term network goals include: 1) development of an information management infrastructure to encourage integration of shared clinical experience and relevant longitudinal studies, 2) investigator training, and 3) public education. Organizational and symposium support has been provided by NIH, NINDS, NIDDK, and ORD (U54-NS065768).

## 1564/T/Poster Board #113

**Newborn Screen and Beyond: An Outreach Education Initiative.** *A. Rajadhyaksha[1], E. Velis[2], S. Deshmukh[1], M. Perez[1], P. Jayakar[1].* 1) Dept of Genetics and Metabolism, Miami Children's Hospital, Miami Fl; 2) Master of Science Program in Health Services Administration Division of Health Management/College of Health Sciences, Barry University, Miami Fl.

**Introduction:** Delayed diagnosis of treatable metabolic disorders remains a healthcare problem due to lack of awareness. We initiated an outreach project to educate healthcare providers on early detection and intervention of treatable metabolic disorders. **Materials and Methods:** Seminars using algorithms based on "red flags" or clinical presentation for early detection and intervention of metabolic disorders were conducted. A general survey on demographics, attitudes and awareness of these disorders included questions as follows: Q1:Are you familiar and comfortable identifying suspected metabolic disorders Q2:Are you familiar with ordering metabolic tests when suspecting a disorder Q3:Are you familiar with medical intervention and treatment of metabolic conditions. Additionally, pre and post-seminar tests on specifics of various metabolic disorders was administered. Responses were analyzed based on the following groups: (a)Gender (b)Experience:<6 years, 6-14 years and ≥15 years (c)Position: attending, resident, medical student and allied health (d)Employment:teaching hospital, private office and non teaching hospital. Analyses of variance and independent and dependent t-tests were performed to identify mean differences between groups. Categorical variables were explored by Chi-Square test. **Results:** Of 65 surveyed participants: 32%, 57% and 31% stated familiarity to Q1, Q2 and Q3 respectively with no statistical difference between the groups. Pretest score analysis showed no significant difference except residents scored significantly higher(M=5.73,SE=3.29) than allied health and medical student(M=43.78,SE=3.39),(F2,80)=3.82,p<0.05). Significant increases in scores between pretest(M=54.14,SE=2.58) and post test(M=66.67,SE= 2.90) in all participants(t(48)5.11, p<0.01)) and groups was noted except for residents (t(14)=1.64,p>0.05) and those with 6-14 years experience (t(7)= 1.30,p>0.05). **Conclusion:** Our findings demonstrate a lack of awareness of metabolic conditions in over half of the care givers surveyed. Test scores significantly increased after seminars indicating the need for continued outreach education. The scores observed in Resident and 6-14 years Experience groups probably reflects the positive impact of current training and continued education for board recertification respectively. The study serves as a foundation for the development of public policy and long-term educational strategies.

## 1565/T/Poster Board #114

**What do the health professionals students know about cleft lip and palate?** *M.C. Silveira[1], R.J.N. Nogueira[2], A.E.S Lima[2], L.A. Magna[1], V.L. Gil-da-Silva-Lopes[1].* 1) Department of Medical Genetics, State University of Campinas, Campinas, São paulo, Brazil; 2) Equipe de Nutrição Enteral e Parenteral, Hospital de Clínicas, State University of Campinas.

Introduction: The cleft lip and/or palate (CLP) are the most common congenital craniofacial defects and may occur on their own or associated with other anomalies. Children born with this congenital defect are subject to diverse complications such as feeding disorders, oral communication disorders, otologic and/or hearing disorders as well as emotional and social problems that are mainly due to anatomical alterations of the face. Objective: The aim of this study, as part of the Brazilian Craniofacial Project, was to characterized the knowledgement of health professions students from the senior year about the management and primary care of cleft individuals. Methods: Students from senior year of medical (MD), nurse(N), speech therapist (ST) and dentistry(D)schools at State University of Campinas were interviewed using a structured questionnaire. After this, in a previous scheduled day for each course, the researcher offered a training to deal with the peculiar situations presented by children with CLP in primary care. The data was analyzed using the Epi Info program version 6.04d and the SPSS version 8.0. Results: From a total sample of 167 students, interviews (64 - Medicine; 38 - Nursery; 17 - Speech Therapist and 48 - Dentist). The data revealed that the future professionals were not preparing for care of CLP individuals. Main difficulties were related to 58,7% affirm to have reasonable slight knowledge on anatomical alterations and 50.3% declare the same reply for knowledge of functional alterations. 1.8% if they only consider completely apt for the accompaniment of these patients. Between that they had presented a reason for this ineptitude 65.7% had indicated unfamiliarity. Conclusion: This investigation should be extended for others universities. However, in view of the prevalence, morbidity of CLP, and others studies conducted by our team, it is possible to suggested that educational programs for non-specialized health professionals working at primary care should be part of health policy. Finnancial Support: CNPq, FAPESP.

## 1566/T/Poster Board #115

**Results of a Needs Assessment to Inform a National Curriculum for Postgraduate Training in Clinical Genetics.** *G.E. Graham[1], S. Langlois[2], A.M. Innes[3], B. Chodirker[4], E. Lemyre[5], T. Costa[6], R. Mendoza-Londono[7].* 1) Children's Hospital of Eastern Ontario and University of Ottawa, Ottawa, ON; 2) University of British Columbia, Vancouver, British Columbia; 3) Alberta Children's Hospital and University of Calgary, Calgary, Alberta; 4) University of Manitoba, Winnipeg, Manitoba; 5) CHU Sainte-Justine, Université de Montréal, Montréal, Quebec; 6) McGill University, Montreal, Quebec; 7) Hospital for Sick Children and University of Toronto, Toronto, Ontario.

In Canada, Medical Genetics is a primary specialty with direct entry from medical school that requires 5-years of residency training under the auspices of the Royal College of Physicians and Surgeons of Canada (RCPSC). The first two postgraduate years are composed of rotations in Internal Medicine, Pediatrics, Maternal-Fetal Medicine and electives. The final three years provide core training in Genetics, including clinical and laboratory rotations, courses and up to 12 months of research to prepare the resident for consultancy practice in what is usually an academic setting. Individuals with a primary RCPSC specialty such as Pediatrics who wish to practice in Genetics instead complete a 3-year CCMG (Canadian College of Medical Geneticists) fellowship in Clinical or Biochemical Genetics. There are currently 39 residents and 10 fellows enrolled in seven MD training programs across the country. Historically the relatively small numbers of trainees in each center and their geographic separation fostered individual approaches, with each program "reinventing the wheel" to provide didactic teaching. This was problematic, particularly for centers with a small number of trainees and limited teaching staff already over-burdened by clinical demands. In 2008, recognizing the potential benefits of collaboration, the seven RCPSC Medical Genetics Program Directors embarked on a pilot project to deliver teaching sessions via TeleHealth video connection from rotating sites across the country. TeleGRaF (TeleHealth for Genetics Residents and Fellows) featured a monthly seminar highlighting genetic disorders in specific Canadian populations including the Anabaptist populations, Ashkenazi Jews, Native Canadians and French Canadians. The success of this project has encouraged us to further develop TeleGRaF as a cost effective strategy to achieve educational objectives and foster strong collaborations between sites. As the next step in the development of a national curriculum, we administered an online needs assessment to all physician trainees enrolled in RCPSC and CCMG programs in Canada, as well as their program directors, staff geneticists and recent graduates. Herein we present the results of our need assessment and their implications for the planning of TeleGRaF 2009-2010.

## 1567/T/Poster Board #116

**Getting Genetics Done: an educational productivity blog by graduate students for getting things done in human genetics research.** *E. Holzinger, W. Bush, S. Turner.* Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

A large portion of graduate students' and post-docs' time is spent trying to find solutions to procedural issues, e.g. finding the right software for a particular analysis, figuring out how to do a particular procedure in a given software, finding new relevant literature, etc. This is time that could be better spent on higher-level tasks, such as designing experiments and interpreting & publishing the ensuing results. There is a high likelihood, however, that someone else working in a related area of human genetics research has faced a similar problem, and has devoted a considerable amount of time to finding a satisfactory solution. Finding a way to obviate this duplication of effort is the motivation for Getting Genetics Done (URL: http://GettingGeneticsDone.blogspot.com/), an actively maintained blog created and written primarily by graduate students in a human genetics Ph.D. program. The target audience of Getting Genetics Done comprises graduate students, post-docs, and analysts working in human genetic epidemiology. Its purpose is to call attention to software, useful web tools, analytical tips, important recently published papers, and other subject matter that will enhance productivity by eliminating the unnecessary time spent finding workflow solutions that others have already discovered.

## 1568/T/Poster Board #117

**Teaching dysmorphology.** *S.M. Nikkel.* Dept of Genetics, Children's Hospital of Eastern Ontario, Ottawa, ON, Canada.

The ability to recognize syndromic diagnoses is a major objective that must be mastered by residents and fellows in Genetic training programs. However there are no guidelines as to how this is to be accomplished. There is an assumption that the trainee will see a spectrum of diagnoses and learn by exposure. Case rounds are a method to provide further exposure, however "interesting" patients may not be available each week. For the extremely rare diagnoses, photographs of classic patients are available for review in texts and databases. Differential lists are learned for specific anomalies. However, it is uncertain as to how often the syndrome is thought of if this key feature is absent. "Theme of the week" was developed in order to expose trainees to a wide variety of syndromes and conditions. Each series is comprised of slides with pictures that have a unifying theme. However, the theme may not be demonstrated in the series. There are a variety of sources where appropriate images can be found. The trainees are asked what they think the theme may be prior to the discussion of the slides. This allows them to think about the conditions in an alternative manner, not just from the key feature. Further discussions of the slides include diagnosing the condition demonstrated, genes/pathways involved, describing the dysmorphology, and management issues. There is willing participation by staff members, as they too like to figure out the theme. Their participation broadens the experience for the trainees due to their input regarding the conditions and their personal clinical experiences. Examples of theme of the week will be demonstrated.

## 1569/T/Poster Board #118

**Alcohol abuse: an innovative multi-disciplinary scientific approach for an unsolved social problem.** *M. Borriello[1,2], E. Alloero[1], P. Schifano[1], M. Antola[1], R. Galuffo[1], A. Soricelli[1], B. Zanini[6], L. Viale[8], L. Canepa[3], M. Altamura[3], C. Saracco[3], M. Burlando[3], E. Andreozzi[4,5], R. Tafuri[7], O. Sansalone[7], G. Borrelli[7], M. Achilli[7], M. Giribaldi[7], M. Annaloro[7], A. Cancellieri[7].* 1) IPSSART "Marco Polo", Genova , Genova, Italy; 2) Faculty of Biotechnology - University Federico II of Napoli, Italy; 3) ITIS "E.Majorana", Genova, Italy; 4) ITCG "Archimede", Napoli, Italy; 5) CEINGE - Advanced Biotechnologies Naples Italy; 6) Faculty of Medicine, University of Genova, Italy; 7) Prefecture of Genova Italy; 8) Scientific High School "M. Champagnat", Genova, Italy.

"Although alcohol abuse is major health problems in many countries, the impacts of alcohol abuse have not always been appreciated. Biological and genetic studies clearly place alcoholism among diseases with both genetic and environmental influences, but persistent stigmas and attribution to moral failure have impeded recognition and treatment of alcohol problems" (Goodman&Gilman) An innovative approach to reduce unaware alcohol abuse is proposed, with a multidisciplinary scientific activity performed in high schools for deeper comprehension of facts, problems, needs: · FACT: increase of alcohol abuse of young Italian population · PROBLEM: increase of biological, psychological and behavioral damages linked to alcohol abuse · NEED: prevent alcohol abuse, building deeper knowledge in school population through a diversified, multi-actor program developed in: 1) Biological Sciences: a) Biochemistry: alcohol metabolism b) Genetics: functional variants in genes involved in alcohol metabolism and its variances attributed to genetic differences in alcohol - and aldehyde-metabolizing enzymes 2) Math: statistical analysis of population behavior to comprehend dimension of the problem and make, where possible, international comparative analysis 3) Law: laws to limit vehicles operation under alcohol influence - comparative analysis in European countries. A pilot study in several high schools of Liguria (north-west of Italy) has been activated in cooperation with University departments and has been supported by governmental entities like the Prefecture of Genova. In a two years period the activities have been: 1. a statistical analysis of data on alcohol consumption on more than 1000 students ranging between 14 and 18 2. a teaching activity in biochemistry of alcohol metabolism in the liver 3. an experimental genetic analysis with several selected classes of students, to study functional variants in ADH gene involved in alcohol metabolism, with lab activity in the field of: a. DNA extraction b. PCR of gene region of interest c. Statistical analysis on detected polymorphisms The pilot study is now developed in several other high schools in North and South of Italy, to enlarge the involved populations of students and teachers and make geographical studies in adolescent populations. The classes will be then followed along the years from the behavioral point of view, to assess the impact of teaching toward deeper knowledge of alcohol abuse at students and family level.

**DNA Day Experience in High Schools on Six Indian Reservations.** *M. Godfrey[1], K. Szarama[2], L. Bronner[1], R.A. Godfrey[1], R.L. Jokela[1].* 1) Univ Nebraska Medical Ctr, Omaha, NE; 2) Dev Neuroscience and Auditory Mechanics, NIDCD/NIH, Bethesda, MD.

One of the most effective ways to capture and retain students' interest in science is to have plenty of hands-on opportunities. Despite the best intentions of most teachers, interactive presentations are less common in places where students' needs are greatest. To help fulfill some of this need we developed a full day DNA Day program for high schools on six Indian Reservations. Our long-standing efforts in these communities have generated trust to enable us to provide educational outreach.

The program was structured to provide background information via visual material and discussion complemented with many hands on science activities. At the start of the program students received a DNA Day booklet to follow the topics and take notes. The program was planned to run an entire academic day with students taking part in all aspects. For the most part, our DNA Days did just that. In two of the schools, however, different students came for their regularly scheduled science class and were exposed to a single aspect of the program. While this was not ideal, we were able to provide some information about the significance of genetics and genomics. In one school the program was modified to fit a half-day schedule since the teacher was unsure of the attention span for most students.

The absence of American Indian role models is partially responsible for the lack of achievement in these disparate populations. To this end we produced a brief video presentation of two American Indian geneticists as role models for these students. More recently, as part of an ongoing program to highlight Native Americans in health and science professions, we have produced a poster and curriculum materials on a Navajo molecular biologist.

More than 400 students participated in DNA Day. An evaluation of their enjoyment, using a Likert scale, confirmed our impression that the hands-on activities were enjoyed more than slide shows or traditional lecture pedagogy. The video of the Native American geneticists was also well received. Evaluation from teachers who participated was also very positive.

These data and our experience shows that faculty of institutions of higher learning has an important role in promoting their profession and discipline to the public in general and to underserved populations in particular.

## 1571/T/Poster Board #120

**Model organisms in teaching Life Sciences.** *A. Pascucci, G. Forni.* ANISN National Association of Natural Science Teacher, Italy.

Basic life processes are conserved among species. As far back as Gregorio Mendel's use of the pea plant as a 'tool' conducive to the understanding of wider-reaching mechanisms, the strategy of employing 'model organisms' such as Drosophila melanogaster, Arabidopsis thaliana, Caenorhabditis elegans, Danio rerio, has been, and still is, extremely commonplace in scientific research. Each model organism has its own advantages and disadvantages. Choosing an appropriate model depends on the exploratory situation one has to face. Use of model organisms even in the didactic field has proved to be an interesting and versatile teaching tool in the classroom approach to both basic biological mechanisms and more recent complex bio-molecular studies. The didactic projects with model organisms such as bacteria, peas, fruit flies, worms and fishes, already been introduced in schools of different levels , are as follows: Inclusive of experimental protocols, student resource/observation files and teacher's guide. Organized in self-standing, graded experiments based on complexity of theme and laboratory techniques and the acquisition of cross-level skills. Inclusive of a number of 'classroom friendly' activities which require neither sophisticated instruments nor fully equipped laboratory facilities. The organisms presented, though greatly varied, have the advantage of being small, cheap and easy to cultivate and well suited to an experimental life indoors. The organisms employed are the very same as those used in research laboratories thus bringing the students 'closer' to science, especially if an attempt is made to create an opportunity for interaction with research centres. Experimental protocols have been developed with the advice of scientists from the Institute of Genetics and Biophysics of the CNR of Naples and University of Naples "Federico II".

## 1572/T/Poster Board #121

**Integrating an authentic research experience into an undergraduate recombinant DNA technology laboratory course.** *B. Quimby.* Department of Cell Biology and Molecular Genetics, University of Maryland, College Park, MD.

National science education reform initiatives recommend that undergraduate biology programs integrate authentic research based laboratory activities into the curriculum. To answer this call, a project-based approach was employed for an undergraduate six week summer Recombinant DNA Technology laboratory course at the University of Maryland. The goals were 1) to apply recombinant DNA techniques to address a real-life problem, 2) to focus on student problem solving skills, and 3) to integrate team work throughout the process. Mutations in the human galactose-1-phophate uridylyl transferase (hGALT) gene result in the metabolic disorder galactosemia. For the majority of the more than 230 mutations in hGALT that have been identified in patients, it is unknown how they affect the protein function to result in disease. The yeast Saccharomyces cerivisiae has been used as a model system for analysis of hGALT. Yeast is an excellent model system for undergraduate work, because it is fast, easy and cheap to work with. To meet the goals set for the course, students were divided into 6 groups of three and each group performed PCR mutagenesis of the hGALT protein and analyzed the effects of the mutations isolated on the function of the hGALT protein using the yeast model system. As this is a multi-step process involving many recombinant techniques the groups had multiple opportunities to work on problem solving skills as the various steps failed for a variety of reasons. The project culminated with each working group presenting their results in a 20 minute presentation to the class that was assessed by their classmates and the instructor based on a defined rubric. Through these group presentations the students demonstrated their ability to assemble data into a coherent story and formulate hypotheses about the novel mutations they had isolated and analyzed. Student responses on surveys administered at the end of the course indicated that students valued ownership of their project and the unknown outcome of their work. Students also reported a better understanding of how the techniques learned in the course could be applied to address a specific scientific problem. Through the use of authentic research to teach recombinant DNA techniques students demonstrated mastery of basic skills and their ability to interpret experimental results. Most importantly, this approach gave students an experiential snapshot of the process of science.

## 1573/T/Poster Board #122

**The Impact of High School Genetics Education and Youth Risk Behaviors on Chronic Disease Prevention.** *J.L. Raiford.* Behavioral Sciences & Health Education, Emory University/Rollins School of Public Health, Atlanta, GA.

Given the effect genomics may have on the prevention of chronic diseases and the paucity of data on genetics education and disease prevention among youth, this study utilized the Utah Youth Risk Behavior Survey (YRBS) to assess (1) the impact of genetics testing awareness on youth risk perception and intention of behavioral change and (2) predictors of interest in family health history and intent to change health behaviors in instances of disease risk among youth. The 2005 Utah YRBS assesses risky health behaviors among youth (e.g., substance use, violence) and includes 4 questions developed by the Utah Tobacco Prevention and Control Program and the Utah Department of Health's Chronic Disease Genomics Program to assess genetics awareness and interest among Utah adolescents. 1,976 Utah high school students (51.3% male, 88.5% white) completed the 2005 YRBS. Study results show that, when controlling for age, those adolescents who were educated regarding genetic testing were 4 times more likely (AOR= 3.8, $p \leq .001$) than those without this education to perceive themselves as at risk for developing a particular disease (e.g., heart disease, diabetes, asthma or cancer) if one of their family members had the disease, and those reporting genetic testing education were more than twice as likely (AOR= 2.4, $p \leq .001$) to report that if a disease ran in their family they would change their lifestyle behaviors to decrease their chances of getting the disease. Moreover, tobacco and drug use and psychological distress reduced interest in learning about family health history and intention to change health behavior. Those adolescents reporting cigarette or marijuana use were less likely to be interested in learning more about their family's health history or report an intention to change health behaviors in the event a disease ran in their family than those adolescents not reporting tobacco or marijuana use. Also, adolescents reporting depressed affect, suicidal thoughts, plans, attempts, and/or injuries from a suicide attempt were less likely to report interest in learning about their family health history than those adolescents not reporting psychological distress. These results demonstrate the importance of educating youth about the nature of genetic testing and its benefits for prevention. This study also highlights individuals at-risk of not benefiting from genetic education, thereby strengthening the rationale for substance use and suicide prevention interventions.

## 1574/T/Poster Board #123

**Culturally and linguistically appropriate genetics education materials for Hispanic/Latino students and families: testing and outcomes.** *L. Stark[1], R. Giles[2], J. Johnson[2], S. Eddings[3].* 1) Genetic Science Learning Center, Univ Utah, Salt Lake City, UT; 2) Utah Department of Health, Salt Lake City, UT; 3) Bach-Harrison LLC, Salt Lake City, UT.

We used a community-based participatory approach, working with teachers and community members, to develop two sets of culturally and linguistically appropriate genetics curriculum materials for Hispanic/Latino students. The bilingual fifth grade materials address inherited traits and the partially bilingual secondary materials address polygenic, multifactorial chronic diseases and family health history. Both curricula include bilingual take-home activities for students to share with their families. The materials were tested in Utah schools with Hispanic/Latino enrollments of 46-64%. The fifth grade materials were tested with 159 students and six teachers. Students showed a significant knowledge gain between the pre and post tests (p<.01) and a significant increase in answer confidence. Most students (77.5%) talked about genetic traits and inheritance with someone in their family. The largest number indicated that they talked to their parents (64.5%), followed by siblings (27.2%). Teachers reported that due to the Spanish-language family materials, students had good conversations with their parents about genetics. The secondary materials were tested with 499 middle and high school students and six Health Education teachers. Approximately half of the classes viewed an introductory movie in which Hispanic/Latino students learned and discussed how genetics, lifestyle and behavior influence one's risk of developing chronic diseases. All students showed a significant knowledge gain between the pre and post tests (p<.01) and a significant increase in answer confidence. Significantly more students completed a family health history if they were in classes that saw the movie (62.7%) than if they were in classes that did not see the movie (45.5%) (p<.001). Significantly more students indicated they talked to at least one family member about the family health history if they were in classes that saw the movie (86.4%) than if they were in classes that did not see the movie (75.6%) (p<.01). These data show that both sets of curriculum materials effectively impacted student learning, that bilingual take-home materials effectively engaged families in genetics learning, and that a culturally-appropriate movie can motivate students to complete a family health history. This project is supported by grant U33MC00157 from the Health Resources and Services Administration, Maternal and Child Health Bureau, Genetic Services Branch and the March of Dimes.

## 1575/T/Poster Board #124

**One example of Genetics Education in High School: obesity and the leptin gene.** *B. Zanini[1], V. Marini[1], M. Marini[1], E. Rovini[2], A. Corda[2], R. Ravazzolo[1].* 1) School of Medicine, University of Genoa, Istituto G. Gaslini, Genova, Italy; 2) National Institute for Cancer Research, Genoa, Italy.

Teaching genetics in high school undoubtedly represents one of the most challenging activity in the post genomic era. While the discoveries of molecular genetics, genomics and biotechnology have been transferred from research laboratories to the textbooks, the mendelian classical genetics remains at the core of the practical activity of genetic training of students. We realize the inadequacy and the insufficiency of the traditional didactics in teaching the new genetics and we describe here an activity which has been undertaken in the context of the official teaching programs in Biology in some Italian high schools, in the city of Genova. Since almost ten years, a working group of Biology teachers in different Italian cities has developed experience in extending teaching of Genetic issues with practical activities offered to high school students. A member of this working group, who is now attending a Research Doctorate course in genetics, has started a program in which a practical laboratory course in Molecular Genetics has been set up. The possibility to attend a doctorate course has been fundamental to allow a strict interaction between a person involved in high school teaching and a university research laboratory, by which an exchange of knowledge is then re-addressed to the school. The course has the objective to teach the students how a DNA variant in a gene of interest, in this case the Leptin encoding gene, can be identified and how genotypes can be tested. The students extract DNA from their own saliva, amplify a segment of the gene of interest by Polymerase Chain Reaction (PCR) and assess individual genotypes by digestion with a restriction enzyme. We emphasize that this type of analysis is simple enough to be followed step by step by each student, under the guide of their teachers who have had an appropriate training before in the same activity. This approach allows to introduce the students to the existence of common variants in human populations and to explain how these might be related to multifactorial conditions, such as obesity in this particular case. The statistical methods to verify whether a molecular variant can be considered as a susceptibility genetic factor are explained with the help of examples taken from known and published work both using a candidate gene approach and a genome wide approach. Moreover, variability in the human genome is also explained in more general terms related to population genetics.

## 1576/T/Poster Board #125

**Team Teaching Genetic Concepts to Ninth Graders.** *L. McCabe[1], E. Stanley[2], T. Huynh[2], J. Martinez[2], J. Thiel[2], J. Truong[2], E. Steja[2], E. McCabe[2].* 1) Dept Human Gen, David Geffen Sch Med UCLA, Los Angeles, CA; 2) University of California, Los Angeles, Los Angeles, CA.

Background: The UCLA Center for Society and genetics (CSG) attempts to anticipate the impact of developments in genetics on individuals and groups. CSG is intensely cross-diciplinary, and currently includes faculty members and students from seven professional schools, 29 departments, and three of the four instructional divisions of the College. CSG developed an undergraduate minor in Society and Genetics and one of the required courses in DNA: Promise and Peril (based on the McCabe's book by that title), which describes how genetics impacts your daily life. Objective: To determine if we could develop team teaching materials for ninth grade students. Methods: UCLA in LA provided grant funding and an introduction to Ms. Woods, Principal, King Drew Magnet High School of Medicine and Science. Ms. Woods welcomed us to her school and introduced us to three of her teachers: Ms. Kong (Life Skills); Ms. Reyes (Biology); and Mr. Zajc (Health). Ms. Kong and Ms. Reyes worked with us the first semester, and Ms. Reyes and Mr. Zajc worked with us the second semester. Results: The King/Drew teachers and UCLA team developed eleven, 90 minute discussions. After the UCLA team met to discuss materials for each discussion. Topics included: DNA forensics; epigenetics; pharmocogenomics; genetic discrimination; newborn screening; genetic bottlenecks; sample ownership; near relative DNA forensic testing; ancestry; gender testing; and designer babies. The students were actively and enthusiastically engaged by the debates, discussion questions, games, plays, powerpoints, videos, and writing exercises. Conclusions: Ninth graders are able to master genetic concepts and consider the impact of genetics in their lives. The stories we used provided a context for the science and encouraged the students to apply genetics to their own experience.

## 1577/T/Poster Board #126

**Are information websites of hereditary breast and ovarian cancer useful? : Evaluation based on web research in Japan.** *M. Izumi, K. Kaneko, S. Yokoyama, N. Gongo.* Genetic Testing Dept. Biomedical Business Div. FALCO biosystems Ltd.

FALCO biosystems (Kyoto, Japan) is a commercial laboratory providing wide range of clinical testing services, including genetic test of BRCA1/2 gene for diagnosing hereditary breast and ovarian cancer (HBOC). We have acquired an exclusive license in Japan for BRCA1/2 gene testing by Myriad Genetics, Inc. (Utah, U.S.). The genetic test of BRCA1/2 is available as a routine clinical test in the U.S. and other Western countries. However, the BRCA1/2 testing is still utilized only in 15 medical centers in Japan. The certified genetic counselors working in FALCO support clinicians and nurses to utilize the BRCA1/2 testing appropriately, for example with providing educational tools for genetic counseling of HBOC. The counselors also created the information website of HBOC for patients/the public to learn more about the hereditary cancer. All our activities follow some related guidelines for genetic testing in Japan. We performed the web research among 359 clinicians (gynecological oncologists or breast cancer specialists) and 1007 patients/families separately to evaluate the information website of HBOC and to survey their attitudes toward the BRCA1/2 testing. More than ninety percent of the clinicians evaluated the website as "good" or "rather good". 58%; of them answered "I am interested in utilizing the BRCA1/2 testing on their clinics/medical centers". On the other hand, about 90%; of patients/families did not browse the website. Once they accessed to the website, 95%; of them evaluated it as "very useful" or "useful". More than half of patients/families did not believe in hereditary breast cancer. However, 70%; of patients/families were "very concerned" or "have thought" about any risk of heritability of breast cancer. About 70% of them were interested in undergoing genetic counseling. Regarding the BRCA1/2 testing, 70%; of patients/families were interested in undergoing it if the conditions (costs etc) were met, 14%; of them answered "I won't undergo the testing". As the reasons, some answered "I feel scared to know the risk" and others answered "To know the risk is not useful". These results will serve as a basis for some improvement of the information website. We need to improve the website recognized by patients/families. They also help us to provide the BRCA1/2 testing more appropriately in Japan. It is necessary to take care of their attitude toward the BRCA1/2 testing to educate them.

## 1578/T/Poster Board #127

**An Integrated Approach to Autosomal Recessive Genetic Diseases in High School Teaching.** *E. Andreozzi[1], M. Borriello[2], G. Esposito[3], A. Perreca[3], F. Salvatore[4].* 1) ITCG Archimede, Naples, Italy; 2) IPSSAR Marco Polo, Genoa, Italy; 3) University Federico II, Biochemistry and Medical Biotechnologies Dept., Naples, Italy; 4) CEINGE-Advanced Biotechnologies, Naples, Italy.

With a prevalence of 1/20,000 (Europe and North America) and an autosomal recessive mode of transmission, hereditary fructose intolerance (HFI) is an uncommon genetic disease. In affected individuals, ingestion of fructose produces such acute and chronic symptoms as hypoglycaemia and progressive liver damage. In recent years, attention has indirectly focused on HFI mainly because of the supposed correlation between fructose-rich diets and a series of metabolic diseases, and the obesity epidemic. Consequently, HFI is a hot topic that can arouse the interest of undergraduate students. Moreover, a discussion of HFI will allow us to apply the Punnett Square and to examine numerous different disease mutations that have been identified in the aldolase B gene in connection with HFI using the real-time polymerase chain reaction (PCR) technique. A series of lessons on HFI will thus lead to a discussion of both social aspects (the national programme of health education) and scientific aspects (genetic mechanisms). On a social level, the main aims are to spread knowledge/awareness about HFI and about the potential harmful effects of fructose-rich diets. On a scientific level, the aims are to learn to apply methods underlying the autosomal recessive mode of transmission of genetic diseases and to learn about the modern laboratory techniques used to identify modifications in the aldolase B gene. These aims can be pursued thanks to the knowledge acquired during the activities of a research doctorate during group work. The instruments used to pursue the aims on the social level of health education consist in a questionnaire designed to identify the students' eating with specific reference to the intake of fructose in the single diets and discussion of the questionnaire results. The discussion will show that exclusion of fructose from a diet can suggest fructose intolerance, and therefore the need for further tests to verify this condition. The instruments used at scientific level consist in the application of the Punnett Square to the transmission of HFI and in access to the PCR instrumentation thanks to the activities of the research doctorate during group work.

## 1579/T/Poster Board #128

**Who said it? When did they say it? How did they know?: Deciding when to trust or trash genetics health information.** *E. Reed[1], M. Weaver[2], A. Chappelle[3], P. Furlong[4], K. Clapp[5], R. Miller[6], M. Blitzer[2], C. Greene[2], S. Terry[3].* 1) NCHPEG, Lutherville, MD; 2) University of Maryland, Baltimore, MD; 3) Genetic Alliance, Washington, DC; 4) Parent Project Muscular Dystrophy, Middletown, OH; 5) FRAXA Research Foundation, Newburyport, MA; 6) National Fragile X Foundation, Walnut Creek, CA.

The Access to Credible Genetics Resources Network (ATCG) is a cooperative effort among researchers and advocacy professionals to develop approaches for addressing concerns about the quality of information available about genetic disorders. Existing evidence-based criteria in medicine provide standards of clinical care or treatment, but do not address standards for educational information about rare, single-gene disorders. To address this gap, the ATCG has developed the Quality Assessment Toolbox (Toolbox) to help developers of genetics educational information create quality materials. We are creating an additional online version of the Toolbox for the general public to serve as a guide in assessing the quality and completeness of educational materials. The development of these tools has raised issues about the definitions of quality, completeness, and accessibility of information, specifically as they pertain to conditions with a genetic basis. To advance these discussions, ATCG is holding a national meeting in September 2009 to bring together individuals who convey complex information to a variety of audiences, including those involved in education, evidence-based care, communication, and policy. Discussion will focus on issues relate to: defining information quality, choosing appropriate content, and utilizing new technologies effectively for education. The structure of the day will be organized around the three content areas of the Toolbox. The discussions of the meeting will be parlayed into tangible products, including publications, which will be distributed widely using the ATCG network. We will gather feedback and evaluations from conference participants. We will present both versions of the QAT and the outcomes of the national meeting.

## 1580/T/Poster Board #129

**The Coriell Personalized Medicine Collaborative: Examining the Utility of Genome-Informed Medicine.** *M. Christman.* President & CEO, Coriell Inst Med Res, Camden, NJ.

The Coriell Personalized Medicine Collaborative (CPMC) is a research study that employs an evidence-based approach to determine the utility of using personal genome information in health management and clinical decision-making1. The CPMC also aims to build a cohort with rich genotypic and phenotypic data with which to discover genetic variants that affect drug toxicity and efficacy, as well as to discover presently unknown gene variants that elevate a person's risk of cancer and other complex diseases. This forward-looking, collaborative effort involves physicians at several hospital partners, scientists, ethicists, genetic counselors, volunteer study participants, and information technology experts. Its goal is to better understand the impact of personalized, or genome-informed, medicine and guide its ethical, legal and responsible implementation2. All participants are genotyped on the Affymetrix 6.0 and D-MET genechips and potentially actionable items are returned to participants and physicians. The study will enroll 10,000 individuals by the end of 2009 with an ultimate goal of 100,000 participants. As of April 2009, there were ~4,000 participants enrolled in the study. There is no charge to study participants. 1. ## 1581/T/Poster Board #130

**Group Genetic Education Sessions: An Alternative Approach to Traditional Genetic Counseling.** *V. Oliva[1], D. Durand[1], M. Johansen[1], M. Rabinowitz[2], J. Follmer[1].* 1) Genzyme Genetics, Miami, FL; 2) Miami Beach Community Health Center, Miami Beach, FL.

**Background:** Given the recommendation to offer prenatal genetic screening and diagnostic options to all patients, there is an increasing demand on obstetricians to provide their patients with appropriate education about their options. Many have decided to refer their patients to genetic counselors (GC) in order to provide this information. Consequently, GCs are inundated, providing education to patients who would not have previously been referred to them. **Objective:** To develop a group genetic education session as an alternative to traditional genetic counseling in order to meet the needs of obstetricians who routinely offer screening and diagnostic options as recommended by ACOG and ACMG. **Methods:** PowerPoint presentations were developed in English and Spanish for a genetic education session for obstetric patients of the Miami Beach Community Health Center. The education session included a discussion of age related aneuploidy risks, maternal serum screening, prenatal diagnosis, and ethnicity screening. The session did not include a family history evaluation and was not intended to replace traditional GC. Bi-monthly group sessions were performed by 2 GCs from Aug-Dec 2008. Following the sessions, patients were given satisfaction surveys which queried 6 areas: was the information easily understood, how well was the available testing explained, how appropriate was the amount of information, did the information help in decision-making, would the patient recommend such a session to others and what was the overall satisfaction. Each area was ranked on a 5-point scale (1-5 strongly disagree to strongly agree). **Results:** Based on survey responses, patients had an overall satisfaction rating of 4.7. Patients reported that the education sessions helped their decision making. When asked if the amount of information presented was acceptable, the overall response was 4.73 on the 1-5 scale. Furthermore, 83% of the patients strongly agreed that the information was easy to understand and 80% of the patients would recommend the education sessions to others. **Conclusion:** An alternative to traditional genetic counseling was developed to meet the demands of obstetricians and patients needing education regarding prenatal screening options. The group education sessions met this need and were seen as highly effective by patients. Although this was a small sample size, this model could be applied on a broader scale to meet the increasing demand for genetic education.

## 1582/T/Poster Board #131

**The Genetic and Rare Diseases Information Center (GARD): Improving access to health information resources through collaboration.** *M. Snyder[1], S. Von Schuch[1], J. Lewis[1], M. Della Rocca[1], D. Lea[2], H. Hyatt-Knorr[3].* 1) Lockheed Martin, Rockville, MD; 2) National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 3) Office of Rare Diseases Research, National Institutes of Health, Bethesda, MD.

In 2001, the Office of Rare Diseases Research (ORDR) and the National Human Genome Research Institute (NHGRI) at the National Institutes of Health (NIH) established the Genetic and Rare Diseases Information Center (GARD) to enhance the public's knowledge of genetic and rare disorders. Over the last 8 years, GARD has responded to nearly 24,000 requests for information on 6,313 specific conditions.

While the majority of GARD users are patients, friends, or family members, the Information Center has responded to more than 2,000 requests for information from researchers, physicians, genetic counselors, nurses, and social workers. Many of these individuals requested help finding clinical or research genetic testing, treatment information, or experts in a particular condition. In response, GARD provided more than 7,000 resources, including referrals to NIH resources and publications, high quality Web sites, advocacy organizations, experts, clinical trials, and genetic services.

In 2008, GARD introduced a new online portal (http://rarediseases.info.nih-.gov/GARD/) to its collection of information resources and questions answered by GARD Information Specialists. The GARD Web pages include an expanding variety of resources that can be used by genetic researchers and healthcare professionals. Information is now available on past and upcoming ORDR cosponsored scientific conferences, making it easy to locate conferences related to a particular disorder. GARD also continues to increase links to resources on clinical and research genetic testing laboratories in the United States and other countries.

Since the launch of the Web pages, GARD has partnered with government agencies to further expand Web content. Last year, GARD collaborated with the Centers for Disease Control and Prevention (CDC) to incorporate information about more than 90 newborn screening diseases from the CDC's GeT-EQuiP portal onto the GARD Web pages. GARD also worked with the Office of Orphan Products Development (OOPD) of the Food and Drug Administration (FDA) to include information about OOPD-approved orphan products for rare diseases. GARD's vast online collection of resources can be a helpful tool for genetics professionals.

## 1583/T/Poster Board #132

**Resource Repository: Revolutionizing access to information.** *A. Chappelle, J. Bialick, S.F. Terry.* Genetic Alliance, Washington, DC.

The genetics and health community needs an accessible and common forum in which to share the wealth of quality information the flows from parent and family groups, community organizations, disease-specific advocacy organizations, professional societies, educational institutions, corporations, and government agencies. Genetic Alliance launched a new and improved electronic Resource Repository in the summer of 2009 (www.resourcerepository.org) that provides the community with free access to a growing collection of documents, links, audio, and video files. Features include the ability to track new content tailored to a user's interests, a robust and intuitive indexing system, the capability to view the most recently uploaded and most often downloaded content, an auto-generated cover page with title, author, and date, and a user-friendly submission process for users to upload their own materials. Users can upload new resources at any time, so information is kept up-to-date. In addition, organizations will be able to host their own entries to the Resource Repository with the look and feel of the host organization's website (through Application Programming Interfaces). These diverse access points will lead to the same vast knowledge network and result in shared information across genres and industries. The ease of use and accessibility of the Resource Repository makes it an invaluable tool for the entire genetics and health community.

## 1584/T/Poster Board #133

***Celestial3D*: A tool for 3D visualization of familial data for genetics education.** *E. Lam[1], R.J. Webster[1], J. Emery[2], L.J. Palmer[1].* 1) Centre for Genetic Epidemiology and Biostatistics, The University of Western Australia, Crawley, Western Australia, Australia; 2) School of Primary, Aboriginal and Rural Health Care, The University of Western Australia, Crawley, Western Australia, Australia.

Traditionally, paper-drawn pedigrees have been represented in two-dimensions (2D) and many current software packages remain true to this standard. However, the representation of large and/or complicated pedigrees in only 2D is cumbersome and reduces the ease of comprehension. The Celestial3D project started with the concept of arranging pedigrees in three-dimensional (3D) space, with the primary purpose of improving the visualization of large/complex pedigrees. The original pilot software for Celestial3D stemmed from applications in epidemiological and pedigree research and offered visualization capabilities only. We have taken Celestial3D to the next stage, using a 3D games engine (Unity) for rendering the pedigrees, which opens new opportunities for added interactivity and enhances functionality for serving its original purpose. These include features such as: on-demand searching/filtering capabilities, dynamic environmental changes and freedom to incorporate building of new pedigrees within 3D space. A primary application focus for this tool has been established in consultation with secondary-school teaching representatives and collaborators in the field of science education, where we have specifically identified the potential for Celestial3D to be used in introducing the concepts of genetics at secondary-school and undergraduate biology classes. Our goal is to develop a complete educational package to instruct students, via a student-friendly 3D environment offered by Celestial3D, to conduct exercises in reading pedigrees, explore and investigate Mendelian genetics that may parallel in-class experimental data and look at complex genetic matters. This renewed approach is hoped to assist educational facilitators in increasing the appeal for students studying subjects involving genetics and encourage future interest at higher education levels. We are also exploring potential clinical applications of Celestial3D.

## 1585/T/Poster Board #134

**Megalourethra: Prenatal Diagnosis, postnatal outcome and autopsy findings. Report of 7 cases.** *H. Amsalem[1], G. Ryan[1], B. Fitzgerald[2], S. Keating[2], P. Salle[3], A. Toi[4], H. Berger[5], D. Chitayat[6].* 1) Department of Ob & Gyn, The Fetal Medicine Unit Mt Sinai Hospital, University of Toronto, Toronto, Ontario, Canada; 2) Department of Pathology and Laboratory Medicine Mt Sinai Hospital, University of Toronto, Toronto, Ontario, Canada; 3) Department of Pediatrics, Division of Urology, The Hospital for Sick Children, University of Toronto, Toronto, Ontario, Canada; 4) Department of Diagnostic Imaging, Mount Sinai Hospital, University of Toronto, Toronto, Ontario, Canada; 5) Department of Ob & Gyn, St. Michael Hospital, University of Toronto, Toronto, Ontario, Canada; 6) The Prenatal Diagnosis and Medical Genetics Program Mount Sinai Hospital, University of Toronto, Toronto, Ontario, Canada.

Megalourethra is a rare form of functional obstructive uropathy, caused by maldevelopment of the penile mesodermal tissue resulting in functional lower urinary tract obstruction. It is subdivided into two types, fusiform with deficiency of both corpus spongiosum and cavernosum and scaphoid with absence of corpus spongiosum. Both types result in severe dilatation of the penile urethra. Postnatally, urination and sexual function are significantly impaired. We report the prenatal diagnosis, postnatal outcome and autopsy findings in 7 cases diagnosed prenatally at 18-24 wk gestation. The main sonographic features were those of partial lower urinary tract obstruction including distended bladder accompanied by cystic dilatation and elongation of the penile urethra. In three of the fetuses, talipes was also diagnosed. Only one case was complicated by mild early oligohydramnios at diagnosis. Three of the pregnancies were terminated and the autopsy confirmed megalourethra and distended bladder. All 4 live born babies needed several urologic procedures which will be described in detailed. Two of them had normal renal function, one had impaired renal function and one developed end stage renal disease at the age of 2 currently awaits renal transplantation. None of the live borne babies was able to urinate normally. CONCLUSIONS: In cases of megacystis, diagnosed by antenatal ultrasound, particular attention should be paid to the appearance of the penis, especially if the amniotic fluid volume is not severely decreased. Parents should be counseled regarding the long term urology outcome which is different than that of most other forms of lower urinary tract obstruction.

## 1586/T/Poster Board #135

**Association of early fetal megacystis with trisomy 18.** *M. Kambich[1], S. Weiss[2], L. Geibel[1], S. MacGregor[1], I. Salafsky[3].* 1) Department of Obstetrics & Gynecology, Center for Maternal and Fetal Health, NorthShore University HealthSystem Evanston, IL; 2) Department of Medicine, Center for Medical Genetics, NorthShore University HealthSystem Evanston, IL; 3) Department of Pediatrics, NorthShore University HealthSystem Evanston, IL.

Fetal megacystis is defined as an abnormal enlargement of the fetal bladder. First trimester diagnosis requires a longitudinal bladder diameter of 7mm or more. The incidence of fetal megacystis is approximately 1 in 1500 pregnancies. Commonly recognized associations include posterior urethral valves, prune belly syndrome, and urethral atresia. We report several cases of early fetal megacystis noted on ultrasound in fetuses who had a subsequent diagnosis of trisomy 18. A retrospective chart review was conducted of all cases of trisomy 18 at our institution in which a ultrasound had been performed on fetuses between 11-21 weeks of gestation for a five year period from January 2003 to December 2008. Six fetuses out of forty-eight affected with trisomy 18 (12.50%) were initially identified with megacystis occurring in the first and second trimester of pregnancy. Three of the five fetuses were identified with megacystis at the time of the first trimster Down syndrome screening examination. The remaining three fetuses (identified in the second trimester) had not undergone first trimester Down syndrome screening, but the extent of the megacystis suggests that the process may have been present in the first trimester. Subsequent to the abnormal ultrasound findings, prenatal diagnosis of trisomy 18 in all fetuses was achieved through cytogenetic analysis utilizing either chorionic villus sampling or amniocentesis, depending on the appropriate gestational age. This review suggests that trisomy 18 should be included in the differential diagnosis of early fetal megacystis. Cytogenetic analysis should be initiated at the time of diagnosis of fetal megacystis. This will allow for accurate genetic counseling and pregnancy management.

## 1587/T/Poster Board #136

**Functional analysis of ATG9B in the human placenta.** *R. Shono[1], T. Yamada[1], I. Furuta[1], M. Morikawa[1], T. Yamada[1], H. Yamada[2], H. Minakami[1].* 1) Department of Obstetrics; Hokkaido University Graduate School of Medicine; Sapporo, Japan; 2) Department of Obstetrics and Gynecology, Kobe Univ., Kobe, Japan.

We previously reported that ATG9B (NOS3AS), the overlapping antisense transcript with endothelial nitric oxide synthase (NOS3) is involved in its post-transcriptional regulation, and encodes an autophagy protein highly expressed in placenta. ATG9A and ATG9B are identified as human homologue of yeast Atg9p. ATG9A is ubiquitously expressed and evolutionarily conserved from yeast to mammalian, whereas ATG9B is tissue-specifically expressed in adult tissues (pituitary gland and placenta) and exists only in vertebrate species but not in lower eukaryotic species. ATG9B has a function to complement ATG9A. The NOS3 locus at chromosome 7q36 has been suggested to be associated with a number of diseases including preeclampsia (PE). In this report, we hypothesized that ATG9B may play important roles in the development of placenta and the pathophysiology and etiology of perinatal disease including PE and placentas after delivery were analyzed to investigate the hypothesis of the function of ATG9B with related genes. A total of 114 placentas (80 from normal pregnancies (NP) and 34 from pregnancy-induced hypertension: PIH) were examined under approval of ethical committee of the institute. After the extraction of RNA, quantitative RT-PCR was performed to measure the expression levels of ATG9A, ATG9B, NOS3, and sONE (short variant of ATG9B). Autophagy activity was determined by the detection of LC3-II shifted from LC3-I through immunoblotting using anti-LC3 antibody. Among samples of NP, the expression of ATG9B increased with advancing GA and those of ATG9B and sONE were higher in the samples with labor onset (LO) than those without LO. ATG9A and NOS3 were not influenced by GA or LO. ATG9A showed positive correlations with NOS3 and inverse correlations with ATG9B. ATG9B showed inverse correlations with NOS3. The autophagy activity was not enhanced along with GA nor LO, suggesting that the increased ATG9B expression with advancing GA and LO in NP does not play a role in the activation of autophagy but may have other function. Next, PIH (PE and gestational hypertension) samples were analyzed and compared with those of NP. The gene expressions were not influenced by GA in PIH. The expression of ATG9B was higher in preterm PIH samples than those in preterm NP without LO. The autophagy activity was more enhanced in PIH than in NP, suggesting that the increased ATG9B expression might have played a role in the activation of autophagy in preterm PIH.

## 1588/T/Poster Board #137

**Abnormal prenatal ultrasound findings and one Ashkenazi Jew parent that carries the R2478_D2512del in *NEB*, as an early warning sign for Nemaline Myopathy.** *H. Yonath[1, 2], M. Berkenstadt[1], H. Reznik-Wolf[1], S. Eisenberg-Barzilai[1], L. Peleg[1,2], V.L. Lehtokari[3], M. Frydman[1,2], E. Pras[1].* 1) Inst Human Gen, Sheba Med Ctr, Ramat Gan, Israel; 2) Sackler Faculty of Medicine, Tel Aviv University, Israel; 3) The Folkhälsan Institute of Genetics, University of Helsinki Finland.

Nemaline Myopathy (NM) is a devastating neuromuscular disease, which is caused by mutations in several genes. One of the genes is Nebulin (NEB), the most common cause for autosomal recessive NM. A common founder mutation, R2478_D2512del was found in Ashkenazi Jews (AJ) with a carrier rate of 1:108. This mutation is included in the prenatal screening in AJ in Israel. We have recently encountered 3 pregnancies with abnormal findings on ultrasound (US) all of which resulted in babies suffering from NM. Only one of the parents in these families, however, carried the deletion mutation in NEB. Case #1: Prenatal US revealed club feet and polyhydramnios. On carrier screening the mother was found to be a carrier of the deletion, and the father was not, both are AJ. Soon after birth the girl was noted to be severely hypotonic and a diagnosis of NM was made on muscle biopsy. DNA testing revealed the second mutation in intron 108, a splice site mutation 17118+1G>A. On RT-PCR the mutation was found to cause skipping of exon 108. Case #2: A newborn girl was diagnosed with severe hypotonia. During the pregnancy there were decreased fetal movements and polyhydramnios. Muscle biopsy was compatible with NM. Molecular testing revealed heterozygosity for the R2478_D2512del in NEB, inherited from her AJ father. The deletion was not detected in the mother who is of Greek and Yemenite origins. Prenatal testing in their next pregnancy with polymorphic markers close to NEB, revealed the same haplotype in the fetus and in the affected child. The pregnancy was terminated. Case #3: Polyhydramnios, decreased fetal movements and arthrogryposis were noted during pregnancy. A previous child had similar findings and died soon after birth due to respiratory failure. The father and the fetus were found to be carriers of the deletion, the mother not, both parents are of AJ. A common haplotype was not identified in the parents that did not carry the R2478_D2512del mutation. A second mutation was found in one of the families, we are currently trying to identify the other two mutations. Ultrasonographic features such as polyhydramnios, decreased fetal movements, club feet and arthrogryposis should promote genetic NM screening. Hence, in Ashkenazi couples with such a presentation both parents should be screened for the deletion mutation and even if only one of them is found to be a carrier, NM should be highly suspected.

**Attitudes of recent and prospective mothers about newborn genetic screening: a survey of 2,266 U.S. women.** *D. Kaufman[1], N. Bonhomme[2], K. Hudson[1], S.F. Terry[2], J. Scott[1].* 1) Genetics & Public Policy Ctr, Johns Hopkins University, Washington, DC; 2) Genetic Alliance, Washington, DC.

INTRODUCTION: Studies of public attitudes about genetic newborn screening (NBS) have focused on high-risk parents and parents of affected children. However, understanding the lay public's opinions on NBS may be useful in the design of expanded NBS programs. To this end, recent and prospective mothers were surveyed about their experiences and opinions on genetic newborn screening. METHODS: An online survey was conducted in two random samples of U.S. women aged 18-45. One sample included women who had given birth in the past three years (recent mothers). The other included women planning to have a biological child in the next three years (prospective mothers). We measured the influence of a disease's severity, age of onset, and a test's positive predictive value (PPV) on support for NBS for a condition. Recent mothers also were asked about experiences with their last child. RESULTS: The response rate was 60%: 1,258 recent mothers and 1,008 prospective mothers participated. A total of 67% of recent mothers and 38% of prospective mothers had heard of NBS before. Among recent mothers, 10% received no information about NBS during their last pregnancy and another 30% felt they did not receive enough information. Although large majorities would prefer to learn about NBS before going to the hospital to deliver, 55% of recent mothers said they received information during or after delivery. After reading a definition of NBS, nearly all women said the goals of NBS were important and supported NBS to improve a baby's health, while 5% of both groups felt NBS should never be done. In both groups, 52% said parental consent should not be required but parents should be able to decline NBS, and 47% said parents should be able to choose which diseases to screen for. The largest concern in both groups was that NBS might not provide accurate results. Majorities expressed interest in NBS for adult onset diseases like colon cancer, and there was low but measurable interest in testing for traits like adult height or artistic ability. Disease severity and age of onset had little influence on support for screening, but there was 10% higher support for use of tests with a higher PPV. CONCLUSIONS: The public both needs and wants information on genetic NBS programs earlier than it is generally being delivered. There is support for NBS for a range of conditions. However, accuracy of tests results is important, as evidenced by the influence of PPV on support for use of a given test.

## 1590/T/Poster Board #139

**Newborn Screening of Congenital Hypothyroid in Shanghai Area.** *G. Tian, H. Xu, Y. Wang, W. Zhu.* Dept. Newborn Screen, Shanghai Children's Hospital, Shanghai, China.

Newborn screening for congenital hypothyroidism has been carried out for 24 years in Shanghai, China. and the prevalence of CH was investigated . A 1:1 matching case control study was performed on two groups of women that delivered normal babies and CH babies, respectively for probing the nosogenesis. Family conditions, conditions in pregnancy and other indicators of two groups of pregnant women were investigated to probe the influence factors on the delivery of CH babies. The incidence of CH tended to increase in the past 24 years, the average is 32.11/100,000 and the average annual increase rate of the incidence was 12.50 %; After iodine complement for the whole population, the incidence of CH tends to increase; Six factors are the main impacting factors for CH, in which the family history of the thyroid disease and the extent of seafood intake during pregnancy are the influence factors are statistically significant. Genetic factor plays important role in the development of CH. It should be set safe upper limit for the amount of iodine taking-in in pregnant women.

## 1591/T/Poster Board #140

**Study on interaction of eNOS and LCHAD in apoE-/- mice onset preeclampsia-like at multiple gestational stages.** *R. Ma, M. Sun, Z. Yang, Corresponding author: Zi Yang zi_yang@email.com.* Peking University Third Hospital, Beijing, China.

Objective: This study aimed to investigate interaction of fatty acid oxidation with nitric oxide in apoE-/- mice onset preeclampsia-like at multiple gestational stages, and to explore the correlation in pathogenesis in early onset preeclampsia. Methods: preeclampsia-like model were established in apoE-/- and wild-type pregnant mice at early, mid and late gestational stages by injecting nitric oxide synthase (NOS) inhibitor L-arginine methyl ester (L-NAME) subcutaneously. Control groups were received normal saline (NS) simultaneously. Groups were subdivided into L-NAME and NS in early, mid and late gestational stages in apoE-/- and WT mice respectively. Plasma lipid levels and production of NO were measured, and histological examinations of placenta were performed. The expression of endothelial nitric oxide synthase (eNOS) and long-chain 3-hydroxy acyl-CoA dehydrogenase (LCHAD) expression were analyzed by RT-PCR and western blot respectively. Data were treated statistically. Results: Compared with NS control groups, total cholesterol (TC), triglyceride (TG) and free fatty acid (FFA) concentration were significantly increased in early and mid subgroups in L-NAME of apoE-/- and WT groups($p<0.05$). But there was no significant difference among the late L-NAME of apoE-/- and WT subgroups and the NS control subgroups ($p>0.05$). A lower NO production were found in early, mid L-NAME subgroups in apoE-/- and WT groups than those of in the NS controls($p<0.05$), whereas no significant difference among the late L-NAME subgroups in apoE-/- and WT and the NS controls ($p>0.05$). The LCHAD expression levels of mRNA and protein showed significantly down-regulated in early and mid subgroups in L-NAME of apoE-/- and WT groups compared with NS controls ($p<0.05$). The eNOS expression levels of mRNA and protein were significantly down-regulated in early and mid subgroups in L-NAME of apoE-/- and WT groups compared with NS controls ($p<0.05$). A positive correlation was found between eNOS and LCHAD at mRNA expression in early and mid L-NAME subgroups in apoE-/- and WT groups. Conclusions: These results suggested that in preeclampsia-like mouse model by L-NAME in early and mid gestational stages, the inhibition of NO may cause hyperlipidemia through the reduction of fatty acid oxidation, which may lead to endothelial dysfunction. Whereas the changes of preeclampsia-like onset at late gestational stage may be maternal vascular response to inhibition of NO.

## 1592/T/Poster Board #141

**Chromosomal aneuplodies other than Down syndrome and trisomy 18 detected through integrated prenatal screening.** *W.S. Meschino[1, 2], T. Huang[1].* 1) Genetics Program, North York General Hospital, Toronto, ON, Canada; 2) Dept. of Paediatrics, University of Toronto, Toronto, ON, Canada.

Objective: To review Integrated Prenatal Screening (IPS) results for trisomy 13, Turner syndrome, triploidy, and other rare chromosomal anomalies. Methods: IPS for Down syndrome was introduced at North York General Hospital (NYGH) in 1999. IPS is carried out in two steps. The first step involves ultrasound nuchal translucency (NT) and maternal serum pregnancy associated plasma protein A (PAPP-A) at 11-14 weeks gestation. The second blood sample is taken at 15-20 weeks for the measurements of maternal serum alpha fetoprotein (AFP), unconjugated estriol (uE3), and total human chorionic gonadotropin (hCG). The final result is based on the integration of the values from both stages. This study reviews IPS results of trisomy 13, Turner syndrome, triploidy and other rare chromosomal anomalies identified in our screening program and assesses whether these anomalies can also be detected by IPS. Results: Between December 1999 and November 2007, 71,477 women were screened using IPS at NYGH. Ten cases of trisomy 13, 11 cases of Turner syndrome (including variants and mosaicism), 8 cases of triploidy, 3 cases of autosomal mosaicism and one case of ring chromosome 7 and monosomy 7 mosaicism were identified among women who completed IPS. IPS detected 7 cases of trisomy 13, 7 cases of Turner syndrome and 7 cases of triploidy. All three cases of autosomal mosaicism and the case of ring chromosome 7 and monosomy 7 mosaicism were also screen positive using IPS. Two cases of trisomy 13, one case of Turner syndrome and the case of ring chromosome 7 and monosomy 7 mosaicism would be screen negative using conventional second trimester triple marker screening. Conclusion: IPS can detect most cases of trisomy 13, Turner syndrome, triploidy, and rare chromosomal aneuploidies that are viable in the second trimester. Some of these anomalies would have been missed by conventional triple marker screening. This study provides useful information for genetic counselling.

**Prediction of preeclampsia by analysis of cell-free messenger RNA in maternal plasma.** *A. Sekizawa, Y. Purwosunu, A. Farina, H. Saito, T. Okai.* Showa University, Tokyo, Japan.

Objective: The purpose of this study was to predict the occurrence of preeclampsia in a series of patients at gestational week 15-20 weeks, with the use of a panel of messenger RNA markers. Materials and Methods: Data from 62 patients with preeclampsia who were asymptomatic at the time of blood testing and 310 control subjects were analyzed. Multivariable analysis was performed with discriminant analysis. Results: Univariable analysis identified vascular endothelial growth factor receptor 1 as the marker with the highest detection rate; placenta-specific 1 with the lowest. Mean estimated score for preeclampsia was 9.4 for control subjects and 72.5 for subjects who experienced preeclampsia. A receiver operating characteristic curve that was obtained with the estimated score for preeclampsia as a test variable yielded a detection rate of 84 percent (95 percent CI, 71.8-91.5) at a 5 percent false-positive rate with an area under the curve of 0.927 ($P < 0.001$). Again, detection rate and score for each patient for classification as preeclamptic correlated with severity. Conclusion: A panel of messenger RNA is able to detect subjects who will experience preeclampsia.

### 1594/T/Poster Board #143

**ADAM12: its utility in first and second trimester maternal serum aneuploidy screening.** *M. Macek[1], H. Kluckova[1], A. Lashkevich[1], R. Vlk[2], I. Spalova[2], D. Chudoba[1], D. Novotna[1], S. Vilimova[1], M. Simandlova[1], M. Turnovec[1], M. Macek Jr[1].* 1) Dept of Biology & Medical Genetics; UH Motol and Charles Univ Prague, Czech Republic; 2) Dept of Obstetrics and Gynecology, UH Motol and Charles Univ Prague, Czech Republic.

The aim of the study was to evaluate the utility of ADAM12 as aneuploidy marker in the first and second trimester maternal serum screening. ADAM12 was measured by DELFIA ADAM12 Research Kit (Perkin Elmer; USA). The control 11-17th week levels were ascertained in frozen (-20ºC) maternal sera from our screening programme from years 2001-2008. For each day at least 30 samples were used for control percentile (P) calculations. Altogether, 59 and 26 sera from first and second trimester, respectively, with different types of chromosomal aberrations were tested. The levels lower than P25 and higher than P75 were stratified in subgroups in order to express the degree of deviation from P50. The P50 levels within 11-17th week were 456-1133 μg/l. Trisomy 21 had highest prevalence in the first trimester within P25-50 range, while in the second trimester it was within P50-75. The 2/5 cases with trisomy 18 were under P5-10 and 3/3 cases with trisomy 13 were under P25. All triploidy cases were under P5. The 5/6 cases with 47,XXX were under P5, while 1/6 was under P25. All 47,XXY and 47,XYY were within the P50-95 range. The 5/11 cases with Turner syndrome (including mosaicism) were within P25-50 and 3/11 cases were within the P75-95 range. In 4 cases with structural chromosomal aberrations and in one mosaic trisomy 10, levels of ADAM12 were under P25. Further prospective studies will determine additional value of ADAM12 for the first and second trimester maternal serum screening. Supported by VZFNM00064203 and NR9448-3/2007.

### 1595/T/Poster Board #144

**Prenatal Screening for Aneuploidies and Neural Tube Defects in a newly set up Genetic Centre at GMCH, Chandigarh, India, 160031 - Results & Experiences.** *G. Kaur[1], B.S. Chavan[1], J. Srivastav[1], R. Atwal[1], G. Randhawa[1], A. Sehgal[2], R. Kaur[3], A. Huria[2], P. Goel[2].* 1) Genetic Centre, Government Medical College and Hospitall, Chandigarh, India 160031; 2) Department of Gynecology & Obstetrics, Government Medical College and Hospitall, Chandigarh, India 160031; 3) Department of Radiodiagnosis, Government Medical College and Hospitall, Chandigarh, India 160031.

The burden of genetic disorders and physical and mental handicap is excessively high in India due to preferential consanguineous marriages in some communities, absence of screening facilities, and lack of awareness among the masses. In a developing country like India, the cost of management of genetic disorders also gets substantial, not only in terms of monetary expenditure but also associated emotional and social distress. However, focus has only recently shifted towards prevention and eradication of genetic abnormal disorders through initiation of early intervention in the form of screening. Introduction of screening facilities on a large scale in any developing country is not easy unless authorities appreciate the necessity of screening for all and integrate it with sustained financial support. This becomes imperative as majority of the population cannot afford these facilities in spite of their availability.

This study was carried out to provide early interventional measures in the form of prenatal maternal serum screening of biomarkers (AFP, hCGβ, uE3) to all pregnant women and establish prevalence of aneuploidies and neural tube defects along with providing pre-test and post-test genetic counseling to all enrolled women.

Prenatal screening was introduced in December'2006. Triple test was offered at nominal charges between 15-19 weeks of gestation. All pregnant women visiting GMCH were enrolled after an informed and written consent; 5ml of blood was taken and tested for a high risk for Trisomy 21 &18 and Neural Tube Defects (NTDs). Around 3500 pregnant women were screened in the period extending December'06 to March'09 and 195(5.57%) high risk cases were segregated; who were further referred for level II fetal ultrasound for all soft markers and amniocentesis.

A single case of Trisomy 21 (DR-0.61) was diagnosed apart from one of gastroschisis and three of anencephaly. The data obtained has also been used to obtain local medians. Prenatal screening proved to be effective because of its early intervention and prevention based approach. Apart from picking up aneuploidies, high risk triple test report also helped in picking up many other prenatal conditions like oligohydamnios, intrauterine fetal demise and other congenital malformations.

### 1596/T/Poster Board #145

**Ancillary benefits of prenatal maternal serum screening achieved in the California program.** *F. Lorey, N. Kazerouni, B. Currier, C. Hodgkinson, S. Goldman, M. Roberson.* Genetic Disease Screening Program, California Department of Public Health, Richmond, CA.

Aim: To evaluate the extent of fetal structural abnormalities, other than neural tube and abdominal wall defects, identified by California's prenatal screening program. Methods: The quad marker prenatal screening records of 539,782 women were examined for both the screening interpretation and the diagnosis of structural abnormalities detected via programmatic follow-up. The time period was from July 16, 2007, to January 16, 2009. Women that were screen-positive for trisomy 21, trisomy 18, neural tube defects (NTDs) or Smith-Lemli-Opitz syndrome (SLOS) received follow-up services at State-authorized prenatal diagnosis centers. Detailed reports of services and diagnostic information were submitted on each patient in order to obtain reimbursement. These reports were linked in a database to the original screening results. Results: A total of 26,324 women received follow-up ultrasound services at State-approved prenatal diagnosis centers in the study time period. Of these women, 1082 (4.1%) were identified as having fetuses with significant structural abnormalities, other than NTDs or abdominal wall defects. In addition to the structural abnormalities, 225 cases of fetal demise, 65 cases of severe oligohydramnios, 1 case of severe polyhydramnios, 1 case of conjoined twins, 20 cases of twin-twin transfusion, 4 molar pregnancies, 4 acardiac twins and 92 cases with placental abnormalities were identified. The total number of women identified with fetuses affected by these structural defects and pregnancy complications far exceeds the number of women identified with fetuses affected by NTDs (n=202) and abdominal wall defects (n=254). The primary focus of maternal serum screening programs (other than aneuploidies) has always been considered to be the detection of NTDs and abdominal wall defects. Conclusion: While prenatal screening programs do not explicitly screen for structural abnormalities other than NTDs and abdominal wall defects, clearly many other structural abnormalities may be associated with a screen-positive status. Thus, the detection of these additional structural defects can be considered an ancillary program benefit. The California Program's follow-up ultrasounds must meet very stringent standards with respect to the practitioner's qualifications and the exam details. These high standards may also contribute to the detection of these abnormalities.

## 1597/T/Poster Board #146

**Preimplantation genetic diagnosis for chromosome reciprocal translocation carriers by triple-color or repeat fluorescence in situ hybridization.** *Y. Tan, D. Cheng, C. Lu, F. Gong, H. Liao, L. Li, G. Lu.* Institute of Reproduction and Stem Cell engineering, Central South University, Changsha, China.

Objective To analyze the outcome of preimplantation genetic diagnosis(PGD) conducted for carriers with chromosome reciprocal translocation by multi-colour or repeat fluorescence in situ hybridization(FISH). Methods A total of 22 couples were performed for PGD after accepting genetic counseling and signing informed consent. Ovarian hyperstimulation, oocyte retrieval and ICSI were carried out as usual. Blastomere biopsy was performed at the 6-8cell stage. Triple color or repeat FISH were performed to ensure to exclue the all unbalanced embryos. Normal or balanced embryos were transferred into uterus on d5. Results A total of 24 PGD cycles were carried out. 282 oocytes were retrieved. The success rate of biopsy, fixation and hybridization were 97.7%, 96.06% and 84.85%, respectively. A total of 22 embryos were transferred and 7 clinical pregnancies were achieved. All clinical pregnancies resulted in healthy babies. No spontaneous abortion occurred. Conclusion Triple-color or repeat FISH was an effective PGD strategy to enhance normal pregnancy for reciprocal translocation carriers.

## 1598/T/Poster Board #147

**Chromosome X-inactivation and FISH studies in a rare case of familial analphoid X-centromere variant.** *PN. Rao[1], F. Nooraie[2], F. Quintero-Rivera[1].* 1) Pathology & Lab Medicine, David Geffen UCLA Sch Med, Los Angeles, CA; 2) Genoptix Medical Laboratory, Carlsbad, CA.

We report a rare case of an analphoid centromere variant of the X chromosome, in a three generation family. A 36-year-old Persian woman was referred for amniocentesis, at 17 wks gestation (G1P0). Prenatal ultrasound was unremarkable, with normal fetal movement and cardiac activity. Interphase FISH on uncultured cells with the Aneuvysion probe-set for chromosomes X,Y,13,21, and 18, exhibited only one X-chromosome signal in all 50 nuclei examined; the results were reported as abnormal consistent with Turner syndrome. A repeat ultrasound was normal, and the couple waited for karyotype studies for pregnancy management. G-banding analysis of 15 in situ colonies from 4 cultures showed a 46,XX karyotype, and no evidence of 45,X cells. In the light of the discrepancy between the interphase FISH and G-banding, FISH investigation using the X/Y-centromere probes was performed on unbanded in situ slides. All metaphase and interphase cells revealed only one X centromere signal. There was no evidence of any signals with variations in intensity or size of the X centromere. Parental chromosomes and X/Y FISH revealed the mother to carry the X-centromere variant. A healthy baby girl was delivered at 40 weeks (apgar 8,9). X/Y FISH on the maternal grandparents' metaphase cells identified the grandfather to carry the variant X-centromere. Replication banding studies were done on the mother and the infant to determine any possible relationship between X inactivation status and the variant X-centromere. This was followed by sequential FISH with the X/Y probes on the same metaphases. These studies showed a skewed X-inactivation, in both the mother and daughter. The X chromosome with the variant centromere (DXZ1 FISH negative) was always active, while the inactive/late-replicating X carried the normal centromere signal. This observation may be purely coincidental and unrelated, since the grandfather with one active X exhibited the centromere variant. It is known that most centromeres are largely made up of alpha satellite sequences, but not required for centromere function. Neocentromeres, which are functional centromeres, located in non-centromeric regions, lack alpha satellite DNA, and form to confer mitotic stability to chromosome fragments. However, an X-centromere variant as observed in this family has never been reported before and the possibility of false positive results due to variations in centromere sequences should be discussed with patients in genetic counseling.

## 1599/T/Poster Board #148

**Altered expression of mRNA and proteins for trisomy 21 affected amniocytes.** *C.-K. Cho[1,2], J. Bayani[1,2], S. Dason[1,2], E.P. Diamandis[1,2,3].* 1) University of Toronto, Toronto, Ontario, Canada; 2) Mount Sinai Hospital, Toronto, Ontario, Canada; 3) University Health Network, Canada.

Down syndome (DS), caused by an extra chromosome 21, affects 1 in 750 live births, and is characterized by cognitive impairment as well as congenital defects and increased risk for several diseases such as leukemia. Three major objectives of DS research include: 1) discovery of more sensitive and specific markers for prenatal screening, 2) understanding molecular mechanisms of DS phenotypes, and 3) finding therapeutic targets. Unfortunately, little is known about the molecular pathogenesis of DS, and no direct genotype-phenotype relationship has yet been confirmed. Proteomic analysis based on mass spectrometry (MS) allows discovery of a large number of proteins in complex biological samples. We have recently generated the most comprehensive list of proteins present in human amniotic fluid (AF) by using high resolution MS, since AF contains the most information of the developing fetus. Based on this result, we hypothesize that quantitative analyses of proteins from amniocytes will reveal novel biomarkers and/or clues to altered molecular mechanisms of a developing fetus affected by DS. We compared the proteome of amniocytes from chromosomally normal and trisomy 21 affected pregnancies (n=3 ea.), including quantitative analysis of secreted, intracellular, and membrane proteins from amniocytes by Stable Isotope Labeling of Amino acids in Cell culture (SILAC). Also, we examined microRNA expressions from these amniocytes by TaqMan Arrays, and performed qRT-PCR for proteins of interest. Over 1200 proteins from normal and DS amniocyte conditioned media were identified and quantified by LTQ-Orbitrap mass spectrometer based on MS/MS spectra ratios of peptides containing isotope-labeled amino acids. At least 5 of these quantified proteins consistently show differential expression between euploid and trisomy 21 affected amniocytes, indicating that they may play a role in DS phenotypes. Candidate proteins were selected based on the quantification between the two conditions and consistency between the triplicates of each condition, and a few have been confirmed by immunoassay and/or multiple reaction monitoring. .

## 1600/T/Poster Board #149

**Array CGH has a 13% yield for clinically significant chromosome imbalances in prenatal samples of pregnancies that eventually resulted in loss or therapeutic termination.** *S. Alliman, B.A. Bejjani, B.A. Torchia, R. Schultz, L.G. Shaffer, A.N. Lamb, J. Coppinger.* Signature Genomic Laboratories, Spokane, WA.

The use of array-based CGH (aCGH) for diagnosis of chromosome imbalances in pediatric patients is increasing and has led to exploration of aCGH applications in the prenatal setting. We evaluated 23 prenatal specimens from ongoing pregnancies that eventually resulted in stillbirth, termination, or miscarriage to address the diagnostic utility of aCGH. Of these, 17/23 (73.9%) were cultured amniocytes, 2/23 (8.7%) were DNA specimens extracted from cultured amniocytes, and 4/23 (17.4%) were cultured CVS specimens. High-resolution oligonucleotide-based aCGH was performed on 22/23 specimens and whole genome BAC-based aCGH was performed on one specimen. Indications for study included multiple congenital anomalies (MCA) in 11/23 (47.8%), cystic hygroma with or without hydrops in 5/23 (21.7%), arthrogryposis or clubbed feet with family history of previous affected pregnancy in 2/23 (8.7%), fetal loss (one with two-vessel cord) in 2/23 (8.7%), and microcephaly, skeletal anomalies, and sex discrepancy in one case each. Karyotypes were reportedly normal for 20/23 cases, with no karyotypic information provided in 3/23 cases. aCGH identified 3/23 (13.0%) clinically significant abnormalities including a de novo 4.8 Mb deletion of 7q35q36.1 in a prenatal specimen submitted for fetal loss and two-vessel cord, a de novo 3 Mb deletion of 17q24.3q25.1 encompassing the SOX9 gene in a pregnancy with MCA suspected to have campomelic dysplasia, and a de novo 6.6 Mb deletion of 9q21.33q22.32 in a pregnancy with MCA. Results of unclear significance were identified in 1/23 (4.3%) cases. These preliminary results demonstrate that high-resolution aCGH is a useful diagnostic tool for detection of submicroscopic chromosome imbalances in these pregnancies, with a 13.0% yield for results of clinical significance. Care should be taken to ensure that a sample type that allows for DNA extraction and FISH analysis is preserved in karyotypically normal pregnancies undergoing loss or termination so that aCGH can be performed.

## 1601/T/Poster Board #150

**Detection rates for fetal anomalies in first versus second trimester ultrasound.** *A. Kang[1], P. Miny[2], H. Struben[1], I. Filges[2], S. Tercanli[1].* 1) Ultrasound Unit, University Women`s Hospital Basel, University Basel, Switzerland; 2) Division of Medical Genetics, University Children's Hospital and Department of Biomedicine, Basel Switzerland.

Objective: The aim of this study was to evaluate the performance of ultrasound screening for fetal anomalies indicating chromosomal anomalies in a two-stage screening concept comparing the detection rates of the 11 to 14 weeks scan and the routine anomaly scan in the second trimester. Methods: In this prospective study a total of 8074 fetuses were examined between 11 and 14 weeks and received a detailed scan of the fetal anatomy in addition to nuchal translucency (NT) measurement for risk assessment of aneuploidy by well trained sonographers. The first ultrasound evaluation had been carried out early between 11+0 13+6 and the second scan late between18 to 24 weeks of gestation performed in the same center. Results: In the study group a total of 128 (1.6%) chromosomal defects were diagnosed. Using NT and maternal age for risk assessment the detection rate for chromosomal anomalies at 11-14 weeks was 83% (106/128) including detection of fetuses with trisomy 21 in 93% (54/58), trisomy 18 in 96% (25/26), Turner syndrome in 80% (8/10), trisomy 13 (6/6) in 100% and other rarer chromosomal defects in 46%(13/28). The overall incidence of fetal malformations (other than increased NT-findings) detected by ultrasound was 3,6% (n=288), 40% of which were diagnosed between 11 and 14 weeks (116/288). The following 2nd trimester scan revealed 102 (35%) supplementary structural anomalies including 5% with additional chromosomal defects. Conclusion: The 11-14 weeks scan detects the vast majority of chromosomal anomalies and about 40% of all structural defects, primarily the severe and lethal forms. These results demonstrate the changing role and growing impact of the 11-14 weeks scan.

## 1602/T/Poster Board #151

**Prenatal molecular diagnostics of trisomy 21 using quantitative APEX-2 assay.** *E. Oitmaa[1], M. Peters[1,3], K. Vaidla[2], R. Andreson[2], R. Mägi[2], N. Tõnisson[6], M. Remm[2], M. Schneider[4], A. Salumets[2,3,5], K. Õunap[6], A. Metspalu[1,2,7].* 1) Biotechnology, University of Tartu, EBC, Tartu, Estonia; 2) Institute of Molecular and Cell Biology, University of Tartu, Riia 23b, Tartu 51010, Estonia; 3) Department of Obstetrics and Gynecology, University of Tartu, L. Puusepa 8, Tartu 51014, Estonia; 4) University of Ulm, Steinhövelstr. 9, ULM 89075, Germany; 5) Nova Vita Clinic, Centre for Infertility Treatment and Medical Genetics, Kaluri tee 5A, Haabneeme, 74001 Viimsi, Harjumaa, Estonia; 6) Department of Genetics, United Laboratories, Tartu University Hospital, L. Puusepa 2, Tartu 51014, Estonia; 7) The Estonian Genome Project of University of Tartu, Tiigi 61b, Tartu 50410, Estonia.

**Objective:** Trisomy 21 is the most frequent chromosomal aneuploidy affecting approximately 1 in 700 live births. Here, we demonstrate a new, fast and reliable method based on one tube multiplex PCR followed by modified Arrayed Primer Extension-2 (APEX-2) for the prenatal diagnosis of trisomy 21 (T21).

**Design & Method:** The T21 APEX-2 assay is based on the comparison of signal intensities of allelic fraction of heterozygous SNPs to discriminate between trisomy and euploid DNA samples after APEX reaction. We used 143 SNPs with high heterozygote frequency (according to HapMap genotype frequency data) from Down Syndrome Critical Region (21q21-21q22) for the analysis. For validation of the T21 assay we used blood samples obtained from T21 patients and euploid individuals and for evaluation of the T21 assay we used DNA samples derived from cultured and uncultured amniocytes (AC). APEX-2 method enables the simultaneous amplification of multiple loci of the template in two phases: the one tube multiplex PCR with SNP- specific primers in the first phase and PCR with the universal primer in the second phase. The multiplex PCR was followed by ExoI/sAP purification step and APEX reaction. APEX microarrays were imaged with the Genorama QuattroImager and genotyping of SNPs was performed by the Genorama Genotyping Software (Asper Biotech Ltd). Differences between allelic ratios of heterozygous SNPs of normal individuals and T21 patients were verified by t-test statistics.

**Results:** We developed APEX-2 microarray assay for the detection of trisomy 21. Analysis of the APEX results revealed that 90 SNPs out from initial 143 SNPs were sufficient for the reliable discrimination between T21 and euploid DNA samples ($p$-value ≤ 0.05 from one or both strand). Fifty three SNPs were excluded from the final set of APEX-2 primers during the assay development due to low call-rate and reproducibility or false signals. In the blind study using 109 clinical samples, the sensitivity and specificity of the T21 assay were both 100%. All T21 assay results were confirmed by conventional cytogenetic study.

**Conclusion:** Our experiments demonstrated that this new approach is suitable for the rapid detection of trisomy 21 in diagnostic laboratories.

## 1603/T/Poster Board #152

**Application of a validated BAC-based array CGH platform for prenatal diagnosis in South Korea.** *J. Park[1], J. Woo[2], S. Shim[3], S. Yang[2], Y. Choi[4], K. Yang[2], D. Cha[3].* 1) Obstetrics and Gynecology, Bundang CHA General Hospital, CHA University, Seongnam-si, Kyunggi-do, Korea; 2) Bio Chip Service, Macrogen Inc., Seoul, Korea; 3) Obstetrics and Gynecology, Kangnam CHA General Hospital, CHA University, Seoul, Korea; 4) Obstetrics and Gynecology, Seoul National University, Seoul, Korea.

Introduction: While conventional G-banded karyotyping still remains a gold standard in prenatal genetic diagnoses, the widespread adoption of array CGH technology for postnatal genetic diagnoses has led to increasing interest in the use of this same technology for prenatal diagnosis. Objective: Here, we describe the development and application of a BAC-based DNA chip that is being used for prenatal diagnosis in South Korea. Method and Result: We have designed a target BAC-based array CGH platform (MacArrayTM M-chip). This array CGH platform specifically targets submicroscopic deletions and duplications for 26 known genetic syndromes of medical significance as well as frequently-observed common chromosomal aneuploidies that are observed prenatally. To validate the array, we obtained genomic DNA from 132 cell lines containing relevant genomic imbalances and specific chromosomal aneuploidies. Experiments were performed in a blinded manner and all known genomic alterations were successfully identified. We then applied this array CGH platform to 98 amniotic fluid specimens that were also subjected to conventional karyotyping. Due to the targeted nature of this array CGH platform, certain chromosomal aberrations could not be detected by array CGH, but were identified via conventional karyotyping including balanced chromosomal rearrangements: 2 cases of inv(9) and 1 case of t(8;11) and two cases of trisomy (trisomy 10 and trisomy 16). However, certain chromosomal aberrations were detected with this array platform that were not oberserved by G-banded chromosomal analysis. For example, we identified eight cases of microdeletions in the Yq11.23 chromosomal region, which harbors the DAZ gene, and may lead to non-obstructive spermatogenesis. FISH analysis confirmed the deletion in all eight cases. Conclusions: We have successfully designed and applied a BAC-based array CGH platform for prenatal diagnosis. This array CGH platform can be used in conjunction with conventional karyotyping and will provide rapid and accurate diagnosis for the targeted genomic regions while eliminating the need to interpret clinically-uncertain genomic regions - certain copy number variants (CNVs).

## 1604/T/Poster Board #153

**Large scale application of QF-PCR for rapid prenatal diagnosis of common chromosome aneuploidies, results of ten years clinical experience.** *V. Cirigliano[1,2], G. Voglino[3], E. Ordoñez[1,2], A. Marongiu[3], P. Cañadas[1], L. Rueda[1,2], E. Lloveras[4], C. Fuster[2], M. Adinolfi[5].* 1) Departament de Genètica Molecular. General Lab. 08029 Barcelona, Spain; 2) Unitat de Biologia. Departament de Biologia Cellular, Fisiologia Immunologia. Universitat Autònoma de Barcelona. E-08193 Barcelona, Spain; 3) Molecular Genetics and Cytogenetics Lab. Promea-Day Surgery, 1026 Turin. Italy; 4) Departament de Citogenètica. General Lab. 08029 Barcelona, Spain; 5) The Galton Laboratory. University College London. NW1 2HE London. U.K.

The QF-PCR test has been developed to allow prenatal diagnoses of chromosome abnormalities in a few hours after sampling. The main advantages of the assay are low cost, speed and automation allowing its application to all pregnancies undergoing prenatal diagnostic procedures. We developed a QF-PCR assay that was employed to test 50.000 clinical samples with results issued in 24 hours. Up to 10 markers were included on the sex chromosomes, 8 on chromosomes 21 and 18 and 6 markers on chromosome 13. The most common referral indications were raised biochemical risk (32%), advanced maternal age (30%), parental anxiety (22%) abnormal ultrasound (7%) and increased nuchal translucency (6%). All samples were also tested by conventional cytogenetic analysis and the results compared. All non mosaic aneuploidies involving chromosomes 21, 18, 13 X and Y were detected with 100% specificity. Several cases of partial trisomies and mosaicism were also identified. Overall 95% of clinically relevant abnormalities were readily detected and termination of the affected pregnancies could be performed without waiting for results of the cytogenetic analyses. When applied in CVS samples the molecular assay allowed discriminating true fetal abnormalities from CPM in several cases thus avoiding further investigations by amniotic fluid sampling. QF-PCR showed 100% sensitivity in detecting clinically relevant chromosome abnormalities in samples referred for advanced maternal age and increased biochemical risk; in fetuses with abnormal ultrasound sensitivity was 95%. Despite being deliberately targeted to chromosomes 13, 18, 21, X and Y the rapid QF-PCR test detected the great majority of chromosome abnormalities in a few hours from sampling. Our results support the possibility of reducing the load of prenatal cytogenetic analysis if pregnancies are carefully monitored by first or second trimester non invasive screening. As a result, invasive procedures should only be performed in high risk pregnancies. In case of abnormal QF-PCR results, medical action can be made available in a few hours after sampling. In cases of negative QF-PCR results cytogenetic analyses might only be performed for fetuses with clear evidence of abnormalities based on ultrasound results. In Countries, where large scale conventional cytogenetic tests are hampered by high cost and lack of technical expertise, QF-PCR may be used as the only prenatal diagnostic test.

## 1605/T/Poster Board #154

**Genetic diversity of three STR Loci for rapid prenatal diagnosis of Down syndrome in Korean Population.** *MH. Lee[1], SY. Park[1], DJ. Kim[1], MJ. Kim[1], HM. Ryu[1,2], YH. Cho[3].* 1) Laboratory of Medical Genetics, Cheil General Hospital & Women's Healthcare Center, Kwandong University College of Medicine, Seoul, Korea; 2) Department of Obstetrics and Gynecology, Cheil General Hospital & Women's Healthcare Center, Kwandong University College of Medicine, Seoul, Korea; 3) Department of Medical Genetics, College of Medicine, Hanyang University, Seoul, Korea.

In order to increase the number of STR loci for rapid prenatal diagnosis of Down syndrome as well as for forensic DNA analysis in Korean population, we have studied three tetranucleotide STR loci on chromosome 21 (D21S1435, D21S1411, and D21S1412). Two hundred genetically unrelated individuals were tested in this study. The loci showed no significant deviations from Hardy-Weinberg equilibrium. The nomenclature is based on the sequence data of the polymorphic region of the microsatellite markers according to the International Society for Forensic Haemogenetics (ISFH) recommendations. The alleles consisted of simple tetra-nucleotide repeat patterns and highly complex repeat patterns. Several alleles revealing the same fragment size but different repeat structures were found. The combined polymorphism information content for three STR loci was 0.991 and combined heterozygosity was 1.0, which is highly informative. The obtained data may be useful for rapid prenatal diagnosis of Down syndrome and also for population genetics research and individual identification in forensic science.

## 1606/T/Poster Board #155

**Prenatal Diagnosis of Tanatophoric Dysplasia Type 1 with Array CGC.** *P. Tavares[1], S.L. Pereira[3], J. Anderson[3], R. Nogueira[1], P. Rendeiro[1], H. Santos[2], A. Palmeiro[1].* 1) CGC Genetics, USA and Portugal; 2) Servico Genetica Medica, Hospital S. Maria, Lisboa, Portugal; 3) Foetal Medicine Unit, Hospital S. Teotonio, Viseu, Portugal.

Skeletal Dysplasias account for over 350 different genetic diseases with bone involvement but variable clinical characteristics (Superti-Furga and Unger, 2007; Krakow,2008), that can be identified in the foetus during the 2nd trimester, usually around 20 weeks. In most cases there is no previous history of skeletal dysplasia, and the foetal diagnosis, based on ultrasound, is difficult and, in approximately 60%, non conclusive (Krakow, 2008). Only the accurate diagnosis of the type of skeletal dysplasia allows a correct approach for physicians and parents about the evolution and natural history of the genetic disorder identified in the foetus, and also the evaluation of the recurrence risk. The early molecular characterization of genes responsible for skeletal disorders, is of main interest for establishing a more precise diagnostic evaluation, namely during the prenatal period. The Molecular Diagnosis of Skeletal Dysplasia by Array CGC test was specially designed for the diagnosis of the most common pathologies referred above, and contains a panel of 26 point mutations, identified in the 6 main genes involved on these skeletal dysplasias: FGFR3 (Achondroplasia, Tanatophoric Dysplasia), COL2A1 (Achondrogenesis type II), SLC26A2 (Achondrogenesis type IB), CRTAP (Osteogenesis Imperfecta recessive type), LEPRE1 (Osteogenesis Imperfecta recessive type) and SOX9 (Campomelic Dysplasia). We present a case of a Prenatal Diagnosis of Tanatophoric Dysplasia through the Molecular Diagnosis of Skeletal Dysplasia by Array CGC test. Second trimester anomaly scan performed at 20 weeks showed all long bones well below the 3rd centile, with telephone receiver shaped femurs; very small chest with a narrow thorax and a normal connected heart. The analysis of the foetal DNA with Molecular Diagnosis of Skeletal Dysplasia by Array CGC detected a c.742C>T mutation (p.Arg248Cys) on FGFR3 gene. This mutation is associated with Tanatophoric Dysplasia Type 1, thus confirming the type of skeletal dysplasia observed in the ultrasound examination. Turnaround time for detection of the mutation and confirmation by sequencing was completed in 1 week. The parents opted for a termination of the pregnancy, which took place uneventfully. This case confirms the importance of this new molecular diagnostic tool in rapid molecular characterization of skeletal dysplasia detected in prenatal diagnosis, allowing genetic counseling based on molecular diagnosis.(www.cgcgenetics.com).

## 1607/T/Poster Board #156

**Hypospadias in males with intrauterine growth restriction due to placental insufficiency: The placental role in the embryogenesis of male external genitalia.** *T. Uster[1], Y. Yinon[2], J. Kingdom[2], L. Proctor[2], E. Kelly[3], J. Salle[4], D. Wherrett[5], S. Keating[6], O. Nevo[7], D. Chitayat[1].* 1) The Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital University of Toronto, Toronto, Ontario, Canada; 2) Department of Obstetrics and Gynecology, Division of Maternal-Fetal Medicine, The Placenta Clinic, Mount Sinai Hospital, University of Toronto, Toronto, Ontario, Canada; 3) Department of Pediatrics, Neonatal Intensive Care Unit, Mount Sinai Hospital, University of Toronto, Toronto, Ontario, Canada; 4) Department of Pediatric Urology, The Hospital for Sick Children, University of Toronto, Toronto, Ontario, Canada; 5) Department of Pediatrics, Division of Endocrinology, The Hospital for Sick Children, University of Toronto, Toronto, Ontario, Canada; 6) Department of Pathology, Mount Sinai Hospital and The University of Toronto, Toronto, Ontario, Canada; 7) Department of Obstetrics and Gynecology, Sunnybrook Health Centre, University of Toronto, Toronto, Ontario, Canada.

Objective: To define the association between early onset intrauterine growth restriction (IUGR) due to placental insufficiency and hypospadias in male offspring. Methods: Prospective cohort study of small-for-gestational age (SGA) male infants with hypospadias managed by a multidisciplinary team over a 5-year period. Antenatal charts and delivery information were reviewed for evidence of IUGR due to placental insufficiency. Results: Thirty SGA male infants were diagnosed with hypospadias/abnormal genitalia after birth, and 4 of them were diagnosed antenatally. Five cases occurred in the smaller pair of discordant IUGR twins, where the larger co-twin appropriate for gestational age in each case, had normal male genitalia. Serial ultrasounds demonstrated features of early-onset IUGR in all cases at a median gestational age of 21 weeks (range 14-31weeks). Twenty-three (79%) pregnancies were subsequently complicated by absent/reversed end-diastolic flow in the umbilical arteries indicating severe IUGR, and 15 (50%) women developed severe pre-eclampsia. Twenty-seven (90%) live births occurred at a median gestational age of 31 weeks (range 27-37); 23 (77%) of the neonates had birthweights <3rd centile. All newborns had normal male karyotypes. In 62% (18/29) the hypospadias was severe. A correlation was found between the severity of the IUGR and the severity of hypospadias as significantly more infants with severe hypospadias were less than the 3rd centile compared to the mild-moderate hypospadias group: 94%(17/18) vs 55%(6/11) respectively, (p=0.02). Other external genital abnormalities apart from hypospadias included micropenis (8), bifid scrotum (9), penoscrotal transposition (6), severe chordee (11) and cryptorchidism (14). Conclusions: This study demonstartes an association between early placental dysfunction and abnormal development of male external genitalia. Careful sonographic evaluation of the genitalia is advised when early-onset placentally-mediated IUGR is found.

## 1608/T/Poster Board #157

**Low Estriol Levels in the Maternal Quadruple-Marker Screen in a Fetus with Cornelia de Lange Syndrome and a Partial Deletion of the *NIPBL* Gene.** *J.R. Goodman[1], P.L. Wilson[1], E.D. Cole[2], J.J. Mulvihill[2], J. Lee[2], S. Li[2], A.F. Wagner[1].* 1) OB/GYN, University of Oklahoma Health Sciences Center, Oklahoma City, OK; 2) Pediatrics, University of Oklahoma Health Sciences Center, Oklahoma City, OK.

We present a 26yo Caucasian female $G_3P_{1102}$ who was referred due to an increased risk for Trisomy 18(1:11) on a maternal quadruple marker screen at 18-6/7wks. Unconjugated estriol(uE3) levels were decreased at 0.30 ng/mL and 0.30 MoM. Her initial U/S did not reveal any abnormalities but was limited by maternal body habitus and fetal positioning. She returned 4wks later. Micrognathia, overlapping fingers on the right hand, bilateral cleft feet with hyperextended 1st toes, and growth restriction were seen. She underwent amniocentesis which revealed a 46,XY karyotype. Smith-Lemli-Opitz (*DHCR7*) sequencing due to the low uE3 level was normal. She was hospitalized due to IUGR and had a repeat C/S due to a non-reassuring BPP at 31wks.

Postnatal genetic evaluation of the fetus revealed a generous posterior fontanelle, synophrys, long eyelashes, micrognathia, cleft palate, hypospadias, unilateral cryptorchidism, left single palmar crease, absent right 2nd finger, bilateral cleft feet with incomplete development of toes on the right. DDx included ectrodactyly ectodermal dysplasia and Cornelia de Lange syndrome (CdLs). Postnatal karyotype confirmed the prenatal findings. Postnatal diagnosis of CdLs was determined by whole genome oligonucleotide microarray analysis that revealed an approximately 312kb loss on the short arm of chromosome 5p13.2 involving the *NIPBL* gene. Annular pancreas was found causing duodenal stenosis. He underwent ex-lap and gastroduodenostomy due to a partial rotational anomaly with emergent tracheostomy at 33d and expired at 37d.

In CdLs, prenatal evaluation is difficult due to non-specific prenatal findings, normal karyotype, and sporadic de novo mutations. Studies have suggested that low 1st and 2nd trimester levels of pregnancy associated plasma protein-A (PAPP-A) are an indicator for this heterogeneous condition that is characterized by pre/postnatal growth deficiency, limb abnormalities, hirsutism, characteristic facial features, developmental delay, and mental retardation. However, PAPP-A can be non-specific. Here, we suggest the addition of estriol to the prenatal evaluation of CdLs. This steroid hormone is produced by the placenta from fetal 16OH-DHEA. It can serve as an indicator for intrauterine growth retardation, fetal distress, and placental function. Low uE3 levels have been associated with trisomy 18, Smith-Lemli-Opitz syndrome, and placental sulfatase deficiency.

## 1609/T/Poster Board #158

**Blinded Analysis of Cultured Amniotic Fluid Samples: Conventional Cytogenetics vs Affymetrix 6.0 Microarray vs Array Comparative Genomic Hybridization (aCGH).** *T.A. Maher[1], J.M. Milunsky[1,2], A. Anguiano[3], R. Owen[3], C.M. Strom[3], A. Milunsky[1,2].* 1) Center for Human Genetics, Boston University School of Medicine, Boston, MA; 2) Department of Pediatrics, Boston University School of Medicine, Boston, MA; 3) Quest Diagnostics, Nichols Institute, San Capistrano, CA.

Single Nucleotide Polymorphism (SNP)/Copy Number Variation (CNV) analysis using oligo probe microarrays, and BAC array-based comparative genomic hybridization (aCGH), are now routinely used in the detection of deletions/duplications to elucidate genomic imbalances of patients with mental retardation, dysmorphic features and/or multiple congenital anormalies. These platforms are capable of finely defining chromosomal regions, amenable to high throughput and able to detect CNVs below the resolution of conventional cytogenetics. At Boston Universtiy, we had previously validated the Affymetrix 500K, 5.0 and 6.0 SNP/CNV microarrays on more than 1000 clinical samples. We now sought to validate the Affymetrix 6.0 SNP/CNV microarray on 34 prenatal samples previously tested by a national reference cytogenetics laboratory to determine the feasibility of SNP/CNV microarray analysis on these samples. The reference cytogenetics laboratory was also testing the samples by aCGH to provide a comparison of the different platforms available. Samples selected by the reference cytogenetics laboratory were received blinded to our laboratory and the 6.0 microarray assay was performed. All the samples were analyzed at a 50 probes/200kb resolution. By SNP/CNV microarray, we determined 15 of the samples to be normal. The quality of DNA in 4 of the samples was insufficient to run the assay. 14 of the samples were determined to contain pathogenic copy number alterations. One sample passed all the QC checkpoints but produced an uninterpretable result. The aCGH analysis produced 18 normal, 15 abnormal and 1 failed results. 14/14 normal and 14/14 abnormal samples showed concordance on both platforms. A normal finding on both platforms was determined for 1 sample with a balanced translocation. Two mosaic samples were discordant on both platforms when compared to the final karyotype. Mosaicism and balanced rearrangements represent important limitations on both platforms. Both the SNP/CNV and aCGH platforms were able to determine the size and physical location of the alterations with slight differences. We report our experiences in the quality of samples, type of results generated and limitations of the different platforms.

**WHOLE GENOME MICROARRAY CGH VS. TARGETED MLPA ANALYSIS IN PRENATAL DIAGNOSIS: A BALANCE BETWEEN SENSITIVITY AND INFORMATIVITY.** *C. Pangalos.* InterGenetics-Diagnostic Genetic Center, Athens, Greece.

Introduction: Our experience, using three different high resolution array CGH platforms in high risk prenatal cases, revealed the benefits but mostly the problems associated with the application of the technique during prenatal diagnosis. For 3 years, we have also applied a targeted approach for the detection of a number of known, recurrent deletion/duplication syndromes. We present data and discuss benefits and potential shortcomings of both approaches. Material & Methods: Fetal DNA was extracted, labeled and hybridized to either an Agilent 4X44K microarray slide (4 samples), Agilent 244K microarray slide (1 sample) or 19K Human BAC Empire Genomics AccuArray (6 samples). Results were evaluated using the Agilent CGH Analytics 3.4.40 software. Also, 799 prenatal samples were analyzed by MLPA for the detection of microdeletion syndromes and subtelomeric rearrangements. Results: Multiple CNV's were identified in 4 prenatal samples/cases, referred due to ultrasound findings and/or karyotypic abnormalities. In one case and after analysis of the parents, the variants were classified as de novo and pathogenic, involving both a subtelomeric deletion and subtelomeric duplication. Common copy number polymorphisms (CNP's) were observed and reported as such. Following MLPA analysis, we detected 2 samples with abnormal findings, both involving well characterized microdeletion syndromes. Conclusions: Although it is obvious that high-resolution array CGH will uncover more abnormalities, there are severe limitations prohibiting their routine use in a clinical prenatal setting: (a) the burden on clinicians and parents, who have to deal with ambiguous information, due to copy number variants of unclear clinical significance, (b) serious time constraints, due to the fact that prenatal testing is increasingly performed at a later gestational age and (c) the high cost associated with the test. In contrast, our experience leads us to favor a targeted approach, by interrogating multiple, recurrent, clinically defined (and constantly updated) pathogenic regions, via standard and custom MLPA as a routine procedure.

## 1611/T/Poster Board #160

**Diagnostic Utility of Array-Based Comparative Genomic Hybridization in a Prenatal Setting.** *M. Shohat[1,2], I. Maya[1], Y. Zalzstein[1], E. Taub[1], B. Davidov[1].* 1) Raphael Recanati Genetic Institute, Rabin Medical Center, Beilinson Hospital, Petah Tikva, Israel; 2) Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel.

Array-based comparative genomic hybridization (aCGH) is a new technique for detecting submicroscopic deletions and duplications across the entire genome. There is limited information regarding aCGH in prenatal settings. Here we present our experience of 239 prenatal aCGH analyses in the Recanati Genetic Institute between 2006 and 2009. During this period there was a 6-fold increase in the number of tests performed per month (from 5 to 30). The indications for testing were: 38% major anomalies on ultrasound (U/S), 24% advanced maternal age (AMA), 17.5% family history of unknown etiology, 16% parental concern, 4.1% abnormal karyotype and 0.4% abnormal serum biochemical screening. Ten cases of abnormal karyotype with unknown significance were sent for aCGH: 4 with de novo translocations, 2 with a marker chromosome, 2 with additional chromosomal material and 2 with partial trisomy. A normal aCGH in 8 of these cases enabled us to reassure the families and the pregnancies were continued, and in 2 cases an abnormal aCGH enabled us to confirm the presence of an unbalanced karyotype and the pregnancies were terminated. Of the remaining 229 cases with a normal karyotype, 86.5% had normal aCGH results and 13.5% had abnormal aCGH results. 12.2% were familial copy number variants (CNV) and three cases (1.3%) had a de novo microduplication by aCGH and were terminated (1 had post axial polydactyly on U/S and AMA, 1 had a heart defect, ventriculomegaly and AMA, and 1 had no abnormality). Our results suggest that prenatal aCGH helps to clarify abnormal karyotype findings and non-specific U/S malformations and therefore should be offered particularly in these cases. In low risk pregnancies (when no indication exists) the rate of detecting an abnormality by aCGH was 1:76, but more cases are needed in order to expand our knowledge and validate our conclusions.

## 1612/T/Poster Board #161

**Preimplantation genetic diagnosis (PGD) in 35 couples with familial chromosome rearrangement: FISH results and outcome analysis.** *S. Weremowicz[1,3], A. Nureddin[2], D.J. Sandstrom[1], K.V. Jackson[2], E. Ginsburg[2,3], C. Racowsky[2,3].* 1) Dept Path-CAMD, Brigham & Women's Hosp, Boston, MA; 2) Dept Obstetrics & Gynecology, Brigham & Women's Hosp, Boston, MA; 3) Harvard Medical School, Boston, MA.

Preimplantation genetic diagnosis (PGD) can allow avoidance of transfer of embryos affected with specific mutations or chromosome abnormalities, so couples at risk avoid the trauma of recurrent pregnancy loss or affected offspring. Since February 2002 - January 2009, PGD was performed at Brigham and Women's Hospital for 35 couples in which one partner had a balanced chromosome rearrangement. Our patients included 28 balanced reciprocal translocation carriers, five Robertsonian translocation carriers, and two inversion carriers. Embryo biopsy was performed in 74 cycles in these 35 couples. FISH analysis, using commercially available probes, was performed on 767 blastomeres from 728 embryos. A single blastomere was assessed for 689 embryos (94.6%). FISH RESULTS: Informative FISH results were obtained for 653 embryos (90%) including 166 embryos (23%) assessed as chromosomally normal or balanced and 487 (67%) assessed with an abnormal/unbalanced FISH pattern. Inconclusive FISH results were reported in 14 embryos (1.9%), and in 61 (8.4%), no FISH result was obtained (32: no nucleus found; 28: fragmented nucleus; 1: failed hybridization). PREGNANCY OUTCOMES: Of the 74 cycles, embryo transfer was canceled in 11 (15%) due to absence of any embryo with a normal/balanced hybridization pattern. In the remaining 63 cycles, 113 embryos were transferred. A positive pregnancy test was obtained in 34 cycles (46% per cycle; 54% per embryo transfer) including six chemical pregnancies, two ectopic pregnancies, 17 term pregnancies with 20 babies delivered and three ongoing viable pregnancies (i.e., beyond 12 weeks) for an overall ongoing/delivered pregnancy rate 27% per cycle and 31.7% per embryo transfer. Spontaneous abortion occurred in five pregnancies with fetal karyotypes: 46,XY and 47,XY,+21, and unknown in 3 cases). One pregnancy was electively terminated (trisomy 21). The overall ongoing/delivered pregnancy rate per couple treated was 54% (20/35). CONCLUSION: Our data compares favorably with published literature and further documents the great value of PGD as an important laboratory diagnostic option for at-risk couples.

## 1613/T/Poster Board #162

**Disocordant increased nuchal translucency thickness in monochorionic twin is a possible predictor of severe TTTS.** *S. Abe, K. Miura, K. Yamasaki, Y. Ikeda, H. Masuzaki.* OB/GYN, Nagasaki Univ. School of medicine, Nagasaki, Japan.

Objectivs ; Twin to twin transfusion syndrome (TTTS) is seen in 15-20% of monochorionic diamniotic twins. However, we are not able to predict which cases have TTTS later, because the pathophysiology of TTTS remains unknown. In clinical, the conditions in cases of TTTS were assessed by the Quintero classification, and the fetoscopic laser photocoagulation (FLP), which is performed in cases of 16-26 weeks of gestation, obtains satisfactory results in Japan. Meanwhile, in utero surgeries such as FLP are invasive approach and always have serious risk of both mother and baby. Therefore, the prediction and the prevention of TTTS later have a great significance in cases of monochorionic twins.Increased nuchal translucency thickness (NT) is used as one of the factors for prenatal screening of chromosomal abnormalities. A few were reported association between increased NT and twin-to-twin transfusion syndrome (TTTS). We studied whether discordant NT at early second trimester predicted affecting severe TTTS. Patients and methods ; We defined discordant NT as different NT thickness which is over 30% discordance between inter-twins and increased NT observed in at least one of the twins. We recruited 13 pairs monochorionic-diamniotic twins (MD twins), 6 cases of discordant NT and 7 cases of concordant NT that we measured NT thickness at 10 to 14 gestational weeks in 2002 to 2008. Other MD twins we have not measured NT thickness at those gestational weeks were excluded. We also evaluated each CRLs at the NT measurement, amnion pocket measurement (AFV) and doppler wave forms of fetus retrospectively. Results ; All 6 cases of discordant NT except 1 case would result in TTTS. One discordant NT case which would not develop TTTS showed that increased NT observed in one of the twins disappear at the 4th day of admission and bed rest. Other discordant NT cases were followed up as outpatients. None of the cases represented chromosomal abnormalities. Conclusions ; Although discordant NT may be an early form of TTTS, at that stage TTTS is still reversible state. Increased NT can be utilized only as a prenatal screening tool for chromosomal abnormalities but also as a useful predictor for TTTS. Discordant NT cases of MD twins should follow up strictly and there is possibilitys that stop developing TTTS.

## 1614/T/Poster Board #163

**First trimester prenatal diagnosis of β-thalassemia through chorionic villus sampling in Pakistan.** *S.M. Bakhtiar[1], D. Sabih[2], K. Ibrahim[2], A. Azhar[1], S.A. Baig[3], M. Tariq[1], M.S. Hussain[1], S.M. Baig[1].* 1) Human Molecular Genetics Lab, National Inst for Biotech and Genet Eng (NIBGE), Faisalabad, Punjab, Pakistan; 2) Multan Institute of Nuclear Medicine and Radiotherapy (MINAR), Multan, Pakistan; 3) Department of Pathology, Children Hospital, Pakistan Institute of Medical Sciences (PIMS), Islamaabad, Pakistan.

β-Thalassemias are a group of heterogeneous recessive disorders common in many parts of the world. Despite the great advances in the treatment of thalassemia, there is so far no cure, but perhaps bone marrow transplantation (BMT) is a possibility. Prevention, using prenatal diagnosis and selective abortion in the cases where the fetus is found to be affected, may be considered as a sensible alternative. β-Thalassemia is the most common monogenic disease in the Pakistani population with an overall carrier frequency of 6%. The objective of our study at National Institute for Biotechnology and Genetic Engineering (NIBGE) was to evaluate the beta-globin gene mutations in cell-free fetal DNA in the first trimester (8-12th weeks' gestation) for the prediction of thalassemia risk at chorionic villous sampling (CVS). Monoplex and multiplex Amplification Refractory Mutation System (ARMS) PCR was used for detection of known mutations and sequencing of the β-globin gene was carried out in case of rare or unknown mutations. In the last one year, CVS from 48 pregnant women were collected for retrospective PND of β-thalassemia in the first trimester of pregnancy. The mutation detection through Monoplex and/or Multiplex ARMS-PCR and sequencing revealed 9 (19%) fetuses affected i.e homozygous and all the 9 couples opted for termination of the pregnancies. The mutations detected in 48 families include IVS-I-5 (G-C), FSC-8/9 (+G), FSC-41/42 (-TTCT), IVS-I-1 (G-T), 619 bp deletion, FSC-5(-CT) and CD-15 (G-A) with frequencies of 39.4% 39.4%, 9%, 7.5%, 1.3%, 1.3% and 0.66% respectively. Only four fetuses were homozygous normal and the remaining 35 were carrier/heterozygote for one parental mutation. There were consanguineous marriages in 39 couples (81%). True homozygosity was detected in 39 couples and nine couples with two different mutations (compound heterozygosity). Compound heterozygosity was detected in three couples who were first degree cousin. Four unrelated couples were also having the same mutation which reflects high frequency and prevalence of β-thalassemia alleles in the local population. Establishment of mutation detection, genetic counseling and prenatal diagnostic facility may facilitate similar programs for other monogenic diseases to control affected births in the Pakistani Population.

## 1615/T/Poster Board #164

**A Case Report of SC Phocomelia and Illicit Drug Use.** *J. Davalos.* Gynecology, Area of health N° 1, Quito, Pichincha, Ecuador.

INTRODUCTION SC phocomelia syndrome (SC) is a rare autosomal recessive disease, its relationship with illicit drug use is not well established.This report is an approach to this problem. First we mention some reports related with SC, birth defects associated with illicit drug use and then we report the case itself. Roberts syndrome (RBS) is characterized by tetraphocomelia, growth deficiency of prenatal onset, craniofacial anomalies, microcephaly and mental deficiency1,2,3.In contrast SC has a milder phenotype with survival to adulthood4. Heterochromatic repulsion (HR) is characteristic for RBS and SC5,6,7.Vega et al. reported a study of RBS confirming linkage to 8p21.2-p12.They also reported eight different mutations in a gene called 'ESCO2' ( establishment of cohesion 1 homolog 2) that causes RBS8. Francke et al. established that RBS and SC are caused by mutation in the same gene (ESCO2)9. The use of methamphetamine, marijuana and cocaine has been associated with cardiovascular, oral clefts and limbs malformations10. Cocaine exposure in utero caused neurobehavioral abnormalities11, placental abruption and premature rupture of membranes12, lower weight (536 g), and smaller head circumference (1.5 cm)13. Prenatal use of methadone and cocaine produced congenital malformations in 6% of offsprings14. METHODS We are reporting a pregnancy in which the fetus showed phocomelia in the 21.6 weeks by ultrasonograph examination. The father uses marijuana, cocaine and alcohol since 10 months ; the mother has a partialy septated vagina. They do not have consanguinity ; they have another normal two years old child. The family history is negative for RBS,SC, other congenital malformations, and illicit drug use . The SC child was born at 32 weeks of pregnancy, with premature rupture of membranes two weeks before the delivery, with respiratory distress, and died on the fourth day of live by cardiorespiratory arrest. We have performed a clinical history, laboratory examinations,pelvic ultrasound and a caryotype. RESULTS The mother's blood and urine examination were normal, her cariotype in lynfocytes was 46.XX. CONCLUSIONS The father's drug addiction could be related with a mutation in his genes and probably the mother's genes could be altered too, because she has a partial septated vagina ; as a result a probable mutation in the gene ESCO2 affected the child with SC.

## 1616/T/Poster Board #165

**Prenatal diagnosis of scalp congenital hemangiopericytoma.** *C. Forrest[3], H.Y.B. Chung[1,2], R. Silver[2], A. Toi[4], S. Blaser[5], G. Taylor[6], S. Viero[6], D. Chitayat[1,2].* 1) Department of Pediatrics, Division of Clinical and Metabolic Genetics, Hospital for Sick Children; University of Toronto, Toronto, Ontario, Canada; 2) Department of Obstetrics and Gynecology, The Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital; University of Toronto, Toronto, Ontario, Canada; 3) The Craniofacial Program, Division of Plastic Surgery,Department of Pediatrics, Hospital for Sick Children; University of Toronto, Toronto, Ontario, Canada; 4) Department of Medical Imaging, Mount Sinai Hospital and University Health Network, University of Toronto, Toronto, Ontario, Canada; 5) Division of Neuroradiology, Department of Pediatrics, Hospital for Sick Children; University of Toronto, Toronto, Ontario, Canada; 6) Division of Pathology and laboratory Medicine, Department of Pediatrics, Hospital for Sick Children; University of Toronto, Toronto, Ontario, Canada.

Hemangiopericytoma (HPC) is a rare form of vascular tumour. It consists of extensive proliferation of pericapillary cells (pericytes). The most common locations are the head and neck, lower extremities and retroperitoneum. HPC can be benign or malignant. Malignant HPC can metastasize to other areas of the body, usually to the lungs. Up to 5-10% HPCs present in childhood and 5-40% occur in the 1st year of life. We report a fetal case of HPC presenting as an ultrasound finding of a forehead mass. Case:The proband was a 23y P1 Caucasian woman and her husband was 22y and of same descent. The couple was healthy and non-consanguineous. Early fetal ultrasounds were normal. IPS was negative. Ultrasound at 19w showed bilateral pelviectasis. A follow-up ultrasound at 32w confirmed the pelviectasis, and also showed a midline mass over the forehead just above the nasal bridge, with slightly amorphous content measuring 4.1 x 4.0 x 3.1 cm. The mass did not appear to penetrate the scalp or skull and no gross abnormalities in the brain were seen. The nose and eyes appeared normal. The findings were confirmed by fetal MRI. The couple decided to continue the pregnancy. Delivery was at 38.8w via CS and was uncomplicated. The birth growth parameters were all normal. The APGAR scores were 9(1) and 10(5). A pedunculated tumor with a large base which measured 4 cm, originating in the right side of the forehead was noted. There were areas of necrosis and excoriation over the skin and no thrill over the tumor. The baby was otherwise not dysmorphic. Complete surgical resection was performed and histopathology was consistent with HPC. Discussion:Congenital HPC behaves in a distinct manner and has excellent prognosis. Etiologically, congenital HPC may arise from a pluripotent cell capable of differentiating into smooth muscle cells, pericytes and retains its capabilities to differentiate into more mature cells, resembling infantile myofibromatosis. A single entity called composite myofibromatosis has been proposed. From our knowledge, this case is the 7th case of congenital/ infantile HPC reported in the literature. Previous cases affect the lip, nose, temporal bone, meninges, the cerebrum and the neck region. Complete surgical resection is the ideal treatment of choice. Since excellent response to chemotherapy has been seen, extensive surgical excision and radiotherapy are to be avoided. Long-term follow-up is recommended as relapse may occur late.

## 1617/T/Poster Board #166

**Attitudes of genetic counselors toward array comparative genomic hybridization (aCGH) testing in a prenatal setting.** *S. Jeddi[1], J. Schmidt[2], V. Vandergon[1], C.G.S. Palmer[3].* 1) California State University-Northridge, Northridge, CA; 2) Cedars-Sinai Medical Center, Los Angeles, CA; 3) University of California-Los Angeles, Los Angeles, CA.

Array Comparative Genomic Hybridization (aCGH) detects chromosomal imbalances at higher resolutions than traditional cytogenetic methods. As a result, aCGH has been recently applied to the prenatal diagnostic field despite the lack of official guidelines governing its use. The purpose of this study is to identify factors explaining genetic counselors' perceptions of the appropriateness of prenatal aCGH testing for 10 scenarios reflecting common prenatal clients' referral indications and situations cited by laboratories offering prenatal aCGH testing. Genetic counselors were eligible to complete an anonymous survey posted on the NSGC ListServ; 238 completed surveys were analyzed. An aCGH appropriateness score [0 (never appropriate) - 20 (always very appropriate)] was computed for each respondent and examined for relationships with genetic counselor and patient characteristics. Five factors were significantly associated with perceptions of aCGH appropriateness: practice setting ($p<0.01$), use of aCGH in own pregnancy ($p<0.01$), perceived knowledge of aCGH ($p=0.01$), patient anxiety ($p=0.03$), and provision of comprehensive care ($p<0.01$). Specifically, working in a prenatal practice setting and having no interest in personally using aCGH were associated with lower aCGH appropriateness scores, whereas higher perceived knowledge of aCGH testing, decreasing patient anxiety, and providing more comprehensive care were associated with higher appropriateness scores. Of these factors, area of practice had the largest effect on genetic counselors' appropriateness scores. Additionally, 91% of genetic counselors indicated that it is very important to consider possibly finding a variant of uncertain significance before discussing this testing with patients. We conclude that variations in genetic counselors' perceptions of appropriateness of prenatal aCGH testing, and, hence, practice patterns, are determined by genetic counselor and patient characteristics. As a promising diagnostic tool, prenatal aCGH testing will continue to be incorporated in patient care, and the development of future guidelines and recommendations regarding its use will be imperative.

## 1618/T/Poster Board #167

**Prenatal diagnosis of a de novo partial trisomy 13q (q14→qter) presented as a translocation at chromosome 4q identified by SKY and aCGH.** *I.N. Machado[1], J.K. Heinrich[1], C. Campanhol[1], R.M. Rodrigues-Peres[1], F.M. Oliveira[2], R. Barini[1].* 1) Institution: Cell Culture and Cytogenetics Laboratory, Fetal Medicine Service, CAISM. Department of Obstetrics and Gynecology. Faculty of Medical Sciences State University of Campinas - UNICAMP 13083-970, Campinas, SP, Brazil; 2) Medical Clinics Department, National Institute of Science and Technology in Stem Cell and Cell Therapy. Faculty of Medical Sciences, Ribeirão Preto, SP, Brazil.

Partial trisomy 13q (q14→qter) is an uncommon chromosomopathy. It has been described with a variable phenotypic expression. We report a 19-year-old pimigravida with a fetus presenting partial absence of the cerebellar vermis, partial agenesis of callosum corpus, hydrops and polyhydramnios at ultrasound evaluation at 28 week's gestation. The cytogenetic result on fetal blood obtained by cordocentesis was 46,XX,add(4) (q28). The parents' karyotypes were normal. A girl was delivery at 34 week's gestation and died within 2 hours, showing several dysmorphic features. An autopsy confirmed the prenatal findings and completed it with the finding of agenesis of diaphragm. Spectral Karyotype (SKY) identified the additional material's origin as to be from chromosome 13. Array-CGH was carried out using a 1Mb resolution BAC array and showed amplification of distal regions of the long arm of chromosome 13 from region 13q14 to qter. This is the first report of a fetus with molecular characterization of a partial trisomy 13q (q14→qter), present as de novo unbalanced translocation at chromosome 4q. Our results confirm the usefulness of molecular characterization of malformed fetuses for prenatal diagnosis and counseling. Also, emphasize the importance of parental karyotyping.

## 1619/T/Poster Board #168

**Microarray-based analysis using cell-free mRNA in pregnant women has a potential to estimate a placental status.** *K. Miura[1], S. Miura[1], K. Yamasaki[1], T. Shimada[1], A. Higashijima[1], S. Abe[1], K. Yoshiura[2], N. Niikawa[3], H. Masuzaki[1].* 1) Dept OB/GYN, Nagasaki University School of Medicine, Nagasaki, Japan; 2) Dept Human Genetics, Nagasaki University School of Medicine, Nagasaki, Japan; 3) Research Institute of Personalized Health Sciences, Health Sciences University of Hokkaido, Hokkaido, Japan.

Objectives; Although the discovery of cell-free placental mRNA in maternal plasma provides new possibilities in prenatal monitoring a heterogeneous condition of placental status, a high-throughput approach is necessary for the clinical application of this novel particle. To resolve this technical issue, we investigated a clinical possibility of microarray-based analysis using cell-free mRNAs in maternal plasma. Materials and Methods; The study protocol was approved by IRB in Nagasaki University. Three each of first trimester, second trimester and third trimester placental tissue samples were obtained from normal pregnant women immediately after termination of pregnancy, respectively. Same amounts of RNA from three placenta or blood samples at each trimester were mixed and applied to GeneChip® analysis (Affymetrix, Santa Clara, CA). Top of the fifty highest placenta specific transcripts, whose signal intensities were more than 2,500 times higher in the placenta tissues as compared to the corresponding whole blood samples, were selected as the placenta specific cDNA in maternal circulation. Comparative cDNA hybridization analysis of cell-free placental mRNA in maternal plasma using the developed cDNA microarray panel, which included placenta specific cDNAs, was performed between 12 pregnant women with preeclampsia and 12 normal control pregnant women who were gestational age matched. Results; First, 50 placenta specific transcripts were identified by comparison between the expression levels in placenta tissues and the corresponding maternal bloods, and the custom cDNA microarray panel was developed. Subsequently, the custom microarray-based comparative cDNA hybridization analysis of cell-free mRNAs in 1.2 mL of maternal plasma was performed in 12 preeclamptic women and 12 normal control pregnant women. The scatter plots of signal intensities showed no changed pattern (pattern A) in 7 cases of mild hypertension and the aberration pattern (pattern B) in 5 cases of severe hypertension. Conclusions; The changes of cell-free mRNA levels could be detected by microarray-based analysis, and the pattern B included a total 17 placenta specific genes, which might be associated with the pathophysiology of hypertension in preeclampsia. Non-invasive overall assessments of cell-free mRNA in maternal plasma became a feasible scheme and have a potential to monitor the placental status during pregnancy.

## 1620/T/Poster Board #169

**Prenatal diagnosis of a fetus with ring chromosome 21 characterized by molecular cytogenetic methods.** *I.D. Papoulidis[1], E. Siomou[1], E. Manolakos[2], T. Liehr[3], A. Vetro[4], A.P. Athanasiadis[5], C. Malamaki[1], O. Zuffardi[4], M.B. Petersen[1].* 1) Eurogenetica SA, Thessaloniki, Greece; 2) Bioiatriki SA, Athens, Greece; 3) Friedrich-Schiller-University, Jena, Germany; 4) Universita di Pavia, Pavia, Italy; 5) Aristotle University, Thessaloniki, Greece.

Ring chromosome 21 is a rare structural chromosomal abnormality resulting, most of the times, from breakage in both arms of the chromosome and subsequent fusion of the two ends. There is a wide spectrum of phenotypes in ring 21 carriers that seems to be associated with different breakpoints of 21p and q arms, but also with somatic loss of the ring. Here we report a case of a fetus that was diagnosed with mos46,XY,r(21)(p11.2q22)[34]/45,XY,-21[4]/46,XY[14] karyotype. Ultrasound examination at 21 weeks' gestation showed no abnormalities and amniocentesis opted due to advanced maternal age. Cytogenetic analysis was performed in the parents and showed the presence of the ring chromosome in 1 out of 100 metaphases in the father, indicating a possible familial transmission. Analysis by Fluorescent In Situ Hybridization (FISH) and comparative genomic hybridization (aCGH) with resolution of 144 kb showed no deletion or duplication. After genetic counseling, the parents decided to continue the pregnancy and postnatal examination just after birth found no congenital abnormalities.

## 1621/T/Poster Board #170

**Prenatal diagnosis and therapy development in harlequin ichthyosis.**
*S. Rajpopat, A.C. Thomas, E.A. O'Toole, D.P. Kelsell.* Centre for Cutaneous Research, Institute of Cell and Molecular Science, Barts and the London School of Medicine and Dentistry, Queen Mary University of London, London, United Kingdom.

Mutations in the ABCA12 gene encoding the ABC transporter underlie the most severe and often lethal form of recessive congenital ichthyosis, harlequin ichthyosis (HI). Affected foetuses display abnormal sonographic features late in the second trimester but identification of these is technically challenging. To improve the clinical care of HI families we have established a major referral centre for HI genetic screening and devised a programme of research to develop new therapeutics for this condition. We have identified mutations in ABCA12 in over 70 families and used this information for prenatal diagnosis both in the UK and in 2 HI families living in Turkey and Pakistan. Chorionic villus DNA was sequenced and compared to the known founder mutation. If termination of pregnancy is being considered, this test is desirable as it offers an earlier and more accurate result than ultrasound.

The barrier function of the skin is severely compromised in HI and approximately 55% of affected babies die in the neonatal period from respiratory distress and sepsis. To assess signalling pathways influenced or regulated by ABCA12, the Illumina array platform was used to compare global gene expression between keratinocytes with/without ABCA12 shRNA. Following Ingenuity Pathway analyses, it was found that components of the nuclear hormone receptor pathway such as RXR-alpha were amongst those dysregulated when ABCA12 expression was ablated. Many of these nuclear receptors are already used as therapeutic targets in hyperproliferative skin disorders. By manipulating components of the nuclear hormone receptor pathway, we aim to target abnormalities in the HI keratinocyte differentiation programme to reduce epidermal thickness, enhance desquamation and improve the lipid balance in HI skin. Towards therapy development we have generated an in vitro model of HI skin with a combination of shRNA targeting ABCA12 and a three-dimensional organotypic co-culture (OTCC) system. This replicates many features of HI skin including epidermal thickness, premature terminal differentiation and aberrant protease expression. Endogenous and synthetic ligands of the nuclear receptor signalling pathway are being tested in the OTCC system and characterised for improved terminal differentiation and lipid content.

## 1622/T/Poster Board #171

**Prenatal diagnosis of monozygotic twins with karyotypes discordant for a dicentric chromosome 13 resulting in functional trisomy 13.**
*J. Richer[1], E. Smith[1], B. Bonin[2], J. McGowan-Jordan[1], E. McCready[1].* 1) Genetics, Children's Hospital of Eastern Ontario , Ottawa, Ontario, Canada; 2) Division of Maternal-Fetal Medicine, Department of Obstetrics and Gynecology, The Ottawa Hospital, University of Ottawa.

A number of monozygotic twins with discordant karyotypes for sex chromosomes or other autosomal aneuploidies have been reported: to the best of our knowledge, this is the first report of monozygotic twins with discordant karyotypes resulting in trisomy 13. Our case involves an isodicentric chromosome 13, as opposed to the more common free trisomy 13. This was a spontaneously conceived first pregnancy in a non-consanguinous Caucasian 35 year old mother and 46 year old father. An ultrasound at 22 weeks gestation showed a monochorionic-diamniotic twin pregnancy. No structural anomalies were reported in Twin A. Twin B had a small omphalocele, suspicion of two vessel cord and two echogenic intracardiac foci. Amniocentesis with sampling of both gestational sacs was performed. Twin A had a normal female karyotype (46,XX) from 24 colonies, thus excluding mosaicism of 12% or greater, at a 95% confidence level. Twin B's karyotype was 46,XX,idic(13)(p1?3), in metaphase from 5 colonies examined. Interphase FISH studies using a probe specific for a locus on 13q14 showed 3 signals in 55 nuclei examined, further supporting the presence of trisomy 13. The twins were identical at all 15 STR loci studied (zygosity studies). The couple was counseled about the possibility of mosaicism in either twin and offered a termination of both fetuses vs a selective termination of Twin B using cord occlusion; they elected not to intervene and continue with the pregnancy. Twin A was phenotypically normal at birth and is now doing well at 1 month of age. Twin B passed away at 4 days with typical features of trisomy 13 such as omphalocele, clefting of the palate and polydactyly. Parental karyotypes were declined for the moment. Different mechanisms have been described to explain discordant karyoytpes in monozygotic twins and a number of reports have described multiple events leading to the observed karyotypes. Some have postulated that genetic heterogeneity likely promotes cleavage of embryos after the two cell masses become discordant, but this does not offer insight into whether the unbalanced karyotype was post-zygotic or not, which would have important implications for counseling this couple regarding the risk of mosaicism. This report will review the clinical presentation, possible cytogenetic etiologies and their implications regarding counseling for this couple.

## 1623/T/Poster Board #172

**Cornelia de Lange Syndrome: germline mosaicism, prenatal, and pregnancy findings.**
*T.P. Slavin[1], N. Lazebnik[1,2].* 1) Genetics, Case Medical Center, University Hospitals, Cleveland, OH; 2) Obstetrics and Gynecology, Case Medical Center, University Hospitals, Cleveland, OH.

Cornelia de Lange Syndrome (CdLS) is a genetic disorder associated with delayed growth, mental retardation, and characteristic facial features. Most cases are sporadic and are due to mutations in the gene NIPBL. We present a case of a 23 year-old G10P2264 woman who has had four affected children with CdLS with identical splice site mutations in exon 2 of the NIPBL gene, 64+1 G>A. Of the living children, two children occurred with one partner, and two children occurred with a separate partner. Maternal blood testing for NIPBL gene mutations was negative, gonadal and/or other tissue testing was not obtained. Although, previously reported as a potential form of inheritance, limited molecular data exist on germline mosaicism in CdLS. This presentation adds to the literature on germline mosaisicm in CdLS and reviews previously reported cases. Additionally, we also report the abnormal prenatal findings such as low pregnancy associated plasma protein A (PAPP-A), increased nuchal translucency (NT), severe intrauterine growth restriction (IUGR), abnormal fetal Doppler studies, as well as pregnancy complications that are not commonly known to be associated with CdLS, such as maternal preeclampsia. In conclusion, germline mosaicism should be part of pregnancy recurrence risk counseling for patients with a previous child affected with CdLS. Presently, the risk is estimated to be 1.5%; however, this figure may need to be increased if similar cases are reported in the future. In addition, specific prenatal parameters when combined with pregnancy course features may aid in the prenatal diagnosis of CdLS.

## 1624/T/Poster Board #173

**A First Report of Paternal UPD 4 Associated with Prenatal Trisomy 4 Mosaicism.**
*T.L. Prosen[1,2,3], S.A. Berry[1,5,6], C. Whitley[1,5,6], M. Mahoney[1,2,4], K. Baker-Lange[1,6], M. Dolan[1,7].* 1) University of Minnesota, Minneapolis, MN; 2) Department of Obstetrics, Gynecology and Womens Health; 3) Division of Maternal-Fetal Medicine; 4) Division of General Obstetrics and Gynecology; 5) Department of Pediatrics; 6) Division of Genetics; 7) Cytogenetics.

A 36-year-old G2P1 female was referred for genetic counseling at 13 wks gestation. The family history was positive for a paternal balanced t(4;12)(q25;q24). G-band analysis performed after CVS revealed trisomy 4 due to 3:1 segregation of the t(4;12). ISCN: 47,XX,+4,t(4;12)(q25;q24). FISH with a centromere 4 probe revealed 81.5% of interphase cells with trisomy 4. A follow-up amniocentesis at 18 wks gestation revealed low level mosaicism. By G-banding, 47,XX,+4,t(4;12)(q25;q24.1) in 3/168 metaphases; 46,XX,t(4;12)(q25;q24.1) in 165/168 metaphases. Interphase FISH similary showed low level mosaicism for trisomy 4 in 13.5% of cells. Uniparental disomy testing further demonstrated paternal UPD. The couple opted to continue the pregnancy. Serial ultrasounds revealed a unilateral choroid plexus cyst at 18 wks gestation that resolved by 21 wks gestation; additionally, although the cerebellum initially appeared somewhat small, measurements improved later in gestation. A fetal echocardiogram was normal. The pregnancy progressed uneventfully until preterm premature rupture of membranes at 35 4/7 wks gestation. After induction of labor, the patient delivered a 1880g (3%ile) female infant with Apgars of 81 and 85. The infant was admitted to the NICU for observation due to prematurity. Transient tachypnea resolved within 24 hrs. Five days of phototherapy were required for hyperbilirubinemia. She was noted to have micrognathia, low, posteriorly rotated ears and small nails. The placenta was remarkable for its small size (204g, <3%ile) and large, somewhat fibrotic stem villi with irregular outlines that lacked a correspondingly increased number of intravillous capillary vessels. Cytogenetic studies of 9 separate placental biopsies showed the predominant cell line to be the unbalanced 3:1 segregation product throughout the placenta (83.5-90.5% trisomic cells by both G-banding and FISH), whereas G-banded analysis of the umbilical cord and G-band and FISH analysis of peripheral blood from the newborn revealed only the balanced t(4;12). A few cases of maternal UPD have been published in the literature and have suggested the absence of maternally imprinted loci on chromosome 4. Continued clinical evaluation of this infant will be helpful for extrapolating to paternal UPD, and to delineate further phenotype-genotype correlations.

## 1625/T/Poster Board #174

**Independent effect of Brain-Derived Neurotrophic Factor gene polymorphism (Val66Met) on attention problems and growth in early life.** *D.O. Mook-Kanamori[1 2 3], M. Zeegers[4], F.C. Verhulst[4], A. Hofman[1], E.A.P. Steegers[5], H. Tiemeier[1 4], V.W.V. Jaddoe[1 2 3].* 1) Epidemiology, Erasmus Medical Center, Rotterdam, Zuid-Holland, Netherlands; 2) The Generation R Study Group, Erasmus Medical Center, Rotterdam, Zuid-Holland, Netherlands; 3) Pediatrics, Erasmus Medical Center, Rotterdam, Zuid-Holland, Netherlands; 4) Child and Adolescent Psychiatry, Erasmus Medical Center, Rotterdam, Zuid-Holland, Netherlands; 5) Obstetrics and Gynaecology, Erasmus Medical Center, Rotterdam, Zuid-Holland, Netherlands.

Background: The Val66Met polymorphism in the brain-derived neurotrophic factor (BDNF) is associated with both attention-deficit hyperactivity disorder and body mass index (BMI) in adulthood. We hypothesized that this gene is also associated with attention problems and growth in childhood. Design and methods: This study was embedded in the Generation R Study, a population-based prospective cohort study. Problem behavior was assessed by Child Behavior Checklist (CBCL) questionnaires at the age of 18 and 36 months. Fetal growth was assessed by estimated fetal weight (ultrasound in second and third trimester) and birth weight. Anthropometrics (weight, height, head circumference) were assessed at 9 time-points between birth and 2 years. BDNF Val66Met genotyping was performed in 3071 children of Caucasian ethnicity. Results: Genotype distribution was 65.8% (ValVal), 30.5% (ValMet), and 3.6% (MetMet). The Val-allele was associated with increased reporting of attention problems at the ages of 18 and 36 months. No associations were observed with fetal growth. Postnatally, the Val-allele was associated with increased weight gain (44.4 grams/year (95% CI: 21.2, 67.5) and height gain (0.062 cm/year (95% CI: -0.003, 0.128) until 24 months of age. Head circumference also tended to be increased in Val-allele carriers until the age of 11 months. Furthermore, weight-to-height ratio (SDS) was increased in Val-allele carriers, leading to an effect of 0.07 SDS (95% CI: 0.01, 0.15) per Val-allele at 24 months. There was no apparent association between attention problems and anthropometric measurements. Stratified analyses showed an independent effect of BDNF genotype on both attention problems and early growth characteristics. Conclusions: This study indicates that the previously found associations of the BDNF polymorphism Val66Met with behavior problems and BMI may start as early as in the first years of life. Furthermore, BDNF Val66Met was independently associated with both attention problems and body composition. Further longer follow-up studies are necessary to examine whether these effects persist throughout childhood.

## 1626/T/Poster Board #175

**Candidate Gene Analysis of Cholesterol Metabolism Genes and Intra-Uterine Growth Restriction.** *K. Borowski[1], J. Murray[2].* 1) Dept OB & GYN, Univ Iowa, Iowa City, IA; 2) Dept Pediatrics, Univ Iowa, Iowa City, IA.

Intra-uterine growth restriction (IUGR) is a complex trait mediated by multiple environmental and genetic contributors. Significant morbidity and mortality are associated with IUGR particularly in the preterm infant. Few genetic association studies have been performed evaluating genetic causes of IUGR although a significant role for genetic factors has been demonstrated in IUGR of unknown etiology. A previous study found a maternal association with *LRP8* and fetal growth. A family based candidate gene study of cholesterol metabolism genes was performed utilizing 129 pedigrees. Twenty-six SNPs in 15 genes were evaluated utilizing tagged SNPs from HapMap#24. Subjects were included in the study if they had a birthweight for gestational age at less than the 10th centile using the Lubchenco growth curve, had no major anomalies and were enrolled at the University of Iowa from 2/2001 until 3/2009 with available DNA. Allelic discrimination was performed using TaqMan genotyping assays from Applied Biosystems. The results were analyzed with a transmission disequilibrium test (FBAT) to determine association with the affected child. In perinatal disorders it is unknown if the risk is in the mother or the child. To determine maternal association a case control analysis was performed with Fisher's exact test, utilizing the father's genotypes as controls. FBAT was performed for all SNPs with none reaching significance. *ABCA1* rs2066716 showed overtransmission of the rare minor allele, with p=0.102. Further analysis of *ABCA1* will be performed in the future. In addition, the prior association described with maternal *LRP8* and fetal growth was not seen in our study. The previous study involved 204 black women of which only 34 had fetal growth restriction, compared to our predominantly Caucasian population of 129 pedigrees all with IUGR. Planned future work includes increasing the number of IUGR subjects, further cholesterol gene analysis as well as analysis of copy number variants in cases of IUGR.

## 1627/T/Poster Board #176

**The heritability of neonatal death in a Utah population.** *K. Ward[1,2], H. Albertsen[2], G. Frech[2], P. Farrington[2], T. Maness[2], S. Dintelman[2].* 1) Lucina Foundation, Salt Lake City, UT; 2) Juneau Biosciences, LLC, Salt Lake City, UT.

Purpose: Neonatal death (death within the first 28 days of an infant's life) is most commonly caused by preterm birth, birth defects, complications arising during pregnancy, infection and asphyxia. The collective literature provides compelling evidence that there may be a genetic component underlying neonatal death, regardless of the specific cause or complication. The present study utilizes an extensive population-based genealogical database to estimate the heritability of neonatal death. Methods: A genealogy database (GenDB) was constructed using more than 50,000 genealogy sources in the public domain. GenDB documents the relationships between more than 30 million ancestors and 3.5 million descendants of approximately 10,000 individuals who moved to Utah in the mid 1800s. Because of privacy issues, most individuals in the genealogy have birth dates prior to 1930. Within this database, we identified two groups of neonatal deaths to compare. We identified a set of about 8,000 infants who died as neonates. We also identified a subset of about 1,000 neonatal deaths who had one or more siblings also die as neonates. For each set of cases we computed the average pairwise kinship coefficient. Controls for each set of cases were matched for gender, birth year, birth place, and ancestry. Summary of Results: We demonstrate that the ancestors of both sets of neonate deaths were more closely related than matched controls, with the set of multiple deaths being more closely related than the full set. The average pairwise kinship coefficient for overall neonate deaths was significantly higher than the matched controls. For the set of neonates with sibs who also died as neonates, the average kinship coefficient was also significantly higher than matched controls. For both sets, the minimum number of founders required to account for the cases was significantly smaller than for the controls. Conclusion: A genetic component contributes to neonatal death and is even more significant in families with more than one neonatal death.

## 1628/T/Poster Board #177

**The importance of accurate gestational age in detecting the association between gene:environment interactions and birth weight.** *J.A. Marsh[1], C.E. Pennell[2], N.M. Warrington[1], S.E. Bolt[1], J.P. Newnham[2], L.J. Palmer[1].* 1) Centre for Genetic Epidemiology & Biostatistics, The University of Western Australia, Perth, Australia; 2) School of Women's and Infants' Health, The University of Western Australia, Perth, Australia.

Background Genome-wide association studies (GWAS) are revolutionising the search for the genes underlying gene:environment (G:E) interactions in early life. Recent data have demonstrated G:E interactions between smoking, polymorphisms in CYP1A1, GSTT1, GSTM1 and FTO and intrauterine growth restriction. Interaction analyses between common environmental exposures and common genetic variants thus have a growing role in early life investigations of chronic disease etiology. It is critical to account for gestational age (GA) in analyses of birth weight (BW). This research assessed the impact of the accuracy of GA estimation on the ability to detect associations of complex gene:environment interactions with BW using an exceptional birth cohort resource with extensive antenatal data. Methods The Raine Pregnancy Study recruited unselected women from the general population at 16-18 weeks gestation. Analyses focused on 2,065 full-term, singleton-births. GA at birth was recorded (1) based on the date of the last menstrual period (LMP) alone and (2) based on extensive ultrasound biometry throughout pregnancy. Multivariate linear regression models of BW were constructed, including parity, sex, maternal smoking and GA as covariates. G:E power calculations were based on 80% power, a MAF≥5%, a continuous environmental exposure, a dominant genetic model, and an $\alpha$ of 10-4. Results GA based on the date of LMP alone and based on ultrasound biometry accounted for 7% and 16% of the total phenotypic variance in BW, respectively. The correlation between the two methods of GA measurement was 0.69. Using LMP-estimated GA alone, studies ~10% larger would be required to detect a true association between BW and a gene:environment interaction compared to ultrasound-estimated GA. In terms of precision of a continuous outcome measure, decreases in BW or GA precision across larger studies would have an even greater impact on power. Conclusion Our results suggest that smaller birth cohort studies with more precise measures of gestational age will be as powerful as larger studies in detecting gene:environment interactions for continuous traits. These findings should be helpful when designing or interpreting analyses of pregnancy cohorts which have GA based only upon LMP.

## 1629/T/Poster Board #178

**Gene-environment interactions define the relationship between the FTO gene, fetal growth and childhood obesity.** *N.M. Warrington[1], J.A. Marsh[1], C.E. Pennell[2], D. Mook-Kanamori[3], L. Briollais[4], S.J. Lye[4], L.J. Beilin[5], J.P. Newnham[2], E. Steegers[6], A. Hofman[3], V.WV. Jaddoe[3], L.J. Palmer[1].* 1) Centre for Genetic Epidemiology and Biostatistics, The University of Western Australia, Perth, Australia; 2) School of Women's and Infants' Health, The University of Western Australia, Perth, Australia; 3) Department of Epidemiology, Erasmus Medical Centre, Rotterdam, the Netherlands; 4) Samuel Lunenfeld Research Institute, Mount Sinai Hospital, University of Toronto, Canada; 5) School of Medicine and Pharmacology, The University of Western Australia, Perth, Australia; 6) Department of Obstetrics and Gynaecology, Erasmus Medical Centre, Rotterdam, the Netherlands.

Background: FTO gene variants have been consistently associated with childhood and adult obesity across multiple populations and racial groups. This study examines the influence of the rs9939609 variant in the FTO gene on fetal and early life growth, which has not yet been explored, and investigates the gene environment and gender interactions. Methods: Participants in the Raine Birth Cohort study were recruited at 16-18 weeks gestation. Analyses focused on 1,079 singleton-birth Caucasians with complete data in antenatal life and childhood. Associations between the rs9939609 variant, fetal growth trajectories and anthropometric measures at birth and throughout childhood were assessed. Analyses were repeated in 3,512 singleton-birth Dutch Caucasians (Generation R Birth Cohort). Results: The allele frequency for obesity risk allele (A) of the rs9939609 variant was 0.39 in both the Raine and Generation R cohorts. In non-smoking mothers the rs9939609 AA genotype was associated with intrauterine growth restriction; however, this effect was reversed in mothers who smoked during pregnancy. This effect, although small, accumulates over time and is consistently modified by maternal smoking for head circumference (HC) (Interaction P=0.007), abdominal circumference (AC) (Interaction P=0.007), femur length (FL) (Interaction P=0.02), and estimated fetal weight (EFW) (Interaction P=0.001). No association was detected between HC/AC ratio and the rs9939609 AA genotype indicating symmetrical growth restriction. The pattern of modification by maternal smoking of the association between the rs9939609 AA genotype and birth anthropometrics was consistent across birth-weight (BW) (P=0.01) and birth length (P=0.04); a similar trend was observed in all neonatal day 2 anthropometry including skinfold thicknesses. Postnatally, the AA genotype was associated with increased BMI by age 14 years, although the effect size was greater in males (Interaction P= 0.0001). Consistent effect sizes and directions from birth to the 1st year of life were replicated in the Generation R Cohort. Conclusion: FTO influences fetal growth trajectories in the 3rd trimester and early life growth. Maternal smoking during pregnancy consistently modified (reversed) the effect of FTO on fetal growth. This study provides evidence of gene-environment interactions influencing the relationship between fetal growth and adult obesity and raises the prospect of early life interventions.

## 1630/T/Poster Board #179

**Microarray Analysis of altered gene expressions in peripheral blood of severe preeclampsia.** *D. Cha[1], J.Y. Kim[1], J.H. Kang[1], K.J. Lee[1], W.B. Han[1], S.H. Kim[2], D.Y. Park[2].* 1) Dept OB/GYN, Kangnam CHA Hosp, Seoul, Korea; 2) Digital Genomics, Seoul, Korea.

Objects : To compare the gene expression profiles between the peripheral blood with preeclampsia and normal pregnancy Material and methods : To investigate how the expression of peripheral blood genes contributes to the mechanisms of preeclampsia, we have analyzed differentially expressed genes using peripheral blood from 10 pregnant women who have preeclampsia and from 10 normal pregnancies. We performed genome-wide expression profiling using high-density oligonucleotide microarrays. The data obtained from 55,000 human genes were normalized and analyzed to identify genes with statistically significant changes in expression. All the analysis was done in FDR (false discovery rate) < 0.01. RT-PCR was randomly done for validation with 12 genes. Results: Among the 55,000 genes that were screened in the microarray, 676 genes were up-regulated and 153 genes were down-regulated. The up-regulated genes included CRIP1, LGTN, OXGR1, NEU3, GALK2, HBG2, and the down-regulated genes included GPI , PTGS2, TMED7, LTA4H. Validation was confirmed by RT-PCR. Conclusions : Differentially expressed genes in the peripheral blood may be associated with the pathophysiology of preeclmpsia in additional to the placenta.

## 1631/T/Poster Board #180

**Maternal and fetal haplotypes in immunity and stress-related genes are associated with preterm birth.** *M.J. White[1], K.K. Ryckman[1,2], N. Morken[3], S. Myking[3], S.M. Williams[1], B. Jacobson[3].* 1) Human Genetics, Vanderbilt University, Nashville, TN; 2) Dept Pediatrics, University of Iowa, Iowa City, IA; 3) Perinatal Centre, Department of Obstetrics and Gynecology, Institute for the Health of Women and Children, Sahlgrenska Academy, Götenburg, Sweden.

Preterm birth (PTB) is a common condition that accounts for 50% of perinatal morbidity and 75% of perinatal mortality. The main aim of this study was to investigate the associations of maternal and fetal haplotypes in candidate genes within the four major proposed PTB pathways in order to identify effects that may not have been detected in single locus association analysis. Methods: After data quality control and pre-processing, 424 maternal DNA samples (217 controls, 207 cases) and 419 fetal DNA samples (216 controls and 203 cases) were analyzed from the Norwegian Mother Child Cohort for haplotype association using Unphased. Haplotype analysis (1,339 SNPs in maternal samples and 1,3333 SNPS in fetal samples) spanning 126 genes was performed on fetal and maternal samples separately. Results: Overall, there were 266 significant haplotype associations discovered in 33 genes in fetal samples and 207 associations in 38 genes were detected in maternal samples. The most significant haplotype in maternal samples was in thyroid stimulating hormone receptor (TSHR) gene ( p= $1.7x10^{-3}$ ) and in fetal samples the interleukin 10 receptor beta (IL10RB) gene had the most significant haplotype association (p=$1.2x10^{-4}$). Pathway analysis of select haplotype associations revealed a significant overrepresentation of haplotype associations driven by multiple genes in the complement/coagulation pathway for maternal samples. In fetal samples there were more haplotype associations than expected by chance in the inflammation and infection pathways. Conclusion: This study identified maternal and fetal haplotype effects not detected by single locus association analysis. This study also validates the assertion that associations in the complement coagulation pathway of PTB are driven by the maternal genome, whereas associations found in the inflammation and infection pathways of PTB are influenced primarily by the fetal genome.

## 1632/T/Poster Board #181

**Maternal and fetal genetic associations in PTGER3 and PON1 with preterm birth.** *K.K. Ryckman[1,2], N. Morken[3,4], M. White[2], D.R. Velez[5], R. Menon[6,7], S.J. Fortunato[6,7], P. Magnus[4], S.M. Williams[2], B. Jacobsson[8,9,10].* 1) Dept Pediatrics, University of Iowa, Iowa City, IA; 2) Center for Human Genetics Research and Department of Molecular Physiology and Biophysics, Vanderbilt University, Nashville, TN; 3) Department of Obstetrics and Gynecology, Haukeland University Hospital, Bergen, Norway; 4) Norwegian Institute of Public Health, Oslo, Norway; 5) University of Miami, Dr. John T. Macdonald Foundation Department of Human Genetics and Miami Institute of Human Genomics, Miller School of Medicine, Miami, FL; 6) The Perinatal Research Center, Nashville, TN; 7) Emory University, Department of Epidemiology, GA; 8) North Atlantic Neuro-Epidemiology Alliances, Department of Epidemiology and Social Medicine, University of Aarhus, Aarhus, Denmark; 9) Perinatal Center, Department of Obstetrics and Gynecology, Institute of Clinical Sciences, Sahlgrenska Academy, Gothenburg, Sweden; 10) Department of Obstetrics and Gynecology, Rikshospitalet, Oslo, Norway.

Objective: The purpose of this study was to identify associations between maternal and fetal genetic variants in candidate genes and spontaneous preterm birth (PTB) in a Norwegian population and to determine the effect size of those associations that corroborate a previous study of PTB. Methods: DNA from 434 mother-baby dyads (214 cases and 220 controls) collected from the Norwegian Mother and Child Cohort (MoBa) were examined for association between 1,430 single nucleotide polymorphisms (SNPs) in 143 genes and PTB. These results were compared to a previous study on European Americans (EA) from Centennial (Cenn) Women's Hospital in Nashville, TN. Odds ratios for SNPs that were corroborated in the Cenn study were determined on the combined MoBa and Cenn studies. Results: In maternal samples the strongest results that corroborated with the Cenn study were in the prostaglandin E receptor 3 gene (PTGER3; rs977214) (combined genotypic p = $3x10^{-4}$). The best model for rs977214 was the AG/GG genotypes relative to the AA genotype and resulted in an OR of 0.56 (95% CI = 0.38-0.82, p = 0.003), indicating a protective effect. In fetal samples the single strongest association in the combined data was rs854552 in the paraoxonase 1 gene (PON1) (allelic association p = 0.001, genotypic p = $7.6x10^{-4}$). The best model was the TT genotype relative to the CC/CT genotypes, and resulted in an OR of 1.69 (95% CI = 1.26-2.27, p = $5.1x10^{-4}$). Conclusions: These studies identify single locus associations with PTB in two populations of European ancestry.

## 1633/T/Poster Board #182

**Cell-free fetal DNA trafficking increases in pregnant women who conceive by *in vitro* fertilization using egg donors.** *K.L. Johnson[1], K. Koide[1], Z. Jarrah[1], I. Peter[2], G. Lambert-Messerlian[3], D.W. Bianchi[1].* 1) Pediatrics, Floating Hospital for Children at Tufts Medical Center, Boston, MA; 2) Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York, NY; 3) Pathology, Women and Infants' Hospital, Providence, RI.

**Objective.** To determine if pregnancies conceived by *in vitro* fertilization using egg donors (ED-IVF) result in increased levels of circulating cell-free DNA compared to spontaneously conceived pregnancies.

**Methods.** We obtained archived maternal serum samples from routine second trimester screening. Sixteen case-control sets were created, matched for gestational age (within 1 week) and time in storage prior to DNA extraction. Each set consisted of a sample from a woman who had a singleton ED-IVF pregnancy with a male fetus, 5 women with spontaneously conceived male fetuses, and 1 woman with a spontaneously conceived female fetus (total=112). Cell-free DNA was isolated and measured by real-time PCR amplification using *GAPDH* and *DYS1* as markers of total and fetal DNA, respectively. Samples were coded and analyzed blindly. Fetal gender was verified at delivery.

**Results.** The sensitivity of *DYS1* detection in women carrying male fetuses was 99.0% (95 of 96), with a specificity of 100% (no *DYS1* detection in 16 women carrying female fetuses). Due to the single false negative result in an ED-IVF case, this set was excluded from subsequent analyses (n=105). The average amount of fetal DNA in maternal plasma from ED pregnancies was 48 genome equivalents (GE)/mL, compared to 30 GE/mL in controls. This was statistically significantly increased (p=0.010), as determined by linear mixed model. *GAPDH* DNA levels were not significantly different between ED-IVF pregnancies and controls (p=0.45).

**Conclusions.** Elevated levels of fetal DNA in serum from women who conceive by ED-IVF may be the result of characteristic placental abnormalities observed in ED-IVF, such as dense fibrinoid deposition in the basal plate and severe chronic deciduitis, which have been previously reported by our group (Gundogan et al. Fertil Steril 2009; Feb 25). Further research is needed to understand the relationship between placental pathology, circulating cell-free DNA levels, and immunogenetic differences between the egg donor and recipient.

## 1634/T/Poster Board #183

**TURNER SYNDROME MOSAICS, CARDIAC RISK AND DONOR OOCYTE IN VITRO FERTILIZATION (IVF).** *A. Kittai, R. Pen, A. Benner, W.G. Kearns.* Shady Grove Center for Preimplantation Genetics, Rockville, MD.

Turner's Syndrome is characterized by short stature and ovarian failure. Cardiac and/or aortic abnormalities are present in a significant percentage of Turner syndrome patients and if spontaneously pregnant or by IVF, these patients are at significant risk of sudden death due to an aortic rupture or a cardiac event. The aortic / cardiac risks and outcome following a donor oocyte IVF cycle of Turner mosaics is unknown. Nineteen infertile female patients with a questionable mosaic Turner syndrome karyotype were enrolled in this study. The standard cytogenetic karyotypes ranged from 46,XX[19]/45,X[1] to 46,XX[44]/45,X[6]. We isolated white blood cells (wbcs) from peripheral blood using a modified microspin/phosphate buffered saline (PBS) wash. Wbc's were fixed using a modified Carnoy's method and fluorescence in situ hybridization (FISH) was performed for chromosomes X and Y. Approximately 500 cells were scored for the sex chromosomes to determine the actual percentage of sex chromosome mosaicism of each woman. All couples received counseling regarding the medical risks of beginning a donor oocyte IVF cycle. All women required a cardiology release for potential cardiac and aortic risks. Seven of the 19 couples enrolled in the study, underwent 13 IVF cycles. Clinical outcomes (embryo transfer, clinical pregnancies and delivery rates) of these cycles were determined. Eighteen of 19 women with questionable Turner syndrome mosaicism by traditional cytogenetics were shown to be true Turner mosaics by somatic cell wbc analysis. The average wbc sex chromosome mosaicism was 5.8% (1-18%). Of the 13 donor egg IVF cycles completed by the 7 couples, one couple had no transfer due to poor embryo quality, there were 2 healthy deliveries and 4 miscarriages (one couple had 2 miscarriages). The women with the healthy deliveries had 3 and 11% wbc mosaicism. In contrast, the women with miscarriages had 3, 4.4 and 6% wbc sex chromosome mosaicism. This preliminary study demonstrates that Turner syndrome mosaics can successfully undergo a donor oocyte IVF cycle following a cardiology release. However, the observed 67% miscarriages (four miscarriages out of six pregnancies from six couples) is 6 times higher than the expected donor oocyte IVF cycle miscarriage rate of 10% from this clinic. This preliminary data suggests that Turner syndrome mosaics, regardless of their percent XO cells, might consider a gestational carrier.

## 1635/T/Poster Board #184

**New insights into the biology of acid ceramidase and Farber disease.** *E. Schuchman, N. Shtraizent, X. He, E. Eliyahu.* Dept Genetics and Genomic Sciences, Mount Sinai Sch Medicine, New York, NY.

Acid ceramidase (AC), the lysosomal hydrolase deficient in Farber Lipogranulomatosis (Farber disease; FD), plays a central role in the metabolism of ceramide, a pro-apoptotic signaling lipid. We have recently shown that the complete knockout of AC expression in mice leads to apoptotic embryo death by the 4-cell stage (Eliyahu et al., FASEB J., 2007). Normal oocytes also expressed high levels of AC, likely providing the enzyme to the newly formed embryos and thereby sustaining survival until expression of the embryonic genome (4-cell stage in mice). AC levels in unfertilized oocytes gradually declined, leading to apoptosis. Based on these findings we hypothesized that AC is an important factor required for oocyte and early embryo survival, and that addition of recombinant AC (rAC) to culture media could sustain their survival in vitro and improve the outcome of in vitro fertilization (IVF). We tested this hypothesis using murine, bovine and human oocytes and/or embryos. In mice and cows, inclusion of rAC in IVF culture media markedly improved the quantity and quality of embryos formed. rAC also slowed apoptosis of unfertilized mouse and human oocytes. Notably, the levels of AC in preimplantation embryos were further correlated with their quality (i.e., high AC in high quality embryos). To extend these findings, we also investigated the use of rAC in other primary cell cultures, and found that as with oocytes and embryos, the enzyme could sustain survival by altering sphingolipid metabolism. Finally, to investigate the role of AC in mammalian development, we have recently constructed conditional AC knockout mice that can be used to inactivate the enzyme at various developmental stages and/or in a cell-specific manner. These mice, together with "hypomorph" knock-in mice we are developing, should provide the first viable models of FD. Funding by NIH grant R01 DK54830.

## 1636/T/Poster Board #185

**Genome-wide methylation analysis in women with trisomic pregnancies.** *CW. Hanna[1], MS. Peñaherrera[1], MD. Stephenson[2], WP. Robinson[1].* 1) Department of Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 2) University of Chicago Recurrent Pregnancy Loss Program, University of Chicago, Chicago, IL, USA.

Trisomy occurs in 6% of clinically recognized pregnancies and accounts for >40% of miscarriages. Aging is associated with a decline in ovarian function and responsiveness to hormonal signals and is the strongest independent risk factor for trisomy. Hormonal balance has been shown to be essential for oocyte development, chromosome segregation, and follicular growth, and thus disruptions in this balance, due to endocrine disorders or exposure to endocrine disrupting chemicals (EDCs), may be associated with meiotic nondisjunction. Endogenous and exogenous changes in maternal hormone environment may result in altered gene expression as a consequence of abnormal DNA methylation. We hypothesize that maternal meiotic nondisjunction will be associated with altered DNA methylation, detectable in blood cells, due to the systemic effects of hormones and EDCs. DNA was extracted from whole peripheral blood from 21 fertile control women (>37 years of age with successful delivery and no history of miscarriage) and 20 women with a history of a trisomic pregnancy at an age of <35 years and/or ≥2 heterotrisomic miscarriages. To identify candidate methylation changes, samples were analyzed using the Illumina GoldenGate Methylation Cancer Panel I, which interrogates 1,505 CpG sites in 807 genes. Candidate methylation changes were identified using Significance Analysis of Microarrays with a false discovery rate of <20% and an absolute difference of 5% methylation. Five CpGs were found to be differentially methylated between cases and controls and are being validated with pyrosequencing in a larger set of 163 samples (63 controls and 100 women with ≥1 trisomic miscarriages). A candidate CpG of interest was located within the promoter of the Myeloid Leukemia Factor 1 (*MLF1*) gene, which was found to be significantly hypomethylated in women with ≥1 trisomic miscarriage (t-test, $p$=0.007), independent of age and blood cell composition. *MLF1* could play a role in risk for nondisjunction through its interaction with MLF1-interacting protein, which is highly expressed in the oocyte and is involved in centromere assembly and chromosome segregation. This study may improve our understanding of maternal meiotic nondisjunction and identify potential epigenetic markers which may be associated with meiotic nondisjunction in humans.

**A diverse phenotypic spectrum in a Chinese family with a novel micro-duplication of 15bp in human steroidogenic factor 1 (SF-1).** *H. Li[1], Y. Chen[1], Y.P. Lei[2], W. Wang[1], J. Ou[1], K.W. Choy[3].* 1) Center for Reproduction and Ge, Nanjing Medical University Affiliated Suzhou Hospi, Suzhou, China; 2) State Key Laboratory of Genetic Engineering and MOE Key Laboratory of Contemporary Anthropology, School of Life Sciences and Institutes of Biomedical Sciences, Fudan University, Shanghai, 200433, P.R. China; 3) Department of Obstetrics and Gynaecology, and Li Ka Shing Institute of Health Sciences, The Chinese University of Hong Kong, Hong Kong, P.R. China.

Objective: Chromosomal imbalance or sub-microscopic copy number variation and some sex-related genes including sex determining region Y (SRY) and steroidogenic factor 1 (SF-1) play important role in the development of both the hypothalamic-pituitary-adrenal and hypothalamic-pituitary-gonadal axes. The phenotypic spectrum associated with heterozygous loss of function mutations in SF-1 can range from complete testicular dysgenesis to mild genital ambiguity. This study is to designed to disclose the etiology of a Chinese family with two members affected by 46,XY sex-reversal phenotype. Methods: G-banding karyotyping, whole chromosome painting and microarray-based comparative genomic hybridization (array-CGH) were performed. Sequencing of SRY and SF-1 genes was performed to clarify the etiology. Results: G-banding karyotyping, whole chromosome painting were all confirmed that the two sisters are 46,XY. To exclude the presence of any sub-microscopic chromosomal imbalance, we performed high-resolution array CGH analysis on the patients' blood samples. Using the 244K array platform from Agilent Technologies, we detected 3 single copy number loss and 2 sing copy number gain of chromosomal materials ranging from 24Kb to 428Kb, including a chromosome region X:134605794-134737947 (within Xq26.3) was detected in the blood sample. Besides a novel 15 bp micro-duplication at c.1075-1089 in the SF-1 gene was identified in the two 46,XY sex-reversal sisters which is inherited from their fertile mother.. Conclusion: This observation comprises the evidence showing that micro-duplication may be the etiology of sex-reversal of 46,XY females.

## 1638/T/Poster Board #187

**CORRELATION PHENOTYPE-KARYOTYPE AND DETERMINATION OF REPRODUCTIVE RISK IN THE WOMEN WITH X CHROMOSOME MOSAICISM.** *R. Baez-Reyes[1,3], JC. Baez -Reyes[2], G. Razo-Aguilera[1,3].* 1) Dept Genetics, Instituto Nacional de Perinatología; 2) Dept Histophatology, Universidad Nacional Autonoma de Mexico; 3) Dept Morphology, Escuela de Ciencias Biologicas, IPN. MEXICO.

INTRODUCTION. Frequency of 11% of cytogenetic abnormalities is calculated in the patients with disturbance of the reproduction, among those the mosaics of sexual chromosomes are included. Mainly of the "X" that have not been studied appropriately until the moment. Reports exist for these patients with abnormal sexual development, gestational loss or newly born with chromosomophaty or children with congenital defects. OBJECTIVE. To know in a sample of mexican women the frequency of the "X" chromosome mosaicism and to correlate it with alterations of the reproduction. MATERIAL AND METHODS. We assisted the couples that went with reproduction alterations, the genetic clinical history, the pedigree and physical exploration having as selection approaches: 1)amenorrhoea primary or secondary 2)sterility primary or secondary 3) recurrent gestacional loss 4)previous children with birth defects 5)previous children with cromosomopathy 6) premature ovarian failure. To the couples that gathered the requirements they were carried out the karyotype in blood GTG Bands with the Moorhead technique, for analysis so much numeric as structural with a resolution of 450 bands. When she was a cell aneuploide in 25 metafases the study it was completed with the technique of FISH in 100 cells in metafase analyzed by case. RESULTS. We study 87 women that were detected with the X mosaicism, with a 19 year-old minimum age and 44 year-old maxim age, more frequent cause to go to the consultation are: 1) recurrent abortion(56), 2) amenorrhoea(12), 3)sterility(7), 4)children with birth defects (7) and 5)abortion and children with birth defects (5), we finding that the "X" chromosome mosaic more frequent it was: 45,X/46,XX/47,XXX(37); 45,X/46,XX(29) and 46,XX/47,XXX(19); 45,X/46,XX/47,XXX/48;XXXX(1) and 46,XX/47,XXX/48,XXXX(1). We gave the resulst and throught their consent they began into the protocol of integral study. CONCLUSIONS. 1)This alteration had not been studied in adequated form., 2)The more frequent cause of consultation is recurrent abortion, 3)The mosaicism that more is present is 45,X/46,XX/47,XXX, 4)The women can to present associate alterations, 5)The risk for the descendant is variable, 6) It's very important the study of the patients into of the protocol, 8)It's very important too to realize methods invasive for the prenatal diagnosis in the event of pregnancy.

## 1639/T/Poster Board #188

**Marked deviations from Hardy-Weinberg Equilibrium suggest the presence of a common variant with recessive lethal effect at 17q21.** *A. Vine, D. Curtis.* Centre for Psychiatry, Queen Mary's School of Medicine and Dentistry, London E1 1BB, UK.

We have recently reported regions in which groups of neighbouring markers exhibit marked deviation from HWE using genotypes in control subjects typed with the Affymetrix 500K marker set made available by the Wellcome Trust Case Control Consortium (WTCCC) (Vine and Curtis, 2009). The most striking of these results was a group of 6 markers on chromosome 17, each of which showed evidence for decreased homozygosity significant at $p<10^{-190}$. Because these deviations were observed in groups of neighbouring markers it does not seem plausible that these results could be explained as genotyping errors of individual markers. The markers were located within 4kb around position 41009000 on chromosome 17.

We have further investigated this phenomenon by studying the same markers typed in 7 cohorts of WTCCC cases, comprising a total of approximately 14,000 subjects, and markers in the same region typed in the HapMap subjects using the Perlegen platform.

The results we obtained consistently show a marked reduction in homozygous genotypes compared to what would be expected under HWE. This is manifest across all sets of samples and across different genotyping platforms.

We conclude that there is a real and marked deviation from HWE at this position on the human genome. The results are consistent with the presence of a common variant having a recessive lethal effect, meaning that subjects carrying two copies of this variant are unlikely to survive to adulthood. Given that this variant seems to be very common, we speculate that its effect is manifest very early in embryogenesis, resulting in early loss, so that overall it has only a modest impact on the reproductive fitness of parents carrying it. Thus, two parents carrying the variant might lose one embryo in every four reproductive cycles, leading to only moderately impaired fertility. Identifying this variant and others with similar effects might prove helpful in understanding genetic facts impacting on human fertility.

## 1640/T/Poster Board #189

**Long Polyglycine Tracts (GGN Repeats) of Androgen Receptor Gene in Cryptorchidism and Hypospadias.** *R. Asadollahi, R. Radpour, Z. Barekati, C. Kohler, XY. Zhong.* Department of Biomedicine, University of Basel, Basel, Basel, Switzerland.

Cryptorchidism and hypospadias are among the most frequent congenital abnormalities in male births affecting 0.3%-0.7% and 2%-4% of births, respectively. In this study, the association between CAG/GGN trinucleotide repeats of androgen receptor gene and the two mentioned congenital malformations was evaluated. We compared 76 cryptorchid and 92 hypospadiac patients (divided into subgroups of glanular, penile, and penoscrotal hypospadias) to 190 normal controls. Length of the CAG/GGN repeat segment was evaluated in exon 1 by using polymerase chain reaction (PCR) sequencing and in exons 2-8 by PCR-single-strand conformation polymorphism (PCR-SSCP). No significant difference was seen in the CAG length of patients versus normal controls. However, GGN numbers were found to be significantly higher (median, 24 vs. 22) in both patients with penile hypospadias (P=.018) and those with a history of cryptorchidism (P=.001) compared to the controls. In addition, GGN number of patients with penile hypospadias was significantly different compared to the other subgroups of hypospadias (P=.001). We were able to identify 12 different CAG alleles and 8 different GGN alleles in the cryptorchid group. Our data suggest the possible association between polyglycin tract polymorphism of androgen receptor gene and cryptorchidism. Further studies are needed to elucidate the possible role of specific CAG/GGC combinations as a susceptible factor.

## 1641/T/Poster Board #190

**CYTOGENETIC ASPECT IN REPRODUCTIVE FAILURE.** *M. GULTOMRUK, E. AKCAY, H. UCAR, R. ULUOCAK, D. DOGAN, H. UNAL, L. ERKAN, E. TUTAR, G. KILIC, N. ERCELEN.* Genetics & Genomic Sciences Center, American Hospital, Istanbul, TURKEY.

To evaluate the cytogenetic study results of 1586 patients with reproductive failure. 1586 patients were analyzed cytogenetically. Peripheral blood cultures were carried out for chromosome preparations and 20 metaphases were analyzed for each patient by at least a biologist and two specialists. 50-100 metaphases were counted in case of mosaicism. 450-550 band level GTG banding technique was used, additionally, CBG-banding, NOR-banding or FISH techniques also used if necessary. We categorized reproductive failures patients into two groups according to their reproductive history: repeated pregnancy loss&poor obstetric history, infertility&repeated implantation failure. In this study, 1586 patients [937 men (59.1%), 649 women (40.9%)] with reproductive failure were analyzed cytogenetically. A total of 138 aberrant karyotypes (8.7%) were diagnosed, corresponding to an abnormality frequency of 9.7% (91/937) for men and 7.2% (47/649) for women. The observed chromosomal abnormalities were structural (40.6%,56/138), numerical (0.7%,1/138) and sex chromosome abnormalities (58.7%,81/138). The following frequencies of abnormalities were found 34.8% (48/138) for translocations, 4.3% (6/138) for inversions and 1.4% (2/138) for other chromosomal abnormalities; 57.2% (79/138) for numerical sex chromosome abnormalities; 1.4% (2/138) for other sex chromosome abnormalities. Abnormalities seen in both groups were translocations, inversions, sex chromosome abnormalities and marker chromosomes. In the first group, karyotyping were performed for 752 patients (382 women and 370 men) and 698 (92.8%) of them were analyzed as normal, 54 (7.2%) of them were analyzed as abnormal. In the second group, 750 (89.9%) patients were found as normal, 84 (10.1%) patients were found as abnormal in 834 patients (267 women and 567 men). 70 of 370 men evaluated for infertility had cytogenetic abnormalities of whom 32 had azoospermia, 3 had oligooospermia. Infertility - the inability to achieve conception or sustain a pregnancy through to live birth - is very common and affects about 15% of couples. The male and female with infertility accurately have higher risk to carry a chromosomal anomaly. The karyotype knowledge enables us to detect the individual affected couple with an increased risk for transmitting an unbalanced chromosomal complement to the embryo which leads comprehensive genetic counselling.

## 1642/T/Poster Board #191

**Sperm mtDNA mutations and oxidative stress- an important pathology in male fertility.** *K. Ihtisham[1], S. Venkatesh[1], R. Kumar[1], MB. Shamsi[1], R. Kumar[2], NP. Gupta[2], RK. Sharma[3], P. Talwar[3], R. Dada[1].* 1) Anatomy, All India Institue of Medical Sciences, New Delhi, Delhi, India; 2) Department of Urology, AIIMS, New Delhi-29; 3) ART center , Army Research and Referral Hospital, N Delhi.

Aim: To screen mtDNA mutations in semen of infertile men with elevated ROS levels. Methods: The study included 50 idiopathic infertile men and 50 fertile controls. Semen analysis was performed according to WHO criteria (1999). ROS in the semen was measured by chemiluminescence assay. Whole sperm mtDNA was sequenced by standard PCR-DNA sequencing method. Results: Infertile group showed significant difference in the sperm count (74.10±15.5 Vs 11.9±5.2), percent sperm motility (68.5±14.6 Vs 14±5.2) and percent normal morphology (62.9±13.3 VS 11±2.2) compared to control men. Infertile group showed significantly (p< 0.001) higher ROS levels (331.55+58.97 cpm) /106 spermatozoa compared to fertile controls (4.2+1.21 cpm) / 106 spermatozoa. mtDNA sequencing revealed that 66% of the infertile group harboured one or more nucleotide changes in the gene ATPase6 & 8, Cytb, ND3, ND4 and ND5 in the mitochondrial genome compared to control men inspite some common nucleotide changes (A750G, A4769G) in both the groups. Conclusions: Approximately 80% of the infertile men showed significantly elevated ROS levels in the semen. Out of these approximately 60% of the infertile men with elevated ROS levels showed significantly higher nucleotide changes in sperm mtDNA when compared to the controls. Therefore, higher frequency of mtDNA nucleotide changes may be responsible for elevated ROS levels that might further increase the incidence of nucleotide changes. These adverse phenomena may also have an impact on DNA integrity that may lead to impaired fertility. Therefore, screening mtDNA mutations in infertile men with severe oxidative stress may help in the better management for infertility treatment.

## 1643/T/Poster Board #192

**Comparative Genomic Hybridization Microarray (aCGH) to Identify Unrecognized Structural Chromosomal Defects Associated with Human Male Infertility.** *C. Jorgez[1], L. Lipshultz[1], D. Lamb[1,2].* 1) Dept Urology, Baylor College of Medicine, Houston, TX; 2) Dept Molecular and Cellular Biology, Baylor College of Medicine, Houston, TX.

OBJECTIVE: Known genetic factors account for approximately 15% of male infertility. Numerical and structural chromosome abnormalities, such as Klinefelter syndrome and microdeletion of the Y-chromosome represent the most commonly known and tested genetic causes. Nevertheless, more than 50% of male infertility may have a genetic cause. Thousands of genes are likely needed for male fertility, yet there are few diagnostic tests available. Our goal is to identify the molecular basis of male infertility. We tested the hypothesis that structural chromosome defects too small to be seen on karyotype are present in infertile men. We searched for regions of chromosome duplication or deletion to identify gene dosage abnormalities associated with non-obstructive azoospermia (NOA). MATERIALS AND METHODS: Fertile and NOA men with normal karyotypes were analyzed by aCGH using 720K NimbleGen arrays (Roche). Analysis was performed with Nexus Copy Number software (BioDiscovery).These high-resolution arrays span most of the genome, allowing detection of submicroscopic chromosome defects and permits definition of the break-points of each duplication or deletion. Each suspected gain or loss was then validated by FISH and QPCR. RESULTS: Chromosome duplications or deletions in nine distinct regions (1q32, 7p14.3, 9q32, 11q13, 14q22, 14q32, 17q12, 19p13, 20q11) that lacked copy number variants were identified in 88% of NOA men. These regions encode genes highly expressed in testis. Other duplicated or deleted chromosomal regions were also found. No duplications or deletions were found on chromosomes 4 or 18. Analysis of several men with known Y-microdeletions in the AZFa, b, and/or c regions showed that the deletions in Yq were more complex then expected based upon the results of a multiplex PCR based assay. In addition, gains in Xp22 and Yp were observed with 2 men presenting Y-chromosome microdeletion together with a duplication of SHOX. CONCLUSIONS: Definition of the genetic cause of male infertility is important for both diagnosis and treatment, because today use of the assisted reproductive technologies allow many otherwise infertile men to become fathers. Nevertheless, these technologies may also allow transmission of unknown defects to their progeny. Consequently, the identification of genetic factors is important for appropriate management of the infertile couple. Array technology identifies unrecognized clinically relevant genetic factors causing male infertility.

## 1644/T/Poster Board #193

**Is Apoptosis a potential marker for sperm quality?** *M.S. Juchniuk de Vozzi[1], C.S. Pereira[1], S.A. Santos[1], I. Pola[1], P.A. Vozzi[1], M.A.C. Vasconcelos[2], A.C.J.S. Rosa-e-Silva[2], L. Martelli[1].* 1) Deparment of Genetics, School of Medicine of Ribeirão Preto, University o, Ribeirão Preto, São Paulo, Brazil; 2) Department of Gynecology and Obstetrics, School of Medicine of Ribeirão Preto, University of São Paulo, Brazil.

Apoptosis is a cell death program involved in different steps of spermatogenesis, first at puberty, at the beginning of spermatogenesis, then in adult testicles by controlling normal spermatogenesis. Many studies have shown that apoptosis deregulation in the germinal cells resulted in male infertility. In addition, apoptosis detection in ejaculated spermatozoa arouses a growing interest in research as a reliable marker of spermatozoon quality. Our objective was to compare the apoptosis markers in sperm of infertile patients to the control group samples. All the infertile patients (n=18) presented oligozoospermia and normal somatic karyotype. The control group was characterized by normal spermogram, normal karyotype and proved fertility. The presence of apoptotic sperm was detected by using the recombinant annexin V conjugated to fluorescein (FICT annexin V) and propidium iodide (PI) nucleic acid binding dye. Both semen analysis and the apoptosis test were performed at the same time. The analysis of 500 cells from the control group has shown a mean value of 83,88 % of live cells, 4.5% of apoptotic cells and 11.47 % of necrotic sperms. The oligozoospermic group presented 75.015% of live cells, 12.19 % of apoptotic sperm and 12.29% necrotic sperm in the sample. Both rates of apoptosis and necrosis showed significant difference between the groups (0.03056 and 0.04207). Necrosis was the preferencial via of cell death in the control group while there was no difference between the frequencies of necrosis (0.1229) and apoptosis (0.1219) in the infertile group. Our findings have shown a significant difference in the apoptosis rates between the control group with proven fertility and the infertile group. We suggest that the apoptosis can be a candidate semen quality marker.

## 1645/T/Poster Board #194

**Genetic causes of male infertility in India.** *A. Khattri[1], N. Gupta[2], B. Chakravarty[2], M. Deenadayal[3], L. Singh[1], K. Thangaraj[1].* 1) Centre for Cellular and Molecular Biology, Hyderabad, Andhra Pradesh, India; 2) Institute of Reproductive Medicine, Salt lake, Kolkata, India; 3) Infertility Institute and Research Centre, Hyderabad, India.

During spermiogenesis chromatin of the sperm becomes highly compact due to sequential replacement of somatic histones by transition nuclear proteins (*TNP*), which are then replaced by protamines (*PRM*). Improper replacement of these proteins can cause sperm DNA damage leading to male infertility. Calmodulin dependent protein kinase 4 (*CAMK4*) phosphorylates the protamines, which is responsible for interaction of protamines with chromatin. Therefore, we screened *CAMK4*, *TNP1* & *2* and *PRM1*, *2* & *3* genes, which are involved in the above functions, in Indian men which includes 300 infertile and 289 fertile men. We have observed a total of 78 polymorphic sites in these genes. Although the frequency of many SNPs was low, 9 mutations in *CAMK4* gene and 15 in *PRM* genes and 3 in TNP genes were observed exclusively in infertile men and 2 SNPs g.-25:C>T in *PRM3* showed significant difference between infertile and fertile men. The g.-25:C>T substitution is present in the upstream of the *PRM3* gene and may be affecting the expression of *PRM3* gene. This novel predicted *PRM3* gene was confirmed for its transcription and full-length transcript was isolated and found to have testis specific expression. We further predicted that many infertile men-specific mutations could cause either loss or appearance of potential binding sites for various splicing factors. The SNPs of *PRM1* and *PRM2* genes were found to be in LD, but not in *PRM3*. Haplotype analysis revealed that the haplotype PRM-H6 and TNP-H3 conferred significantly increased risk for infertility. We addressed for first time the association SNPs and haplotypes of *CAMK4*, *TNP* and *PRM* genes with male infertility in ethnically matched Indian men. Further analysis of these genes on other populations is required to validate them as a candidate for infertility in males. In another aspect of our study we are looking for the genes those are up/down regulated in testis of infertile vs fertile men using Affymetrix microarrays for expression analysis. Currently we are analyzing and validating microarray results using Real Time PCR. These results will be presented during the conference.

## 1646/T/Poster Board #195

**Familial Frameshift SRY Mutation Inherited from a Mosaic Father: new insights into Testicular Dysgenesis Syndrome.** *C. Le Caignec[1], B. Isidor[1], C. Capito[2], F. Paris[5], S. Baron[3], N. Corradini[4], B. Cabaret[4], M.D. Leclair[2], M. Giraud[1], D. Martin-Coignard[6], A. David[1], C. Sultan[5].* 1) CHU Nantes, Service de Génétique Médicale, Nantes, France; 2) CHU Nantes, Service de Chirurgie Infantile, Nantes, France; 3) CHU Nantes, Clinique Médiale Pédiatrique, Nantes, France; 4) CHU Nantes, Service d'Oncologie Pédiatrique, Nantes, France; 5) Service d'Hormonologie, Hôpital Lapeyronie, CHU Montpellier, Montpellier, France; 6) Unité de Génétique Clinique, Centre Hospitalier du Mans, Le Mans, France.

Context: The SRY gene encodes a transcription factor responsible for initiating testis differentiation. Mutations in SRY almost always result in XY sex-reversal with pure gonadal dysgenesis and an increased risk of gonadal tumour. Most of these mutations are de novo affecting only one individual in a family. Only a small subset of mutations is shared between a phenotypically normal father and one or more of his affected children. Incomplete penetrance and somatic mosaicism are two hypotheses that may explain a normal phenotype in a father carrying a SRY mutation. Patients-Results: We describe a family with two sisters with XY sex-reversal and pure gonadal dysgenesis and a phenotypically normal brother. A novel constitutional frameshift SRY mutation was identified in both sisters and was absent in the brother. The single base-pair deletion (c.71delA) led to a premature stop-codon in position 60 of the protein removing entirely the HMG domain and the DNA-binding domain of SRY. The father of the three children presented with hypospadias, cryptorchidism, testicular seminoma and oligoasthenozoospermia, an association termed testicular dysgenesis syndrome (TDS), and the SRY mutation in a mosaic state in the peripheral blood and the tumour. Conclusions: This observation of somatic and germinal mosaicism for a SRY mutation may explain the variable penetrance in some familial gonadal dysgenesis. Importantly, the present report is the first one describing the association of SRY mutation in a male with TDS. This suggests that mutations in a sex-determining gene may contribute to the pathogenesis of TDS.

## 1647/T/Poster Board #196

**A role for methylation of the hMLH1 promoter in loss of hMLH1 expression in patients with non-obstructive azoospermia.** *F. Sun, H. Tian, J. Lian.* Sch Life Sci, Univ Sci Tech China, Hefei, China.

Decreased numbers of meiotic recombination hMLH1 foci have been demonstrated in infertile men. However, little is known about the mRNA and protein expression of hMLH1 in patients with non-obstructive azoospermia (NOA). This study is aim to identify the expression level of hMLH1 and its methylation status in the testes of normal controls and of patients with NOA. The expression level of hMLH1 mRNA and the localization of hMLH1 protein in the testes of 3 controls and 3 patients with NOA were performed by the reverse transcription-PCR and immunohistochemistry, respectively. Methylation specific-PCR was used to study whether the promoter regions of hMLH1 were methylated. The genome DNAs of both normal and NOA patients' testes were modified by bisulfate and the CpG islands (region B or region C) of hMLH1 promoter were amplified with unmethylation or methylation primers. The pathological types of NOA patients were subdivided as sertoli cell only syndrome (SCOS), hypospermatogenesis and germ cell arrest. The levels of hMLH1 mRNA were decreased in testes of patients with germ cell arrest and SCOS compared to that in normal controls, however, no obviously decreased levels of hMLH1 mRNA were found in patients with hypospermatogenesis. Immunohistochemical results indicated that hMLH1 proteins were exclusively expressed in primary spermatocyte. The expression levels of hMLH1 were also found to be significantly reduced in patients with germ cell arrest. Complete absence of hMLH1 expression was observed in SCOS, since these testes have no any meiotic cells. Similar to the expression levels of hMLH1 mRNA in patients with hypospermatogenesis, no significant alteration in hMLH1 levels in these patients. Aberrant promoter methylation of hMLH1 was detectable in these cases. Defective hMLH1 expression was identified in patients with NOA, which was strongly related to their testicular pathological types. Methylation of the hMLH1 promoter may be a mechanism for loss of hMLH1 expression in male infertility.

## 1648/T/Poster Board #197

**Single nucleotide polymorphisms and a novel mutation (311C→A) in sperm nuclear proteins gene of Indian infertile men.** *S. Venkatesh[1], M. Kumar[1], M. Tanwar[1], MB. Shamsi[1], R. Kumar[2], NP. Gupta[2], R. Dada[1].* 1) Anatomy, Lab Molec Reproduction & Gen, New Delhi, India; 2) Department of Urology, AIIMS, New Delhi, India.

Aim: Sperm testicular proteins, the protamines and transitional nuclear proteins play a crucial role in sperm nuclear condensation. Mutation in any of the corresponding genes or aberrant post translation modification may lead to abnormal sperm chromatin condensation leading to male infertility. Therefore the study was aimed to screen nucleotide changes in protamine (PRM 1 & 2) and transitional nuclear protein (TNP 1 & 2) genes in Indian oligozoospermic men. Methods: The study included 30 oligozoospermic men and 20 fertile controls. Semen analysis was performed according to WHO (1999) guidelines. Sperms were separated from leukocytes, epithelial cells and debris by density gradient method. Sperm DNA was isolated by phenol-chloroform method. PRM and TNP genes were amplified, and purified by guanidinium thiocyanate method. The final products were sequenced by standard PCR-DNA sequencing protocol. The nucleotides were numbered from the first nucleotide of the corresponding gene. Results: Sperm count (10.52 ± 4.20 Vs 92.32 ± 23.44), and progressive sperm motility (28.50 ± 12.25 Vs 62.5± 21.5) were significantly compromised in oligozoospermic men compared to controls. In total, 6 nucleotide changes were observed in the study out of which, 139C→A in PRM1gene was found to be common in patients and controls, but 1083C→A in PRM2 gene was found to be present at higher frequency in patients than controls. However, a novel mutation in PRM 2 gene (311C→A) changing amino acid threonine to asparagines was observed in one patient (sperm count-17million/ml) with 50% abnormal head morphology and 15% forward motility. However, we found a SNP 839 T→C in TNP1 gene in 4% of the patients but not in controls. TNP2 mutation analysis showed a SNP 991C→T in TNP2 gene in 30% of the controls but not in the patients.. Conclusion: The frequency of SNPs observed in PRM genes was similar in both oligozoospermic and controls except a novel mutation (311C→A) in the exon of PRM2 gene. This mutation might be associated with the abnormal sperm parameters, by altering the PRM2 protein conformation that could lead to infertility. This is the first of kind of study in PRM and TNP genes in Indian infertile population. Higher frequency of SNPs and rare novel mutation in Indian infertile population could be the reason for impaired fertility in this population. Further larger number of studies screening for these variants and its correlation with assisted reproductive outcome is warranted.

## 1649/T/Poster Board #198

**Cystic Fibrosis screening in Italian infertile couples.** *A. Saluto[1], A. Murro[1], A. Celeste[1], A. Marongiu[1], G. Del Noce[2], G. Voglino[1].* 1) Laboratory of Molecular Genetics, PROMEA S.p.A, Turin, Italy; 2) Division of Andrology, PROMEA S.p.A, Turin, Italy.

Cystic Fibrosis (CF) is the most common autosomal recessive genetic disorder primarily affecting Caucasian populations caused by mutations in the Cystic Fibrosis Transmembrane Regulator (CFTR) gene, with an incidence of about 1/2500 live births and a prevalence of 1/28. CFTR gene testing is currently performed in couples undergoing Assisted Reproduction Techniques (ART), because of the high prevalence of healthy carriers in the population and the pathogenic relationship with Congenital Bilateral Absence of Vas Deferens (CBAVD). CF has a complex phenotype with manifestations in many organs but involvement of the respiratory tract is the dominant clinical feature. Thus far, more than 1600 mutations in the CFTR gene have been identified; the most common mutation is ΔF508, whose prevalence varies among populations of different geographical and ethnic backgrounds, accounting approximately for the 70% of the mutations in European patients. Our aim was to evaluate the frequency of CFTR mutations in infertile couples referred to our center for Assisted Reproductive Techniques (ART) (either IVF-ICSI or IUI). We analysed 3632 infertile couples in the last six years (2003-2008); molecular analysis of the CFTR gene was performed on genomic DNA extracted from peripheral blood lymphocytes by using OLA assay (Cystic Fibrosis Genotyping Assay, Abbott Laboratories, Germany). The 3.5% (254/7264) of the tested patients showed the presence of a CFTR gene mutation corresponding to a prevalence of 1/28; 171/254 mutations (67%) were ΔF508 in agreement with previous studies for the Italian population (Riccaboni et al. 2008). In one patient we identified two mutations, N1303K and R347H in different CFTR alleles; he was 38 years old and the cause of infertility was CBAVD. This patient had a history of recurrent bronchitis and was recovered for three months for chronic obstructive bronchopathy with no indications for CF. The combinations of CBAVD and chronic sinopulmonary disease is a confirm that some patients with bilateral absence of the vas deferens may have a mild form of Cystic Fibrosis; moreover, some patients with a mild form of CF could be undiagnosticated (Gilljam et al. 2004).

## 1650/T/Poster Board #199

**PREIMPLANATATION GENETIC SCREENING (PGS) FOR ANEUPLOIDY IN 143 COUPLES UNDERGOING DONOR EGG *IN VITRO* FERTILIZATION (IVF) CYCLES REDUCES THE MISCARRIAGE FROM 10% TO 2.7%.** *R. Pen[1], A. Benner[1], J. Liebermann[2], P. Browne[3], W.G. Kearns[1].* 1) Shady Grove Center for Preimplantation Genetics, 15001 Shady Grove Rd., Suite 220,Rockville, MD 20850; 2) Fertility Centers of Illinois, 900 N. Kingsbury, River Walk 6 Chicago, IL 60610; 3) Shady Grove Fertility RSC, 15001 Shady Grove Rd., Suite 400, Rockville, MD 20850.

We determined the prevalence of aneuploidy, the miscarriage rate and the number of healthy deliveries in couples undergoing donor egg IVF cycles.

One-hundred forty-three couples underwent donor egg IVF-PGS due to poor outcomes from prior fertility therapy. Laser-assisted embryo biopsy was performed on day-3 and PGS was done on 1869 cleaving embryos from 143 initiated cycles. The mean donor age was 26.5 years (21- 31). Multi-color fluorescence *in situ*hybridization was used to determine aneuploidy for chromosomes 13, 14, 15, 16, 17, 18, 21, 22, X and Y. Hybridization, stringency washes and fluorescent microscopy was performed. Clinical outcomes (aneuploidy, embryo transfer, clinical pregnancies and delivery rates) of these cycles were determined. Clinical pregnancy was defined by ultrasound identification of an intrauterine gestational sac and fetal heart beat.

All 143 women had an embryo transfer. Four percent (75/1869) of the embryos were not diagnosed due to poor embryo quality and cell lysis. Forty-eight percent (861/1794) of the embryos were aneuploid for at least 1 of the 10 chromosomes tested. Seventy-three percent (681/933) of the cytogenetically normal embryos developed into a blastocyst. The clinical pregnancy rate was 77% (110/143) per patient and 77% (110/143) per embryo transfer. The miscarriage rate was 2.7% (3/110). The delivery rate was 65% (93/143) not including fourteen additional viable gestations beyond 15 weeks. There were no misdiagnoses nor identified mosaic embryos.

This aneuploidy screening data from donor egg cycles provides insight into the presence of aneuploidy in a low risk population. Nearly 50% of donor egg embryos were aneuploid. The pregnancy rates were similar in these patients to those undergoing donor egg IVF without PGS. However, PGS lowered the expected miscarriage rate observed in our donor oocyte IVF cycles from 10 % to 2.7%. This suggests that PGS in this patient group successfully screens and selects for embryos most likely to achieve a successful outcome, the delivery of a healthy baby free of a genetic disease.

**Gene location matters: polar body analysis has limited informativity in centromeric genes.** *G. Altarescu, T. Eldar-Geva, B. Brooks, E. Haran-Zylber, I. Varshaver, E.J. Margalioth, E. Levy-Lahad, P. Renbaum.* Zohar PGD Lab & IVF Unit, Shaare Zedek Medical Ctr, Jerusalem, Israel.

Objective: To assess the degree of heterozygosity and percent of allele drop out (ADO) of polar body 1 (PB1) analyzed during Preimplantation Genetic Diagnosis (PGD) for monogenic diseases. Introduction: PGD is performed by biopsy of blastomeres or polar bodies (PBs) utilizing mutation detection and multiple polymorphic marker analysis to minimize misdiagnoses. Because only maternal alleles are analyzed in PBs, the chances of finding informative markers are higher than in blastomere analysis. An additional advantage is the sequential analysis of PB1 and PB2: when PB1s are heterozygous, this significantly decreases the degree of misdiagnosis due to ADO. However, when PB1 are homozygous, ADO can never be ruled out and additional blastomere biopsy may be required. Methods: Retrospective analysis of all PB-PGD cycles performed in our unit from 2004 till present for monogenic disorders and determination of the frequency of heterozygosity of PB1 and ADO for each gene tested.Results: Twenty seven diseases were tested by PB PGD in 68 families, a total of 1157 PB1 were diagnosed. The PB1 heterozygosity frequency was 6 - 100% and ADO rates were 4 -23%.We found that all genes we tested which were located within 5 Mb of the centromere (GJB2 and 6, NF1, RET and SMAX1, 236 PB1s) showed very low heterozygous PB1 rates (6 to 12%), whereas any genes located greater than 10Mb from the centromere showed an average of 80% heterozygosity (sd= 11%). ADO rates ranged from 4% for the SMAX1 locus to 23% for the EMD locus and were not related to the position of the gene on the chromosome. Conclusion: Genes residing close to the centromere show a low frequency of heterozygosity of PB1 and therefore PB PGD should not be considered for these disorders. The ADO rates were similar with the previous reported data.

## 1652/T/Poster Board #201

**PREIMPLANTATION GENETIC DIAGNOSIS FOR CRYPTIC TRANSLOCATION CARRIER COUPLES.** *E. AKCAY[1], E. TUTAR[1], M. GULTOMRUK[1], L. ERKAN[1], B. BALABAN[2], B. URMAN[2], N. ERCELEN[1].* 1) Genetics & Genomic Sciences Center, American Hospital, Istanbul, TURKEY; 2) American Hospital, Women' s Health Center, Istanbul, TURKEY.

To present the preimplantation genetic diagnosis results of reciprocal and robertsonian translocations that were analyzed in 26 ICSI/PGD cycles for 20 couples. Cytogenetic analysis was performed on cultured lymphocytes derived from peripheral bloods of couples. Two telomeric probes with two or one centromeric probes for the chromosomes involved in the translocation were analyzed on metaphase spreads of translocation carrier individual. Each blastomere biopsied from third day embryo analyzed with these telomeric and centromeric probes. They were also analyzed for common aneuploidies with PGT probe [13, 18, 21, X, Y (Vysis, Inc.)]. Preimplantation genetic diagnosis was performed for 26 translocation carrier cycles. Average maternal age was 32.4 years. 233 oocytes were retrieved, 189 of them were in M2 and 165 2PN (87.3%) embryos were observed. Average of 1.7 normal embryos were transferred in 17 cycles. 153 embryos were analyzed and only 20.3% (31/153) were normal or balanced. 16.3% (14/86) of embryos were analyzed normal or balanced in reciprocal translocations, while 25.4% (17/67) of embryos were analyzed normal or balanced in robertsonian translocations. Clinical pregnancy per embryo transfer (ET) was 20% (2/10) and 42.9% (3/7) in reciprocal and robertsonian translocations, respectively. 5 clinical pregnancies were resulted. 5 babies (3 singleton and 1 twin) were delivered, 1 singleton pregnancy still going on. Individuals that carry chromosomal translocations can produce chromosomally unbalanced gametes and they are at an increased risk for chromosomally abnormal fetus (1). Preimplantation genetic diagnosis should be recommended for poor prognosis translocation carrier couples to reduce number of pregnancy losses and to have successful pregnancy. In the literature, a significant decrease is observed in spontaneous abortions in translocation heterozygotes, from 81% before PGD to 13% after PGD [Munne et al., 2000]. There is no clinical abortion case in our transferred cycles. In conclusion, PGD significantly decreased losses and increased the number of viable pregnancies(P<0.001)(2). REFERENCES: 1. ## 1653/T/Poster Board #202

**PGD On 3,270 Embryos From 343 Cycles Due To Parental Reciprocal Translocation, Robertsonian Translocations Or Pericentric Inversions.** *A. Benner, R. Pen, A. Siegel, A. Kittai, W.G. Kearns.* Shady Grove Center for Preimplantation Genetics, Rockville, MD.

Carrier couples with a structural chromosomal abnormality are at great risk of producing genetically unbalanced gametes. Therefore, these couples are at high risk of producing genetically unbalanced progeny. This study of 343 PGD cycles from referring *in vitro* fertilization (IVF) clinics was performed to determine embryo structural chromosome imbalances due to parental structural chromosome rearrangements.

Two-hundred twenty-eight patients underwent 343 IVF cycles and PGD for genetic imbalances due to their structural chromosome abnormalities. Laser-assisted embryo biopsy was performed on 3,270 day-3 embryos. Multi-color fluorescence *in situ* hybridization (FISH) using telomere and/or genomic loci DNA probes was used to determine embryonic genetic balances of the chromosome(s) involved in the parental structural aberrations. Parental structural chromosome rearrangements included reciprocal translocations, Robertsonian translocations and pericentric inversions. Clinical pregnancy (CP) was defined by ultrasound identification of an intrauterine gestational sac and fetal heart beat. Of all cycles, 29.2% (100/343) had no transfer because all tested embryos were either 1) genetically unbalanced or 2) genetically balanced but found to be morphologically abnormal in development and quality on the day of transfer. Just over 7.6% of the embryos had no diagnosis because of poor embryo quality and cell lysis. The total CP for 218/228 patients for all structural chromosome aberrations was 37.6% (82/218); 41.2% (42/102) for reciprocal translocations, a 34.7% (33/95) CP rate for Robertsonian translocations and 33.3% (7/21) for pericentric inversions. The overall biochemical pregnancy rate was 8.7% (19/218) per patient and the miscarriage rate was 8.7% (19/218) per patient. We've had 42 deliveries with an additional 19 viable ongoing clinical gestations (most are beyond > 12 weeks). If all of these ongoing pregnancies continue to healthy deliveries, our overall delivery rate will be 28% (61/218). The remaining 10 patient transfers are awaiting hCG results.

This data shows that PGD for structural chromosome abnormalities is a viable option for carrier couples of a structural aberration to have a healthy child free of a genetic disorder.

## 1654/T/Poster Board #203

**Polar body analysis with Array-CGH in a clinical trial.** *T. Buchholz[1], M. Klehr-Martinelli[1], B. Seifert[2], M. Bals-Pratsch[2].* 1) Gyn-Gen-Lehel, Center for Polar Body Diagnosis, Munich, Germany; 2) Center for Reproductive Medicine, Regensburg, Germany.

Chromosomal aneuploidies are the major cause of pregnancy loss or implantation failure. Therefore many efforts are in progress to establish assays for the detection of aneuploidies in preimplantation genetic diagnosis (PGD). In the past years, we were able to gain much experience with polar body (pb) analysis by fluorescence in situ hybridisation (FISH). Both aneuploidy testing and translocation analysis are well established in our lab. The main disadvantage of this technique is that only a maximum of 10 chromosomes can be analysed. In order to analyse all 23 chromosomes, we are using an Array-CGH procedure. To get sufficient DNA from the sample, each pb is amplified by whole genome amplification. The array carries 600 bac clones covering the whole genome to detect gain or loss of chromosomes. To test the feasibility in a clinical setting with the restriction of the German embryo protection law, we started a clinical trial, including 10 patients (mean age 37,4 years). Following a standard IVF protocol (2.-4. cycle) oocytes retrieval was carried out in all 10 patients (mean no of MII oocytes 11,6). Both pbs of max 5 oocytes (in two cases only of 2 or 3 oocytes) from each patient were extracted and amplified. All array analyses were successfully carried out, leading to an average of 42% euploid oocytes. Following the embryo transfer of a maximum of 2 day-3-embryos, 3 clinical pregnancies could be achieved in 7 patients; further 3 patients are still awaiting pregnancy testing. The study is ongoing and so is the follow up of the patients. Due to our preliminary results, we conclude that further studies, especially to confirm the benefit in regard to clinical pregnancy and baby take home rates for particular subgroups of patients, need to be carried out.

## 1655/T/Poster Board #204

**OUTCOMES OF PREIMPLANTATION GENETIC DIAGNOSIS FOR SINGLE GENE DISORDERS.** *N. ERCELEN[1], H. COMERT[1], L. ERKAN[1], O. ILBAY[1], B. YAZAR[1], R. MERCAN[2], A. ISIKLAR[2], B. BALABAN[2], B. URMAN[2].* 1) Genetics & Genomic Sciences Center, American Hospital, Istanbul, TURKEY; 2) IVF Center, American Hospital, Istanbul, TURKEY.

OBJECTIVE: To present the results of Preimplantation Genetic Diagnosis (PGD) studies for the identification of a causative gene mutations together with/without Human Leucocyte Antigen (HLA) typing in several single gene disorders. METHODS: Preimplantation HLA matching was only applied on parents requesting treatment of their affected children. Following standart IVF protocol, single embryonic cells were removed from 3rd-day embryo following oocyte pick-up. Negative control for each blastomere was also prepared to control the contamination risk. Multiplex semi-nested PCR by using specific primers and polymorphic markers specific for each disease was applied for the mutation analysis. To detect and avoid misdiagnosis due to allele drop out (ADO), a haplotype analysis for father, mother and affected child was performed for each family before the preimplantation HLA typing. HLA genes from blastomeres were tested together with short tandem repeats (STRs) in the HLA regions by using multiplex semi-nested PCR system. RESULTS: 281 embryos were analyzed for different single gene disorders in 38 PGD cycles performed for 27 couples.7,4 embryos were analysed per cycle. 23,5% of total embryo analysed (66/281) were selected and transferred. Average of 1,7 embryos were selected for each cycle. 105 embryos from 15 cycles of 11 couples were analyzed for specific gene mutation and HLA compatibility. 17 unaffected embryos which were HLA matched to their affected siblings were selected and transferred. Two clinical pregnancies obtained from the PGD for HLA typing resulted in 3 healthy live-births who are potential donors of stem cells for their affected siblings. One was twin and the other was singleton. Interestingly, each one of twins was stem cell donors for each of their thalassemia major sisters. Few months ago, cord blood sample of one of twins was used for transplantation of his HLA compatible affected sister. Totally, obtained 9 clinical pregnancies (clinical pregnancy rate/ ET cycle: 32%) resulted in 10 healthy live-births: 5 of them were singleton, one was twin and one was triplet. CONCLUSION: These outcome data showed that due to its accuracy and efficiency, application of single-cell PCR based DNA analysis is a useful tool for the PGD of monogenic disorders. In addition, HLA typing during PGD not only offers production of unaffected offspring , but also possible treatment of affected siblings.

## 1656/T/Poster Board #205

**Distinguishing balanced from normal embryos in preimplantation genetic diagnosis (PGD) for chromosomal rearrangements.** *A. Kuliev, J. Cieslak - Janzen, Z. Zlatopolsky, I. Kirillova, Y. Ilkevitch, Y. Verlinsky.* Reprod Gen Inst, Chicago, IL.

Preimplantation genetic diagnosis (PGD) is the only hope for carriers of balanced chromosomal translocations for having an unaffected child, without facing risk for repeated spontaneous abortions. It is presently performed by interphase FISH analysis, which cannot distinguish the normal from balanced embryos, and also fails detecting small inversions and insertions, for which no locus specific probes are commercially available. To overcome this limitation, we introduced different methods for conversion of interphase nucleus into metaphase. One of them involves the fusion of biopsied blastomeres with mouse zygotes, which despite being practical is labor intensive and may raise ethical concerns. The other is based on the chemical induction, involving the exposure of selected single blastomeres to caffeine. We performed PGD in 474 cases of balanced rearrangements, overall, 227 of which were done by conversion, including 94 by chemically method. This resulted in transfer of 112 normal embryos in 69 cycles, 34 pregnancies and 5 spontaneous abortions. The overall number of predicted unbalanced embryos (73%) was similar in conversion and interphase methods, with a total of 581 balanced or normal embryos transferred in 354 cycles, resulting in 130 clinical pregnancies (38%), and birth of 104 unaffected children, with no misdiagnosis. Overall, only 21 pregnancies resulted in spontaneous abortions (16%), suggesting at least a four-fold reduction of spontaneous abortion rate, compared to non-PGD couples.

## 1657/T/Poster Board #206

**Use of microarray CGH for Preimplantation Genetic Diagnosis.** *S. Munne, C. Gutierrez-Mateo, JF. Sanchez-Garcia, S. Tormasi, R. Prates, N. Goodall, T. Escudero, P. Colls.* Reprogenetics, Livington, NJ.

Introduction - Preimplantation Genetic diagnosis (PGD) to screen against chromosomally abnormal embryos has been extensively applied using FISH with 9-12 probes. Recently, CGH has been used for PGD to screen all chromosome abnormalities in a single cell. However, CGH is time consuming and is not compatible with embryo biopsy on day 3 of development and day 5 transfer, thus CGH is usually done on embryos on day 5 of development(blastocysts) and then the embryo is frozen until results are obtained. Unfortunatelly, embryo freezing may imperil embryo survival. Here we present the first clinical results using array CGH, which allows day 3 biopsy of a single cell, obtain results in 24 hours, and to transfer by day 5 without the need of embryo freezing. Materials and Methods- Single day 3 embryos were biopsied, single blastomeres amplified, fluorescently labeled and hybridized onto BlueGnome 24sure BAC arrays. The normal embryos were replaced to women undergoing IVF. The abnormall embryos were fixed and analyzed by 12 probe FISH and reanalyzed if necessary in subsequent hybridizations for other chromosomes found to be abnormal by aCGH. Preliminary results have shown that full chromosome abnormalities were reliably diagnosed with a 6% error rate, but not so structural abnormalities. Thus, only full chromsome abnormalities were taken into account. Results- Five cycles of IVF and PGD were performed in women with a history of recurrent miscarriage. Thirty five embryos were biopsied, of which 3 did not produced aCGH results (9%). Twenty one embryos were classified abnormal by aCGH (65%); 13 had single or double aneuploidy events and 8 were chaotic. Eleven embryos were classified as normal and ten were replaced, the other having arrested in culture. The majority of abnormal embryos (19) were fixed and analyzed by FISH. The abnormalties detected by aCGH were confirmed by FISH in 95% of them. The 9 and 12 FISH probe would have classified 76%; and 81%, respectively, of embryos as abnormal. Conclusions- aCGH seems to detect 19% more abnormal embryos than FISH with 12 probes and with a 5% error for full chromosome abnormalities. We consider the test to be ready for clinical application of PGD, and now it remains to see if this technique will be supperior to FISH in improving pregnancy rates and reducing miscarriages.

## 1658/T/Poster Board #207

**Trophectoderm Biopsy, preimplantation aneuploid screening (PGS) and a fresh embryo transfer within an in vitro fertilization cycle (IVF) is a viable alternative to day-3 blastomere biopsy and PGS.** *A. Siegel[1], R. Pen[1], A. Benner[1], J. Liebermann[2], M. Katz-Jaffe[3], W. Schoolcraft[3], W.G. Kearns[1].* 1) Shady Grove Center for Preimplantation Genetics, 15001 Shady Grove Rd, Ste. 220, Rockville, MD 20850; 2) Fertility Center of Illinois, 900 N. Kingsbury, River Walk 6, Chicago, IL 60610; 3) Colorado Center for Reproductive Medicine, 10290 RidgeGate Circle, Lone Tree, CO 80124.

We determined whether trophectoderm biopsy and PGS for 10-chromosomes is a viable alternative to day-3 blastomere biopsy and preimplantation genetic screening.

Participating patients either had ≥ 3 frozen blastocysts or good quality day-4 or day-5 growing blastocysts in culture. All patients had an indication for PGS, primarily > 2 prior miscarriages. Biopsied trophectoderm cells (mean = 5) were fixed using a modified Carnoy's method and FISH was performed for chromosomes 13, 14, 15, 16, 17, 18, 21, 22, X and Y. All PGS results were complete within 24-hours of biopsy and only embryos normal for all tested cells and chromosomes were recommended for transfer.

One-hundred fourteen blastocysts were biopsied from 33 patients. Of the frozen blastocysts, 78% survived the thaw and 67% re-expanded. All trophectoderm cells from each embryo were successfully diagnosed. Forty-one percent (47/114) of the blastocysts were PGS normal. Of the 33 patients, 3 had no transfer due to the presence of an abnormal cell(s). Of the patients undergoing embryo transfer, there was a 70% (21/30) clinical pregnancy rate (CP) as defined by a fetal heartbeat and gestational sac. The biochemical pregnancy rate was 3% (1/30) and there were no miscarriages.

This study shows the feasibility and efficacy of doing a blastocyst biopsy and PGS with transfer within 24-hours of biopsy. The outstanding clinical pregnancy rate, low biochemical pregnancy rate and no miscarriages strongly suggests that blastocyst biopsy and PGS may be a less-invasive and more beneficial option to day-3 blastomere biopsy and PGS.

## 1659/T/Poster Board #208

**RESULTS OF 373 ICSI/PGD CYCLES IN POOR PROGNOSIS PATIENTS.** *E. TUTAR[1], M. GULTOMRUK[1], L. ERKAN[1], B. URMAN[2], N. ERCELEN[1].* 1) Genetics & Genomic Sciences Center, American Hospital, Istanbul, TURKEY; 2) Women's Health Center, American Hospital, Istanbul, TURKEY.

Objective: To present results of 373 ICSI/PGD cycles in poor prognosis patients with one of indications of advanced maternal age (AMA), recurrent implantation failure (RIF), recurrent spontaneous abortions (RSA), severe male factor (SMF) or translocation carrier (TRL). Materials and Methods: Aneuploidies: Embryos biopsied on day 3 were fixed on slide(s), hybridized with PB probe (Vysis,Inc.) and analyzed for chromosomes 13, 16, 18, 21, 22 at the first round. They were also hybridized with 4-Color CUSTOM Probe (Vysis, Inc.) and analyzed for chromosomes 15, 17, X and Y at the second round. Translocations: Metaphases derived from peripheral bloods of carrier individuals were analyzed for chromosomes involved in translocation. Blastomeres biopsied from day 3 embryos were analyzed for chromosomes involved in translocation and for common aneuploidies (13, 18, 21, X, Y). Euploid or normal (balanced) embryos were transferred on day 5. Prenatal diagnosis was recommended in case of pregnancy. Results: 2087 embryos were analyzed in 373 ICSI/PGD cycles. 1955 (93.7%) of them were diagnosed as normal (35.8%) or abnormal (64.2%). Average maternal age was 36.1. 5.6 embryos were analyzed and 1.7 embryos were transferred for each cycle from total 456 (23.3%) transferred ones. Clinical pregnancy was documented in 72 of 274 transferred cycles which was yielded 26.3% clinical pregnancy/ET rate. Implantation rate was observed as 18.3%. 64 healthy babies were delivered and there are 6 ongoing pregnancies. Most frequently observed aneuploidy was monosomies (44.7%) which were followed by trisomies (23.1%), polyploidies (19.7%) and nullisomies (12.5%). Discussion: Most common reason for early pregnancy loss is aneuploidy in oocytes or embryos which increases with maternal age and may be also increased in chromosomally normal couples with recurrent early pregnancy loss or repeated unsuccessful IVF cycles although morphologically high quality embryos were transferred. Therefore, PGD has been recommended for use in conjunction with IVF to select and transfer only chromosomally normal embryos and thereby to improve the clinical outcome (1). References: 1. Preimplantation genetic testing: a Practice Committee opinion, Fertil Steril_ 2008;90:S136-43. 2008 by American Society for Reproductive Medicine.

## 1660/T/Poster Board #209

**Genetic Problems of Assisted Reproductive Technology (ART) in Japan.** *N. Takeshita, T. Sekine, T. Taniguchi, A. Oji, M. Saigusa, H. Hayashi, Y. Mastue, A. So, Y. Katagiri, M. Morita.* Obstetrics & Gynecology, Toho Univ Sch Med, Tokyo, Japan.

The first birth of a child by in vitro fertilization (IVF) in 1978 was a landmark event not only in the field of medicine but also for the general public. On the other hand, some alarming issues including the genetic problems associated with reproduction technologies have also been reported. A total of 700 centers currently provide reproductive healthcare services in Japan, where one out of 60 babies is now born by ART procedures. Against this background, a long-term follow-up for newborns is indispensable from the viewpoint of genetic issues. When taking the propagation of variable genes to the next generation into account, one of the possible genetic problems of concern in such babies is microdeletion in the azoospermic factor (AZF) region of the long arm of the Y-chromosome, which may be transmitted through ICSI. The AZF region has been reported in many articles to be a complex structure known as the palindrome. Attention should also be paid to numerical and structural changes of the sex chromosome and autosome. Since around 2001, the existence of an important relationship has been reported between ART and epigenetic diseases such as changes in genome imprinting. The reprogramming of genetic expression may occur in the gametes and embryos in respective stages. According to previous reports, ART may also be related to such processes of reprogramming. In addition, a preimplantation genetic diagnosis, which has already been approved for certain indications in Japan, is now increasingly being carried out in Western countries. Aneuploidy screening for chromosomes is also now performed more frequently than the earlier genetic diagnosis.

**The 3-dimensional distribution of human chromosomes in sperm.** *T. Liehr[1], F. Hunstig[1], S. Bhatt[1,2,3,4], F. Pellestor[2,3,5], K. Mrasek[1], A. Weise[1], I. Simonyan[6], R. Aroutiounian[7], M. Manvelyan[1,6,7].* 1) Jena University Hospital, Institute of Human Genetics and Anthropology, Jena, Germany; 2) INSERM U847, Montpellier, France; 3) University of Montpellier I, Montpellier, France; 4) Baylor College of Medicine, Houston, Texas, USA; 5) Department of Reproduction Biology, CHU Montpellier, Montpellier, France; 6) Research Centre of Maternal and Child Health Protection, Yerevan, Armenia; 7) Department of Genetic and Laboratory of Cytogenetics, State University, Yerevan, Armenia.

Nuclear architecture studies in human sperm are sparse. By now performed ones were practically all done on flattened interphase nuclei. Thus, studies close at the in vivo state of sperm, i.e. on three-dimensionally conserved interphase cells, are lacking by now. Only the position of 14 chromosomes in human sperm was studied, yet. Here for the first time a combination of multicolor banding (MCB) and three-dimensional analysis of interphase cells was used to characterize the position and orientation of all human chromosomes in sperm cells of a healthy donor. We could show that the interphase nuclei of human sperm are organized in a non-random way, driven by the gene density and chromosome size. Overall, here we present the first comprehensive results on the nuclear architecture of normal human sperm. Future studies in this tissue type, e.g. also in male patients with unexplained fertility problems, may characterize yet unknown mechanisms of infertility. Supported in parts by DAAD (A0704616/Ref326), Evangelische Studienwerk e.V. Villigst, Ernst-Abbe-Stiftung, IZKF Jena and DFG (LI 820/9-1, 436 ARM 17/11/06, 436 RUS 17/88/06, LI 820/11-1, LI 820/13-1, LI 820/15-1, LI 820/21-1).

## 1662/T/Poster Board #211

**Identification of Copy Number Variants (CNV) Associated with Recurrent Pregnancy Loss.** *E. Rajcan-Separovic[1], D. Diego-Alvarez[2], W. Robinson[2], Y. Qiao[1,2], C. Harvard[1], C. Fawcett[3], C. Tyson[3], M. Stephenson[4].* 1) Dept Pathology (Cytogenetics), Child & Family Research Inst, Vancouver, BC, Canada; 2) Dept Medical Genetics, Child & Family Research Inst, Vancouver, BC, Canada; 3) Cytogenetic Lab, Royal Columbian Hospital, New Westminster, BC, Canada; 4) Dept Obstetrics and Gynecology, University of Chicago, Chicago, IL.

Recurrent early pregnancy loss (RPL), defined as two or more miscarriages of less than 10 weeks of gestation, affects 3-5% of couples trying to establish a family. In 40% of couples with RPL, no factor is identified, despite extensive evaluation. We initiated an array CGH study of miscarriages from couples with RPL to assess for submicroscopic chromosomal changes, termed copy number variants (CNVs), in chromosomally normal diploid (46,XX or 46,XY) miscarriages. Array CGH was performed on extracted DNA from the diploid miscarriages and on DNA from peripheral blood from both partners, to determine whether CNVs, if present, were de novo or inherited from one of the partners. Extensive demographics and obstetrical histories were obtained from the RPL couples, as well as embryopathology results from the miscarriages, to correlate the CNV results with clinical findings. Twenty diploid miscarriages from 16 couples with a history of RPL have been studied to date. Eleven unique, previously unreported CNVs were detected in 8 of the miscarriages and all were inherited from one of the partners. Five unique CNVs were detected in one of the partners but these CNVs were not found in the miscarriage DNA. The most intriguing candidate miscarriage CNVs found to date are: a) CNVs containing genes maternally imprinted in the placenta (inherited from female partners), b) CNVs occurring on the X chromosome (inherited from female partners and c) CNVs with a putative role in miscarriage (inherited from either partner). Copy number alterations of two candidate miscarriage genes maternally imprinted in the placenta, CTNNA3 (alpha T catenin) and TIMP2 (Tissue Inhibitor of Metalloproteinases 2), were screened for in a cohort of 200 women with RPL and 63 fertile controls (women giving birth after the age of 37 and with no history of infertility) using a Quantitative Multiplex Fluorescent PCR of Short Fragments (QMPSF) assay. Copy number alteration of CTNNA3 was identified in 2/200 of the RPL women and 0/63 fertile controls. Our preliminary results suggest that alterations of genes maternally imprinted in the placenta, such as CTNNA3, may be responsible for recurrent pregnancy loss in a small percentage of couples presenting with RPL. Array CGH appears to be a useful technology to identify novel biomarkers associated with recurrent pregnancy loss.

## 1663/T/Poster Board #212

**Molecular Study of Internal Apoptotic Pathway BAX and BCL2 Genes and Mitochondrial Genome in Idiopathic Repeated Pregnancy Loss.** *S. Seyedhassani[1,2], M. Houshmand[2], S. Kalantar[1], G. Modabber[2], A. Aflatoonian[1].* 1) Medical Genetics Dept, Res/Clinical Ctr Infertility, Yazd, Iran; 2) National institute for genetic engineering and biotechnology, Tehran, Iran.

Introduction: About 1 in 300 couples involve with Repeated Pregnancy Loss ( RPL ) and the main part of them remains unknown. Apoptosis plays a role in early human development and embryonic loss.The aberrant expression of apoptotic related genes is seen in RPL. It seems internal apoptotic pathway and mitochondria as a main core of it, have important role in fertilization and proliferation of the cells. Bax is an important nuclear gene in mitochondrial pathway of apoptosis.This protein forms a heterodimer with BCL2, and functions as an apoptotic activator. Material and methods: 335 consecutive cases were studied. Genetic counseling, clinical, paraclinical, and cytogenetic studies were done for each couple. We analyzed the familial pedigree of them and then screened the idiopathic cases. In total 96 females who were suffered from idiopathic RPL. 1-Four multiplex PCR are done on each sample for detection of mitochondrial deletions. 2-Mitochondrial D-loop part consisting of the hyper variable regions is analyzed by PCR-sequencing method. 3-Bax gene is evaluated by PCR-sequencing method for promoter region and all seven exons. 4-Bcl2 gene is evaluated by PCR-sequencing method for promoter region and PCR-SSCP for the exons. Results: 1-No mitochondrial deletions were found in 96 DNA samples. 2-D-loop region was evaluated by direct sequencing and we found 166 different variations in our study population. Among them, 95 variations were seen in RPL cases , 28 in control samples , and also 43 in both of them . 3-Change of A to G in promoter region of Bax gene was seen at nt. -55 in 93 females (96.87%) . Discussion: 1-Some of these nucleotide alterations might be involved in repeated pregnancy loss and could be included in a panel of molecular biomarkers for susceptibility in pregnancy loss and even failure of in-vitro fertilization. 2-A high rate of mutation in mitochondrial DNA in the D loop was found in samples from patients with RPL relative to healthy controls . 3-In seven SNPs that were found in case and control groups, we found significant difference between groups ($P<0.05$) (T16126C, T16189C, C16223T, C16294T, T16311C, T16362C, T16519C) . From the RPL group mutations, 15 SNPs were significant and four mutations was novel (A503G, A335G , T217C , C114ins.) 4-We believe that mutation in Bax gene will lead to early apoptosis.

***NAT2* haplotypes modify the effects of smoking, alcohol, and caffeine on fertility.** *K. Taylor[1], L. Murray[1], C. Small[1], M. Wilson[2], W. Tang[2], M. Bouzyk[2], M. Marcus[1].* 1) Dept Epidemiology, Emory Univ, Atlanta, GA; 2) Emory Biomarker Service Center, Atlanta, GA.

Purpose. The enzyme N-acetyltransferase 2 (*NAT2*) is responsible for metabolizing and detoxifying xenobiotics such as caffeine, tobacco smoke, pesticides, and prescription drugs. Common polymorphisms in the *NAT2* gene determine haplotypes that have slow or fast acetylator phenotypes and follow distinct metabolic pathways. The slow haplotypes have been associated with increased risk of bladder cancer, hepatocellular carcinoma, endometriosis, and other conditions. We investigated whether *NAT2* haplotypes affected time to pregnancy or modified the effects of xenobiotic exposures on time to pregnancy. Methods. We conducted a prospective cohort study investigating fertility in a population of 470 women office workers ages 20-41 who were at risk for pregnancy. Fertility was measured by counting the menstrual cycles until a pregnancy occurred (time to pregnancy). Information on exposures and covariates was collected in an intake interview and in daily diaries. Urine samples were collected and served as the source of DNA. Three *NAT2* polymorphisms (rs1799929, rs1799930, and rs1208) were genotyped in 319 women using the Beckman SNPStream system. Discrete survival analysis was used to determine whether *NAT2* haplotypes modified any effects of alcohol, smoking, or caffeine on time to pregnancy. Results. The 319 women were each followed for an average of 8 menstrual cycles, resulting in 124 pregnancies. 161 women carried two copies of the slow haplotype and were determined to be slow acetylators. Increasing levels of alcohol, smoking, and caffeine were all associated with increased time to pregnancy in a dose-response manner. The most fertile women were nonsmokers who consumed less than three alcoholic drinks per week and less than 200 mg of coffee per day. There was no main effect of *NAT2* haplotype or genotypes on time to pregnancy. Interaction was observed between the *NAT2* haplotype and smoking, alcohol, and caffeine; slow acetylators were more susceptible to the effects of all three exposures. These associations and interactions remained after adjustment for potential confounders. Conclusion. When studying the effects of xenobiotics on human health, it may be of scientific importance to incorporate genetic information about relevant metabolic enzymes. This is of particular importance when estimating the effects of these exposures among those with varying levels of genetic susceptibility.

**Comparison of Self-Contained Gene Set Methods for Gene Expression Studies.** *B. Fridley, G. Jenkins, J. Biernacka.* Hlth Sci Res, Mayo Clinic, Rochester, MN.

Gene set methods incorporate prior biological knowledge into statistical analyses and aid researchers in the interpretation of the results. Over the past few years, multiple approaches for gene set analysis have been proposed for expression and SNP data. The various methods can be divided into two types: competitive and self-contained. Benefits of the self-contained methods are that they can be used for genome-wide, candidate gene, or pathway studies; and these tests are more powerful then the competitive methods. We investigated numerous self-contained methods that can be used for both continuous and discrete phenotypes. To assess the power and type I error rate for the approaches, an extensive simulation study was completed in which the scenarios varied according to: correlation between genes within a pathway, number of genes in a pathway, number of associated genes, effect sizes, and the sample size. The following methods were assessed: tail strength (TS), principal component analysis (PCA) using either 80% of the explained variation threshold, first PC or top 5 PC, a global model, Kolmogorov-Smirnov (KS) test, Fisher's method based on asymptotic and empirical distribution. Results from simulations in which genes were independent showed that the KS and TS methods perform the worst for most scenarios, while the PCA using 80% variation threshold and Fisher's methods preformed the best for the majority of scenarios.

**ParaHaplo: A Program Package for Haplotype-based Whole-genome Association Study using Parallel Computing.** *K. Misawa, N. Kamatani.* RIKEN, Minato-ku, Japan.

Since more than one million of single nucleotide polymorphisms (SNPs) are analyzed in genome-wide association study (GWAS), multiple comparisons are problematic. To cope with multiple-comparison problems in GWAS, haplotype-based algorithms were developed to correct for the multiple comparisons at multiple SNP loci in linkage disequilibrium. The permutation test can also control problems inherent in multiple testing; however, the calculation of exact probability and the execution of permutation tests are both time-consuming. Faster methods for calculating exact probabilities and executing permutation tests are needed. We developed a set of computer programs for the parallel computation of accurate P values in haplotype-based GWAS. Our program, ParaHaplo, is targeted to workstation clusters using the Intel Message Passing Interface (MPI). We compared the performance of our algorithm with that of the regular permutation test on CHB and JPT of HapMap. ParaHaplo can detect smaller difference between two populations than SNP-based GWAS. We also found that parallel-computing technique made ParaHaplo 100-fold faster than non-parallel version of the program. The executable binaries and program sources are available at http://sourceforge.jp/projects/parallelgwas/?_sl=1.

## 1667/T/Poster Board #216

**Penalized estimation of haplotype frequencies from sibs.** *K. Zhang.* Dept Biostatistics, Univ Alabama at Birmingham, Birmingham, AL.

Haplotype inference plays an important role in association studies because haplotype based analysis can provide additional power for gene mapping but haplotypes of diploid individuals cannot easily be acquired by experiments. Therefore, many EM based methods have been developed to infer haplotypes and estimate their frequencies from unrelated individuals as well as general pedigrees. One drawback of these methods is that many rare haplotypes with low explanatory power can be included, especially in the presence of missing data. This problem becomes more severe when haplotypes are estimated from sibs because the completely missing genotypes of parents must be included in the analysis in order to take the relationship between sibs into account. To discourage the conclusion of rare haplotypes with low explanatory power, we propose a penalized method for haplotype inference. Specifically, a linear penalty is imposed to haplotypes with low frequency and the penalty levels off for haplotypes with frequency greater than a prespecified threshold. Then the penalized likelihood is used to infer haplotypes and estimate their frequencies by a general minorize-maximize (MM) algorithm. The partition-ligation technique is also implemented to handle large number of markers. We evaluate its performance and compare it with several available methods for haplotype inference from sibs through extensive simulations. Our results indicate that our method outperforms other available methods in most situations.

## 1668/T/Poster Board #217

**Use of Multiple Controls in a Genome-wide Association Study.** *A. Kuchiba[1], H. Sakamoto[1], S. Ohnami[1], A. Saito[2], S. Chiku[3], H. Totsuka[4], T. Yoshida[1].* 1) Genetics Division, National Cancer Center Research Institute, Tokyo, Japan; 2) Statistical Genetics Analysis Division, StaGen Co., Ltd., Tokyo, Japan; 3) Science Solutions Division, Mizuho Information and Research Institute, Inc., Tokyo, Japan; 4) Bioinfomatics Group, Research and Development Center, Solution Division 4, Hitachi Government and Public Corporation System Engineering Ltd., Tokyo, Japan.

Genome wide association studies (GWAS) have been widely adopted as a potentially powerful approach for common complex diseases. Most GWAS feature case-control designs, in which issues related to optimal and appropriate selection of control samples often arise. In case-control studies, researchers often find an opportunity to include more than one control series. This seems to be the case especially for GWAS, in response to the increasing demand for a large, high-power collaborative study by sharing data and/or samples. Some GWAS simply pool and use a "combined control" derived from different sources primarily to enhance the power. However, these association studies can have biased estimators caused by combining multiple sources. Another approach is to demonstrate a consistent association over multiple case-control studies between a single common case and several control populations; the observed associations then appear more robust, and the power may be also improved, as compared to a single case-single control comparison. However, the amount of information extracted will be overestimated, and the summary estimates may not be appropriate, because there is a correlation in the analyses due to the shared case population. Here we describe a method of generalized least squares to take the correlation into account. The method also considers between-control heterogeneity by a random effects model. Statistical performance of this screening approach will be compared with the simple "combined control" approach by simulation studies. An application of the proposed method will be illustrated using our GWAS data on the hospital-based gastric cancer cases (originated from various parts of Japan), one control population from a metropolitan area and the other from a single rural town. Although the basic of an association study is a nested case-control design, our approach will aid a proper and efficient use of precious control resources to prioritize the SNP-disease associations for the next stage of investigation.

## 1669/T/Poster Board #218

**Mediating effects of smoking and chronic obstructive airway disease on the relationship between the CHRNA5-A3 genetic locus and lung cancer risk.** *J. Wang, M.R. Spitz, C.I. Amos, A.V. Wilkinson, X. Wu, S. Shete.* Dept Epidemiology, UT MD Anderson Cancer Ctr, Houston, TX.

Recent genome-wide association (GWA) studies of lung cancer have shown that the CHRNA5-A3 region on chromosome 15q24-25.1 is strongly associated with an increased risk of lung cancer. However, different etiological explanations for the association between genetic variants and lung cancer have been provided. We applied rigorous statistical approaches, including mediation analysis and Bayesian network techniques, to examine the mediating effect of smoking behavior and self-reported physician-diagnosed emphysema on the relationship between the CHRNA5-A3 region genetic variant rs1051730 and the risk of lung cancer. Our results showed that rs1051730 is a causal factor for lung cancer, and it is associated with lung cancer through smoking behavior and COPD. We also showed that COPD is an intermediate phenotype that explains most of the effect of smoking behavior on lung cancer. Our results also suggested that smoking behavior is a mediator of the relationship between rs1051730 and COPD. Finally, we found that environmental tobacco smoke (ETS) is not a mediator for the relationship between rs1051730 and lung cancer among never smokers.

**A Two-Stage Genome-wide Association Study of Young-Onset Hypertension in Han Chinese Population of Taiwan.** *KM. Chiang[1,9], HC. Yang[2], YJ. Liang[2], CM. Chung[1], HY. Ho[3], CT. Ting[3], TH. Lin[4], SH. Sheu[4], WC. Tsai[5], JH. Chen[5], HB. Leu[6], WH. Yin[7], TY. Chiu[8], C. Fann[1], JY. Wu[1], SJ. Lin[6], YT. Chen[1], JW. Chen[6], WH. Pan[1].* 1) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 2) Institute of Statistical Science, Academia Sinica, Taipei, Taiwan; 3) Taichung Veterans General Hospital, Taichung, Taiwan; 4) Kaohsiung Medical University Chung-Ho Memorial Hospital, Kaohsiung, Taiwan; 5) National Cheng Kung University Hospital, Tainan, Taiwan; 6) National Yang-Ming University School of Medicine and Taipei Veterans General Hospital, Taipei, Taiwan; 7) Cheng Hsin Rehabilitation Medical Center, Taipei, Taiwan; 8) Min Sheng General Hospital, Taoyuan, Taiwan; 9) Graduate Institute of Life Sciences, National Defense Medical Center, Taipei, Taiwan.

Hypertension is a common and complex disorder. To identify its susceptibility genes may contribute to genetic screening and treatment for hypertension. Although many large scale genome-wide association studies have been performed, only a few studies have successfully identified the loci that are related to the hypertension, not to mention the scanty Asian studies. Young-onset hypertension (YOH) may be a more feasible target disorder to investigate than the late-onset one due to its stronger genetic component. We performed a two-stage genome-wide association study to map YOH susceptibility genes. In the first stage, we analyzed 400 YOH cases and 400 age and gender matched controls with BMI adjusted in all the analyses. Illumina HumanHap550 Genotyping BeadChip was used for genotyping. Two different analyses, exact conditional logistic regression with p-value combination tests combined a truncated product p-value procedure and a sliding-window procedure and with the genome-wide haplotype association tests combined haplotype trend regression and a sliding-window procedure, were used to identify potential SNPs which are validated in the second-stage by an independent set of 600 cases and 600 age and gender matched controls. In the conditional logistic regression analyses, genotype information was either treated as nominal (AA, AB and BB) or ordinal (1, 2 and 3) and all of the results were adjusted by the false discovery rate (FDR). Finally, there were 20 and 24 SNPs with strong association signals (the ranges of the $-\log_{10}$FDR are 5.16 to 7.57 and 6.18 to 10.35) selected by the p-value combination analyses with a window size of 7 and 9, respectively. A total of 36 genes were implicated and some of these genes have been related to the hypertension and cation channel or metabolism. In the haplotype analyses, four loci were selected for its strong association signals ($-\log10p > 5$) which flank 11 genes. Some of these genes are related to the angiogenesis. All of these SNPs are currently being validated with the additional 600 case-control pairs.

## 1671/T/Poster Board #220

**Nonsynonymous single nucleotide polymorphisms of essential hypertension in Korean.** *K. Hong[1], H. Jin[1], J. Lim[1], Y.S. Cho[2], M.J. Go[2], J. Jung[3], J. Lee[3], J. Choi[4], C. Shin[5], S. Lee[6], H.K. Park[1], B. Oh[1].* 1) Biomedical Engineering, Kyung Hee University, Seoul, Seoul, Korea; 2) Center for Genome Science, National Institute of Health, Seoul, Korea; 3) DNA Link, Inc., Seoul, Korea; 4) EQUISPHARM co., Ltd, Gyeonggi-do, Korea; 5) Department of Internal Medicine, Korea University Ansan Hospital, Gyeonggi-do, Korea; 6) Department of Internal Medicine, Kyung Hee University East-West Neo Medical Center, Seoul, Korea.

The 95 percent of hypertension, not knowing the obvious cause, is known as essential hypertension which is considered polygenic, resulting from accumulation and combination of a number of genetic and environmental risks. At present, no causative variation of essential hypertension has been reported. To identify causative variations influencing on blood pressure and hypertension, we investigated the association using 1,180 SNPs that cause amino acid change (nonsynonymous SNPs; nsSNPs) in Korean Association REsource consortium (KARE) from the Affymetrix 5.0 SNP array platform. The genotypes of 1,180 nsSNPs are tested for the association with systolic blood pressure and hypertensive status. Subjects were taken from two community-based independent cohorts, Ansung (n = 4,183) and Ansan (n = 4,659), South Korea. Five SNPs (rs16835244, rs2286672, rs6265, rs17237198, and rs7312017) were significantly associated with systolic blood pressure and replicated the associations in both cohorts. Among the five SNPs, two SNPs (rs16835244 and rs2286672) were maintained the association with hypertension risks. The SNP rs16835244 replaces 288th Ala of arginine decarboxylase by Ser and the SNP rs2286672 replaces 172nd Arg of phospholipase D2 gene by Cys. The multiple alignments of peptide sequences reveal the evolutionary conservation of the amino acid residues among orthologs from vertebrates. The ADC gene governs the metabolic pathway of L-arginine into agmatine. Agmatine, the decarboxylation product of arginine and known as a putative neurotransmitter, has been known to be involved in the control of vascular smooth muscle tone. The PLD2 also regulates the endocytosis of angiotensin II receptor, type 1 (AGTR1), and the impaired PLD2 regulation may play a role in the pathogenesis of hypertension. In this study, we applied a different strategy and identified candidate nsSNPs for the blood pressure as well as hypertension in two independent cohorts. Even though these finding are remained to be verified by other populations, the genetic variants will be helpful to guide the study of the underlying mechanism the regulation of the blood pressure as well as the development of the new therapeutic medicines.

## 1672/T/Poster Board #221

**Detecting causal genetic effects for survival.** *P.J. Lipman[1], J.D. Muehlschlegel[2], S.C. Body[2], C. Lange[1].* 1) Department of Biostatistics, Harvard School of Public Health, Boston, MA; 2) Brigham and Women's Hospital, Harvard Medical School, Boston, MA.

In this communication, we present a new statistical approach to detect causal genetic effects on survival after surgery in the presence of genetic associations that might influence survival as well and thereby could confound the results. Using causal inference methodology, the proposed method is based on standard statistical methodology and can be implemented straightforwardly. Using simulation studies, the theoretical properties of the approach are verified and the power is assessed for realistic scenarios. The practical relevance of the approach is illustrated by an application to survival after cardiac surgery.

## 1673/T/Poster Board #222

**Rapid exact likelihood-based quantitative trait association analysis in large pedigrees.** *T.D. Dyer, V.P. Diego, J.W. Kent Jr., H.H.H. Göring, J. Blangero.* Dept Genetics, SW Foundation Biomed Res, San Antonio, TX.

Quantitative trait association analysis in large pedigrees is a formidable computational task due to the necessity of taking the non-independence among relatives into account. With the growing awareness that rare sequence variants may be important in human quantitative variation, association study designs involving large pedigrees will increase in frequency due to the greater chance of observing multiple copies of rare variants amongst related individuals. Therefore, it is important to have statistical genetic test procedures that utilize all available information for extracting evidence regarding genetic association. Optimal testing for marker/phenotype association involves the exact calculation of the likelihood ratio statistic which requires the repeated inversion of potentially large matrices. In a genome-wide association context, such computation may be prohibitive for those without access to super-computing clusters. Several widely-used approximations attempt to reduce this computational burden but invariably lead to test statistics exhibiting reduced power. In this study, we provide a new approach for speeding up exact likelihood calculations for association analysis. For quantitative traits, analysis of genetic association involves joint modeling of a measured genotype fixed effect and residual polygenic random effects. The new method uses eigenstructure techniques to dramatically simplify the complex matrix manipulations that are required in full likelihood calculation. Following a spectral decomposition of the kinship matrix, the resultant orthogonal matrix of eigenvectors and their eigenvalues can be used to transform the original non-independent phenotypic data into uncorrelated data. A linear up-dating of this transformation that is a function of the current value of the estimated residual heritability is all that is required to reduce the multivariate likelihood function to a function of univariate likelihoods. For genome-wide association analysis, this procedure need only be performed once and the resulting transformation stored. The achieved reduction in computational burden is sufficient that researchers with large pedigrees need no longer resort to inefficient approximate methods. This approach also leads to an analytical method to rapidly calculate power functions for association in arbitrarily large complex pedigrees. These procedures are being added to our general statistical genetic computer package, SOLAR.

## 1674/T/Poster Board #223

**Using imputation of classical HLA alleles to fine map disease association signals within the MHC.** *S. Leslie, L. Moutsianas, A. Dilthey, P. Donnelly, G. McVean.* Department of Statistics, University of Oxford, 1 South Parks Road, Oxford, OX1 3TG, United Kingdom.

Genetic variation at classical HLA alleles is a crucial determinant of transplant success and susceptibility to a large number of infectious and autoimmune diseases. Large-scale studies involving classical type I and type II HLA alleles are currently limited by the cost of allele typing technologies. Recently we developed a statistical method using SNP variation within the MHC region to predict alleles at key class I (HLA-A, HLA-B and HLA-C) and class II (HLA-DRB1, HLA-DQA1, HLA-DQB1) loci. This uses a population genetic approach, combined with a database of individuals with known HLA and SNP alleles within the MHC region, to predict HLA alleles for individuals for which only SNP information is known. The method promises to facilitate large-scale experiments, including disease-association studies and vaccine trials, where detailed information about HLA type is valuable. To date investigation of the method has been limited to small databases (approximately 60 - 240 individuals) and previous studies have shown that increasing the database size results in a significant improvement in the accuracy of the method. We show results for a study using a database of over 2,000 individuals of European heritage with classical HLA typing for both Class I and Class II HLA alleles. We particularly consider the effect of using imputations on the power to detect associations in GWASs and the ability to fine map associations to particular HLA alleles or groups of alleles, and also to combinations across several HLA loci. We apply our method to detecting associations between HLA alleles and disease phenotypes and show results on the efficacy of using HLA allele imputation in such a setting. We also provide software to apply the method to SNP data derived from major SNP typing platforms.

## 1675/T/Poster Board #224

**On the genome-wide analysis of copy number variants in family-based designs: Methods for combining family-based and population based information for testing dichotomous or quantitative traits, or completely ascertained samples.** *A. Murphy[1,2,3], A. Rogers[1,2], J. Chu[1,2], B.A. Raby[1,2,3], C. Lange[2,3,4].* 1) Channing Laboratory, Brigham and Women's Hospital, Boston, MA; 2) Harvard Medical School, Boston, MA; 3) Center for Genomic Medicine, Brigham and Women's Hospital, Boston, MA; 4) Department of Biostatistics, Harvard School of Public Health, Boston, MA.

We propose a new approach for genome-wide association testing association between copy number variants (CNVs) and clinical phenotypes in family-based designs. Our new methodology integrates the population level and family level data available in family-based designs into a more powerful association test, which can be used to test either quantitative or dichotomous phenotypes, and if control CNV data are available from a public repository, can also be used in completely ascertained samples. We extend the framework developed by Won et al. (submitted) and Lasky-Su et al. (submitted) for testing association between SNPs and quantitative traits or affection status in completely ascertained samples, respectively, to the CNV probe intensity data, using the FBAT-CNV statistic introduced by Ionita-Laza et al. (2008). Like the methodology for testing SNP associations, our approach increases power of the FBAT statistic, while preserving the robustness of the test against population admixture and stratification. We show, via simulation studies, that our methodology boosts the power of the FBAT statistic to levels comparable to that of population-based designs. Using genotype intensities, we illustrate the practical relevance of our approach in a genome-wide association study of lung function in a population of child asthmatics.

## 1676/T/Poster Board #225

**Evaluation of robust statistical methods for small, real-world pharmacogenetic studies.** *N. Bing, L. Li, L. Budde, G. Kazeem, M. Nelson.* Statistical Genetics, GlaxoSmithKline, Durham, NC.

Pharmacogenetic research conducted during drug development is generally limited to data collected in clinical trials. As a result, sample sizes are often small and continuous endpoints of interest can be highly skewed, which presents several challenges for hypothesis testing. We have evaluated penalized maximum likelihood logistic regression (PMLLR) and permutation testing as robust methods for analysis of binary and continuous endpoints, respectively. Binary endpoints with small sample sizes can result in small or zero cell counts for many genetic variants. Statistical methods based on large sample assumptions, such as traditional logistic regression, are unreliable in this situation. Although Fisher's exact test is appropriate for small sample sizes, it does not allow for covariates. We found that PMLLR provides a robust test of genetic association when covariates are required and compares favorably with Fisher's exact test when analyzing datasets with very small sample size or highly polymorphic variants, such as HLA. Inflation of type I error is an obvious concern when fitting models with the skewed continuous endpoints. Although logarithm transformation and/or censoring are commonly applied in practice, they are often insufficient to remove such inflation, particularly when dealing with small sample sizes. Permutation testing with an ordinary least squares model, where the correlation between endpoint, covariates and genotype is preserved, provides the specific tests of interest and controls the type I error rate. Suitable transformation of the endpoint combined with permutation has greater statistical power than permutation tests using the untransformed endpoint. In general, for genetic association hypothesis testing, we recommend PMLLR for case control analyses, if covariates are needed in the model; and permutation test for quantitative trait analyses, if endpoint is skewed. The applicability of such robust statistical methods has been demonstrated in several of our real-world pharmacogenetic studies with reliable results.

**Identification of Association between disease and multiple markers within a candidate region via sparse partial least squares regression.** *H. Chun[1], D. Ballard[2], J. Cho[3,4], H. Zhao[1,3].* 1) Department of Epidemiology and Public Health, Yale University, New Haven, CT; 2) Program in Computational Biology and Bioinformatics, Yale University, New Haven, CT; 3) Department of Genetics, Yale University, New Haven, CT, USA; 4) IBD Center, Division of Gastroenterology, Department of Medicine, Yale University, New Haven, CT, USA.

Although genome wide association studies have led to the identifications of hundreds of genes underlying dozens of traits in recent years, most published studies have primarily used single marker-based analysis. Intuitively, more information will be utilized when multiple markers are jointly analyzed. As a result, many methods have been proposed in the literature for association analysis between traits and multiple markers. Among these methods, simulation and real data analyses have shown that it is often more effective to reduce the dimensionality of the markers in a region through principal components analysis of all the markers first, and then perform association analysis between traits and the first several principal components. However, one major limitation of this approach is that the principal components are derived purely from marker genotypes, without consideration of their relevance to traits. Furthermore, these components are constructed as linear combinations of all the markers even when only a limited number are potentially relevant to traits. In this presentation, we propose to use sparse partial least squares regression to derive the components that are linear combinations of only relevant markers. This approach is able to use information from both traits and marker genotypes. Extensive simulation and real data analyses on a Crohn's disease data set suggest the superiority of this approach over all existing methods.

## 1678/T/Poster Board #227

**Effect estimates in a 2-stage design: from genome-wide association to sequencing.** *L. Faye[1 2], S.B. Bull[1 2], L. Sun[1 3].* 1) Dalla Lana School of Public Health, Univ Toronto, Toronto, ON, Canada; 2) Prosserman Centre for Studies of Complex Traits in Human Populations, Samuel Lunenfeld Research Institute, Mount Sinai Hospital; 3) Department of Statistics, University of Toronto, Toronto, ON.

Genome-wide association studies (GWAS) of complex diseases and quantitative traits aim to detect regions of genetic association for further intensive study; however, tag SNPs may not entirely capture the variation at the underlying causal loci. Advancements in sequencing technology have made targeted sequencing in a region of interest a feasible way to localize a potential causal variant. A 2-stage design can limit costs by sequencing (Stage II) a subset of the GWAS (Stage I) samples in region(s) identified via significant tag SNPs. In this work we explore the consequences of 2-stage designs for the bias and variance of the genetic effect estimate (e.g. odds ratio) in both the GWA and sequencing stages. Selection bias in genetic effect estimation arises because the same sample is used for both gene discovery and effect estimation. This phenomenon is also known as the Winner's Curse and its effect in linkage analyses and in case-control association was demonstrated by Goring et al (2001) and Garner (2007), respectively. In the 2-stage design, the correlation (rho) between the tag SNP and causal variant, and the proportion (pi) of Stage I samples used for Stage II sequencing add complexities to the understanding of the Winner's Curse. We quantify the effect of the Winner's curse in the 2-stage design through rho and pi. We develop analytical expressions for the bias and variance of the effect estimates at the tag and causal SNPs, and evaluate them numerically for various 2-stage study designs. Besides genotyping cost, the effect of pi is mainly on the variance of the estimate, and if pi is too low, estimates in stage II may not be reliable due to large variance. When the causal SNP is rare, variance inflation is exacerbated by low minor allele frequency. The effect of rho, however, is less straightforward. In comparison to the genetic effect of a true causal variant, the effect estimate at a tag SNP is attenuated if rho is low (Dudbridge 2008). On one hand, as rho increases, selection at the tag SNP exerts greater influence on the estimate at the causal SNP, increasing bias. On the other hand, power increases as rho increases, which decreases the effect of selection. The balance between these two trends determines the degree of bias at the causal SNP estimate. Understanding the contributions of these factors is informative for proper study design as well as for analysis and interpretation of sequencing data.

## 1679/T/Poster Board #228

**Comparing imputation accuracy using local and HapMap haplotype reference panels in a candidate gene study of iron phenotypes.** *L. Turkovic[1], C.C. Constantine[1], J.B. Carlin[1,2,3], K.J. Allen[2,3], L.C. Gurrin[1].* 1) Centre for MEGA Epidemiology, University of Melbourne, Melbourne, Victoria, Australia; 2) Murdoch Children's Research Institute, Melbourne, Victoria, Australia; 3) Department of Paediatrics, University of Melbourne, Melbourne, Victoria, Australia.

Imputation of genotypes offers the opportunity to explore disease associations at untyped loci by exploiting the correlation implied by linkage disequilibrium between SNP genotypes observed in an external reference dataset (e.g. HapMap), where only some of these SNPs have been typed in the study samples. A related scenario is the availability of additional genotyping of a sub-sample of the participants (perhaps via re-sequencing), which can then be used as a reference dataset for imputing genotypes for SNPs that were typed on a subset of participants. We examine one such scenario in the HealthIron (HI) study, a sub-study of an Australian cohort of 31192 people of northern European descent. A random sample stratified by HFE was genotyped for 476 SNPs in 44 genes of iron metabolism. Samples from about 20% of participants (n=188) were subjected to further genotyping with re-sequencing of variants in exonic regions of some of these candidate genes. We compared the accuracy of genotype imputation for those participants without re-sequencing data using two different haplotype reference panels: one based on SNPs from HapMap (Phase II) and another using re-sequencing data from the HI study. Imputation was performed by using IMPUTE (Marchini, Nat Gen 07). Imputation accuracy was assessed by leaving out each SNP in turn, imputing genotypes for that SNP and comparing to the observed genotype, then calculating percentage of matches between predicted and observed. Three different reference panels were used: 1) HapMap SNPs 2) HI SNPs restricted to those available in HapMap 3) full HI data. For SNPs in the CYBRD1 gene (ferric reductase), scenarios 1) to 3) used 17, 17 and 26 SNPs respectively to build the imputation model. For SNPs where the probability of a correct call exceeded 0.9, 86%, 92% and 98% of imputed genotypes were called, with concordances of 97%, 99% and 99%. Improved concordance and less uncertainty in genotype calling was apparent for genes with larger number of SNPs. One such example is TF gene (transferrin), using 25, 25 and 43 SNPs respectively and calling threshold of 0.9: 92%, 93% and 94% of imputed genotypes were called and 97%, 99% and 99% of those were correct. Use of a local reference panel out-performed HapMap even when local data were restricted to SNPs appearing in HapMap only. The decreasing cost of sequencing makes establishing a local reference set feasible, and might improve the precision of estimated measures of association.

**Incorporating Covariates into Multipoint Linkage Disequilibrium Mapping in the Case-Parent Design.** *Y.F. Chiu[1], H.Y. Kao[1], K.Y. Liang[2], W.H. Pan[3].* 1) Biostatistics and Bioinformatics, National Hlth Res Inst, Zhunan, Miaoli, Taiwan; 2) Department of Biostatistics, Bloomberg School of Public Health, Johns Hopkins University, Baltimore, USA; 3) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan.

Most complex diseases are manifested by the joint effects of genes, environmental factors, and their interactions. Incorporating environmental factors and interactions into association mapping can help localize the locus of the disease. The case-parent design, which involves affected offspring and both of their parents, permits testing and estimating offspring- and maternally-mediated genetic effects. As a result, researchers often adopt this design to assess gene-environment interactions, and particularly for early onset diseases with rare disease alleles. The present study develops a robust multipoint fine-mapping approach to incorporate covariates into the association mapping of case-parent designs. Incorporating quantitative or qualitative covariates into this fine mapping through parametric and non-parametric modeling makes it possible to assess or account for main covariate effects and gene-covariate interaction effects while localizing the disease locus. Simulation results indicate that the efficiency in estimating the disease locus increases considerably when incorporating a covariate associated with the disease. This is especially true when the genetic effect of the disease locus is small. The proposed approach was applied to a young-onset hypertension data sample. The relative efficiency of estimating the locus of young-onset hypertension increases 110-fold after incorporating triglyceride (TG) into the association mapping while localizing the disease variant in the lipoprotein lipase (LPL) gene in the non-parametric model. By incorporating the information of a SNP into the fine-mapping, the proposed method further assesses the gen-gene interactions between the SNP and the disease locus using the parametric model. Results suggest that with the incorporation of covariates, the proposed method can not only improve efficiency in estimating disease loci, but also elucidate the etiology of a complex disease.

**Adjustment for multiple, correlated tests in pathway analysis of sex steroid hormone levels in pre- and postmenopausal women from the Breast and Prostate Cancer Cohort Consortium (BPC3).** *L. Beckmann[1], A. Huesing[1], V.W. Setiawan[2], R. Ziegler[3], S. Hankinson[4], R. Kaaks[1], BPC3 consortium.* 1) Dept Clinical Epidemiology, German Cancer Research Ctr, Heidelberg, Germany; 2) Department of Preventive Medicine, Keck School of Medicine, University of Southern California, Los Angeles; 3) Division of Cancer Epidemiology and Genetics, National Cancer Institute, Bethesda, MD; 4) Channing Laboratory, Brigham and Women's Hospital and Harvard Medical School, and Department of Epidemiology, Harvard School of Public Health, Boston, MA.

Background: In this study, we present a new approach to control the family-wise error rate in association analysis of traits with SNPs in multiple genes within a pathway, which requires careful adjustment for the number of tests as well as the correlation between the SNPs due to linkage disequilibrium (LD).

Data: The approach is evaluated in an analysis of the association of 700 SNPs in 36 genes in the sex steroid pathway in a pooled sample from the European Prospective Investigation into Cancer and Nutrition (EPIC) and the Nurses' Health study (NHS). Levels of the androgens dehydroepiandrosterone (DHEAS), androstenedione (Δ4), and testosterone (TESTO), as well as the estrogens estrone (E1) and estradiol (E2), and sex-hormone binding globulin (SHBG) were measured in blood samples of women who subsequently developed breast cancer and in matched control subjects (n=3,852).

Methods: We performed linear regression on each SNP for four models: recessive (rec), dominant (dom), codominant (cod) and log-additive (add), and defined $p_{min}=\min(p_{rec}, p_{dom}, p_{cod}, p_{add})$, the minimum p-value. For all SNPs within a gene, 1,000 permutations were used to adjust for multiple testing (number of SNPs and the four tests), and correlation due to LD using a step-down-min-p-algorithm. The adjusted p-values were Bonferroni-corrected by the number of genes. The minimal adjusted p-value among the SNPs within a gene was considered as the global p-value of this gene.

Results: Significant signals for association were found for pre- and post-menopausal women between SHBG levels and SNPs in the *SHBG* gene ($p<10^{-3}$). In postmenopausal women, we found globally significant results for association of E1 and E2 with SNPs in the gene encoding aromatase *CYP19* ($p<10^{-3}$), and in the follicle stimulating hormone receptor gene *FSHR* ($p<10^{-3}$). SNPs in the estrogen receptor gene *ESR1* were also found to be associated with estrone ($p<10^{-3}$). For DHEAS, we found significant associations with SNPs in *FSHR* ($p<10^{-3}$), and a SNP in the aldo-keto reductase gene *AKR1C3* ($p<10^{-3}$). Our results confirm previous findings regarding genes *SHBG* and *CYP19* while the associations with *FSHR* and *AKR3C1* provide new insights. The proposed procedure to control the family-wise error rate offers a practical approach to adjust for multiplicity in genetic pathway analyses.

## 1682/T/Poster Board #231

**Detection of foeto-maternal genetic effects: an evaluation of methods.** *M. Bourgey[1], J. Healy[1], M-H. Roy-Gagnon[1,2], D. Sinnett[1,3].* 1) Hemotologie-Oncologie, CHU Sainte-Justine, Montreal, PQ, Canada; 2) Department of Social and Preventive Medicine, Faculty of Medicine, University of Montreal, Montreal, PQ, Canada; 3) Department of Pediatrics, Faculty of Medicine, University of Montreal, Montreal, PQ, Canada.

Multifactorial diseases with early onset likely include complex genetic components involving both the affected individual's inherited genotype and parentally mediated mechanisms. The mother plays a crucial role not only as genetic parent but also as foetal environment. Hence, a maternal genotype may damage a foetus through its effect on the intrauterine milieu regardless of whether the genotype is present in the foetus. Distinguishing between maternal and foetal genetic influences is thus essential in studying the genetic basis of early onset disorders. In this study, we use simulation experiments to evaluate the performance of two approaches to test for foetal and maternal genetic effects: Cordell et al.'s stepwise conditional logistic regression (CLR) approach, which uses triads (affected offspring and their parents), and Weinberg et al.'s log-linear, likelihood-based hybrid design (HD). In addition to triads, the latter includes unrelated control individuals and their parents. Recruiting parents of controls can be very difficult and increases genotyping costs. Thus, we also investigate a log-linear, likelihood-based approach that does not include parents of controls (HD-NPC). We use an ongoing study of an early-onset complex disease (Acute Lymphoblastic Leukemia) to guide our simulations. We investigate the type I error and power of the different approaches to detect the genetic effects of the child, the mother, and the foeto-maternal interaction. Since the main drawback of not having the parents of the controls is the need to assume mating symmetry, we also assess the impact of mating asymmetry on the performance of the different methods. We simulate varying levels of mating asymmetry based on a statistic that we developed to measure mating asymmetry. In practice, when choosing study designs and analytical approaches, investigators need to compromise between accuracy and power and feasibility of the design in terms of sample ascertainment and costs. Our results provide useful information to guide investigators studying foeto-maternal genetic effects.

**SNPs as epidemiological tools in Mendelian Randomization studies of the role of biomarkers in disease.** *T. Frayling[1], J. Perry[1], The. DIAGRAM1 consortium[10], G. Paulisso[2], T. Sparso[3], C. Langenberg[4], H. Grallert[5], C. Palmer[6], A. Morris[6], V. Steinthorsdottir[7], A. Jackson[8], M. Boehnke[8], T. Hansen[3], O. Pedersen[3], T. Illig[5], N. Wareham[4], I. Barroso[9], M. McCarthy[10], L. Ferrucci[11], M. Weedon[1].* 1) Genetics of Complex Traits, Peninsula Medical School, University of Exeter, UK; 2) Department of Geriatric Medicine and Metabolic Diseases, Second University of Naples, Naples, Italy; 3) Institute of Biomedicine, University of Copenhagen, Denmark; 4) Medical Research Council (MRC) Epidemiology Unit, Addenbrooke's Hospital, Cambridge, UK; 5) Helmholtz Zentrum Muenchen. German Research Center for Environmental Health Institute of Epidemiology, Germany; 6) Ninewells Hospital and Medical School, University of Dundee, Scotland, UK; 7) Decode genetics, Iceland; 8) Centre for Statistical Genetics, Ann Arbor, Michigan, USA; 9) Metabolic Disease Group, Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK; 10) Oxford Centre for Diabetes, Endocrinology and Metabolism, Headington, Oxford, UK; 11) Gerontology Research Center, National Institute on Aging, Baltimore, Maryland, United States of America.

Many circulating biomarkers are associated with metabolic diseases such as type 2 diabetes but it is not known if altered levels of biomarkers causally influence diseases, or are the result of confounding or secondary to disease. Recent GWAS studies have identified common SNPs near the IL18, SHBG and BCMO1 genes that are robustly associated with circulating levels of IL18, SHBG and Beta-Carotene respectively. We aimed to use the principle of Mendelian Randomization to test the hypothesis that gene variants known to alter circulating levels of biomarkers increase the risk of type 2 diabetes, to the extent expected given the correlations between gene variants and biomarker levels and biomarker levels and Type 2 diabetes. We used data from 1200 members of the InCHIANTI study to estimate the correlation between biomarkers and type 2 diabetes. We next used type 2 diabetes case control studies consisting of 4107 cases and 5187 controls from the DIAGRAM consortium, and, where there was initial evidence of association (p<0.01), a total of 20,394 cases and 28,470 controls. A 1 standard deviation (SD) increase in IL18, Beta-Carotene and SHBG levels was associated with type 2 diabetes odds ratios of 1.65 (1.36-2.02), 0.68 (0.56-0.82) and 0.73 (0.59-0.89), respectively. The IL18 (rs2250417), BCMO1 (rs6564851) and SHBG (rs1799941) variants were associated with 0.28, 0.27 and 0.21 per-allele SD increases in IL18, Beta-carotene and SHBG levels respectively. Observed odds ratios for IL18 and BCMO1 variants with type 2 diabetes were 1.00 (95%CI:0.99-1.03), P=0.39) and 0.98 (0.93-1.04) P=0.57) respectively, which were each less strong than the expected effects of 1.15 (1.09-1.21) and 0.90 (0.85 - 0.95). In contrast, using 20,394 cases and 28,470 controls, the observed odds ratio for the SHBG variant and type 2 diabetes was 0.93 (0.91-0.96) P=0.000001, which was consistent with the expected effect. In conclusion, Mendelian randomization studies provide preliminary evidence that raised SHBG levels causally reduce the risk of type 2 diabetes, but that raised levels of Beta-Carotene and IL18 do not. Mendelian randomization represents another way in which GWAS-findings can contribute to improved biological insights of disease.

## 1684/T/Poster Board #233

**Avoiding the high Bonferroni penalty in genome-wide association studies.** *X. Gao[1], L.C. Becker[2], D.M. Becker[2], J.D. Starmer[3], M.A. Province[1].* 1) Div Statistical Genomics, Washington Univ, St Louis, MO; 2) Department of Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 3) Department of Genetics, University of North Carolina at Chapel Hill, Chapel Hill, NC.

A major challenge in genome-wide association studies (GWASs) is to derive the multiple testing threshold when hypothesis tests are conducted using a large number of single nucleotide polymorphisms. Permutation tests are considered the gold standard in multiple testing adjustment in genetic association studies. However, it is computationally intensive, especially for GWASs, and can be impractical if a large number of random shuffles are used to ensure accuracy. Many researchers have developed approximation algorithms to relieve the computing burden imposed by permutation. One particularly attractive alternative to permutation is to calculate the effective number of independent tests, Meff, which has been shown to be promising in genetic association studies. In this study, we compare recently developed Meff methods and validate them by the permutation test with 10,000 random shuffles using two real GWAS data sets: an Illumina 1M BeadChip and an Affymetrix GeneChip® Human Mapping 500K Array Set. Our results show that the simpleM method produces the best approximation of the permutation threshold, and it does so in the shortest amount of time. We also show that Meff is indeed valid on a genome-wide scale in these data sets based on statistical theory and significance tests. The significance thresholds derived can provide practical guidelines for other studies using similar population samples and genotyping platforms.

**Finding Unique Filter Sets in PLATO: Preparation for Efficient Interaction Analysis.** *B. Grady, S. Dudek, M. Ritchie.* CHGR, Vanderbilt Univ, Nashville, TN.

In the current era of genetic research, genome wide association studies (GWAS) are frequently used in an attempt to identify common genetic variants that predispose to risk for disease. Although the genotyping technology used to implement GWAS has progressed rapidly, the analysis methodologies for detecting associations has lagged behind. In particular, the methods to detect interactions between multiple variants in GWAS datasets have not been well developed. It is possible that the estimated heritability of many common diseases could best be explained by interactions between multiple susceptibility loci. The Platform for the Analysis, Translation, and Organization of large-scale data (PLATO) is a filter-based method which brings together many analytical methods in an effort to solve this problem. It allows a user to filter a dataset down to a subset of the original genetic variants before running subsequent methods, which may be especially useful for interaction analysis. In order to streamline PLATO for the efficient analysis of data, we wanted to determine which of 24 analytical filters were producing partially or fully redundant results. Using a kappa score to identify agreement between filters, we were able to group the methods into 4 meta-groups. We then tested the MAX statistic as put forth by Sladek et al. [Sladek et al., Nature 445:881-85 (2007)]. In a simulation study, one filter from each of the four meta-groups were selected and then run on 100 datasets containing effects on the order of an odds ratio of 1.5 as additive, dominant and recessive single-locus effects and a total of 1000 SNPs. They were also run on 1000 datasets containing no effect to determine the Type 1 error rate of the approach. To find the MAX statistic, the four filters were run on each SNP in each dataset and the smallest p-value among the four results was taken. Subsequently, one thousand permutations were performed to build a null distribution to compare the initial result against. In this way, the power of the MAX statistic was determined for detecting each of the three effects. The Type 1 error and false positive rates were also examined. The results show that the PLATO approach with the MAX statistic has higher power to find all types of effects and a lower false positive rate than any of the individual filters alone. In the future we will extend the concept of PLATO with the MAX statistic to interaction analyses.

## 1686/T/Poster Board #235

**How to Select the Covariates for a Propensity Score Approach to Correction for Population Stratification Bias?** *H.-Y. Huang, L.-Y. Wang, W.-C. Lee.* Institute of Epidemiology, College of Public Health, National Taiwan University, Taipei, Taiwan.

The case-control association study has gained in popularity for mapping disease-susceptibility gene(s) of complex human diseases. However, the study is prone to population stratification (PS) bias, which is an issue if both the allele frequencies and the disease prevalences vary across population strata. A genomic propensity score (GPS) approach (Zhao et al, 2009) had been proposed to correct for the PS bias that considered both genetic (null markers) and non-genetic factors (confounders such as age, sex, gender, exposure status of smoking, drinking, and race). In general, the non-genetic factors, say, the environmental exposures, include (a) risk factors, which are associated with the disease under study and (b) null exposures, which have no effect on the disease under study. These environmental exposures can be measured and defined clearly and easily. In this paper, we propose a propensity score approach to correct for PS bias that focuses on the “null exposures”. We compare our method with GPS. Also, the evaluation of the number of null exposures used in the propensity score approach and the characteristics of the null markers are studied in this paper. We conduct simulation studies to evaluate the performance of this method. Our results show that even if the propensity score method considers only a group of null exposures that have no effect on the disease, the PS bias can still be well adjusted for and be consistently corrected. The more null exposures used in the estimation of propensity scores, the greater the bias reduction can be. We also find that in certain situations, adjusting for the risk factors in a genetic association study can increase the magnitude of PS bias instead of decreasing it. In summary, by adjusting for the propensity scores based on the null exposures, our method provides a convenient and robust tool for obtaining almost unbiased estimates of population-based genetic association studies.

## 1687/T/Poster Board #236

**Admixture Mapping Provides Evidence of Association of loci on chromosome 1 with obesity.** *S.J. Kang[1], J.L. Butler[2], B. Tayo[3], G. Lettre[4], C.W.K. Chiang[2], R. Hackett[5], C. Guiducci[5], T. Nguyen[5], T. Feng[1], A. Adeyemo[6], C. Rotimi[6], A. Luke[3], H. Lyon[2], J. Hirschhorn[2,5], R. Cooper[3], X. Zhu[1].* 1) Dept Epidemiology & Biostat, Case Western Reserve Univ, Cleveland, OH, usa; 2) Children’s Hospital Boston and Harvard Medical School, MA, USA; 3) Loyola University Chicago Stritch School of Medicine, Chicago, IL, USA; 4) Montreal Heart Institute, Universite de Montreal, Montreal, QC, Canada; 5) Broad Institute of Harvard and MIT, Cambridge, MA, USA; 6) NIH Intramural Center for Genomics and Health Disparities, Bethesda, MD, USA.

Obesity is a heritable trait and it has been shown that African Ancestry is positively correlated with BMI. To identify genetic variants associated with obesity, we performed admixture mapping analysis with an obesity related trait-BMI using Affymetrix 6.0 platform in unrelated 247 high and 456 low BMI African Americans from Maywood, IL. We first identified 2606 highly ancestry informative SNPs (AIMs) from the SNPs that passed QC. Using the ancestry estimated at each AIM by the software ADMIXPROGRAM, we performed case-only and case-control admixture mapping analyses. We observed two loci with case-control Z-score >3.0 on chromosome 1 (rs12067308, Zcase-control=3.28) and chromosome 2 (rs14230, Zcase-control=3.14). The corresponding local maximum case-only Z-scores on chromosome 1 is 1.89 at rs12067308, and 1.18 at rs14230. We then restricted the analysis on a 18 Mb region based on 1 unit drop of case-control Z-score on chromosome 1 and tested the association of SNPs genotyped on Affymetrix 6.0. Further we only tested the SNPs with allele frequency difference >0.2 between HapMap CEU and YRI data. Among such 1850 SNPs, we observed 92 SNPs with p-value<0.05. We further performed association analysis for the 92 SNPs in 1188 unrelated Nigerian samples. We observed 2 SNPs (rs12065422 and rs782224) with p-values <0.05 and their risk directions are consistent with that in Maywood cohort. SNP rs12065422 was further genotyped in two independent African-American cohorts with sample sizes 756 and 494 respectively. Although not significant in each of the two cohorts, the meta-analysis of combining the 4 cohorts resulted in a p-value of 0.00029 for rs12065422. In summary, we did not identify any regions with very strong admixture signals, and within the region with the best signal, no SNPs were more strongly associated than expected by chance. It remains possible that the SNP with the best evidence for association, rs12065422, could be contributing to an admixture signal, but follow-up studies would be required to determine whether this SNP is associated with obesity.

## 1688/T/Poster Board #237

**On genome-wide association studies in family-based design: An integrative analysis approach combing ascertained family-samples with unselected controls.** *J. Lasky-Su[1,2,3], B. Himes[1,3], S. Weiss[1,2,3], C. Lange[1,2,3,4].* 1) Dept Med, Brigham & Womens Hosp, Boston, MA; 2) Center for Genomic Medicine, Brigham and Women’s Hospital, Boston, MA; 3) Harvard Medical School, Boston, MA; 4) Harvard School of Public Health, Boston, MA.

Large numbers of control individuals with genome-wide genotype data are now commonly available through various public and private databases. These controls individuals are often used in case-control genome-wide association studies (GWAS) to increase the overall statistical power. Often these controls are “unselected” for the disease of interest, meaning that the individuals have the disease of interest at the rate that is prevalent in the population. Although outside controls are commonly being incorporated into case-control GWAS, they have not yet been incorporated into a family-based setting. In this communication, we propose an approach to integrate unselected controls in the genome-wide analysis of an ascertained family-based sample. This analysis approach follows three steps. First, we perform a family-based association test. Second, we use the between family information in conjunction with the genotypes from properly matched controls individuals in a Cochran-Armitage (C-A) trend test. The p-values from the C-A trend test are then calculated by rank-ordering the individual test statistics in order to minimize the effects of population stratification. Third, we generate a combined p-value using the p-values from the first two steps. The proposed method fully utilizes the information in the controls to increase the power of the overall approach, while maintaining the original robustness of the family-based analysis against confounding. In the presence of population substructure, population-based adjustment methods can be incorporated in the approach to further increase the statistical power and limit population stratification. Simulation studies were used to assess the achievable power levels and compare them with other analysis approaches. We found that this analysis approach is substantially better than the standard family-based analysis and achieves power levels that are considerably higher than those of case-control designs with unselected controls. We illustrate the approach by an application to a genome-wide association analysis of asthmatic parent offspring trios and publically available control individuals.

## 1689/T/Poster Board #238

**A Phylogenetic Approach for Correction of Population Stratification in Genetic Association Studies.** *M. Li[1], L.-S. Wang[2].* 1) Department of Biostatistics and Epidemiology, University of Pennsylvania School of Medicine, Philadelphia, PA; 2) Department of Pathology and Penn Center for Bioinformatics, University of Pennsylvania School of Medicine, Philadelphia, PA.

The rapid development of genotyping technology and extensive cataloguing of SNPs across the human genome have made genetic association studies the mainstream for gene mapping of complex human diseases. For many diseases, the most practical approach is the population-based design with unrelated individuals. Although having the advantages of easier sample collection and greater power than family-based designs, unrecognized population stratification in the study sample can lead to both false-positive and false-negative findings, and might obscure the true association signals if not appropriately corrected. To solve this problem, we develop a novel method -- PHYLOSTRAT, which corrects for population stratification by using phylogeny constructed from SNP genotypes and principal coordinates from multidimensional scaling analysis. This hybrid approach efficiently captures both discrete and continuous population structures. By extensive simulations and the analysis of a synthetic genome-wide association dataset from the Human Genome Diversity Project, we show that our method outperforms several existing population stratification correction methods, including the genomic control approach and the EIGENSTRAT approach, in terms of controlling type I error rate and requiring fewer number of random SNPs for inference of population structure. Given the flexible nature and the hierarchical characteristic of phylogenetic trees, we anticipate that our method will well capture complex population structures in human populations, and thus provides a useful tool for genetic association studies.

## 1690/T/Poster Board #239

**Search of genes associated to skin test against Leishmania antigens.** *L.C. Pereira, L.M. Garrido, A.P. Fioretti, R.G.M. Ferreira, C.E.M. Kawamata, F.A.B. Santos, L.M.A. Camargo, H. Krieger.* University of São Paulo, São Paulo, Brazil.

Leishmania is a protozoan that may cause a tropical disease endemic at the Amazonian region, affecting about 2,000 individuals every year, with a mortality ratio close to 10%. In Brazil there are two forms of leishmania: cutaneous and visceral, both transmitted by the insect of the subfamily Phlebotominae. The test of Montenegro is an immunological technique of delayed skin hypersensitivity with 86% to 100% of specificity. It is performed by inoculating a small amount of leishmania antigen in the arm and after 48 hours it is possible to observe a papule. This papule is measured and if the papule size is equal or larger than 5mm the individual is taken as positive to leishmania infection. A sample composed of 60 individuals from Monte Negro (10° 15' S, 63° 18' W), located at the Amazonian region in the state of Rondonia was ascertained in order to verify the association of some genetic markers and Montenegro phenotypes leishmania susceptibility. Five Taqman (Applied Biosystems) SNP genotyping probes were chosen based on available literature informative. A case control test, showed that no significant association could be detected with all SNP (ds1084617 (P= 0.050); the same happened with ds1084293 (P=0.893); ds11693991 (P= 0.963); ds1747360 (P=0.714) and ds1659795 (P=0.769)). Although SNP ds1084617 showed a border line $X^2$ value, it should be tested in larger samples in order to clarify its effect (CAPES, CNPQ).

## 1691/T/Poster Board #240

**Evaluating the relationship between imputation error and statistical power in genetic association studies.** *L. Huang[1], C. Wang[1], N.A. Rosenberg[1,2].* 1) Center for Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI; 2) Department of Human Genetics, University of Michigan, Ann Arbor, MI.

Genotype imputation methods have afforded genome-wide association (GWA) studies significantly increased power to detect trait-associated genetic variants in high-density SNP genotype data, especially in populations that are genetically similar to populations in the International HapMap Project. The success of imputation-based GWAs can be partly attributed to the dramatic increase in the number of markers that can be tested for association compared to earlier tag SNP approaches. However, imputed genotypes are seldom known with certainty, and errors in these imputed genotypes - even at low rates - might substantially reduce the statistical power of an imputation-based association test. Using genome-wide SNP data (>500,000 markers) from 29 populations, we determined the relationship between genotype imputation error rates and the sample size inflation required to achieve statistical power at an imputed marker equal to that obtained if genotypes at that marker were known with certainty. For markers with common alleles (minor allele frequency > 0.1), imputation error rates of ~2-5% led to considerable inflation in the required sample size (~15-40%). In some African populations that are genetically distant from the HapMap populations, higher imputation error rates of ~8-10% led to a sample size increase as high as ~50-100%. In general, for markers with a minor allele frequency of 0.3, each 1% increase in the imputation error rate was associated with at least a ~7% increase in the required sample size. Our results will inform the use of imputation both in current SNP-typing studies and in forthcoming sequence-based studies, and they suggest that power and sample size calculations should account for a potentially considerable loss of power from even modest levels of imputation error.

## 1692/T/Poster Board #241

**A Novel Association Test for Analysis of Admixed Populations.** *X. Wang[1], X. Zhu[2], C. Li[3], M. Li[1].* 1) Department of Biostatistics and Epidemiology, University of Pennsylvania, Philadelphia, PA; 2) Department of Epidemiology & Biostatistics, Case Western Reserve University; 3) Department of Biostatistics, Vanderbilt University.

Admixed populations offer a unique opportunity for mapping complex human diseases that have large disease allele frequency differences between the ancestral populations. However, association analysis in such populations is challenging because population stratification caused by local ancestry differences between cases and controls may lead to spurious association. This problem can be exacerbated in genome-wide association studies, which typically involve large numbers of subjects. It is thus urgent to develop statistical methods for association analysis of admixed populations. Here we develop a novel association test that simultaneously utilizes information provided by SNP marker genotypes and ancestry informative markers (AIMs). Our method is based on a retrospective likelihood framework which models the conditional distribution of a test SNP given disease status of a study subject and genotypes of AIMs surrounding the test SNP. The parameters involved in the likelihood include allele frequency and penetrances at the test SNP for each of the ancestral populations. This retrospective likelihood allows us to explicitly model local ancestry differences between study subjects and thus eliminates the effect of population stratification at the test SNP. To estimate local ancestry, we use ANCESTRYMAP. We then test for association by a likelihood ratio test. To evaluate the performance of our method, we conducted simulations and compared with the simple allelic and genotypic association tests, and the multi-dimensional scaling (MDS) approach which adjusts for global ancestry defined by principal components obtained from AIMs. Our results indicate that both our method and the MDS approach yield correct type I error rates when there is population stratification at the test SNP. Since our method adjusts for the local ancestry while the MDS approach considers the global ancestry, we will conduct further investigations to evaluate performance of these two approaches when the local ancestry is different from the global ancestry. We note that compared to other approaches, our method is flexible. With the proposed likelihood framework, we can easily extend our method to the analysis of family data and quantitative traits. We believe that this novel method will provide a useful tool for the analysis of admixed populations.

**Univariate/Multivariate Genome-Wide Association Scans Using Data from Families and Unrelated Samples.** *L. Zhang[1,2], Y-F. Pei[1,2], J. Li[2], C.J. Papasian[2], H-W. Deng[1,2,3].* 1) The Key Laboratory of Biomedical Information Engineering, Ministry of Education, Institute of Molecular Genetics, School of Life Science and Technology, Xi'an Jiaotong University, Xi'an 710049, P. R. China; 2) Basic Medical Sci, UMKC Sch Medicine, Kansas city, MO; 3) Center of System Biomedical Sciences, Shanghai University of Science and Technology, Shanghai 200093, P. R. China.

As genome-wide association studies (GWASes) are becoming more popular, two approaches, among others, could be considered to improve statistical power for identifying genes contributing subtle to moderate effects to human diseases. The first approach is to increase sample size, which could be achieved by combining both unrelated and familial subjects together. The second approach is to jointly analyze multiple correlated traits. In this study, by extending generalized estimating equations (GEEs), we propose a simple approach for performing univariate or multivariate association tests for the combined data of unrelated samples and nuclear families. In particular, we adjust for population stratification by integrating principal component analysis and transmission disequilibrium test strategies. In addition, the proposed method allows for multiple siblings as well as missing parental information. Simulation studies show that the proposed test has improved power compared to two popular methods, EIGENSTRAT and FBAT, by analyzing the combined data, while correcting for population stratification. In addition, joint analysis of bivariate traits has improved power over univariate analysis when pleiotropic effects are present. Application to the Genetic Analysis Workshop 16 (GAW16) data sets attests to the feasibility and applicability of the proposed method.

## 1694/T/Poster Board #243

**Fast Model-Based Estimation of Ancestry in Unrelated Individuals.** *D.H. Alexander[1], J. Novembre[2], K. Lange[3].* 1) Department of Biomathematics, UCLA, Los Angeles, CA; 2) Department of Ecology and Evolutionary Biology, UCLA, Los Angeles, CA; 3) Departments of Biomathematics, Human Genetics, and Statistics, UCLA, Los Angeles, CA.

Population stratification has long been recognized as a potential confounding factor in genetic association studies. Estimated ancestries, derived from multi-locus genotype data, can be used as covariates to correct for population stratification. One popular technique for estimation of ancestry is the model-based approach embodied by the widely-applied program STRUCTURE. Another approach, implemented in the program EIGENSTRAT, relies on principal component analysis rather than model-based estimation and does not directly deliver admixture fractions. eigenstrat has gained in popularity in part due to its remarkable speed in comparison to STRUCTURE. We present a new algorithm and a program, ADMIXTURE, for model-based estimation of ancestry in unrelated individuals. ADMIXTURE adopts the likelihood model embedded in STRUCTURE. However, ADMIXTURE runs considerably faster, solving problems in minutes that take STRUCTURE hours. In many of our experiments we have found that ADMIXTURE is almost as fast as EIGENSTRAT. The runtime improvements of ADMIXTURE rely on a fast block-relaxation scheme using sequential quadratic programming for block updates, coupled with a novel quasi-Newton acceleration of convergence. Our algorithm also runs faster and with greater accuracy than the Expectation-Maximization (EM) algorithm incorporated in the program FRAPPE. Our simulations also show that ADMIXTURE's frequentist estimates of the underlying admixture coefficients and ancestral allele frequencies are as accurate as STRUCTURE's Bayesian estimates. On real world datasets, ADMIXTURE's estimates are directly comparable to those from STRUCTURE and EIGENSTRAT. Taken together, our results show that (a) admixture's computational speed opens up the possibility of using a much larger set of markers in model-based ancestry estimation, and (b) its estimates are suitable for use in correcting for population stratification in association studies.

## 1695/T/Poster Board #244

**A new Family-based Association Test for multiple tightly linked markers.** *Y. Dai, J. Dong, R. Jiang.* Mathematical Science, Michigan Technological University , houghton, MI.

We proposed a new multi-marker test for a family-based association study of a genome-wide scan and candidate region detection. Multi-marker tests usually work better to detect an underlying genetic variant over a genomic region than the single test, especially for the detection of complex diseases, since multi-marker tests consider the joint information over the whole region. In this report, the novel multi-marker family-based association test is based on the genotype scores after wavelet smoothing which can be used to extract the maximum common variation from the multiple tightly linked markers. When multiple markers are correlated because of linkage disequilibrium (LD), we might expect that identification of the common variation would capture more of the genetic signal encoded in this region. The new Family-based Association Test regards the multi-marker genotypes in the specified region as a signal. After wavelet transformation, the signal would be transformed into the time-frequency space which is used to describe the signal in a more efficient way, since wavelet transform naturally deals with noisy signals like Genetic data. After using an empirical Bayesian thresholding with adaptability to the sparse and dense signals based on the spatial ordering of SNPs, the genetic signal over multi-markers could be compressed into the mortified genotype scores after wavelet smoothing. The new test is formed based on the phenotype and the adjusted genotypes to detect the association between the phenotype and these SNPs. Using wavelet smoothing can suppress noise automatically under different LD patterns and enable a significant amplification of the genetic variation, while it keeps the genetic information contained in the spatial ordering of SNPs. The new multi-marker family-based association test can be applied to a wide range for both qualitative and quantitative traits. It would be a potentially powerful method for family-based genetic study of multiple tightly linked markers and can also provide an alterative tool for the detection of underlying causative genetics variants. In the simulation study, we examine the type-I error and compare the power with other FBAT tests under different LD patterns. It has the correct type-I error rate when applied to data with population stratification and is more powerful than single-marker family-based test followed by Bonferroni correction. The proposed test is constantly superior when the parent traits are missing.

## 1696/T/Poster Board #245

**Assessing False Discovery Rate in Large-Scale Family Based Association Testing.** *W. Wang[1], I. Chang[1,2], L. Chuang[3], T. Quertermous[4], C.A. Hsiung[1].* 1) Division of Biostatistics and Bioinformatics, Institute of Population Health Sciences, National Health Research Institutes, Zhunan, Miaoli, Taiwan; 2) National Institute of Cancer Research, National Health Research Institutes, Zhunan, Miaoli, Taiwan; 3) Department of Internal Medicine, National Taiwan University, Taipei, Taiwan; 4) Division of Cardiovascular Medicine, Falk Cardiovascular Research Center, Stanford University, CA, USA.

We present a model-free approach to conditional false discovery rate (cFDR) for a large-scale simultaneous family based association tests (FBATs). When association between a set of markers in a candidate gene and a group of phenotypes is studied by FBATs, we indicate that a *joint* null hypothesis distribution for these FBATs can be obtained by the fundamental statistical method of conditioning on sufficient statistics for the null hypothesis. Based on the *joint* null distribution of the class of FBATs obtained, we use its conditional expected number of tail counts, given the central count, under the null hypothesis to define the cFDR. This conditional approach to false discovery rate takes advantage of the correlation between the FBATs. The usefulness of this approach is illustrated by providing false discovery rates to a genetic study on the association between *PTPN1* and a group of blood pressure related phenotypes, for which several significant findings were reported in testing the null hypothesis that the marker loci and the trait loci are unlinked.

## 1697/T/Poster Board #246

**Combining next generation sequencing and genotype imputation to identify rare risk variants in common complex disorders.** *S. Zöllner[1,2,3], M. Zawistowski[1,3].* 1) Dept Biostatistics, Univ Michigan, Ann Arbor, MI; 2) Dept Psychiatry, Univ Michigan, Ann Arbor, MI; 3) Center for statistical Genetics, Univ Michigan, Ann Arbor, MI.

Results from genome wide association studies (GWAS) illustrate that common variants are insufficient to explain the heritability of most common traits. Rarer variants may be major contributors to common complex diseases and can now be evaluated using emerging next generation sequencing methods. Typically, statistical power is likely insufficient to evaluate rare causal variants individually; instead genes are assessed for an excess of rare variants among cases. Here, we introduce a novel method for identifying genes where the distribution of rare variants differs between cases and controls. The basic algorithm consists of three steps: First we select all rare polymorphisms and apply bioinformatics tools to infer functionality. As resequencing studies discover large numbers of rare variants, we assign weights to each variant to focus on variation that is likely to be functional. Second, we add the weighted minor allele frequency of all rare polymorphisms independently in cases and controls and thus generate a statistic summarizing the excess of rare variation in each group. Third, we assess significance by permutation, generating one p-value for every gene studied. Using simulated data, we identify the most powerful weighting scheme under several genetic models and show that our method is substantially more powerful than the commonly used private allele method. A major advantage of our method is that it can be applied even when only a subset of the data is sequenced and the rest is genotyped for a dense marker panel, for example, when candidate genes identified in a GWAS are subsequently sequenced in a subset of individuals from that study. By imputation, the rare variants that are detected by resequencing can be evaluated in the entire sample. As most imputation methods perform poorly for rare variants, we optimize an existing method (MACH). Based on this improved rare variant imputation, we show that including imputed genotypes increases the power of our test considerably. Finally, we illustrate how our method can be applied to existing GWAS data, by imputing rare variants genotyped in HAPMAP or the 1000 Genomes samples, and show results from two re-analyzed GWAS.

## 1698/T/Poster Board #247

**Regression multi-marker tests for gene-based genetic association analysis.** *S. Bull[1,2], Y. Yoo[1], L. Sun[2,3].* 1) Samuel Lunenfeld Res Inst, Mount Sinai Hospital, Toronto, ON; 2) Dalla Lana School of Public Health, Univ Toronto, Toronto, ON; 3) Dept of Statistics, Univ Toronto, Toronto, ON, Canada.

Background: Treating a gene as the unit of analysis may reduce the multiple testing burden and capture the effect of susceptibility genes more efficiently. The best analytic approach however depends on the underlying genetic model which is generally unknown; e.g. whether there is a single causal locus or multiple common or rare causal variants within a gene. Regression analysis of multiple SNPs can reveal individual SNP associations as well as provide global evaluation.

Methods: We examine tests based on a weighted linear combination of parameter estimates (LC-B) or test statistics (LC-Z) in multi-SNP regression analysis. The test statistics have central and non-central 1 df chi-square distributions under the null and alternative respectively, and the weights depend on the regression coefficient covariance matrix and SNP correlation. However, because the LC tests lose power if the SNP effects have opposite direction, we propose multi-bin tests (MLC-B and MLC-Z) which formulate the linear combination within each bin constructed by SNPs in close linkage disequilibrium ($r^2$>0.5). We compare these methods with other multi-marker tests: the multi-df generalized Wald test, and the 1 df minimum P test adjusted for multiple testing according to test statistic correlations. Numerical and simulation studies were based on HapMap genotype/haplotype data combined with specification of alternative genetic models involving multiple causal loci for a quantitative trait. We assigned the quantitative trait given the haplotype configuration at the causal loci, assuming a normal trait distribution. Using observed multi-SNP LD , we varied the selection of SNP markers included in the regression and observed the effect of the relationship between tag and causal SNPs. Power was calculated using the joint genotype distribution and the expected value of regression coefficients and covariance matrix. Type I error and power were verified empirically..

Results and Conclusions: The multi-marker LC tests were generally more powerful than the minimum P test in the case of multiple causal loci. Depending on the relationship between causal loci and the tag SNPs used in the analysis, LC test power can exceed Wald test power especially when many SNPs are included in the regression. The multi-bin LC tests were more robust to the problem of opposite SNP effects and generally slightly more powerful than the Wald test with fewer df.

## 1699/T/Poster Board #248

**A generalized family-based association test for dichotomous traits.** *W.M. Chen[1,2], A. Manichaikul[3], S.S. Rich[1].* 1) Center for Pubic Health Genomics, Univ Virginia, Charlottesville, VA; 2) Dept of Public Health Sciences, Division of Biostatistics and Epidemiology, Univ Virginia, Charlottesville, VA; 3) Depart of Biomedical Engineering, Univ Virginia, Charlottesville, VA.

Recent advances in genotyping technology make it possible to utilize large scale association analysis for disease gene mapping. Powerful and robust family-based association methods are crucial for successful gene mapping. We propose a family-based association method, the Generalized Disequilibrium Test (GDT), in which the genotype differences of all phenotypically discordant relative pairs are utilized to assess association within a family. The improvement of GDT over existing methods is three fold: 1) Information beyond first-degree relatives is incorporated efficiently, yielding substantial gains in power compared to existing tests; 2) The GDT statistic is implemented using a robust technique that does not rely on large sample theory, resulting in further power gains, especially at high levels of significance; and 3) Covariates and weights based on family size are incorporated. Advantages of GDT over existing methods are demonstrated by extensive computer simulations and by application to recently published large scale genome-wide linkage data from the Type 1 Diabetes Genetic Consortium (T1DGC). In our simulations, the GDT consistently outperforms other tests (such as PDT and FBAT) for a common disease and frequently outperforms other tests for a rare disease; the power improvement is > 13% in 6 out of 8 extended pedigree scenarios. All of the six strongest associations identified by the GDT have been reported by other studies, while only three or four of these associations can be identified by existing methods (including PDT, FBAT, TDT, 1-TDT, GEE, and MQLS). For the T1D association at gene *UBASH3A*, the GDT resulted in genome-wide significance ($P = 4.3\times10^{-6}$), much stronger than the published significance ($P = 10^{-4}$). The GDT is implemented in freely available software.

**Assessing gene-set enrichment in genome-wide association studies.** *L.S. Chen[1], U. Peters[1,3], C.M. Hutter[1], J.D. Potter[1,3], L. Hsu[1,2].* 1) Public Health Science, Fred Hutchinson Cancer Center, Seattle, WA; 2) Biostatistics, University of Washington, Seattle, WA; 3) Epidemiology, University of Washington, Seattle, WA.

Insight into genetic susceptibilities underlying complex diseases can be enhanced by considering functionally related set of genes simultaneously. We develop an algorithm called "Gene-set Ridge regression in ASsociation Studies (GRASS)", using a novel form of regularized logistic regression which is tailored to gene-set association analysis. Specifically, it selects concerted signals from all of the genes and jointly assesses their associations with disease risk. We show that this algorithm performs well in situations with a large number of predictors compared to sample size. We apply GRASS to a colon cancer genome-wide association study and identify TGF-beta signaling, p53 signaling and the colorectal-cancer pathway as the top statistically significant enriched pathways.

**Internal consistency of ancestry proportion estimates and genetic background variables.** *J. Divers[1], D.T. Redden[2], A. Amit[2], T.M. Beasley[2], R.J. Carroll[3], C.D. Langefeld[1], D.B. Allison[2].* 1) Dept Biostatistical Sciences, Section on Statistical Genetics and Bioinformatics, Wake Forest University Health Sciences, Winston-Salem, NC 27103; 2) Department of Biostatistics, Section on Statistical Genetics, University of Alabama at Birmingham, Birmingham, Alabama 35216; 3) Department of Statistics, Texas A&M University, College Station, TX 77843.

Population stratification and admixture are concerns in genetic association studies. Failure to adequately control for them in genetic association tests may lead to inflated type I error rates or loss of power. Structured association tests (SAT), where individual ancestry proportion estimates computed using ancestry informative markers (AIMs) or a measure genetic background computed using principal component analysis (PCA) are used as covariates to control for confounding, are widely applied in current genetic association studies. We have showed that the SAT approach can be cast in the general linear model framework, and as such implicitly assumes that the predictors are measured without error. However, independently of the approach chosen to estimate the underlying confounding effect, the resulting estimate should be seen as imperfect measurement of the true underlying confounding factor. Ignoring the measurement error inherent to these estimates may limit the ability to control for the underlying confounding factors. Measurement error correction methods offer a way to overcome this problem but require an a priori estimate of the measurement error variance. We have shown how Cronbach's alpha, a measure of internal consistency typically used for measuring the reliability of items that compose a scale, can be applied to provide an upper bound of this variance. Specifically, we showed that one can compute 22 estimates of individual ancestry proportions, one for each chromosome, and combine them to obtain a global measure of ancestry, and more importantly an estimate of the measurement error variance. We now show how this approach can be extended to account for the fact that chromosomes on the human genome do not have the same length and that longer chromosomes are likely to be more informative than shorter ones since they are likely to host more AIMs. We also show how the variance-covariance matrix for the measurement error component can be estimated when the admixed population result from mating between more than two ancestral populations, or when PCA is used to provide a measure of genetic background as is usually the case for the genome-wide association studies. Finally, we used simulation studies to validate the proposed methods.

## 1702/T/Poster Board #251

**Genome-wide association study identified novel susceptibility loci for Adiponectin in a population-based cohort of African Americans.** *A. Doumatey, A. Adeyemo, J. Zhou, G. Chen, D. Shriner, H. Huang, C. Rotimi.* Center for Research on Genomics and Global Health , NHGRI,National Institutes of Health, Bethesda, MD.

Adiponectin is exclusively produced by adipose tissue and has anti-diabetic and anti-atherosclerotic properties. Circulating adiponectin is decreased in obesity and type 2 diabetes. In vitro studies have reported that adiponectin production is regulated by other factors such as cytokines including tumor factor necrosis alpha (TNF-a), Interleukin-6 and glucocorticoids. In vivo studies of adiponectin regulation and adiponectin related pathways are not only few but lack a global and systematic approach. Thus, the physiological regulation of adiponectin remains unclear. In this study, we used the genome-wide association (GWA) strategy to systematically find gene network that may be associated with circulating adiponectin in a population-based cohort of African Americans enrolled from the Washington, DC metropolitan areas. We used the Affymetrix 6.0 fixed SNPs array to genotype a total of 898 unrelated African Americans. After quality filters, the analysis focuses on experimentally determined 806,047 autosomal SNPs. Plasma adiponectin was measured in all genotyped individuals using an immunoassay method (ELISA) from R&D systems. All the analyses were controlled for age, sex, BMI and ancestry proportion. We found significant associations with plasma adiponectin and multiple genetic variants including SNPs rs1982453 in the contactin-5 (CNTN5) gene, p=8.9x10-13, rs12279202 in importin-7 (IPO7) gene, p=3.01x10-10; rs11659639 near the Melanocortin 4 receptor (MC4R) gene, p=4.24x10-8; rs2238776 in the T-box 1 (TBX1) gene p=8.4x10-9; and rs13201744 near F13A1 gene=1.65x10-8; In addition, we observed significant associations with a cluster of 5 SNPs (rs16838686, rs6728303, rs7575199, rs12617342, rs16838663) in the THSD7B gene with p-values ranging from 4x10-6-8.7x10-7. In summary, we observed significant associations in two genes (IPO7, MC4R) that have been previously linked to obesity in multiple human studies. Also, we observed several novel associations that conceptually fall in pathways that are consistent with our knowledge of adiponectin functions and regulation pathways.

## 1703/T/Poster Board #252

**DNA-pooling enables cost-efficient genome wide association studies.** *M.A. Earp, M. Rahmani, A.R. Brooks-Wilson.* Genome Sciences Centre, University of British Columbia, Vancouver, British Columbia, Canada.

Genome-wide association studies (GWAS) using high-density microarrays are being used to map loci contributing to complex traits in human populations. The cost of individually genotyping all of the samples necessary for these studies limits the use of this approach. DNA pooling can be used in the GWAS design to dramatically reduce genotyping cost. Individual samples are physically pooled to create a composite DNA sample that is run on the genotyping array of choice. For each loci on the array, a pool allele frequency is calculated. The allele frequency difference between case and control DNA pools is used to nominate a small subset of loci for individual genotyping and association analysis. We have carried out a simulation study to determine how to design a maximally powered DNA-pool-based GWAS given practical limitations such as available samples and cost. The CaTS power calculator was used to calculate power values for individual and pool-based GWAS given different sample sizes and replicate arrays (Skol et al, 2006). For the pool-based GWAS simulations, the effective sample size, relative to the individual genotyping design, was calculated based on an empirical estimate of the error associated with pooling (MacGregor et al, 2008). In this simulation, given 600 samples per case and control, 4 arrays extracted 76% of the available information from the samples, with a 150-fold reduction in the number of arrays. The minimum genotype relative risk (GRR) detectable at 80% power was 1.65 for individual genotyping and 1.73 for 4 replicate arrays on a single DNA pool. A similar pool-based-GWAS using 4 arrays on 1000 cases/controls would have 94% power to detect a GRR = 1.65, and at 80% power to detect a GRR of 1.47. An inverse exponential relationship exists between the number of replicate arrays used and the information extracted from the available samples. As sample size decreases, fewer replicate arrays are needed to extract a given percentage of information from a pooled DNA sample. For example, 2, 13, and 35 replicate arrays would be needed to extract 90% of the information from the 200, 600, and 1000 cases and controls. In conclusion, by increasing sample size, DNA-pool-based GWA studies can remain highly powered but with dramatic reductions in cost (up to 100 fold). For 600-2000 cases and controls, increasing the number of replicate arrays beyond 15 does not yield significant gains in power. A higher density array could be considered to increase power.

## 1704/T/Poster Board #253

**Prioritizing "Multi-hit" Genes for Replication in GWAS for Specific Language Impairment (SLI).** *P.D. Evans[1], E. Gamazon[1], K. Kelsey[2], J.B. Tomblin[2], D.L. Nicolae[1], N.J. Cox[1].* 1) Genetic Medicine, The University of Chicago, Chicago, IL; 2) Communication Sciences and Disorders, Iowa City, IA.

The SCAN database (SNP and Copy number ANnotation; http://www.scandb.org) provides physical and functional annotation for SNPs and CNVs from public databases, pairwise and multilocus linkage disequilibrium (LD), as well as an indication of whether a SNP is a significant predictor of transcript levels for one or more genes (assessed in LCLs from CEU and YRI trios using the Affymetrix Exon 1.0 ST Array). Our research shows that SNPs reproducibly associated with complex human traits are also more likely to predict transcript levels for one or more genes. Thus, we have developed a "multi-hit tool" for use with the SCAN database that utilizes the physical, LD and transcript expression level information. We first annotated each SNP to a set of genes based on physical location and LD. A gene has physical/LD annotation contains the given SNP or contains a variant that is in LD with that SNP ($r2 > 0.5$); thus, a SNP may have none or several genes in its physical/LD annotation set. A gene has expression annotation to a SNP if the SNP is a predictor of transcript levels for that gene (at a user-specified p-value threshold). The multi-hit tool identifies all genes that are implicated by at least two independent SNPs ($r2 < 0.3$) in the input SNP list. We applied the multi-hit tool to results from a GWAS on specific language impairment, a highly heritable disorder characterized by deficits in language development in a child despite normal overall intelligence. Multi-hit gene lists were then created for 2 quantitative and 1 dichotomous phenotypes using associated SNPs with a p-value of 10-4 or better and a threshold for expression of 10-4. We assessed the significance of the resulting multi-hit gene lists by tallying the length of the multi-hit gene lists created with the multi-hit tool from 1,000 SNP sets created randomly from SNPs with the same minor allele frequency (within .05 bins) and included on the Affymetrix 6.0 platform used for the actual SLI GWAS. All 3 of the SLI phenotypes had significantly more genes multiply implicated than would be expected given the number of input SNPs and their allele frequency distribution. Among the genes most strongly implicated were: AGXT2L2, which has been implicated in autism, ATOH8, which has been shown to have a role in CNS development, KLF16, which plays a role in dopamine regulation, and NAB2, which plays a role in myelination.

## 1705/T/Poster Board #254

**Comprehensive haplotype association tests for genome wide data of myopia in Chinese schoolchildren.** *Q. Fan[1], Y-J. Li[2,3], LK. Goh[4], M. Seielstad[5], TL. Young[2,4], SM. Saw[1,6].* 1) Department of Epidemiology and Public Health, National University of Singapore, Singapore, Singapore; 2) Center for Human Genetics, Duke University Medical Center, Durham, NC; 3) Department of Biostatistics and Bioinformatics, Duke University Medical Center, Durham, NC; 4) Duke University-National University of Singapore Graduate Medical School, Singapore; 5) Genome Institute of Singapore, Singapore; 6) Singapore Eye Research Institute, Singapore National Eye Center, Singapore.

Context: The Singapore Cohort study Of the Risk factors for Myopia (SCORM) is a 10-year longitudinal study of refractive error change in school children aged 7 to 9 years. A total of 1116 DNA samples from SCORM Chinese participants were genotyped using the Illumina HumanHap 550 and 550 Duo Beadarrays. Genome wide single locus association analyses were completed. Objective: The goal of current study was to evaluate the haplotype association results using haplotype association score approaches and two haplotype sharing analytical tests. Methods: In this study, multiple haplotype approaches were performed on chromosomal regions where top four SNPs derived from single locus association tests. Multiple refractive error phenotypes were evaluated, such as spherical equivalent, myopia (SE < -0.50 D), and high-grade myopia (SE < -6.00D). We analyzed all SNPs for each chromosome, as well as tag SNPs. Haplotype tests were conducted for sliding windows of various sizes (2-5 markers) and step size of one SNP for each chromosome. Suggestive evidence of association was declared if the p-value from the haplotypes global test is <10e-5 and smaller than any single-locus p values. Univariate p-values of significant regions were examined for all makers. The analysis were carried out using PLINK and software R. The tag SNPs were extracted from whole genotyped SNPs by using Haploview. Results: Genotypes of 929 subjects with right eye SE data from the 4th annual study visit were analyzed (mean SE=-2.03D, SD=2.27). We identified 11,982 (chr 11) and 9299 (chr 13) tag SNPs. For chromosome 11, 7 haplotype regions on chr 11 were identified. The smallest haplotype global p value is 3.7x10e-15, which mapped across two gene regions. A cluster of significant haplotypes mapped to MYP 7 with a global p value of 9.1x10e-6 and two significant haplotypes (CAA and CAG). In addition, one tagSNP within this haplotype also showed single locus association (p= 1.0x10e-5). For chromosome 13, there were three regions with smaller global p values < 10e-10. A significant 3 tag SNP cluster was noted in a gene region involved in regulation of cell proliferation and cell motility and this association is mainly attributable to the haplotype GAG. Conclusions: These results demonstrate that haplotype association can identify myopia susceptibility loci, which were not necessarily discovered by GWAS single-locus approach.

## 1706/T/Poster Board #255

**Two-locus Analysis for Genome-wide Association Studies.** *S. Fang, Q. Sha.* Mathematical Sciences Dept, Michigan Technological Univers, Houghton, MI.

A genome-wide association (GWA) study is an approach that involves scanning markers across the whole genome to find genetic variations that contribute to a particular disease. The completion of the Human Genome Project in 2003 and the International HapMap Project in 2005 made it possible to find the genetic contributions to diseases. Considerable successes have been reported using this strategy. On the other hand, joint effects of genes play an important role in GWA studies, especially when detecting genes with moderate marginal effect but strong joint effect with other genes. However, to evaluate the joint effects requires heavy computing in GWA studies; and many multiple-marker tests have lower powers due to large degrees of freedom. In this article, we propose a novel two-stage approach, which is promising to analyze GWA studies, to address these problems. In the first stage, all single nucleotide polymorphisms (SNPs) are ranked by a single-marker test which can assess the association of a single SNP and the disease. Then we use a SNP clustering algorithm to group the highly correlated SNPs within a certain physical distance and select a SNP with the smallest p-value as a representative in each cluster. In the second stage, we test the two-locus joint effects based on the representatives with the highest ranking. We use a likelihood ratio test to test each two-locus joint effects under two-locus monotonic models. Comparing with a regular two-stage method, the proposed method not only does reduce the computational burden, it also increases the power by reducing the number of tests. We perform simulation studies to investigate the power and type I error under different scenarios. The results show that our two-stage approach is more powerful and efficient than a single-marker method and a regular two-stage analysis based on the genotypic test.

## 1707/T/Poster Board #256

**A Natural Aggregation Function for Pathway/Network-Based Approaches to GWAS and Gene Expression Analysis.** *D. Heckerman[1], C. Kadie[1], X. Zhang[1], J. Schymick[2], J. Ravits[3], B. Traynor[2], J. Listgarten[1].* 1) Microsoft Res, Los Angeles, CA; 2) Nat. Inst. on Aging, NIH, Bethesda, MD; 3) Benaroya Res. Inst., Seattle WA.

Early genome-wide association studies (GWAS) focused on the association between one or a small number of SNPs and a phenotype. Such studies were likely to miss associations where a large number of SNPs have a mild influence on the phenotype. Thus, following the approach of gene-set enrichment analyses (GSEA) where similar considerations apply, researchers have begun to look for associations based on sets of SNPs corresponding to pre-defined or learned gene sets. A necessary component of such approaches is an aggregation function that quantifies the relationship between a set of SNPs and the phenotype. We present a novel class of functions that naturally capture this relationship and can also be applied to GSEA. The central idea is to quantify the relationship between a set of SNPs and a phenotype by how well those SNPs predict the phenotype. Given SNP and phenotype data from a collection of individuals, we train a probabilistic classification/regression model that predicts the phenotype based on SNPs using data from some of the individuals, and apply this trained model on the remaining data, yielding a probability distribution over the phenotype for each individual. Finally, we test for associations between aspects of this distribution and the actual phenotype observations using standard methods to obtain a p-value for the SNP set. For example, when the phenotype is binary, we can test for an association between the probability of having the phenotype and actually having the phenotype. When the phenotype is continuous, we can test for an association between the mean of the predictive distribution and the outcome. The approach can also be applied to GSEA, where gene expression rather than SNPs are used to predict experimental conditions (or phenotype). We have applied this approach to GWAS with binary phenotype variables using data from KEGG to define SNP sets, 50/50 train/test splits, L1-regularized (lasso) logistic regression for the classification model, and the Mann-Whitney test for association. The approach yields uniformly distributed p-values on null data (obtained by permuting phenotype on real data). When applied to a GWAS data set from the US for the disease ALS, three pathways are significant at the 0.05 level after Bonferroni correction: neuroactive ligand-receptor, complement and coagulation cascades, and axon guidance. On an independent data set from Italy, these pathways show support with p-values of 0.005, 0.02, and 0.0002, respectively.

**Using public control genotype data to increase power and decrease cost of case-control genetic association studies.** *L.A. Ho[1], E.M. Lange[1,2].* 1) Dept. of Biostatistics, Univ North Carolina, Chapel Hill, NC; 2) Dept. of Genetics, Univ North Carolina, Chapel Hill, NC.

Genome-wide association (GWA) studies are a powerful approach for identifying novel genetic risk factors associated with human disease. A GWA study typically requires the inclusion of thousands of samples to have sufficient statistical power to detect single nucleotide polymorphisms (SNPs) that are associated with only modest increases in risk of disease given the heavy burden of a multiple test correction that is necessary to maintain valid statistical tests. The financial costs of performing a GWA study remains prohibitive for many scientific investigators anxious to perform such a study using their own samples. A number of cost remedies have been suggested, including the utilization of two-stage genotyping designs and, most recently, free genotype data on publicly available controls. Herein, we compare the statistical power of association studies using cases and screened controls to studies that are based only on, or additionally include, free public control genotype data. We describe a two-stage replication-based study design, which uses free public control genotype data in the first stage, composed of the complete set of SNPs, and follow-up genotype data on study controls in the second stage, composed of a reduced set of SNPs that demonstrate evidence for association in the first stage. In our two-stage design, the division of cases between the first and second stages is chosen to optimize power. We assess the impact of systematic ancestry differences between study cases and public controls and batch genotype effects, resulting from genotyping cases and public controls at different times and on different platforms, on our proposed two-stage design. We show that the proposed two-stage replication-based design can dramatically increase statistical power and decrease cost of large-scale genetic association studies, over association studies that do not utilize public control data, while preserving many of the advantages inherent when using an epidemiologically matched set of controls. We note that the proposed two-stage is particularly advantageous when the number of study controls is limited.

**A Fundamentally Different Approach to the Analysis of Genome-Wide Association Studies.** *W.D. Jones, J.S. Parker.* Statistics and Bioinformatics, Expression Analysis, Inc., Durham, NC.

Genome-wide association studies (GWAS) are population studies used to determine genomic regions significantly associated with disease susceptibility or other phenotypic traits. The GWAS analysis process is often laborious and is made unnecessarily difficult by the implicit requirement that all SNPs be genotyped as accurately as possible, often resulting in inaccuracies under various conditions (e.g., in the presence of copy number variants, low MAF, sample processing batch effects). We have developed a method that performs rigorous statistical association of SNPs with binary or continuous outcomes without the genotype call requirement, enabling more SNPs and more samples within a study to be analyzed, thus improving power. The method utilizes an analysis of the matrix decomposition of allelic intensity measurements, coupled with the identification and removal of latent but unwanted data "dimensions" that originate from hidden subpopulation structure and technical artifacts. In summary, by keeping the individual study measurements in their original form (i.e., in the intensity continuum), we are able to more robustly handle latent unwanted data structures within the GWAS dataset. Using this method, we will demonstrate the ability to simultaneously analyze associations of outcomes with SNP polymorphisms and copy number, whereas prior to this method, these analyses were typically performed separately. We will further demonstrate the utility of this method using publicly available GWAS datasets from CGEMS and WTCCC, where we confirm many of the same SNPs found significant in the initial published analyses (Wellcome-Trust Case-Control Consortium, *Nature*, 2007, Yeager et al., *Nature Genetics* 2007, Hunter et al., *Nature Genetics* 2007) while simultaneously finding new SNP associations, including copy number associations.

**Using Maximal Segmental Score to Estimate Region-specific P-values in Genome-wide Association Studies.** *Y.C. Lin[1,2], C.S.J. Fann[3], I.B. Lian[4], C.J. Chang[5].* 1) Institute of Biomedical Informatics, National Yang-Ming University; 2) Bioinformatics Program, Taiwan International Graduate Program, Academia Sinica, Taipei 115, Taiwan; 3) Institute of Biomedical Sciences, Academia Sinica, Taipei 115, Taiwan; 4) Department of Mathematics, National Changhua University of Education, Changhua 500, Taiwan; 5) Graduate Institute of Clinical Medical Sciences, Chang-Gung University, Taoyuan 333, Taiwan.

Background: Genome-wide association testing has become a powerful tool for identifying susceptibility genes underlying common complex diseases. The advent of genotyping technology has greatly increased marker density and the number of association tests performed. Multiple-test correction methods such as Bonferroni and FDR controlling method (FDRc) tend to be conservative and yield low power and various approaches had been proposed to overcome the problem. Aim: We proposed to use the method of maximal segmental score (MSS) to estimate region-specific p-value to locate genomic segments most likely harbor the disease gene via a simulation study. We compared MSS with other tests, eg. longest significance run (LSR) that also consider multiple markers simultaneously. Method: We considered a sequence of p-values obtained by marker-wise tests, eg. family- or population-based association. At the first step, the p-values were transformed into a sequence of scores according to a specific scoring system. Second, MSS was applied to scan the sequence of scores to identify the region with the highest cumulative score, ie. "maximal excursion", and the tail probability was calculated. The segment with a significant high score would suggest the existence of putative disease genes within the region. Simulation: We simulated SNP genotype data of 100 and 200 markers for 1000 trio families with allele frequencies 0.075, 0.1 and 0.15. The intermarker distance was generated from a left-truncated normal distribution with mean 6 kb and standard deviation 10.7kb. The location of the disease gene was assigned to be within the two central markers and the disease haplotype was comprised by 10 markers clustering around the disease gene. An additive disease model was assumed with a 10% penetrance and relative risks 1.5, 1.8 and 2. For comparison, four different MSS scoring systems were considered in transforming the test results. Result: Under the simulation scenario of 100 markers with allele frequency 0.075 and relative risk 1.8, the power was 0.79, 0.37 and 0.065 and false discovery rate was 0.02, 0.02 and 0.28 for MSS, LSR and Bonferroni, respectively. Results for other scenarios showed similar trend. Conclusion: The proposed MSS method has better power and lower false discovery rate comparing to region-c (e.g. LSR) and locus-specific tests (e.g. Bonferroni test, FDRc). The proposed MSS method provides an efficient exploratory tool for the analysis of dense genetic markers.

**Multiple Component Linear Mixed Models to Correct for both Population Structure and Expression Heterogeneity.** *J. Listgarten, C. Kadie, D. Heckerman.* eScience, Microsoft Res, Los Angeles, CA.

The presence of hidden structure is known to be a significant confounding factor in association studies, leading to spurious signal and loss of power when not properly accounted for. Because of the large scale of genome-wide association studies, these factors can often be learned from the data itself and then corrected for, using, for example, Principle-Components based approaches or probabilistic, generative models such as mixed models. Such methods have shown large success in a variety of experimental set-ups. On the one hand, some studies have used these approaches to account for hidden population structure such as race, or family and/or cryptic relatedness, where this structure is defined in the space of SNP data. On the other hand, some studies have used these approaches to account for "expression heterogeneity", that is, hidden structure defined in the space of microarray expression data and arising from batch effects, sample preparation, and environmental factors, for example. In eQTL studies, where one is looking for association between SNPs and expression phenotypes, both types of hidden structure can be present and thus both need to be accounted for. We propose a novel linear mixed model approach that uses two variance components to account for these two confounding factors: (1) an expression-based component, and (2) a SNP-based component. We show that on data containing both of these kinds of structure that our model performs better in terms of calibration of the test statistic (using quantile-quantile plots) and in terms of power of detection (using ROC curves), than models which tackle only one of these two confounding factors. Additionally, because two variance components are used beyond a residual variance component, SVD-based efficiency tricks useful for a single-component model can no longer be applied, and so we have devised alternative methods for efficiently computing the mixed models over large sets of hypotheses.

## 1712/T/Poster Board #261

**Shared controls for genome-wide association studies.** *S. Mukherjee[1,2], O. Kilpivaara[3], J. Simon[5], R. Kurtz[4], S. Olson[5], R.L. Levine[3,4], R.J. Klein[2].* 1) Gerstner Sloan-Kettering Graduate School of Biomedical Sciences, New York, NY; 2) Cancer Biology and Genetics Program, Memorial Sloan-Kettering Cancer Cancer Center , New York, NY; 3) Human Oncology and Pathogenesis Program, Memorial Sloan-Kettering Cancer Cancer Center , New York, NY; 4) Department of Medicine, Memorial Sloan-Kettering Cancer Cancer Center , New York, NY; 5) Dept of Epidemiology and Biostatistics, Memorial Sloan-Kettering Cancer Cancer Center , New York, NY.

Genome wide association (GWA) studies have been advocated as the method of choice for identifying genetic variants associated with complex diseases. In a classical GWA study design, cases and controls are matched for ethnicity, age, sex, socio-economic background and other environmental factors. Recently, the concept of shared controls for GWA study such as the blood donor cohort in the Wellcome Trust Case Control Consortium (WTCCC), has been shown to be a possible approach. We are interested in investigating the idea of using controls from published GWA studies as shared controls for our datasets. There is a critical need to develop methodologies to match cases with shared controls. Our objective is to determine power using shared controls and to develop an algorithm to allow the use of shared controls in GWA studies. In our investigation, we used controls from WTCCC as shared controls for a study of myeloproliferative neoplasms (MPN). In that study 217 cases were genotyped on the Affymetrix platform. Similarly, 2200 Cancer Genetic Markers of Susceptibility (CGEMS) study controls were used as shared controls for a study of pancreatic cancer. In that study, we had initially genotyped 174 cases and 177 controls on the Illumina platform. After performing quality control and removing ambiguous SNPs (A/T or G/C), a common set of SNPs was used to combine data from different sources. To determine potential population stratification biases that could be introduced by the shared controls, we carried out principal component analysis(PCA) using EIGENSTRAT. Analytical power calculation and simulation studies were performed. The result demonstrates the presence of population substructure in both studies. For MPN GWA study, 113 cases and 2959 control individuals who cluster on the first two principle components were selected for association test. Four SNPs with P-values $<10^{-7}$ including a JAK2 SNP rs10974944 were significantly associated with MPN risk after correcting for residual population stratification and multiple testing. The validation was done in an additional MPN cases to confirm our findings. We did not identify any significant marker associated with pancreatic cancer in the present study. In summary, a JAK2 SNP associated with MPN was identified using shared controls. Shared controls is a promising approach to increase the power of a study. Thus a systematic method to use shared controls will substantially lower time and cost of GWA studies.

**Estimation of the Null Distribution of Fisher's Exact Test P-values in GWA Studies.** *Y. Okada[1,2], K. Yamamoto[2], R. Yamada[1,3].* 1) Functional Genomics, Human Genome Center, Institute of Medical Science, the University of Tokyo; 2) Department of Allergy and Rheumatology, Graduate School of Medicine, the University of Tokyo; 3) Center for Genomic Medicine, Kyoto University.

The assessment of variable inflation of test statistics is an essential process to avoid the spurious associations when a large number of null hypothesis are tested, as in the case of genome wide association (GWA) studies. Variable inflation can be quantified by comparing the observed distribution of test statistics with their expected distribution under the null hypothesis without the inflation, such as genomic control method for $\chi^2$ test statistics. Because $\chi^2$ test is inaccurate and the use of exact test is recommended, when the contingency tables have low expected values, it is useful to correct variable inflation of exact test statistics (p-values). Although the null distribution of $\chi^2$ test statistics is arithmetically given, it is not the case for exact test p-values. Therefore we planned to estimate the null distribution of exact test p-values for a set of tables to be tested as a preparation step to correct variable inflation of them, as below.

For each table in the table set, we calculated the discrete probability density function (p.d.f.) of p-values that the marginal counts of the table could give, and averaged the discrete p.d.f.s of all the tables in the table set, which was our estimated null distribution of exact test p-values for the the table set. We generated simulation case-control genotype data of SNP markers, in a range of variable inflation (Wright's Fst=0~0.001). For each genotype data, we calculated Fisher's exact test p-values of the allelic 2x2 tables of the SNPs, and then estimated the null distribution of Fisher's exact test p-values.

Observed distributions of Fisher's exact test p-values indicated higher degree of variable inflation, as the value of Fst increased. On the other hand, estimated null distributions of Fisher's exact test p-values did not indicate significant differences among Fst. When no variable inflation was induced (Fst=0), observed distributions of Fisher's exact test p-values followed their estimated null distributions.

Our method estimated the null distribution of Fisher's exact test p-values without variable inflation, from the sets of the contingency tables that included the variable inflation.

**Utilizing known risk genes in GWA case control studies.** *M. Ostensson[1], A. Torinsson Naluai[2], S. Nilsson[1].* 1) Mathematical Statistics, Chalmers University of Technology, Gothenburg, Sweden; 2) Clinical Genetics, Gothenburg University, Gothenburg, Sweden.

When searching for genetic variants in common diseases we typically need to take the strongest environmental risk factors into account in order to increase the statistical power to detect the much weaker genetic effects that are present. For the same reason known genetic risk factors of importance can be utilized to increase the power of detecting weaker genetic effects. As an illustration of this we have reanalyzed the GWA from van Heel et al in 2007 for coeliac disease (CD). In CD some alleles at the HLA class II genes DQA and DQB are more or less mandatory. Together they form the molecules DQ2 or DQ8. While 95% av all CD patients carry these molecules, they are also present in about 25% of the population, so most carriers are healthy. From this observation it becomes clear that a case control study of CD in practice have three groups. Patients, HLA-negative controls (lacking both DQ2 or DQ8) and HLA-positive controls (carrying DQ2 or DQ8). For the frequencies of non-HLA alleles associated with CD we would typically find $p_1>p_2>p_3$ where $p_1$, $p_2$ and $p_3$ are frequencies in patients, HLA-negative controls and HLA-positive controls and where $p_2$ would be the population frequency. The most common statistic when searching for associated SNPs is based on a chisquare test in a 2x2 contigency table of of allele counts. Implicitly this test use the hypotheses $H_0$:$p_1=p_2=p_3$, while $H_1$ is $p_1{}^1p_2=p_3$. Due to the previous reasoning we suggest considering another hypotehsis $H_{1a}$:$p_1 > p_2 > p_3$ or $p_1 < p_2 < p_3$ which can be tested by isotonic regression or rather monotonic regression since we need a two-sided alternative. Another option would be to use an alternative like $H_{1b}$:($p_1 > p_2 > p_3$ or $p_1 < p_2 < p_3$) and $p_2=(p_1+2p_3)/3$ indicating that we assume HLA-negatives to be closer to HLA-postives than to patients. The optimal mixture will of course be model dependent. This can be tested by Cochran-Armitage trend test. Using some of the SNPs that were later confirmed in the extended study by Hunt et al in 2008 we compared the ranks and p-values for markers run and found e.g. rs11938795 and r21738074 moving from ranks 88 and 503 to 26 and 16 respectively, when isotonic regression was used. When a trend test was used the same SNPs changed their significance from $1.7x10^{-4}$ and $1.2x10^{-3}$ to $2.6x10^{-5}$ and $6.0x10^{-5}$ respectively.

**Whole Genome Association Analysis of Height Growth Curves Using Curve-Based Multivariate Distance Matrix Regression.** *R.M. Salem[1], E.N. Smith[2], S.S. Murray[2], M. Shaw[2], S. Srinivasan[3], W. Chen[3], G.S. Berenson[3], E.J. Topol[2], D.T. O'Connor[1], N.J. Schork[2].* 1) Univ California, San Diego, La Jolla, CA; 2) Scripps Genomic Medicine, TSRI, La Jolla, CA; 3) Tulane University, New Orleans, LA.

Height is a classical polygenic trait that has long been of interest to genetics researchers. Adult height is a highly heritable trait that follows a regular growth profile: rapid increase in the first four years, followed by a linear phase and an S-shaped curve from onset of adolescence into early adulthood. Several recent genome wide association (GWA) studies have focused on adult height. These studies identified associations with several Single Nucleotide Polymorphisms (SNPs) many of which have been replicated. However, the proportion of the variability explained by these SNPs is small, with modest effects on adult height. A significant limitation of these studies is that they only assessed adult height (state) and hence ignore the developmental trajectory that leads to adult height. It is arguable that ignoring the 'dynamic' nature of height from birth to adulthood will compromise the understanding of the biological effects of DNA sequence variations. We conducted a GWA study of height that exploits dissimilarity among the longitudinal height profiles of individuals with different genotypes. We introduce a novel non-parametric statistical framework to model and analyze the entire height growth profile, which we term 'Curve-Based Multivariate Distance Matrix Regression' (CMDMR). The proposed framework takes advantage of the subject specific height trajectory, which can be modeled with one of several nonlinear parametric and nonparametric models. This framework is applied to height growth data from the Bogalusa Heart Study. We also compared our GWA study results with those obtained with traditional statistical analyses approaches. We identified 7 novel variants in 6 loci (FAM19A1, FGF20, SCD5, MAP3K7, GLCCI1 and TJP2) associated with height profiles using parametric curves (all p-values <1e-6). Additionally, we assessed n=146 previously reported adult height GWAS SNPs, and replicated associations in the BMP2, CHCHD7-RDHE2, DLEU7, EFEMP1, GNA12, HHIP, Histone class 2A, HMGA2, LCORL, PDGFRA, PITX1, PXMP3- ZFHX4, SOCS2, SPIN1-CCRK, and ZBTB38 loci. The CMDMR approach is flexible and provides insights into the dynamic nature of complex traits.

## 1716/T/Poster Board #265

**Assessment of the use of genetic principal components for combining genetic association studies over ethnicity.** *S.A. Santorico.* Department of Mathematical and Statistical Sciences, University of Colorado, Denver, CO 80217, USA.

With our shared population history, it is expected that some genetic causes of disease will be common to multiple ethnic groups. Given differences in environmental background and exposures, we would also expect some effects to differ in presence as well as magnitude. To date, studies of the genetics of complex disease have typically been conducted separately by ethnicity. This has been done so as to avoid detection of genes that appear to be associated with disease but that rather reflect differences in disease prevalence and differences in the frequency of gene mutations in the ethnic groups. By keeping studies separate, false findings are minimized; however, the power to find genetic effects is lessened compared to being able to use a combined sample over all studies. With the availability of dense SNP genotyping, e.g, 100,000 to 500,000 SNPs genotyped over the genome, there is now the potential to adjust for this confounding. A recent method by Price et al (2006) proposes the use of principal components analysis on the full set of genotypes to construct independent axes of genetic variation. The information from these axes, also called genetic principal components, can be used to correct for differences in a candidate marker's variation across the ancestral populations. In an application to genetic data collected across Europe, Novembre et al (2008) were able to show how the variation over the axes of genetic variation reflected the actual geography over Europe. In particular, the first axis reflected a northwest gradient over Europe whereas the second axis reflected a southwest gradient over Europe. That is, an individual with high values on both axes would be reflective of a person of Russian origin whereas an individual with low values on both axes would be reflective of Spanish or Portuguese heritage.

While these results provide validation that the method is reflecting geographic, and hence to a fair extent ancestral history, the method has not been adequately assessed in its application to genetic studies of association. Here, the method of Price et al (2006) will be assessed by using simulations based on HapMap data. Does correction for ancestry by way of genetic principal components protects against false positive genetic associations? Is there power to detect common genetic associations and power to detect a genetic effect that differs over ethnic groups? These results will provide guidelines for making the most of available data.

## 1717/T/Poster Board #266

**On the optimal ranking of SNPs from genome-wide case-control scans.** *I. Tachmazidou[1], M. De Iorio[2], F. Dudbridge[1].* 1) Medical Research Council, Biostatistics Unit, Cambridge, United Kingdom; 2) Department of Epidemiology and Public Health, Imperial College, London, United Kingdom.

With the increase in the number of genetic association studies carried out in the hope of discovering single nucleotide polymorphisms (SNPs) involved in the etiology of complex diseases, there is a pressing need for methods that optimally measure statistical significance. We propose to extend the optimal discovery procedure (ODP) of Storey (2007) for statistical significance testing in genome-wide association studies (GWAS). Our aim is to optimally rank the tests according to their significance, so as to uncover as many true positive signals as possible without incurring too many false positives. The advantage of ODP compared to single significance tests is that when testing each SNP it borrows strength across tests by using information from all SNPs typed in the study. In particular, the ODP for a specific SNP involves considering the alternative and null distribution not only of that SNP, but also of the entire dataset for that SNP. In this way, independent SNPs with similar effect sizes will reinforce each other, and therefore tests that capture common signal structure in the dataset are enhanced.

Storey (2007) has shown that the ODP is an optimal multiple-testing procedure in the sense that it maximizes the expected number of true positive results at each fixed level of expected number of false positive results. However, the exact ODP cannot be known in practice, so we propose several estimators based on both prospective and retrospective likelihoods. We wish to examine how much accuracy is lost when using the estimated ODP. Through simulation studies, we investigate the performance of the estimated ODP, p-values from univariate logistic regression and asymptotic Bayes factors (BFs) (Wakefield 2008). Our results indicate that, whereas the exact ODP is never outperformed, the estimated ODP offers advantages over p-values and BFs only in extreme simulation scenarios. However, in realistic scenarios the estimated ODP yields a similar number of true positives compared to p-values and Bfs, although the rankings returned by the various methods were not identical. Therefore, in practice, we expect the ODP to perform similarly to univariate logistic regression and BFs when testing multiple hypotheses, and no method exhibits a clear advantage in power.

## 1718/T/Poster Board #267

**A HMM-based optimal Multiple Testing procedure for GWAS.** *Z. Wei[1], W. Sun[2], K. Wang[3], H. Hakonarson[3,4].* 1) Department of Computer Science, New Jersey Institute of Technology, Newark, NJ; 2) Department of Statistics, North Carolina State University, Raleigh, NC; 3) Center for Applied Genomics, The Children's Hospital of Philadelphia, Philadelphia, PA; 4) Division of Genetics, Department of Pediatrics, The Children's Hospital of Philadelphia, Philadelphia, PA.

Genome wide association studies (GWASs) search for correlation between a phenotypic trait, often a disease, and common genetic variants across an entire genome in an unbiased manner. Such studies promise to identify genetic variants with small effects. In a GWAS, it is typical to test hundreds of thousands of markers simultaneously and to then apply Bonferroni correction to control for family-wise error rate. However, Bonferroni correction is overly conservative, often excluding weak valid associations. It has therefore recently been proposed to control the false discovery rate (FDR) by the Benjamini and Hochberg procedure (BH). It has been shown that BH can effectively control the FDR in case-control association studies, improving sensitivity compared to Bonferroni correction. However, with both approaches, as dependency between markers increases the sensitivity of the study decreases. To improve the efficiency of a GWAS, it would be desirable to control the FDR by employing a precise model to capture the dependencies among markers. We propose to use a Hidden Markov Model (HMM) to capture the dependencies among SNPs. We have developed an optimal multiple testing procedure (PLIS) that employs an HMM. We prove analytically that PLIS controls the FDR at the nominal level and is optimal in the sense that it has the best sensitivity among all valid FDR procedures. Simulation results demonstrate that PLIS improves on conventional FDR procedures in detecting disease associated SNPs. We apply PLIS to a GWAS data set generated on the Illumina genotyping platform for 1,008 Type 1 diabetes (T1D) cases and 1,000 controls. At FDR level 0.0001, PLIS identifies a total of 1,841 SNPs, including 1,217 SNPs from the HLA region, as disease associated. These include 7 of the 15 T1D loci confirmed in a recent meta-analysis, while BH identifies only 3 of the 15 at the same FDR level. With respect to negative control, PLIS does not claim as disease-associated two loci that failed to replicate in follow-up studies, namely the gene for collagen type 1 a2 (COL1A2; rs10255021) and rs672797, in the vicinity of latrophilin 2 (LPHN2). By contrast, the GWAS claims significant associations for these loci after Bonferroni correction. In conclusion, the signal-to-noise ratio in a GWAS can be greatly enhanced by incorporating the dependency structure in a multiple testing procedure. Our proposed PLIS procedure suggests a promising direction for large-scale GWASs.

## 1719/T/Poster Board #268

**A universal, robust genome-wide association studies in family-based designs and an application to four genome-wide association studies.** *S. Won, C. Lange.* Harvard School of Public Health, Boston, MA.

For genome-wide association studies in family-based designs, we propose a new, universally applicable approach. The new test statistic exploits all available information about the association, while, by virtue of its design, it maintains the same robustness against population admixture as traditional family-based approaches that are based exclusively on the within-family information. The approach is suitable for the analysis of almost any trait type, e.g. binary, continuous, time-to-onset, multivariate, etc, and combinations of those. We use simulation studies to verify all theoretically derived properties of the approach, estimate its power and compare it with other standard approaches. We illustrate the practical implications of the new analysis method by an application to a lung-function phenotype, forced expiratory volume in one second (FEV1) in 4 genome-wide association studies.

## 1720/T/Poster Board #269

**Identify less frequent variants with large effect sizes.** *C. Xing.* McDermott Ctr, Univ Texas SW Medical Ctr, Dallas, TX.

The genome-wide association study (GWAS) becomes the prevalent study design in human genetic mapping. However, its success so far is constrained to identifying common variants with modest effect sizes, which explain a small fraction of heritability of complex traits. Conventional methods to identify association in GWAS are to prioritize signals purely by p-values and select those meeting the genome-wide significance level, and thus they favor detecting common variants. Here we attempt to improve the power of GWAS by detecting association of low frequent variants with effect sizes comparable to or even larger than that of common variants. We first investigated the allelic distribution of SNPs from the Affymetrix Genome-Wide Human SNP Array 6.0 in the Atherosclerosis Risk in Communities (ARIC) Study population, which implied that a considerable amount of information on less frequent variants lies in the commercial arrays. Further, we conducted a genome-wide screen for plasma fasting glucose levels using a false discovery rate control procedure accounting for allele frequency, and another genome-wide screen for stature using a regularized statistic in the European American (EA) population of the ARIC study. Both screens identified associations for less frequent variants that were missed by conventional methods. The associations were also positive in the African American (AA) population of the ARIC study, and we replicated the finding in both EA and AA populations of the Dallas Heart Study. This study reveals that there is a cache of less frequent variants in the commercial arrays, and this group of variants can be valuable if proper analytical approaches are used in GWAS.

## 1721/T/Poster Board #270

**Statistical aspects of shared controls in genome-wide association studies.** *D. Zaykin.* Dept Biostatistics, NIEHS/NIH, Res Triangle Park, NC.

I investigate the issue of correlation between results of GWAS due to usage of shared controls, a design that was employed by the 2007 Wellcome Trust Case Control Consortium study. For the commonly used trend test statistic, I find that the correlation between chi-square statistics for two diseases depends on the ratio of the control to the case sample sizes, but not on the allele frequency. I use this result to obtain chances of observing a small association p-value for a disease, given that a small P-value for another disease was observed. Further, I derive a P-value correction that accounts for correlation caused by the usage of shared controls. The method is surprisingly precise in approximating and correcting the actual distribution of P-values obtained with a case-control test. This approach appears to be useful for study designs that share common controls, especially regarding diseases that may imply common, genetically mediated etiology.

**A nonparametric analysis for multiple cases and shared control study.** *X. Zhan, J. Kang, X. Xia.* Biostatistics Dept, University of Michigan, Ann Arbor, MI.

In multiple disease case control genome-wide association (GWA) studies, it is common to sample shared control group and different case groups from each disease. In such a study design, classical methods are applicable for separately analyzing each disease. However, when jointly analyzing more than one disease, these methods might produce biased results, because the underlying mechanisms of multiple diseases are usually correlated. In this paper, we develop a novel p-value function based nonparametric method to detect the strongest association signals in the whole genome for multiple diseases. Also, we propose a new multiple comparisons for p-value functions to control the overall Type-I error taking the advantages of compound symmetric correlation structure of test statistics. Simulation studies show that our method reduces bias and has better performance than analyzing diseases separately. For Welcome Trust Case Control Consortium (WTCCC) study where 3000 shared controls and 7 common diseases with 1000 cases for each disease, our method lowers statistical threshold of the GWA study and thus it has potential to detect other signals while not falsely ignoring known genetic signal.

**A comparison of single and multi-SNP methods to summarize genetic variation at candidate loci.** *A.E. Hendricks[1], R.H. Myers[2], K.L. Lunetta[1].* 1) Department of Biostatistics, Boston University School of Public Health, Boston, MA; 2) Department of Neurology, Boston University School of Medicine, Boston, MA.

Recently, Genome Wide Association Studies have provided an abundance of data. Despite the wealth of genetic information, most of the genetic heritability for complex diseases is still not explained. Willer et al. (2009) found that the eight most highly associated genetic loci explain only 0.84% of the variation in BMI despite estimates indicating that 40-70% of the variation in BMI is due to genetic factors. Thus, to explain the remaining genetic heritability many researchers are moving beyond single marker analysis to more complex analyses that model the relationship between the disease and two or more genes such as gene-gene interaction, gene network analysis, and gene-set enrichment. A shared obstacle for these methods is determining how to represent or summarize the genetic information within each gene or region that is used in the analysis. Common techniques include using the SNP with the lowest p-value, haplotype(s), or principal components (PC) analysis. Here we also present a simple joint summary method that uses stepwise selection to select the jointly significant SNPs within a gene region and then create a per-individual summary measure by summing the number of risk alleles per SNP weighted by the SNP's regression estimate from the joint model. We use these four methods to summarize the gene region SNCA located on chromosome 4q22.1, which has been implicated in Parkinson's Disease (PD), and evaluate their significance using a permutation procedure. Using a sample of 1783 PD cases and controls in the SNCA gene region, we find the top SNP (rs356229) near the 3' end of SNCA. We also find a 3 SNP haplotype spread out throughout the gene region, and after performing stepwise selection, we retain 9 SNPs in the joint model. For the PC analysis we choose the third PC, PC3, as the PC summary measure as it is most significantly related to cases status. We find some overlap in the SNPs chosen for each summary method. Most notably, the top single SNP appears in the 3 SNP haplotype as well as in the 9 SNP joint model and is in the top 10 most highly weighted SNPs in PC3. Thus, not surprisingly, we see moderate pair-wise correlation between the four summary methods (range: 0.38-0.69) each of which is highly significant (all p-values < 2.2e-16). In addition, we compare the type-I-error and power of each method using simulated data that retain the LD structure of the SNCA region.

**The SEESEQ method: Semiparametric Estimating Equations for SEQuence data.** *D.D. Kinnamon, E.R. Martin.* Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL.

**Purpose:** Association analysis with sequence data is challenging due to the large number of both common and rare variants and the high rate of missing genotypes. We have developed a statistical method that improves on variant-by-variant analysis by combining information on numerous sequence variants into a small set of parameters without knowledge of allelic function.

**Methods and Results:** We assumed variant genotypes (minor allele heterozygotes or homozygotes) are present at a rate in the population conditional on local sequence position scaled to [0,1] and affection status. The natural log of this rate can be related to position by a linear model representing a complex nonlinear function with a small number of parameters. By fully interacting model terms with affection status, case-control differences in the population variant distributions can be estimated as differences in log variant rates and a joint Wald $\chi^2$ test constructed. We derived estimating equations for these model parameters and determined their theoretical properties in the presence of linkage disequilibrium (LD) and missing genotypes. To verify our approach, a population of 10,000 sequences of 10,000 base pairs with LD was generated under a standard coalescent model. Under a null disease model, 1,000 1:1 case-control samples with 10% missing genotypes were drawn with replacement from this population and SEESEQ applied to each.

If the log variant rate model is correctly specified, parameter estimates from SEESEQ are consistent and asymptotically normal with a closed-form covariance matrix, even with LD and missing data. In samples of 200 or 500 total subjects, the mean parameter estimate from the constant log variant rate model nearly equaled the log of the population mean variant rate. Mean estimates of case-control differences in constant, linear, and 3-knot natural cubic spline log variant rate models were all near zero, and the corresponding Wald $\chi^2$ tests had actual Type I errors close to the nominal level for $\alpha = 0.01$ and 0.05.

**Conclusion:** SEESEQ yields consistent estimates and controls Type I error, even with LD and missing data. Because it does not require multiple testing corrections or knowledge of allelic function to determine how to combine variants, it is expected to provide a powerful alternative to existing approaches for rare and common variant analysis.

## 1725/T/Poster Board #274

**Bayesian multivariate phenotype modeling for genome-wide association studies.** *J. Marchini[1], J. Pereira-Gale[1], M. McCarthy[2].* 1) Dept Statistics, Oxford Univ, Oxford, United Kingdom; 2) Oxford Centre for Diabetes, Endocrinology and Metabolism (OCDEM), Churchill Hospital, Old Road Headington, Oxford, OX3 7LJ, UK.

The majority of genome-wide association studies have been carried out using a single binary or single quantitative trait as the phenotype of interest. For many diseases several potential phenotypes may be available so it is natural to ask the question of how best to test for association in the presence of multiple phenotypes. We consider the case where there are two phenotypes : one case-control phenotype and one quantitative phenotype. We have developed a joint probit and linear regression model for this situation that explicitly models the residual error between the two phenotypes. We work in a Bayesian framework and use a flexible prior structure on the association parameters and correlation parameter. Currently we use a computationally efficient Importance Sampling scheme to estimate the marginal likelihood under both a null and alternative model in order to calculate a Bayes Factor for association and posterior estimates of the parameters of the model. On simulated data, across a variety of different combinations of effect sizes for both traits and various levels of residual correlation we observe a boost in power up to 10% over a marginal analysis of each trait or when combining the marginal analysis in simple ways. One interesting observation is that for fixed levels of association with each trait the power of the joint analysis increases as the residual correlation becomes more negative. We have also applied the method to real data at two SNPs (rs1121980 and rs9939609) at the FTO locus in a total of 3314 samples with Type 2 Diabetes (T2D) disease status and Body Mass Index (BMI) as the case-control and quantitative phenotype respectively. Marginal analysis of the T2D and BMI phenotypes produces $\log_{10}$ Bayes Factors of 2.60 and 5.22 at rs1121980 and 2.97 and 5.13 at rs9939609 respectively. Our joint model produces $\log_{10}$ Bayes Factors of 5.99 and 6.09 at the two SNPs. The prior structure used on the association parameters was the same for the marginal and joint models and we used a uniform prior on the residual correlation between the traits. This analysis further acts to illustrate that a joint analysis of distinct but related phenotypes can provide a boost in the signal of association. We have also investigated the use of the Bayesian Linear Model for multiple quantitative phenotypes and compared to marginal analysis methods we find similar boosts in power.

**A unified framework for testing multiple phenotypes for association with genetic variants.** *M. Stephens.* Statistics & Human Genetics, Univ Chicago, Chicago, IL.

In many ongoing genome-wide association studies, multiple related phenotypes are available for testing for association with genetic variants. In most cases, however, these related phenotypes are analysed independently from one another. For example, several studies have measured multiple lipid-related phenotypes, such as LDL-cholestrol, HDL-cholestrol, and Triglycerides, but in most cases the primary analysis has been a simple univariate scan for each phenotype. This type of univariate analysis fails to make full use of potentially rich phenotypic data. While this observation is in some sense obvious, much less obvious is the right way to go about examining associations with multiple phenotypes. Common existing approaches include the use of methods such as MANOVA, canonical correlations, or Principal Components Analysis, to identify linear combinations of outcome that are associated with genetic variants. However, if such methods give a significant result, these associations are not always easy to interpret. Indeed the usual approach to explaining observed multivariate associations is to revert to univariate tests, which seems far from ideal. In this work we outline an approach to dealing with multiple phenotypes based on Bayesian multivariate regression. The method attempts to identify which subset of phenotypes is associated with a given genotype. In this way it incorporates the null model (no phenotypes associated with genotype); the simple univariate alternative (only one phenotype associated with genotype) and the general alternative (all phenotypes associated with genotype) into a single unified framework. In particular our approach both tests for and explains multivariate associations within a single model, avoiding the need to resort to univariate tests when explaining and interpreting significant multivariate findings. It also has potential application to the joint analysis of ``intermediate" phenotypes with clinical endpoints, and for the analysis of change (eg drug response) phenotypes. We illustrate the approach on examples, and show how, when combined with multiple phenotype data, the method can improve both power and interpretation of association analyses.

## 1727/T/Poster Board #276

**Entropy based marker selection and Mantel statistics in candidate gene analysis of oxidative stress related mechanisms and breast cancer risk in the MARIE study.** *A. Schulz[1], P. Seibold[1], R. Hein[1], D. Flesch-Janys[2], C. Fischer[3], L. Beckmann[1], J. Chang-Claude[1].* 1) Cancer Epidemiology, German Cancer Research Centre (DKFZ), Heidelberg, Germany; 2) Department of Medical Biometry and Epidemiology, University Medical Center Hamburg-Eppendorf, Hamburg, Germany; 3) Institute of Human Genetics, University of Heidelberg, Heidelberg, Germany.

Haplotype analysis is a well established option for testing association in candidate genes. Often, when haplotypes are estimated statistically, an algorithm based on expectation maximisation (EM) is used. There is, however, no gold standard to decide which markers to jointly include in the EM haplotype estimation when the marker set is too large to estimate haplotypes for all markers at once. We combined an entropy based marker selection algorithm (EMS) with Mantel Statistics using haplotype sharing, a test for marker-phenotype association. Preliminary results show that this approach can improve the identification of causal loci in simulated candidate gene scenarios. Here, we apply the new approach to a real data set of a breast cancer case-control study, investigating genes in oxidative stress related mechanisms. The used data consist of 1628 postmenopausal breast cancer cases and 1947 controls matched by year of birth and study region from the German population-based case-control study MARIE. 131 single nucleotide polymorphisms (SNPs) in 20 candidate genes were analyzed. The SNPs were mainly tagging SNPs ($r^2$>0.8) in genes involved in oxidative stress related mechanisms. In the first stage of the new statistical approach, markers in one gene are screened by an entropy-based criterion of multilocus linkage disequilibrium and selected if they increase the linkage disequilibrium. Haplotypes are then estimated locally for the selected markers. In the second stage, haplotype sharing analysis is applied to the resulting haplotype distribution. This approach is compared to pointwise conditional logistic regression (LR). All test statistics are adjusted for potential breast cancer risk factors. LR yielded ten nominally significant variants (p<0.05), mostly in genes coding for members of the thioredoxin system and in the gene for metallothionein 2A (*MT2A*). The EMS Mantel statistics yielded significant results for four variants, two in *TXN2* and two in *MT2A*, corresponding to the four most significant variants of the LR. The most significant one, rs2281082 in *TXN2* for LR , was inversely associated with breast cancer risk ($p_{trend}$=0.002). The odds ratio compared to the wildtype was 0.79 (95% CI: 0.68-0.92) for the heterozygotes, and 0.78 (95% CI: 0.52-1.17) for the common homozygotes. Using EMS Mantel statistics, the most significant was rs1580833 in *MT2A* (p=0.0007).

**Haplotype construction in admixed populations.** *H. Xu, V. George.* Dept Biostatistics, Med Col Georgia, Augusta, GA.

Haplotype-based analysis is an important approach in human genetic studies, especially in the studies of complex diseases. Haplotypes for human can be determined experimentally, which are however, costly and time-consuming. Statistical construction of haplotype from multi-locus genotype data has been shown to be an effectively approach. Current methods do not take account of population structure. Our previous research shows that population structure could affect the performance of these methods. In this study, we propose new methods for haplotype construction in the presence of population structure. One is based on the maximum-likelihood and the other is an Bayesian approach. Simulation results show that the new methods have increased accuracy compared to the current methods ignoring population structure. This could have important implications in haplotype analysis using admixed populations or samples from metropolitan populations where extend of population structure is expected to be high.

## 1729/T/Poster Board #278

**Unraveling HLA Disease Associations from Genome Scan Data.** *J. Farrell.* Genetics Program L320, Boston University Medical, Boston, MA.

Recent genome-wide association studies (GWAS) have been very successful in finding single nucleotide polymorphisms (SNPs) in the Major Histocompatibility Complex (MHC) which are significantly associated with many diseases. These GWA studies detected significant MHC locus associations with auto-immune diseases, infectious diseases, inflammatory diseases, adverse drug reactions and lung cancer. However, the extensive linkage disequilibrium in the region has often made it very difficult to unravel the HLA risk alleles driving many of these significant disease signals. I have developed a novel method to predict the HLA alleles from SNP data to ascertain their role in these MHC-related diseases. This approach precisely predicts 4-digit HLA types for HLA-A, HLA-B, HLA-C, HLA-DRB1 and HLA-DQB1 alleles from SNPs typed in genome wide association studies. The overall precision and true positive rate for the HLA predictions are greater than 96% among the 2000 test cases used for validation. The actual and predicted HLA allele frequencies are highly correlated ($R^2$=1.0). It is now feasible to comprehensively and efficiently examine the role of common HLA alleles in genome scans showing disease association in the MHC region. The underlying 4-digit HLA type associated with many MHC-related diseases can now be unraveled without the expensive and laborious HLA typing of subjects in large-scale genome wide association studies. Using the predicted HLA genotypes, the utility of this approach is demonstrated with the re-analysis of 6 GWA studies for the following MHC-related diseases: ankylosing spondylitis, autoimmune thyroid disease, multiple sclerosis, psoriasis, rheumatoid arthritis and lung cancer.

## 1730/T/Poster Board #279

**A novel method for the joint detection of multiple risk SNPs.** *I. Hallgrímsdóttir[1], A. Albrechtsen[2, 3], T. Korneliussen[3], J. Witte[1, 4], R. Nielsen[5].* 1) Biostatistics & Epidemiology, UCSF, San Francisco, CA; 2) Department of Biostatistics, Copenhagen University, Copenhagen, Denmark; 3) Department of Biology, Copenhagen Universtiy, Copenhagen, Denmark; 4) Institute for Human Genetics, UCSF, San Francisco, California; 5) Department of Integrative Biology and Department of Statistics, UC Berkeley, Berkeley, California.

Genome-wide association studies (GWAS) have identified numerous loci associated with complex traits. However, the cumulative effects of these loci are much smaller than would be expected based on estimates of heritability for all complex traits studied to date, and it is clear that the current approach of performing single SNP tests in GWAS has only identified a small subset of the causative loci. Possible reasons for this include allelic and locus heterogeneity. To identify risk loci under such models we need to consider the combined effects of multiple SNPs. We have developed a new statistical model for joint detection of multiple risk SNPs. We define sets of SNPs, preferrably chosen so that all SNPs in a set are within the same gene, or within genes in the same pathway. For each set we test the null hypothesis that none of the SNPs are associated with the trait, against the alternative that some subset of them are associated with the trait. We work within a mixed model framework. The method's strength lies in testing in a statistically efficient manner; for each set of SNPs we perform only one test, by summing over all possible subsets of risk SNPs. We first consider quantitative trait models and show in a simulation study that the method has high power over a range of different genetic models. For models with 5 or more risk SNPs, each with a small marginal effect our method has >80% power even for a modest sample size of 500 individuals, while a single locus method has very low power. We compare our method to other existing methods and discuss an extension to dicotomous phenotypes.

**Inferring genotypes using resequencing data for fine mapping disease loci.** *J. Maller[1,2], G. McVean[1,2], P. Donnelly[1,2], 1000 Genomes Project, Wellcome Trust Case Control Consortium.* 1) Department of Statistics, University of Oxford, Oxford, United Kingdom; 2) Wellcome Trust Centre for Human Genetics, Oxford, United Kingdom.

INFERRING GENOTYPES USING RESEQUENCING DATA FOR FINE MAPPING DISEASE LOCI Julian B. Maller, Gilean McVean, Peter Donnelly, 1000 Genomes Project, Wellcome Trust Case Control Consortium Department of Statistics, University of Oxford, Oxford, UK Wellcome Trust Centre for Human Genetics, Oxford, UK Fine scale association mapping is a primary and increasingly common strategy for following up a whole genome association scan. The new generation of sequencing technologies has enabled the cost-effective deep-resequencing of 10s to 100s of samples, which provides a more complete catalogue of variation in regions of interest prior to fine mapping. Additionally, the 1000 Genomes Project will soon release genome-wide resequencing data for 100s of samples. If this sort of sequence data could be used to accurately infer genotypes at both known and novel SNPs in an original disease-study sample, it has the potential to greatly improve fine mapping efficiency. We attempted to assess both the accuracy of phasing and imputing from resequencing data, as well as the effectiveness of using such imputation to improve fine mapping efficiency. This analysis was performed using fine mapping data across 13 loci, regional resequencing data across 5 loci, and the 1000 Genomes Project pilot data. In the context of fine mapping, a critical metric is how results of association analysis of the imputed data compare to results from real genotypes. Using a Bayesian framework, and given certain assumptions, one can assign each SNP a relative weight of evidence within each fine mapping region. For each of the fine mapping regions, we took the smallest set of SNPs corresponding to 95% of the regional weight of evidence, and looked at what proportion of the regional weight those SNPs correspond to in the imputed results. Results from imputation using our resequencing on average placed 67% of the weight on SNPs from the 95% set from the real data, and imputing using 1000 Genomes data placed 86% on average on those SNPs. While the imputed data varied in accuracy, for common (MAF ≥ .05) SNPs it was sufficiently accurate to confidently exclude SNPs from fine mapping, define subsets of SNPs on which to focus efforts, as well as localise association signal and refine the region of interest.

## 1732/T/Poster Board #281

**Bayesian modelling categorical anti-C1q data in UK SLE families.** *S. Hunnangkul.* Department of Epidemiology and Population Health, London School of Hygiene and Tropical Medicine, London, UK.

Systemic lupus erythematosus (SLE) is an autoimmune disorder disease, influenced by genetic and environmental factors.To date the aetiology of this disease is still unclear.Circulating immune complexes are possibly causing organ dysfunction.Kidney disease and SLE are both heritable, thus it is possible that anti-C1q levels was heritable. Up to now, the heritability of anti-C1q has not previously been described in any publications. A total of 3117 anti-C1q measurements data in 829 SLE families with at least one affected offspring in SLE were used in this project, with SLE defined according to the American Rheumatism Association(ARA)revised in 1982. As the anti-C1q data are non-normal and data transformation did not help much to solve the problem of excess zeros and non-normality. The non-normal anti-C1q response can be categorised into 3 groups with 2 cut-points and 4 groups with 3 cut-points using median and the quantiles(p25,p50,p75) as the cut-off values respectively. We propose the proportional odds model with ordered categorical response of anti-C1q in order to understand the relationship of anti-C1q between parents and siblings as well as heritability estimates of anti-C1q. A Bayesian approach with variance component analysis using WinBUGS is used to modelling with family effects. The heritability of anti-C1q is computed with different priors in variance components such as Gamma distribution Ga(2,2) and Half-normal distribution N(I,0.10)(0,), N(I,0.25)(0,). Comparing the proportional odds models between different cut-points; it is obvious that the results from the 2 cut-point models were similar to the 3 cut-point models. In terms of precision, the use of 4 ordered response categories with 3 cut-points fit the model better than the use of 3 ordered response categories with 2 cut-points as the results illustrated small standard errors and small variation in 95% credibility interval. It means the higher number of order response categories, the better model is fit. The 3 cut-point model with the prior Gamma distribution Ga(2,2) and half-normal distribution HN(0.25) provided more accurate results with small variation in heritability estimates. The heritability estimates from both 2 cut-point and 3 cut-point models with different priors suggested 18%-22% of variation in anti-C1q. Heritability estimates were based on the latent variable that we generated anti-C1q with different categories.

## 1733/T/Poster Board #282

**Fine mapping of multiple causal MHC variants using shrinkage regression.** *C. Vignal[1,2], A. Bansal[1], D. Balding[1].* 1) Imperial College, UK; 2) GlaxoSmithKline, UK.

Rheumatoid arthritis (RA) has often been associated with the MHC, most notably with a group of alleles termed the shared epitope (SE) at *HLA-DRB1*. Additional MHC loci may play a role but inference is hampered by the extent of linkage disequilibrium (LD) in the region. The aim of the current study is to identify non-*DRB1* risk loci using a penalised multivariate approach and assess the robustness of the models derived.

Genotype imputation, incorporating HapMap subjects (CEU parents), was used as a means to jointly analyse SNPs from the Wellcome Trust Case Control Consortium (WTCCC) and the GoRA study, a case-control study for RA. The combined GoRA-WTCCC dataset comprised 6575 subjects and about 6600 part-imputed SNPs from the MHC, plus *HLA-DRB1*. We applied a Bayesian-inspired logistic regression approach to all markers jointly, to select SNPs while adjusting for the effect of *HLA-DRB1*. The latter is often modelled simply using SE-status, but we present results to show that co-adjusting for an additive effect of the 0101 allele improves fit. Parameter inference was based on the posterior mode, with non-zero values indicating marker-disease associations. We investigated two prior distributions: the double exponential (DE) prior, corresponding to the LASSO in logistic regression, and the normal-exponential-gamma (NEG) prior, also called the Hyper-Lasso (HLASSO).

After controlling for type-I error, the penalised approaches greatly reduced the number of positive signals compared to single-SNP association tests, suggesting that correlation between predictors might be better-handled. The HLASSO results were sparser but similar to the LASSO results. In both models, the robustness of the retained variables was verified by bootstrapping. Our findings suggest that variable selection using LASSO or HLASSO show a substantial benefit in identifying risk loci in regions of high LD through the derivation of sparse models.

**Multipoint Association Mapping Using Data from Triads and Unrelated Subjects with Incorporation of Covariates.** *C. Lee, Y. Chiu.* Division of Biostatistics and Bioinformatics, Institute of Population Health Sciences, National Health Research Institutes, Taiwan, R.O.C.

Case-controls designs are commonly adopted in association studies as the unrelated subjects are easy to collect; however, spurious association is often observed due to population stratification. To avoid spurious association from population stratification, trios (or triads) designs comprising an affected child and two parents have been recommended where the cases and controls are matched in genetic ancestry and are therefore robust to population stratification. The multipoint linkage disequilibrium mapping proposed by Liang et al. (2001) for trios data is robust to the underlying genetic model of a disease, as only one assumption that there is no more than one disease gene in the chromosomal region is required. Additionally, instead of doing hypothesis testing to detect the disease locus in regular association analysis approaches, it provides the estimate for the disease locus and the variance around it through the generalized estimating equation (GEE) method by simultaneously incorporating all the markers' information; therefore, confidence intervals for the disease locus could also be constructed. In practice, case-parents trios data can be used as a follow-up and confirmatory test for the gene-disease association detected by case-control studies; or, additional unrelated controls can be used as supplemental data to case-parents trios studies to improve statistical power for detecting association, in particular, for late-onset diseases. It is important to extend this robust multipoint association mapping with incorporation of covariates to combine data from case-parent trios and unrelated controls in the present study.

**Joint analysis of nuclear families and unrelated controls: pitfalls and benefits.** *C.A. Markunas, A.E. Ashley-Koch, S. Schmidt.* Center for Human Genetics, Duke University Medical Center, Durham, NC, USA.

Several genetic association methods allow for the joint analysis of families and unrelated controls. Our goal was to evaluate under what situations the addition of unrelated controls to family data is most beneficial and when it might lead to inflated type I error rates. UNPHASED (Dudbridge 2008) was selected to perform both single locus and haplotype analysis on simulated datasets containing the following structures: 1) 500 nuclear families with three offspring (at least 2 affected), 2) 500 nuclear families plus 500 unrelated controls, and 3) 500 unrelated cases and controls. In addition, three linkage disequilibrium (LD) patterns with moderate, low, and no pairwise LD ($r^2$) and different levels of multilocus LD between a disease gene and nearby markers were simulated. As expected, there was a positive relationship between the power of the single locus analysis and the strength of pairwise LD. Under low pairwise LD, haplotype analysis was substantially more powerful than single-locus analysis, and the addition of unrelated controls to the nuclear families provided the greatest benefit. For example, the gain in power for the joint unrelateds and family analysis was 13-16% for the single-locus analysis vs. 27% for the haplotype analysis (RR=2, MAF=0.3, log-additive model). An important assumption of methods which combine nuclear families and unrelated controls is that they represent the same, homogeneous population. Thus, we tested how robust UNPHASED was to disease minor allele frequency (MAF) differences in the families compared to the unrelated controls. Based on our preliminary findings, the type I error rate was drastically inflated in the presence of moderate disease MAF differences; however, the inclusion of an indicator variable in the model was surprisingly effective in maintaining correct type I error rates. In summary, the likelihood-based method implemented in UNPHASED is useful for taking advantage of publicly available control data, especially for low phenotypic misclassification rates. We expect that imputation methods for a joint analysis of families and unrelated controls will further improve the power to detect association in regions of low pairwise LD.

## 1736/T/Poster Board #285

**Functional Mapping of Age-specific Changes in Body Mass Index with Genome-wide Association Studies.** *K. Ahn[1], K. Das[2], S.J. Finch[3], S.S. An[4], D. Mauger[1], V.M. Chinchilli[1, 2], R. Wu[1, 2].* 1) Dept Public Health Sci, Penn State Col Med, Hershey, PA; 2) Dept Statistics, Pennsylvania State University, Hershy, PA; 3) Dept Applied Math and Statistics, Stony Brook University, Stony Brook, NY; 4) Dept Environmental Health Sci, Johns Hopkins University, Baltimore, MD.

A growing body of evidence shows that cardiovascular disease is correlated with the changes in body function and shape. Thus, by investigating age-specific changes in body mass index (BMI), it is possible that the developing timing of cardiovascular disease can be predicted. Here, we develop a new statistical model for functional mapping of genes that control the rate of change of BMI with age through a genome-wide SNP scan. The model is derived within a mixture framework for genetic mapping, in which a nonparametric approach is implemented to model genotype-dependent values of BMI over age and a semiparametric approach implemented to model the covariance structure of longitudinal data. We particularly investigate the covariance structure of longitudinal data measured at subject-specific unevenly-spaced time intervals. The model provides a quantitative platform to test the interplay between genetic actions and the pattern of development. The model is used to analyze a real data set collected in the Framingham project, aimed to determine "factors influencing the development of heart disease." This analysis leads to the identification of several significant SNPs responsible for the developmental trajectories of BMI. The utilization of the model is validated through simulation studies.

## 1737/T/Poster Board #286

**Pathway-based scan analysis of genome-wide association data.** *T. Nishiyama[1,2], K. Takahashi[3], T. Tango[3], H. Kishino[4].* 1) Doctor of Public Health Program in Biostatistics, Japan; 2) Department of Information and Biological Sciences, Graduate School of Natural Sciences, Nagoya City University, Japan; 3) Department of Technology Assessment and Biostatistics, National Institute of Public Health, Japan; 4) Laboratory of Biometry and Bioinformatics, Graduate School of Agriculture and Life Sciences, University of Tokyo, Japan.

Despite great success of genome-wide association studies (GWAS) in identification of genes underlying complex diseases, the current GWAS have focused only on examining significance on a SNP-by-SNP basis. One of the biggest challenges facing GWAS is a lack of sufficient power to detect small effects as significant. To overcome this limitation, gene set analysis (GSA) methods of analyzing SNP data in GWAS have recently been proposed. However, GSA methods of GWAS do not use gene-pathway structure information, represented by gene products as graph nodes and graph edges between these nodes. Instead of focusing only on the SNPs that are grouped as gene-sets, we propose genome-wide association analysis that incorporates pathway structure information. As a proof of concept, we performed GWAS on a set of 52 cases and 52 controls genotyped for almost 11 000 SNPs, based on pathway structure information on KEGG. To detect clustering of significantly associated SNPs on KEGG pathway, scan statistics were applied with a variable window size. We treated the smallest P values as our statistic of interest and determined its overall significance level. We applied this method based on existing statistics used for GSA methods, such as MAXMEAN and Gene Set Enrichment Analysis (GSEA). The results demonstrated that this new method for GWAS was able to identify biologically meaningful sub-pathways associated with the trait examined. The performance of our scan-statistics approach is extensively compared with GSA methods.

## 1738/T/Poster Board #287

**Tiled regression: the use of regression methods in hotspot defined genomic segments to identify independent genetic variants responsible for variation in quantitative traits.** *A.F. Wilson[1], Y. Kim[1], H. Sung[1], J. Cai[1], F.J. McMahon[2], A.J.M. Sorant[1].* 1) Genometrics Section, Inherited Disease Research Branch, NHGRI, NIH, Baltimore, MD; 2) Genetic Basis of Mood and Anxiety Disorders, NIMH, NIH, Bethesda, MD.

The assumptions of independence between observations and between independent variables are a major theoretical underpinning of much of traditional statistics. However, as the density of genetic markers increases, ultimately encompassing genome wide sequence variants, the correlations between markers increases, depending in large part on the linkage disequilibrium (LD) structure in the sample. Rather than focusing on identifying markers that best characterize LD blocks, stepwise regression is used to identify independent markers that are responsible for additive effects on a quantitative phenotype. To address this issue, the genome is divided into segments based on predefined "hotspot" regions (i.e., well defined regions of increased recombination). Let the term "tile" denote both the sequence of DNA between two hotspot regions and the hotspot region itself. A tile may include many markers in one or more LD blocks. In tiled regression, each SNP or sequence variant is assigned to a tile based on chromosome and physical position. A test of the overall multiple regression model, where the regression coefficients for all the genetic variants are set to 0, is performed on the SNPs or sequence variants in each tile in order to determine if any marker in the tile made a significant contribution to the overall regression. Stepwise regression (forward with a backward look) is then used to select the important markers in each tile. If the multi-colinearity between markers within LD blocks is high, stepwise regression can be used from the outset. Thereafter, the significant markers in independent tiles are combined in higher order stepwise regressions. The tiled regression framework can be extended to include qualitative traits with stepwise logistic regression, and to family data that can be represented in a linear regression context with methods such as the Regression of Offspring on Mid-Parent (ROMP) or Generalized Estimating Equations (GEE). The tiled regression method for quantitative traits is illustrated with data from the STAR*D study (Sequenced Treatment Alternatives to Relieve Depression) [Rush et al., 2004]. The method classified 705 SNPs from 68 genes into 197 tiles. Results are similar to those reported by McMahon et al. [2006], with the most significant marker being rs7997012.

**Evaluation of Mixed-Model Approaches for Control of Population Structure in Human Genetic Association Studies.** *N. Liu[1], H. Zhao[2, 3], D. Allison[1].* 1) Dept Biostatistics, Section on Statistical Genetics, Univ Alabama at Birmingham, Birmingham, AL; 2) Dept of Epidemiology and Public Health, Yale Univ, New Haven, CT; 3) Dept of Genetics, Yale Univ, New Haven, CT.

In genetic studies, associations between genotypes and phenotypes may be confounded by unrecognized population stratification and/or admixture. Studies have shown that even in European populations, which are thought to be relatively homogeneous, population stratification exists and can affect the validity of association studies. A number of methods have been proposed to address this issue in recent years. Among them, the approaches based on mixed-model have several advantages compared to other methods. However, these approaches have not been thoroughly evaluated on large human datasets. The objectives of this study are to (1) evaluate various methods based on mixed-model for genetic association mapping using human data, (2) compare the performance of different marker-based kinship matrices, (3) understand the effect of each component of these mixed-model approaches in genetic association mapping. To achieve these goals, we generate simulated datasets based on HapMap data under various scenarios. Preliminary results indicate that the approaches based on mixed-model perform well in controlling for population stratification/admixture compared with other methods. However, these methods do not necessarily eliminate the confounding effect of population stratification/admixture in genetic association studies.

**Bayesian Testing of Genetic Association in Meta-analysis.** *X. Wen[1], M. Stephens[1,2].* 1) Dept Statistics, Univ Chicago, Chicago, IL; 2) Dept Human Genetics, Univ Chicago, Chicago, IL.

Testing genetic association is a challenging problem in meta-analysis settings, where different studies may have different sample sizes and/or different genotyping platforms. We propose a new Bayesian procedure to perform single marker association test in case/control studies. Our formulation explicitly considers the retrospective nature of study design, and our hierachical modeling enables variation of effect sizes across studies. Furthermore, for untyped SNPs, our method applies an efficient imputation approach and take into account of the uncertainty of imputed allele frequencies.

## 1741/T/Poster Board #290

**Model Selection Strategies in Genome-Wide Association Studies.** *S.L. Keildson[1,2], A.P. Morris[2], M. Farrall[1,2].* 1) Cardiovascular Medicine, University of Oxford, UK; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, UK.

Unravelling the complex genetic architecture of many common diseases is a continual challenge in the field of human genetics. Complex disease phenotypes are often controlled by the action of multiple genes, the effects of which may be confounded by environmental factors and epistasis, and therefore traditional attempts to map the loci that play a role in complex disease susceptibility have been largely unsuccessful. While genome-wide association studies have proven to be successful in identifying many new disease-susceptibility loci, the extension of these studies beyond the scope of single SNP analyses have been limited. The incorporation of multi-locus methods of analysis may, however, have the potential to increase the power of genome-wide association studies to detect genes of smaller effect size as well as the genes that interact with each other and the environment. We have carried out large scale simulations of four multi-locus model selection techniques in order to compare the type I error rate and power of each method. We simulated quantitative phenotype data for a range of genetic models and generated genotype data for 10 SNPs from HapMap ENCODE regions using HAPGEN. To this data, we applied four regression techniques encompassing additive main effects, implemented using R software packages: forward selection, backward selection, Lasso and Bayesian model averaging. Adjustments were made to each method in order to reduce the initial type I error rate to approximately 5% and then the power of each method to detect associations in the simulated data at these adjusted type I error rates, was calculated over 1000 simulated populations. At a type I error rate of 0.053, the Lasso method generally showed the highest power over a wide range of genetic models, followed by forward and backward selection, both of which had estimated type I error rates of 0.058. While Bayesian model averaging proved to be the least powerful model selection technique, it also had the lowest frequency of false positive results (0.038). Forward selection and a combined method of lasso and bayesian model averaging was then applied to real lipoprotein(a) data and yielded results consistent with those published in the literature.

**A non-parametric method for global test of associations for a large number of SNPs in case-control association studies.** *Y. Li, J.J. Liu.* Human Genetics , Genome Inst Singapore, 60 Biopolis street, #02-01, S138672, Republic of Singapore.

Gene-gene interactions have long been recognized to be indispensable in deciphering the genetic etiology of common complex human diseases. When single nucleotide polymorphisms (SNPs) are used as genetic variants in case-control association studies, the routine method for gene-gene interaction detection is to test pair-wise SNP interaction among all SNPs or among all SNPs in different genes. Due to the large number of interaction tests involved when a medium number of SNPs are considered, we are always encountered with the issue of low power incurred by the multiple testing. On the other hand, SNPs in different genes in a biological pathway may individually have small effects, or individual SNP pairs have small interaction magnitude, but they show detectable joint effects or joint interactions as they play roles in a concerted way. AML, Admixture Maximum Likelihood, is an efficient method to test joint effects, which assumes that all the SNPs convey the same effect and have the same probability to be associated. However, AML will fail to detect joint associations when all the main effects are weak. We here propose a non-parametric global test method for a large number of SNPs in case/control association studies which considers all the orders of interactions (including main effects) implicitly in one test. Specifically, we map the genotypes at the given SNPs to an infinite dimensional space, which contains all the orders of interactions among any of the SNPs, then compare the distribution of this mapped space between the control subjects and the case subjects by making use of the "kernel" trick, avoiding explicit computation in the mapped infinite dimensional space. The advantage of our method is that we do not need to specify a particular form of interaction (e.g., second order or third order), neither need to specify among which SNPs there exist interactions. Simulations showed that our method had higher power of association detection than existing methods when the joint interactions are detectable while all the main effects are weak.

**Multi-locus analysis of genome-wide association data via novel application of multivariate statistical and model selection techniques.** *A. Morris.* Wellcome Trust Centre for Human Genetics, Univ Oxford, UK.

Genome-wide association (GWA) studies have been successful in identifying novel loci contributing to complex human traits. However, despite these successes, much of the genetic contribution to the trait variance remains unexplained. Typically, GWA studies are analysed using single SNP tests. However, a gain power might be expected by modelling the effects of multiple SNPs, simultaneously, within a gene or small genomic region. In such regions, "local axes" of genetic variation can be defined by applying multivariate statistical techniques to SNP genotype data. The leading axes encompass most of the genetic variation in the region, and take account of linkage disequilibrium between SNPs. Testing for association with these axes reduces the overall burden of multiple testing. Furthermore, by considering these axes, jointly, in a generalised linear regression framework, it is possible to model the effects of multiple causal variants, simultaneously.

A simulation study was undertaken to evaluate the power of multivariate-based analyses of SNPs in a 50 kb region in a study of 1000 cases and controls. Three approaches to the selection of axes of genetic variation for inclusion in the regression model were considered: (i) the leading axes explaining 80% of genetic variation in the region; (ii) the leading axes explaining 90% of variation; and (iii) the leading axes with minimum Bayesian information content (BIC) among those explaining 90% of variation. Over all simulations, selecting axes by means of the BIC is the most powerful multivariate-based analysis approach. When disease risk is determined by a single causal variant, there is little difference in power between single SNP and multivariate analyses. However, in the presence of two independent causal variants, there are noticeable gains in power for the multivariate analyses.

Multivariate-based analysis of a 50kb sliding window across a GWA study of type 2 diabetes from the Wellcome Trust Case Control Consortium (2000 cases and 3000 controls) revealed: (i) stronger signals of association than single SNP tests for many of the now established loci; and (ii) multi-locus signals of association, not identified through single SNP tests, that warrant follow-up.

**A Bayesian approach to genetic association studies with family-based designs.** *M. Naylor[1], S.T. Weiss[2], C. Lange[1].* 1) Dept Biostatistics, Harvard School of Public Health, Boston, MA; 2) Channing Lab, Brigham and Women's Hospital, Boston, MA.

For genomewide association studies with family-based designs, we propose a Bayesian approach. We show that standard TDT/FBAT statistics can naturally be implemented in a Bayesian framework. We construct a Bayes factor conditional on the offspring phenotype and parental genotype data and then use the data we conditioned on to inform the prior odds for each marker. For the construction of the prior odds, the evidence for association for each single marker is obtained at the population-level by estimating the genetic effect size in the conditional mean model. Since such genetic effect size estimates are statistically independent of the effect size estimation within the families, the actual data set can inform the construction of the prior odds without any statistical penalty. In contrast to Bayesian approaches that have recently been proposed for genomewide association studies, our approach does not require assumptions about the genetic effect size; this makes the proposed method entirely data-driven. The power of the approach was assessed through simulation. We then applied the approach to a genomewide association scan to assess association between single nucleotide polymorphisms and body mass index in the Childhood Asthma Management dataset.

## 1745/T/Poster Board #294

**Gene set analysis in genome-wide association studies.** *N. Tintle.* Mathematics, Hope College, Holland, MI.

Gene set analysis is now a standard method for analyzing gene expression data. In contrast to traditional gene expression data analysis which examines significance gene-by-gene, gene set analysis is used to establish the significance of biologically relevant sets of genes. Recently, gene set analysis has been proposed for the analysis of single nucleotide polymorphism data in genome-wide association studies (GWAS). First attempts to use gene set analysis in GWAS have proposed the use of Gene set Enrichment Analysis (GSEA) and methods based on Fisher's exact test (FET), arguably the two most popular gene set analysis methods for gene expression data. However, recent advances in gene set analysis for gene expression data have proven to be more powerful and robust than GSEA and FET. I will present results showing that these newer methods can be used for gene set analysis of GWAS to increase power compared to GSEA and FET. Results are based on analysis of real and simulated GWAS data. I will also present a number of open, practical questions about best practices for the use of gene set analysis in GWAS.

**Phenotype Harmonization in a Multi-Site Genome-Wide Association Study: GENEVA.** *S.N. Bennett[1], A.L. Fitzpatrick[1], N. Caporaso[2], K. Williams[1], J. Udren[1], B. Weir[1], GENEVA.* 1) Biostatistics, Univ Washington, Seattle, WA; 2) Division of Cancer Epidemiology and Genetics, National Cancer Institute, National Institute of Health, Bethesda, MD.

Purpose: GENEVA (Gene Environment Association Studies) is a multi-site genome-wide association study developed as part of the NIH-wide Genes, Environment and Health Initiative (GEI) aimed at accelerating understanding of genetic and environmental contributions to health and disease. Its aims are to identify genetic variants related to common complex diseases, identify variations in gene-trait associations related to environmental exposures, and address potential pathways to outcomes in various populations. The 8 Phase I and 6 Phase II studies in this consortium have disparate interests including oral clefts, addiction, cardiovascular disease, lung cancer, type 2 diabetes, maternal metabolism and birth weight interactions, dental caries, prematurity, lung health, blood pressure, prostate cancer, venous thrombosis, stroke and glaucoma. One of the major analytic challenges is the wide range of phenotypes. The GENEVA Coordinating Center (CC) is charged with coordinating activities related to data collection, harmonization and management, and facilitating cross-study analyses. This paper describes the processes undertaken by the CC and issues that have arisen. Methods: The CC created a web-based survey to identify phenotypic data common across studies. For identified areas of interest, the CC and Phenotype Harmonization Subcommittee (PHS) convened a series of investigator-led Working Groups (WGs) to evaluate feasibility and logistics for cross-study analyses. WGs identify and define variables to be shared, identify covariates, recommend the most appropriate analytic method and draft an analysis plan using a template developed by the CC and PHS chair. The CC assigns a unique GENEVA ID to each individual. The CC provides WGs with statistical summaries of phenotypic data and harmonizes the covariates. The CC has established a centralized relational database containing each study's phenotypic data, data dictionary, individual-level consent, public use or GENEVA-only use status, and harmonized data. Results: The PHS identified 8 areas of common interest: alcohol use, anthropometrics, caffeine use, type 2 diabetes, oral health, psychiatric history, reproductive history and tobacco use. With the added Phase II studies, new WGs are being established. The CC is harmonizing 9 covariates, has assigned 62,935 GENEVA IDs and incorporated 4 studies' data into a centralized database. Four WGs have completed analysis plans and are starting shared data analyses.

**Accounting for sample structure in large scale genome-wide association studies using a variance component model.** *H. Kang[1,2], J. Sul[3], S. Service[4], N. Zaitlen[5], S. Kong[6], N. Freimer[6,7,8], C. Sabatti[6,9], E. Eskin[3,6].* 1) Computer Science and Engineering, University of California, San Diego, La Jolla, CA; 2) Department of Biostatistics, University of Michigan, Ann Arbor, Ann Arbor, MI; 3) Computer Science Department, University of California, Los Angeles, Los Angeles, CA; 4) Center for Neurobehavioral Genetics, University of California, Los Angeles, Los Angeles, CA; 5) Bioinformatics Program, University of California, San Diego, La Jolla, CA; 6) Department of Human Genetics, University of California, Los Angeles, Los Angeles, CA; 7) The Jane and Terry Semel Institute for Neuroscience and Human Behavior and Los Angeles, Los Angeles, CA; 8) Department of Psychiatry, University of California, Los Angeles, Los Angeles, CA; 9) Department of Statistics, University of California, Los Angeles, Los Angeles, CA.

In the last couple of years, genome wide association studies have opened up a series of intriguing research directions, identifying a number of loci possibly implicated in a variety of complex traits. A serious concern in the interpretation of these results is the possibility of confounding effects due to sample structure. Typically, this is modeled as either of two extreme manifestations: population stratification or hidden relatedness. We here propose an efficient variance component approach that allows to deal with general types of sample structures. Unlike approaches based on principal components, which rely on the major axes of the pairwise genetic relatedness matrix, our method uses the entire matrix in modeling correlation between phenotypes of sample subjects. A similar mixed effect strategy has proven successful in model organism association mapping. Here we take advantage of the fact that each locus involved in human polygenic traits has a relatively small effect and we estimate the variance components only once in the genome scan. This makes it computationally feasible to process large sample sizes. We analyze data on 10 quantitative traits in the Northern Finland Birth Cohort 1966 (NFBC66), and 7 disease phenotypes in the Wellcome Trust Case Control Consortium (WTCCC). The proposed methodology consistently eliminates the over dispersion of the test statistics that cannot be fully resolved by including principal components in the regression tests. Moreover, simulation studies suggest that the proposed approach results in values of the test statistics at the tails of the distribution that might be more accurate than what is achievable with genomic control correction. The software to carry out described analysis is available at http://genetics.cs.ucla.edu/emmax.

## 1748/T/Poster Board #297

**Principal Component Score Prediction for Related and Unrelated GWA Samples.** *S. Lee[1], F.A. Wright[1,2], F. Zou[1,2].* 1) Biostatistics, University of North Carolina, Chapel Hill, NC; 2) Center for Environmental Bioinformatics,University of North Carolina, Chapel Hill, NC.

Principal component (PC) analysis is used as one of the leading population stratification control approaches for genome-wide association studies (GWAS). In PC analysis, PC scores are used to estimate ancestry structure of study subjects. It is well known that PC analysis is sensitive to the presence of related samples, resulting in a distorted view of population structure. To avoid this problem, a subset of independent samples can be used for PC analysis, from which PC scores of excluded samples are subsequently estimated. However, this common PC score prediction method is substantially biased, in a sense that the predicted PC scores tend to be shrunken towards 0 compared to the scores computed using all samples. This bias is particularly large for studies with moderate population substructure, or unequal representation of samples from different subpopulations. In this talk, we will describe a novel method using recent results on random matrix theory to adjust for prediction bias, and is applicable to both sets of related and unrelated samples. We will demonstrate this bias correction method using both simulated and real GWAS data.

## 1749/T/Poster Board #298

**Cystic Fibrosis: An 'Inclusive' Disease - Demonstrated by Analysis of Population Stratification.** *W. Li[1], L. Sun[4,5], C. Taylor[1,4], R. Dorfman[2], A. Cojocaru[1], J. Zielenski[2], P. Durie[3], M. Corey[1,4], LJ. Strug[1,4].* 1) Child Health Evaluative Sciences, The Hospital for Sick Children, Toronto, ON, Canada; 2) Genetics and Genomic Biology, The Hospital for Sick Children, Toronto, ON, Canada; 3) Physiology and Experimental Medicine, The Hospital for Sick Children, Toronto, ON, Canada; 4) Dalla Lana School of Public Health, University of Toronto, Toronto, ON, Canada; 5) Department of Statistics, University of Toronto, Toronto, ON, Canada.

**Introduction** A common misconception, shared by researchers and the general population alike, is that Cystic Fibrosis (CF) only affects people of European descent. This can be seen in the lack of detailed ethnicity information collected in CF research studies. The Carleton University Students' Association went as far as canceling CF fundraisers, claiming CF is not an "inclusive" enough disease for massive fundraising efforts. Although historically this may have been the case, the diverse ethnic make-up of Canada suggests that the face of CF might also be changing. Armed with genome-wide SNP data on 1437 unrelated Canadian CF patients with pancreatic insufficiency (CFPI) from the Canadian Genetic Modifier Study (GC2), shown to be representative of the Canadian CF population, we set out to better understand the ethnic make-up of the Canadian CF population using Principal Component Analysis (PCA). **Methods** EIGENSTRAT (Price et al. 2006) was used to perform PCA, and the top 3 significant PCs were examined in 3D plots. We also seeded the CFPI data with SNPs from 6 HapMap3 (http://www.hapmap.org) populations including the Europeans (CEU), East Asians (CHB+JPT), Yoruba (YRI), African Americans (ASW), Indians (GIH) and Mexicans (MEX). **Results** No clear structure was observed in the top 3 PCs extracted from the CFPI samples alone. Seeding with the HapMap3 data, CEU, YRI and CHB+JPT formed three separate tight clusters, while GIH, MEX and ASW formed three short continuous arms pointing to the CEU cluster. CFPI exhibited a tripod structure with most of the subjects forming a cluster at the apex of the tripod, on top of the HapMap3 CEU cluster. Indeed, this CFPI cluster consisted of mostly self-reported 'Caucasian' subjects. However, the rest of the subjects scattered along the CEU-GIH, CEU-MEX and CEU-ASW arms, suggesting population admixture. Furthermore, neither CHB+JPT nor YRI encompassed any of the variation. **Discussion** CFPI samples that distributed along the CEU-ASW arm were either self-reported 'African' or 'mixed'; and those distributed along the CEU-MEX and CEU-GHI arms were either 'Caucasian' or of 'Other' ethnicity. **Conclusion** Our PCA suggests that the Canadian CF population contains many individuals with mixed ancestries. Given the ethnic complexity of this population, it is crucial to guard against potential spurious association in CF studies by incorporating either detailed ethnicity information or PCs.

## 1750/T/Poster Board #299

**Clustering based on Genetic Ancestry.** *N. Timofeev[1], S.H. Hartley[1], C.T. Baldwin[2], D.A. Dworkis[3], L.F. Farrer[1,3], M. Gladwin[4], E.S. Klings[3], J.N. Milton[1], T.T. Perls[3], M.H. Steinberg[3], P. Sebastiani[1].* 1) Department of Biostatistics, Boston University, boston, MA; 2) Center for Human Genetics, Boston University School of Medicine, Boston, MA; 3) Department of Medicine, Boston University School of Medicine, Boston, MA; 4) Vascular Medicine Branch, National Heart, Lung and Blood Institute and Critical Care Medicine Department, Clinical Center, National Institutes of Health, Bethesda, MD.

Genome wide association studies (GWAS) have become increasingly popular in the genetic community to identify disease associated genes. Population stratification is a major confounder causing spurious associations in GWAS and occurs when differences in allele frequencies of single nucleotide polymorphisms (SNPs) are due to the ancestral differences between cases and controls rather than the disease. Principal components analysis (PCA) is a widely used approach to detect population substructure using genome wide data and to adjust genetic association for stratification by including the top principal components in the analysis. An alternative solution to the population stratification problem in association studies is genetic matching of cases and controls that requires, however, well defined population strata for appropriate selection of cases and controls. With this objective in mind, we developed a novel algorithm to cluster individuals into groups based upon similar ancestral backgrounds using the principal components computed by PCA. Our algorithm utilizes k-means clustering of the most informative principal components to iteratively group individuals into clusters and a novel index that includes accuracy, stability and between-cluster distance to choose the appropriate number of clusters. We tested the algorithm on 151 subjects from 7 African populations in the Human Genome Diversity Project to demonstrate that the algorithm accurately clusters individuals. Our algorithm also discriminated fine groupings of Caucasians of European descent in a large cohort of Caucasian centenarians and their controls. In addition, examination of the ancestral substructure and the amount of Caucasian admixture in a large cohort of African American sickle cell disease patients using this algorithm revealed that African Americans with sickle cell disease are significantly less admixed than African Americans without sickle cell disease and have ancestries similar to either the Yorubans and Mandenkas or the Bantu population, ethnic groups located on the western coast of Africa.

## 1751/T/Poster Board #300

**Local Ancestral Inference in Admixed Populations.** *c. Zhu[1], S. Han[2], X. Liu[3].* 1) Department of Agronomy, Kansas State University, Manhattan, Kansas 66506,USA; 2) Division of Human Genetics, Department of Psychiatry, School of Medicine, Yale University, New Haven, Connecticut 06511, USA; 3) Human Genetics Center, School of Public Health, University of Texas at Houston, Houston, Texas 77030, USA.

The genome of an admixed individual represents a mixture of alleles inherited from multiple ancestral populations. Inferring ancestral information along the chromosomes is particularly useful in admixture mapping or correcting population stratification for genomewide association study in recently admixed populations. The most popular Hidden Markov chain model based methods for inferring local ancestry require that each pair of ancestry informative markers (AIMs) should be independent of each other in the ancestry populations. In the current study, we introduced a new method for inferring locus ancestry state based on copying process model which can handle highly correlated marker sets. Copying process model assumes that a new haplotype is produced by ancestral haplotype through copying, recombination and mutation. When combined with penalty score model and dynamic programming approach, the method could infer a single most likely combination of ancestral states (i.e., the pathway of copying process) of all polymorphic sites of the derived haplotype. Using a simple hybrid-isolation admixture model, we evaluated the existing methods for inference of population structure under dense SNPs marker sets, especially in the scenario of highly correlated SNPs. We investigated the performance of our proposed method using a series of simulation experiments and empirical datasets and found that the new method is accurate and robust when highly correlated dense marker set was used. A through comparison of the new method with the existing commonly used methods such as STRUCTURE or ANCESTRYMAP is still undergoing.

**Risk Prediction Model Establishment for Complex Genetic Diseases.**
*J. KANG[1], A. Kim[2], J. Cho[2,3], H. Zhao[1,3].* 1) Department of Translational Informatics, Yale University, New Haven, CT; 2) Digestive Diseases, Yale University School of Medicine, New Haven, CT; 3) Genetics, Yale University School of Public Health, New Haven, CT.

Background: Recent advances in high-density genotyping technology have made it possible to conduct genome-wide association studies (GWAS) to detect genetic variants that are associated with risk for complex diseases. However, the prediction of genetic risk of a complex disease using GWAS data remains a challenging problem because complex traits are likely affected by many genes, environmental risk factors, and interactions among them where most of which only confer a very small effect on disease risk. In addition, small sample size relative to the number of markers available is another issue in building meaningful risk models, where the number of features far exceeds the number of samples. When sample size and effect size are both small, the effect size for a given variant is often estimated with considerable uncertainty, which leads to subpar prediction performance because it is critical to identify genetic variants truly associated with disease and also appropriately quantify their effects. Method: We have conducted a systematic study to evaluate the effects of sample size, effect size, the number of selected features, and the specific prediction methods on prediction accuracy. Based on our observations, we have proposed a novel statistical method for disease risk prediction based on GWAS data. To assess of the utility of our methods in real data, we constructed a risk prediction model based on GWAS data collected for Crohn's Disease, a subtype of inflammatory bowel disease that is believed to have a complex etiology. We evaluated the performance of the prediction model by examining its area under ROC (Receiver Operating Characteristic) curve. Results: Our approach has been found to work well under a number of simulation scenarios. For Crohn's disease data, using a cross validation scheme, the median AUC (area under curve) among the twenty runs was $0.766 \pm 0.018$. Comparisons between our proposed method and other methods demonstrated the improved performance of our method.

## 1753/T/Poster Board #302

**Pathway-Based Analysis of Genome-Wide Association Studies using Random Forests.** *Y. Meng.* Metabolic Disease Initiative, Broad institute of Harvard and MIT, Cambridge, MA.

Most current approaches to analyzing genome-wide association studies (GWAS) test each variant individually and without regard to their genetic context. Although this comprehensive and unbiased approach has advantages and has proved to be successful in identification of candidate genes in many complex diseases, it is widely accepted that not all variants have been identified. Recently, more genes are being identified by testing copy number variants (CNVs) and copy number polymorphisms (CNPs), and by increasing samples sizes through joint analysis of multiple GWAS. While such approaches are yielding new associations, power for identifying common variants of weak association is still limited. An alternative and complementary approach is to use prior biological information to analyze GWAS data at the level of genes, sets of genes, and biological pathways. This may contribute to the statistical and explanatory power of discovering new genes and biological processes that influence complex human diseases and traits, especially when high degrees of allelic and locus heterogeneity exist as is the case for many complex human diseases.

Pathway-based analyses have generated some success in gene expression studies, and have been recently applied to GWAS data using similar approaches - GSEA (Gene Set Enrichment Analysis), and hypergeometric distribution. Many machine learning methods, including Random forests (RF) can take into account SNP interaction effects as well as main effects without requiring model specification, therefore have the advantage of capturing the interaction effect over the other approaches. The machine learning methods have been applied often in expression studies, but have just started to gain popularity in genetic analysis, but still not on the genome-wide scale due to large volume of the data (1 million SNPs). However, if we test SNPs on the pathway level, the computation burden is much smaller, therefore practically feasible. In this paper, we apply the pathway-based analysis using Random Forests, which was first developed for gene expression data analysis, to GWAS data analysis. We also compared Random Forests with GSEA and hypergeometric method. Here, we discuss the methodological factors of pathway-based analysis using Random Forest by applying these approaches to TGEN GWAS data of Alzheimer's Disease.

**Assessment of Associations in Neuroimaging GWA Studies with Multi-dimensional Phenotypes.** *J.C. Roddey[1], O.A. Andreassen[2,3], A.M. Dale[1,4], Alzheimer's Disease Neuroimaging Initiative.* 1) Dept. of Neurosciences, University of California, San Diego, La Jolla, CA; 2) Division of Psychiatry, Ulleval University Hospital, Oslo, Norway; 3) Institute of Psychiatry, University of Oslo, Oslo, Norway; 4) Dept. of Radiology, University of California, San Diego, La Jolla, CA.

A neuroimaging genome-wide association study (GWAS) can involve high dimensional genetic data (e.g. 1,000,000+ SNPs) and potentially even higher dimensional imaging phenotype data. The number of subjects in a neuroimaging GWAS is typically less than 1000, rarely more than several thousand, and the reported effect sizes in prior studies have been relatively small. In light of these factors, an exhaustive search for highly significant associations between genetic variants and univariate imaging phenotypes probably will suffer from low statistical power after correction for multiple comparisons. This problem can be ameliorated via a priori selection and analysis of weighted combinations, or projections, of the multidimensional imaging data (e.g. choosing a single imaging feature, or the mean of all features). However, this approach will be insensitive to real associations involving unselected phenotypic combinations. Therefore, methods that minimize prior assumptions about optimal projection directions while maximizing the sensitivity of association tests are required. We have developed a set of algorithms similar to ridge regression and regularized canonical components analysis (CCA) for identifying significant associations of genetic variants with projections of multidimensional phenotypes. We applied the algorithms to data from two independent studies: Thematically Organized Psychosis research (TOP), and the Alzheimer's Disease Neuroimaging Initiative (ADNI). The genetic variants were SNPs (500,000+ SNPs in each study), and the phenotypes were brain structure measures derived from 3D MRI data. For each SNP, an optimal projection direction in multidimensional phenotype space was learned from training data, and it was used to obtain a derived univariate phenotype for subjects in the test set. Assaying the associations in test sets minimized the risk of false positives. We identified SNPs located within and near genes involved in brain development, including several implicated in microcephaly (MCPH), that were significantly associated with specific patterns of cortical areal expansion in the discovery sample (TOP). A subset of the findings replicated in the second sample (ADNI). Since the genotyping platform was not the same in the two studies, we used MACH to impute genotypes at unassayed SNPs in the HapMap CEU reference sample. We used EIGENSTRAT to control for ancestral differences among subjects.

**Improved Ranking and Selection of Single Nucleotide Polymorphisms in Association Studies.** *H. Schwender[1], K. Ickstadt[2], I. Ruczinski[1].* 1) Department of Biostatistics, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 2) Department of Statistics, TU Dortmund University, Dortmund, Germany.

A major goal of the analysis of data from association studies is the detection of SNPs exhibiting an impact on the risk of developing a disease. The typical strategy for identifying such SNPs is to carry out SNP-specific (marginal) tests such as the Cochran-Armitage trend test, rank the SNPs by their p-values, and declare SNPs with a Bonferroni corrected p-value less than a prespecified level (typically, 5%) to be significant. Although this certainly is an acceptable strategy for a first pass through the data, it has several drawbacks. On the one hand, employing a Bonferroni correction is much too conservative when simultaneously testing hundreds or thousands of SNPs that are partly highly correlated due to linkage disequilibrium. On the other hand, this strategy does not take the multivariate data structure of the SNPs into account, and therefore does not allow to identify SNPs that only show an effect on the disease risk when interacting with other SNPs. A solution to these problems is to employ regression or discrimination methods such as logic regression that explicitly search for interactions of variables, and thus enable the detection of disease-associated SNPs without a marginal effect. Based on the output of such procedures the importance of each SNP for a good prediction of the response of a study can be quantified, which in turn can be used to test the SNPs. In this presentation, we will propose a testing method that makes essential use of this idea to enable a more appropriate ranking of SNPs than univariate testing, and thus to improve the detection of disease-associated SNPs. We will furthermore show how an empirical Bayes approach can be applied to the resulting test statistics to control the false discovery rate at a certain level leading to a less conservative approach than the Bonferroni correction. Finally, it will be described how the proposed method can be extended to test biological sets of SNPs (e.g., SNPs belonging to the same LD-block or gene) and other types of responses (e.g., quantitative and multi-categorical responses).

**Tiled Logistic Regression for Response to Antidepressant Treatment.**
*H. Sung[1], Y. Kim[1], J. Cai[1], A. Sorant[1], F. McMahon[2], A. Wilson[1].* 1) Genometric Section, Inherited Disease Research Branch, National Human Genome Research Institute, NIH, Baltimore, MD; 2) Genetic Basis of Mood and Anxiety Disorders, National Institute of Mental Health, NIH, Bethesda, MD.

A new method called "Tiled Regression" has been developed and is described elsewhere for quantitative traits [Wilson et al., pers. comm.]. In this method, the genome is divided into independent regions, or tiles, and the SNPs or sequence variants within each tile are analyzed with multiple and stepwise regression to identify only those markers within the tile that have independent and significant additive effects on the phenotype. Markers identified in independent tiles are then reanalyzed, again with stepwise regression, in an attempt to identify all independent markers that have a significant effect on the phenotype. In this study, tiled regression is extended to include logistic regression for qualitative or dichotomous traits. Tiled logistic regression was applied to a binary trait "responder status" in data from the STAR*D (Sequenced Treatment Alternatives to Relieve Depression) study [Rush et al., 2004]. This trait was derived from the relative improvement in QIDS-C16 (a standard depression score) over a period of antidepressant treatment. 1096 white subjects were categorized according to high or low levels of improvement and were analyzed with 705 SNP markers in candidate genes. The analyses were done with tiles defined in two different ways: by hotspot regions (within and between high-recombination "hotspots") and by gene (within and between known genes). In most cases, no more than one marker was chosen from any tile. At a significance level of 0.05, seven SNPs were selected for the final model using hotspot-based tiles and eight using gene-based tiles, with five SNPs appearing in both models. In both models, the SNP rs7997012 on chromosome 13, part of the HTR2A gene which encodes the serotonin 2A receptor, had the most significant p-values (0.00116 and 0.00163 using hotspot- and gene-based tiles, respectively). This is the same SNP previously noted by McMahon et al. [2006].

**A case study of a statistical tool for fine-scale mapping.**
*R. Young[1], S. Padmanabhan[2], V. Macaulay[1].* 1) Statistics Dept, University of Glasgow, United Kingdom; 2) BHF Glasgow Cardiovascular Research Centre, University of Glasgow, United Kingdom.

Various methods have been proposed to identify the genetic basis of diseases that are caused by both genetic and environmental conditions, with the treatment of multiple testing often in the foreground. The effectiveness of four approaches is here assessed, in particular (1) 'Treescan' proposed by Templeton et al.(*Genetics 169:441-453*), (2) a single site analysis based on Treescan (3) analysis adjusted by Bonferroni correction and (4) a novel method that uses Bayes Factors in place of the F statistics used in the Treescan and single SNP methods. Data sets have been simulated under a wide variety of conditions and the simulator and analyses have been implemented in R, with a graphical user interface provided by 'rpanel'. These data sets were used to test the effectiveness of each method in finding a simulated known causal variant that increases a continuous phenotypic score, thus avoiding categorizing individuals as either case or control. Initial results suggest that the most suitable method depends strongly upon the conditions imposed on the simulated data, which are chosen according to numeric values that are consistent with real data. There is however an indication that the use of Bayes Factors in this context will provide some advantages over the frequentist methods, depending on hyperparameter choices. Each method is also applied to a real data set involving heart rate and blood pressure measurements, and the use of the Bayes Factors methods detects a possible causative SNP that the other methods have insufficient power to detect.

## 1758/T/Poster Board #307

**Using a local extension of HapMap 3 to raise SNP imputation quality and to identify CNV tag-SNPs in population isolates.**
*S. Ripatti[1,2], I. Surakka[1,2], K. Kristiansson[3], V. Anttila[3], M. Innouye[3], M. Daly[4], L. Moutsianas[5], M. Hurles[3], A. Palotie[1,3,4], L. Peltonen[1,2,3,4].* 1) Institute for Molecular Medicine Finland FIMM, Helsinki, Finland; 2) Public Health Genomics Unit, National Institute for Health and Welfare, Helsinki, Finland; 3) Wellcome Trust Sanger Institute, Hinxton, UK; 4) The Broad Institute of Harvard and MIT, Cambridge, Massachusetts, USA; 5) University of Oxford, Oxford, UK.

The introduction of HapMap 3 reference data set combining data from two commercially available dense marker chips has made it possible to create similar local reference samples with relatively low cost. This is particularly useful for populations not included in the HapMap 3 and for genetically homogeneous population isolates. In this work we illustrate with Finnish data how a local reference of 81 Finns (40 individuals from general population and 41 individuals from late settlement Kuusamo region) with 1.6 million SNP markers and 2.8 million probes for CNV detection can efficiently be used for two aims: 1) to gain precision in imputation quality of population samples with lower density markers, and 2) to identify SNPs tagging CNV regions in local populations. With a Finnish population-based sample of 2138 individuals, we show that the average $R^2$ between imputed and directly genotyped markers raises from 0.85 to 0.91 with Hapmap3 CEU +TSI reference and joint Hapmap3 + Finnish reference, respectively, when imputing SNPs in Illumina 370K resolution to Illumina 610K resolution. In a subset of 429 individuals with both parents being born in a regional bottleneck population originating from some 400 chromosomes 400 years ago, the $R^2$ raised from 0.85 to 0.94. The imputation quality gain was largest in the lower frequency SNPs with 1% < MAF < 5%. The strong LD structure and dense probe set also allowed us to identify SNPs tagging CNV regions. We investigated 13500 putative CNV loci and initially identified 4980 regions in our Finnish reference data. For these 4980 loci, we tested for an association between summarized CNV probe signal intensities and SNP genotypes. We found 908 distinct CNV loci which were tagged by one or more SNPs with $R^2 > 0.50$ and 475 CNV loci tagged with $R^2 > 0.80$. To evaluate the gain in using population specific data in CNV tagging, we compare the tag-SNPs identified by Hapmap3 CEU and TSI CNV genotyping, and tag-SNPs discovered in analysis of our Finnish reference data. Finally, we illustrate how the better imputation quality and tag-SNP identification provide statistical power gain for detecting associations with metabolic traits in our Finnish population-based cohorts with special emphasis on lower frequency SNPs and CNVs. The population specific HapMap 3 datasets are thus beneficial for providing improved resolution for imputing and increase in statistical power for detecting association.

## 1759/T/Poster Board #308

**MSGene - A novel and publicly available database of genetic association studies in multiple sclerosis.** *C.M. Lill[1], M.B. McQueen[2], B.-M.M. Schjeide[4], U. Zauft[4], S. Bagade[3], F. Zipp[1], L. Bertram[3,4].* 1) Cecilie Vogt Clinic for Neurology, Charité - University Hospital, Berlin, Germany; 2) University of Colorado, Boulder, CO, USA; 3) Genetics and Aging Research Unit, MassGeneral Institute for Neurodegenerative Disease, Massachusetts General Hospital, Charlestown, MA, USA; 4) Neuropsychiatric Genetics Group, Max Planck Institute for Molecular Genetics, Berlin, Germany.

Multiple sclerosis (MS) is a genetically complex disorder that shows familial aggregation without following Mendelian inheritance. Rather, it is governed by a variety of genetic and non-genetic factors, which define an individual's risk to develop the disorder. In the past two decades, hundreds of reports have been published claiming or refuting genetic association between putative MS genes and disease risk. In addition, several genome-wide association studies (GWAS) have been reported, highlighting putative novel MS loci that need further validation. Similar to the situation in other genetically complex diseases, this wealth of information is becoming increasingly difficult to follow, evaluate, and most importantly to interpret. To this end, based on methodology previously developed by our group (Bertram [2007] Nat Genet 39(1):17-23), we are currently building a database ("MSGene"), which will serve as an exhaustive, unbiased, and regularly updated resource of all MS genetic association studies published in peer-reviewed journals. Data for MSGene will be gathered following systematic searches of the scientific literature, and will summarize essential characteristics of each study, including sample size and ethnicity of the investigated populations, as well as gene-specific results and genotyping details (e.g. genotype and allele frequencies). Following this strategy, we have now systematically collected and summarized over 800 MS genetic association papers reporting on over 2000 polymorphisms across 445 independent loci. In addition to these candidate gene-based studies, MSGene also provides detailed summaries of the five currently published GWAS. An integral part of MSGene is the systematic computation of random-effects meta-analyses for all polymorphisms with sufficient available genotype data. Of the 93 meta-analyses currently available in MSGene, 17 genetic variants in 14 loci show significant effects across all published studies (with average odds ratios of ~1.3, ranging from 1.1 to 1.6); nearly half of these were originally implicated by GWAS (e.g. *CLEC16A*, *IL7R*). All data collected as part of this project - including the results of the up-to-date meta-analyses - will be made publicly available at http://www.msgene.org, scheduled to go online in September 2009. At the meeting, we will provide a synopsis of the current status of the MS genetics field, with a particular focus on those loci showing significant summary odds ratios.

## 1760/T/Poster Board #309

**C-Reactive Protein levels and body mass index: elucidating direction of causation through a reciprocal Mendelian Randomization design.** *N. Timpson[1], B. Nordestgaard[2], R. Harbord[3], J. Zacho[2], T. Frayling[4], A. Tybjaerg-Hansen[5], G. Davey Smith[1].* 1) MRC CAiTE Ctr/Social Med, Bristol Univ, Bristol, UK; 2) Department of Clinical Biochemistry, Herlev Hospital, Copenhagen, Denmark; 3) Department of Social Medicine, Bristol Univ, UK; 4) Institute of Biomedical and Clinical Science, Penninsular Medical School, Exeter Univ, Exeter, UK; 5) Department of Clinical Biochemistry, Rigshospitalet, Copenhagen Univ Hospital, Faculty of Health Sciences, Copenhagen, Denmark.

We used genetic data to help assign direction of causality within a network of observational associations; a procedure which is problematic outside of randomised experiments. Through the application of reciprocal Mendelian randomisation, we employ confirmed genetic associates of BMI (FTO, rs9939609) and CRP (CRP, rs3091244) to interrogate observational associations between C-reactive protein (CRP) and BMI (body mass index) in the Copenhagen General Population Study (n>37,000). In this population, the observational change in logCRP for a standard deviation increase in BMI can be summarised in a ratio of geometric means of 1.36(1.35, 1.37), which approximates to a 0.65 unit increase in circulating CRP (at the median and in sex-adjusted analyses). In efforts to avoid measured confounding in observational studies of BMI and CRP, analyses using CRP variation to re-estimate the causal effect of circulating CRP on BMI yielded null effects (change in BMI per unit change in logCRP -0.30(-0.78, 0.18), p=0.2). However, those using FTO variation to assess this association as driven by BMI, confirmed observational associations between BMI and CRP (ratio of geometric means of CRP per unit change BMI 1.06(1.02, 1.11), p=0.002). These data suggest that the observed association between circulating CRP and BMI is driven by BMI, with CRP being a simply a marker of elevated adiposity. Reciprocal Mendelian randomisation has applicability in determining direction of causality within inter-correlated biological networks. Methods such as this provide an approach for delivering immediate and clinically applicable information, which operates at a level above that of basic genetic associations.

## 1761/T/Poster Board #310

**A New Statistic in Evaluating Imputation Reliability.** *P. Lin[1], Z. Zhang[1], S. Hartz[1], S. Saccone[1], J. Wang[1], M. Schuckit[2], J. Tischfield[3], L. Bierut[1], J. Rice[1], COGA Collaborators, COGEND Collaborators, GENEVA.* 1) Washington Univ in St L, St. Louis, MO; 2) School of Medicine, University of California, San Diego, CA; 3) Dept of Genetics/Human Genetics Institute, Rutgers University, Piscataway, NJ.

Imputation is commonly used in genome wide association studies to boost power. Statistics for measuring the accuracy of imputation are frequently inadequate for evaluating the quality of imputation because concordance due to chance increases dramatically as alleles become more rare. Specifically, imputation accuracy, a measure of the concordance rate between the imputed and observed genotypes for each SNP, as well as average maximum posterior probability, dramatically over-estimates reliability when minor allele frequencies are low. Here we introduce a new statistic, the imputation quality score (IQS), as an improved measure to differentiate between well-imputed SNPs and poorly-imputed SNPs. IQS adjusts for chance agreement and addresses the inflation of false positive rate arising from imputation error. We used about 4000 individuals genotyped on the Illumina 1M array for SAGE, one study in the Gene Environment Association (GENEVA) project. We randomly divided the data into two subgroups labeled cases and controls. In cases, original genotypes were retained only for SNPs on the Illumina 550K array; these were then imputed to the full Illumina 1M array. In controls, original genotypes were retained for all SNPs on the Illumina 1M array. The initial Q-Q plots showed many false positives with values of -log(P) exceeding 100, reflecting imputation error. In order to improve the Q-Q plots, we compared the effect of filtering by traditional imputation quality measures to filtering by IQS. Traditional measures were unable to distinguish well-imputed SNPs from poorly-imputed SNPs. But, after using IQS to filter out poorly-imputed SNPs, we successfully adjusted the Q-Q plot back to an acceptable level. This demonstrates the IQS's potential usage in combining genotype data from different arrays.

**Methylation and gene expression microarray data integration.** *S. Sun.* Math Biosci Inst, Ohio State Univ, Columbus, OH.

DNA methylation plays a very important role in the silencing of tumor suppressor genes in various tumor types. In order to gain a genome-wide understanding of how changes in methylation affect tumor growth, the differential methylation hybridization (DMH) protocol has been developed and large amount of DMH microarray data have been generated. However, it is still not clear how to integrate these high throughput methylation data with gene expression data to obtain a clear picture of the role of methylation in the whole genome. In this poster, we propose a novel three step procedure for data integration: (1) using a quantile regression method to identify genes that are commonly hyper-methylated, (2) identifying the co-expression network, and (3) using the idea of one-to-many mapping to find the methylated hub genes that are significantly associated with genes in each network. This procedure is illustrated in breast cancer cell line data.

## 1763/T/Poster Board #312

**How much variation is there among copy number variation algorithms? A case study using the Affymetrix SNP Array 6.0.** *E.J. Atkinson[1], M. de Andrade[1], J. Eckel-Passow[1], W. Bamlet[1], M. Matsumoto[1], S. Maharjan[1], S. Kardia[2].* 1) Div Biomedical Statistics, Mayo Clinic, Rochester, MN; 2) Epidemiology, University of Michigan, Ann Arbor, MI.

As the number of genome wide association studies (GWAs) increase, an additional benefit is the ability to investigate copy number variation (CNV). CNV data obtained from GWA SNP chips is a relatively new technology and there are an increasing number of software packages devoted to extracting CNV data. However, there has been no formal comparison exploring the impact that these different software packages have on the corresponding results. We extracted CNV data from the Affymetrix SNP Array 6.0 on 854 samples of hypertensive sibships from Rochester, MN, using PennCNV, Canary, and the R packages CRLMM and aroma.affymetrix. Variations among normalization, impact of "bad" samples, and choice of a reference sample were explored. A comparison of these four software packages will be discussed using the hypertensive data.

## 1764/T/Poster Board #313

**Genome-Wide Association Studies (GWAS): Performance comparison between Illumina® 1M BeadChip and Affymetrix Genome-Wide Human SNP Array 6.0 (Affy 6.0) GWA arrays.** *K. Hetrick[1], B. Marosy[1], M. Zilka[1], C. Oncago[1], J. Romm[1], H. Ling[1], K. Barnes[2], E. Pugh[1], K. Doheny[1].* 1) Center for Inherited Disease Research (CIDR) and Genetic Resources Core Facility (GRCF) SNP Center, IGM, JHUSOM, Baltimore, MD; 2) Johns Hopkins Asthma and Allergy Center, Johns Hopkins University, 5501 Hopkins Bayview Circle, Baltimore, MD.

CIDR provides high quality genotyping services and statistical genetics consultation to investigators working to discover genes that contribute to common disease. Previously, we only offered GWA SNP genotyping services using Illumina products. As part of our process to evaluate offering an Affy 6.0 array service to our investigators, we performed a side by side experiment investigating performance between the two arrays. Sample and SNP statistics were analyzed on a sample set consisting of related and unrelated study and HapMap samples with 4 replicate pairs (136 total samples). Illumina data was analyzed with Illumina's BeadStudio and Affymetrix was analyzed with birdseed v2 in Affymetrix's Genotyping Console. In order to determine a call rate threshold for Affymetrix data, we looked at the discordance rate between both sets of data where the SNPs matched. As a sample's call rate fell to 98% on Affymetrix (matching Illumina call rate >99%), the discordance rate rose above 1%. Mean sample call rates were 99.0% (SD 0.6%) for Affymetrix and 99.5% (SD 0.2%) for Illumina. Error rates in replicates were 0.25% (Affymetrix) and 0.02% (Illumina). Mendelian error rates were 0.71% (Affymetrix) and 0.04% (Illumina). After applying a SNP technical filter (call rate <85%, >2 replicate errors), mean autosomal SNP call rates were 99.29% (SD 1.84%) for Affymetrix and 99.80% (SD 0.97%) for Illumina. Estimates of the proportion of unusable SNPs for an association study (call rate <90%, HWE <10-6 or MAF <1% in autosomal SNPs) were 12.4% (Affymetrix) and 10.4% (Illumina). Further experiments were done to evaluate the ability to detect mixed genomes as well as the effect of DNA concentration on both arrays. In related mixtures (50/50, 75/25, 90/10 and 95/5), >10% mixture failed call rate on Illumina with error rates <0.04% for passing mixtures; while >25% mixture failed call rate on Affymetrix with error rates <0.23% for passing mixtures. In unrelated mixtures (50/50, 66/33, 85/15, 90/10), all call rates were <98%. Nine identical HapMap aliquots were assayed using a DNA concentration gradient ranging from 10 ng/ul to 300 ng/ul. QC measures were stable across the range for Illumina while a decrease in data quality was demonstrated for Affymetrix below 50 ng/ul. These experimental results provided us the confidence to provide Affy 6.0 as a genotyping service. (Please see Romm, et al., Barnhart, et al., Ling et al. abstracts for related information).

## 1765/T/Poster Board #314

**Quality score recalibration of next-generation sequencing reads : application to the 1000 Genomes data.** *A. Menelaou, J. Marchini.* Department of Statistics, University of Oxford, Oxford, United Kingdom.

Next-generation sequencing technologies are making it possible to carryout whole-genome sequencing at the population scale and are likely to be widely used in all aspects of human genetics research. These technologies produce short sequencing reads together with Phred scores for the read bases. These Phred scores encapsulate the uncertainty of read bases and should ideally be propagated through to any subsequent analysis of the data, such as novel SNP detection. We have investigated whether improvements in the calls and their estimates of Phred scores can be improved through the use of contextual information about the read such as the flanking sequence content, flanking base Phred scores and the position in the read of the base. To do this we selected all the aligned reads from 10 2Mb regions on chromosome 20 in 16 CEU individuals from the April release low coverage pilot project of the 1000 Genomes data. We used the program samtools to retrieve the subset of reads overlapping SNPs present in both the HapMap2 and HapMap3 datasets. In each individual we then focussed exclusively on reads where the HapMap2 and HapMap3 genotypes both reported the same homozygote genotype and we took the genotyped allele to constitute the truth underlying that read. We excluded reads that showed evidence of indels and had low mapping quality (< 60). The raw error rate for this set of reads was 1.018%. Examination of the raw data indicated noticeable variation in error rate according to the context of the sequence read and the position of the base in the read. We fit several different neural network models to try to predict the true allele based on the available contextual information about each read. The best model we found consisted of 1 level of 4 hidden units and included the following predictors : the read base, the flanking read bases, the Phred score at the read base, the sum of the Phred scores at the flanking bases and the relative position of the read base in the read. This model gave a cross-validated error rate of 0.994%. All the reads that were corrected by this recalibration had Phred scores below 10. The re-calibrated Phred scores from our model are well calibrated at scores above 20 but show a slight underestimation of accuracy at lower scores. Our results illustrate that contextual information can be used to improve the overall all error rate of the reads and have the potential to save as many as $10^{10}$ reads in the 1000 Genomes project.

## 1766/T/Poster Board #315

**Analysis of homozygous runs of SNPs in the 11 HapMap 3 populations.** *F.J. Boehm, T.R. Bhangale, B.S. Weir, GENEVA.* Dept Biostatistics, Univ Washington, Seattle, WA.

Extended tracts of homozygous single nucleotide polymorphisms (SNPs) arise due to a multi-generational dynamic interplay among inbreeding, recombination, and other processes. Lencz et al. and others have developed methods for association mapping using runs of homozygosity. Characterization of homozygous runs in the eleven diverse HapMap3 populations represents a first step in the process of identifying potential disease-associated genomic regions in populations of differing continental ancestry. Additionally, our methods may aid in the detection of genotyping errors. We identified runs of homozygosity in the 11 HapMap3 populations. One novel aspect of our approach is that we implemented a hidden Markov model to identify sites of genotyping errors within homozygous runs, thus allowing more accurate determination of run lengths. In this sense, our methods may be applicable to data cleaning procedures in genome-wide association studies. After we identified the runs for each subject, we compared the number of runs and lengths of runs per subject by continental ancestry group. Furthermore, we investigated regions of shared homozygosity among subjects of a given continental ancestry. We further characterized the homozygous runs by examining the total probe intensities of those SNPs on the Affymetrix 6.0 chip. A region of decreased total probe intensity that coincides with a run of apparent homozygosity suggests that that particular region of homozygosity is explained by a hemizygous deletion that led to a monoallelic state, while no change in the total probe intensity over a run of homozygosity suggests that the region is one of biallelic homozygosity. Thus, our methods allow for detection of a second class of genotyping error. Given the current interest in genome-wide association studies (GWAS), we feel that our multifaceted characterization of runs of homozygosity in genome-wide SNP data is a valuable resource to those investigators who seek to identify disease-associated genomic regions and has potential value in GWAS data cleaning procedures.

## 1767/T/Poster Board #316

**Genotype Calling for Trisomic Samples.** *S. Cheong[1], E. Feingold[2].* 1) Dept Biostatistics, Univ Pittsburgh, Pittsburgh, PA; 2) Dept Human Genetics, Univ Pittsburgh, Pittsburgh, PA.

Genotypes are "called" from raw intensity data using statistical clustering techniques, and software packages are available to do this for various genotyping technologies. For individuals with chromosomal abnormalities, however, standard genotype-calling software cannot be used. We describe several approaches to calling genotypes for a large sample of individuals with Down syndrome. We develop a method that first applies standard genotype-calling algorithms and then adjusts the calls to handle the trisomy, and compare it to a previously-published method that clusters the trisomic genotypes de novo. We illustrate and test both approaches with on several datasets.

## 1768/T/Poster Board #317

**Accurate IBD inference identifies cryptic relatedness in 9 HapMap populations.** *A. Dimitromanolakis[1], A.D. Paterson[2,1], L. Sun[1,3].* 1) Dalla Lana School of Public Health, University of Toronto; 2) Genetics and Genomic Biology, The Hospital for Sick Children, Toronto; 3) Department of Statistics, University of Toronto.

The HapMap project has been very successful in mapping human genetic variation. If numerous cryptic relationships exist among founder individuals in the dataset, the accuracy of allele frequency calculations, estimation of LD patterns, selection of tag SNPs, population stratification analysis and association studies could all be adversely affected. We extended our previous work (McPeek and Sun, 2000), developed for genome-wide linkage data, with PREST-plus, suitable for both population and family based genome-wide association studies, and we applied an accurate likelihood-based IBD inference via the EM algorithm to the most recent release (#27, phase 3) of HapMap data. Cryptic relatedness was detected in 195 of the 1002 founders (20%) . Among the 271 founder pairs that were shown to share more that 10% of their genome (p.IBD.0 < 0.9), we found strong evidence for first-degree relatives, including 21 parent-offspring and 27 full-sibling pairs. In particular, among the 4 phase II populations, we identified 4 related pairs in the CEPH founders and 3 related pairs in Yorubans in Ibadan. Among the 11 phase III populations, a very extended family structure was uncovered in Maasai, where 119 of the 180 founders were found to be related. Additional closely related pairs were present in 6 other populations. The results were validated using the method of moments IBD inference algorithm implemented in PLINK (Purcell et al., 2007). We would like to emphasize the importance of checking for cryptic relatedness in genetic studies and provide an outline of the necessary steps to achieve this, by the use of PREST-plus and companion post-processing R scripts assisting the interpretation of the results.

**Overcoming Data Quality and Copy Number Detection Issues in Genome-Wide CNV Association Studies.** *C. Lambert[1], G. Linse[1], J. Grover[1], D. Hawkins[2], J. Forsythe[1].* 1) Golden Helix, Inc, Bozeman, MT; 2) School of Statistics, University of Minnesota, Minneapolis, MN.

Incorporating copy number variations into genome-wide association studies promises to explain more of the heritability of common diseases than that accounted for by SNPs alone. This potential goldmine however, has been plagued by myriad of technical and experimental challenges. We examine the most persistent issues observed in over 20 CNV GWAS studies conducted by us and our collaborators. These include huge batch effects, genomic waves, mosaicism, T-cell artifacts and poor signal-to-noise ratios, all of which can lead to false positive and negative CNV detection and subsequent association findings. To address these issues we describe a novel principal component analysis approach that simultaneously corrects for batch and wave effects and population stratification, while significantly improving signal-to-noise ratios. We address the challenge of lingering batch effects in CNV regions. We then describe optimal segmentation methods which use dynamic programming to detect copy number segment boundaries on either a per-sample (univariate) or a multi-sample (multivariate) basis. Unlike Hidden Markov Model methods, which assume the means of different copy number states are consistent, optimal segmenting methods properly delineate segment boundaries in the presence of mosaicism, even at a single probe level, and with superior sensitivity and false discovery rates. We then outline several approaches to genome-wide scans for CNV association, demonstrating the utility of these methods on a series of large-scale GWAS.

## 1770/T/Poster Board #319

**Comparisons of calling strategies on Affymetrix® 6.0 arrays (Affy 6.0) using Birdseed v2.** *H. Ling, K. Hetrick, B. Marosy, S. Pottinger, J. Gearhart, C. Boehm, J. Romm, E. Pugh, K. Doheny.* CIDR, Johns Hopkins University, Baltimore, MD.

The Center for Inherited Disease Research (CIDR) provides high quality genotyping services and statistical genetics consultation to investigators working to discover genetic variants that contribute to common diseases. Recently, we have begun to offer an Affy 6.0 genotyping service and use Birdseed v2 to call genotypes. As Birdseed is a multiple-chip calling algorithm, genotype calls can be made either by using all samples (call-by-project) or a subset of samples that were processed in the lab together (call-by-batch) for each study. To find an appropriate calling method for our lab, we assessed the performance of the two calling methods by examining a set of SNP as well as sample level QC metrics. The analysis was performed on a case-control study of T2DM, our 1st Affy project, which includes 2,007 AA samples. After excluding samples that failed our daily QC filters, 2,143 samples including 46 blind duplicates and 90 HapMap controls were called by Birdseed v2 using the two SNP clustering approaches. Data were analyzed in PLINK and SAS. The mean sample call rate (CR) was 99.5% for call-by-project and 99.72% for call-by-batch with an average genotype concordance rate of 99.92% between the two methods. 21 samples showed a CR difference greater than 1%. Among the 70 related HapMap samples, the mean Mendel error rate was 0.10% for both methods. The error rates per blind duplicate pair were less than 1% in both methods. In total, 906,600 SNPs (868,157 autosomal) were called for each sample. Similar to sample level QC metrics, call-by-batch showed a higher autosomal SNP CR but lower concordance rate (both HapMap and blind duplicate) than call-by-project. Although call-by-project had a slightly higher number of Mendel errors than call-by-plate (27,641 vs. 27,004), after removing SNPs with CR below 95%, the number of Mendel errors drops 31% for call-by-project and 7.8% for call-by-batch. In addition, nearly 59% and 29% SNPs with CR below 95% have Mendel errors when called by project and by batch, respectively. By comparing these statistics between the two calling methods, we found 4.2% SNPs have CR difference greater than 1%, and 0.08% SNPs have a MAF difference greater than 10%. 10,224 and 8,696 SNPs had HWE P-value $< 10^{-5}$ for call-by-project and call-by-batch. Among 861,495 SNPs that were above this threshold for at least one method, 6,655 showed a difference in -logP greater than 5. Our current practice is to release genotypes called using both strategies.

## 1771/T/Poster Board #320

**Single-sample QC for the Affymetrix Next Generation Genotyping Platform.** *Y. Lu, E. Wang, M. Moorhead, T. Webster, S. Cawley.* Affymetrix, Inc. 3420 Central Expressway Santa Clara, CA 95051.

Sample QC is an important analysis step in any Genome Wide Association Study. It is well known that the quality of genotyping results is affected by the sample quality and the data quality of samples used in the genotype clustering. Therefore, it is particularly useful to be able to perform single-sample QC analysis to identify and exclude all low-quality samples before running genotype clustering.

We have developed a new set of single-sample QC metrics for the Affymetrix next generation genotyping platform, a two-color ligation based genotyping assay. The metrics assess the single sample quality at both the single-color level and the two-color level. Our results show that the two-color level QC metric is strongly correlated with the overall data quality for the sample and effectively identifies and removes low quality samples. These metrics are helpful both in the process of optimizing the system and in for use in future association studies.

## 1772/T/Poster Board #321

**Impact of sample pretesting in a high through-put genotyping facility.** *B. Marosy, C. Boehm, B. Craig, J. Romm, C. Oncago, M. Zilka, M. Adams-Carr, Y. Osimokun, K. Hetrick, H. Ling, E.W. Pugh, K.F. Doheny.* CIDR/GRCF-IGM, JHU-SOM, Baltimore, MD.

DNA samples received by CIDR undergo pre-testing (if funding supports this step) prior to production genotyping to confirm gender, detect Mendelian inconsistencies, assess sample quality and provide a genotype barcode to track samples through production lab processing and data release. Problems are reported allowing for samples to be replaced, dropped or information to be corrected. We present results for 12 GWA projects and 17 linkage and custom SNP projects that were genotyped using the Illumina® Infinium and GoldenGate platforms. Data was collected on sample problems identified at pre-testing and prior to data release. Investigator responses to problems reported at the pre-testing phase were categorized based on the outcome for each sample problem and whether replacing a sample or changing sample information fixed the problem.

| Total samples | 41748 (GWA) | Avg/ GWA proj | Range/ GWA proj | 22786 (non-GWA) | Avg/non-GWA proj | Range/non-GWA proj |
|---|---|---|---|---|---|---|
| Testpanel problem | 1676 | 4.0% | 0.3%-10.7% | 822 | 3.6% | 0%-8.6% |
| Problem fixed | 1552 | 3.7% | 1%-10.6% | 578 | 2.5% | 0%-6.1% |
| Problem not fixed | 124 | 0.3% | 0%-0.8% | 244 | 1.1% | 0%-3% |
| New at release | 359 | 0.9% | 0%-2% | 485 | 2.1% | 0%-9.1% |

Pre-testing has proven to be a helpful tool to aide in providing high quality genotyping data by validating sample information, evaluating sample quality and minimizing costs. For example, for an average GWA study of 3,000 samples, the pre-testing process saves $40,000. For the GWA project with the greatest number of identified problems, over $300,000 was saved.

## 1773/T/Poster Board #322

**Evaluating the Effects of Batch Composition and Size on BRLMM Genotype Calls for the Affymetrix 500K Array.** *K. Miclaus, MAQC Genome-Wide Association Working Group.* Statistics, SAS Inst Inc, Cary, NC.

The Affymetrix GeneChip Human Mapping 500 K array is a popular choice for Genome-Wide Association Studies (GWAS). Recent findings have highlighted the importance of accurate genotype calling algorithms to reduce inflation in Type I and Type II error rates. Differential results due to genotype calling errors can introduce severe bias into case-control association study results. With data from the Wellcome Trust Case Control Consortium, 1991 individuals with coronary artery disease (CAD) and 1500 controls from the UK Blood Services (NBS) genotyped on the Affymetrix 500 K array, different batch sizes and compositions were used in the Bayesian Robust Linear Model with Mahalanobis distance classifier (BRLMM) genotype calling algorithm in order to assess the batch effect on downstream association analysis results. Results show that the composition (cases and controls genotyped simultaneously or separate) as well as size (number of individuals processed by BRLMM at a time) can create 2-3% discordance in the SNP results for quality control and statistical analysis and may contribute to the lack of reproducibility between GWA studies. Changes in batch size are largely responsible for differential SNP results, yet we find evidence of an interactive effect of batch size and composition that contributes to discordant results in the list of significantly association loci.

## 1774/T/Poster Board #323

**Automated evaluation of signal intensities - cluster validity measures are great.** *A. Ziegler[1], A. Schillert[1], O.-J. Frahm[1], T. Zeller[2], D.F. Schwarz[1], S. Blankenberg[2].* 1) Inst Med Biometry & Statistics, Univ Luebeck, Luebeck, Germany; 2) Johannes Gutenberg University Mainz, Germany, Dept. Of Medicine II.

The visual inspection of signal intensity plots (cluster plots) by two experienced independent readers is standard in the quality control of genome-wide association studies (GWAs). This process is time-consuming and expensive, and therefore restricted to candidate single nucleotide polymorphisms (SNPs) in practice. Thus, the valid judgement of signal intensities for all SNPs from a GWA through an automated procedure would be helpful. Even more so, meta-analyses which require imputed genotypes and machine learning approaches like random forests would greatly profit from this. So far, only few approaches for automatically evaluating signal intensities have been proposed [Plagnol et al. 2007 PLoS Genet, 3:e74, Schillert et al. 2009 BMC Proc, in press; Teo et al. 2008 Ann Hum Genet, 72:368-74]. We embed the problem of signal intensity plot inspection in the well-developed theory of measuring cluster validity in cluster analyses. We propose various measures for judging cluster compactness, cluster homogeneity, cluster connectedness, cluster separability and combinations of these criteria. We jointly evaluate these criteria through a random forest approach and propose a simple combination of the aforementioned criteria. The criteria are evaluated using 3300 samples from the Gutenberg Heart Study which has been genotyped using the Affymetrix Genome-Wide Human SNP Array 6.0 in conjunction with Birdseed 2. The gold standard for signal intensity plots is provided through ratings from two independent readings of experienced readers for 5000 SNPs which successfully passed the standard quality criteria (call rate, minor allele frequency and deviation from Hardy-Weinberg equilibrium). We show that a simple combination of cluster validity measures show satisfactory agreement between visual and automated inspection of signal intensity plots. The proposed approach is extremely helpful for reducing the laboratory workload.

## 1775/T/Poster Board #324

**Does it matter which genotype calling algorithm is used for the Affy SNP 6.0?** *M. de Andrade[1], E. Atkinson[1], W. Bamlet[1], M. Matsumoto[1], S. Maharjan[1], S. Kardia[2].* 1) Div Biomed Statistics, Mayo Clinic, Rochester, MN; 2) Epidemiology, University of Michigan, Ann Arbor, MI.

As the number of genome wide association studies (GWAs) increases, SNP results are being obtained using different platforms and different calling algorithms. However, there has been no investigation focusing on the impact these algorithms might have on the results of a genome-wide association study. We will focus our work on the Affymetrix 6.0 platform where there are two genotype calling algorithms (GCA) available: Birdseed and CRLMM. These two algorithms have different recommended workflows including SNP and sample quality control selection criteria. We have evaluated these two GCAs and have come up with some best practice guidelines. For instance, Affymetrix suggests filtering samples based on contrast quality control (CQC) values prior to running Birdseed, using only samples with CQC > 0.4. On the other hand, CRLMM uses the sample quality score (SNR) and recommends that samples should be flagged with SNR values < 5. Based on our own experience we conclude that it is important to use these screening algorithms and that there is a strong correlation between these two algorithms. We used results from both GCA in our GWA and found that the study results were similar and that there appeared to be no systematic difference. We will present our results using 854 samples of hypertensive sibships from Rochester, MN.

## 1776/T/Poster Board #325

**A simple test for detecting genotyping errors using linkage disequilibrium information.** *B. Han[1], B. Hackel[2], E. Eskin[2,3].* 1) Dept Computer Sci, Univ California, San Diego, La Jolla, CA; 2) Dept Computer Sci, Univ California, Los Angeles, Los Angeles, CA; 3) Dept Human Genet, Univ California, Los Angeles, Los Angeles, CA.

In genetic association studies using high-throughput genotyping technologies, genotyping errors can occur at certain positions of single nucleotide polymorphisms (SNP) resulting in spurious associations. Tests based on Hardy-Weinberg equilibrium (HWE) may fail to detect these errors if the error SNPs do not deviate from HWE. Recent availability of reference datasets allows us to estimate the linkage disequilibrium (LD) between SNPs. The LD information can be used to detect genotyping errors under the following reasoning. If a significant peak of p-values is due to a true association, nearby correlated SNPs will show a mountain-looking shape of significance. If a significant peak is due to genotyping error, nearby correlated SNPs will show a flat non-significant p-values. However, there is no known method that incorporates this information, which often leads to a non-systematic manual examination of errors. We propose a simple statistical testing called TED (genoTyping Error Detection) that systematically detects genotyping errors using the LD information. Given a significant SNP, commonly used statistics at nearby SNPs asymptotically follow a multivariate normal distribution (MVN). The null and alternative MVN densities can be approximated using the LD information and the effect size estimated at the significant SNP. Then, the likelihood ratio of two densities conforms a TED statistic. Assuming reference data is correct, TED is optimal if the effect size is correctly estimated. Even if the effect size is incorrectly estimated, TED still controls type I error rate. The performance of TED is stable and dependent little on the choice of nearby SNPs. TED is applied to the WTCCC data and systematically removes SNPs that are previously removed by a manual examination.

## 1777/T/Poster Board #326

**A Method to Impute Genotypes at Untyped SNPs.** *Z. Zhang[1,2], H. Qin[1], S. Zhang[1,3], Q. Sha[1].* 1) Mathematical Sciences, Michigan Technological Univers, Houghton, MI; 2) School of Computer Science and Technology, Heilongjiang University, Harbin,150080, China; 3) Department of Mathematics, Heilongjiang University, Harbin 150080, China.

In genome-wide association studies, only the genotypes of tagging single nucleotide polymorphisms (SNPs) are typed only. If we can fill in the gap of genotypes of causal untyped SNPs, the genome-wide association study can be more powerful. In this article, we propose an efficient ImPutation Expectation-Maximization (IPEM) algorithm to infer the genotypes at untyped marker loci. We utilize the linkage disequilibrium (LD) structure of an available reference dataset to infer genotypes at untyped SNPs in the dataset of a new study. The proposed approach is independent of statistical models and significantly outperforms the popular hidden Markov model (HMM) approach (Marchini et al., 2007) in terms of inferring accuracy and computational efficiency. We illustrated the practical advantages of our algorithm by applying it to 22 chromosomes on the amyotrophic lateral sclerosis (ALS) dataset and using the HapMap dataset as the reference dataset. Compared with the popular HMM method, the proposed algorithm improved inferring accuracy by 2-7% and doubled the computational efficiency.

## 1778/T/Poster Board #327

**Parallel genotype calling using neighboring loci for Affymetrix SNP 6.0 platform.** *Y.T. Chen[1], S.N. Hsu[2], C.Y. Tang[1], W.P. Hsieh[2].* 1) Department of Computer Science, NTHU, Hsinchu, Taiwan; 2) Institute of Statistics, NTHU, Hsinchu, Taiwan.

Current high throughput technologies allow researchers to genotype a huge number of Single Nucleotide Polymorphisms (SNPs) for several thousands of samples with arrays. The array-based data needs a genotype calling step before the data can be used in the genome-wide association study. The transformation from continuous intensity to discrete genotypes usually requires classification techniques on the features combined from several probes in the Affymetrix platforms. Most of the algorithms work on a SNP-by-SNP base and process multiple arrays at the same time. The most popular approaches include BRLMM, CRLMM and Birdseed. The call rates and concordance rates are generally very high for most experiments with SNP arrays using any one of the methods, but none of these methods give a satisfying solution to SNPs of low quality. In addition, only Birdseed has detailed performance reported on Human SNP 6.0 arrays. Hence, we try to include extra information and propose two improvements in this study. The first one is to include the features from the nearby SNPs. It implicitly integrates the strength of linkage disequilibrium as the features are transmitted together and have linkage structure in it. The idea has been widely used in the imputation techniques, which is based on the genotype data. We work on the intensity data directly instead of working on the genotype data as a second step to correct the errors in the calling step. The second suggestion is to include arrays of high quality from other experiments. Based on our empirical study, the call rates can be enhanced by increasing the sample size in the batch when adopting multi-array genotype calling methods. There is no need to match the sample sources as long as the extra arrays are of good quality. We will report the overall performance with samples from the HapMap project and genotyped with SNP 6.0. There are two experiments conducted by both the Affymetrix and Broad Institute and 906,600 SNP markers are assessed. The comparison is made for our proposed method as well as CRLMM, BRLMM and Birdseed. The result shows that the inclusion of neighboring SNPs has an edge on tightly linked regions where $r^2 > 0.8$.

## 1779/T/Poster Board #328

**BRLMM-P: an adaptable SNP genotyping algorithm for a variety of Affymetrix arrays.** *S. Cawley, P. Dickinson, R. Lu, A. Pirani, T. Webster, E. Hubbell.* Affymetrix, 3420 Central Expressway, Santa Clara, CA 95051, USA.

"BRLMM-P" is a genotyping method that takes normalized data from two alleles across multiple arrays and generates genotypes and confidences for each experiment and SNP. In the context of its development, much consideration has been given to extension of the framework to new situations, allowing for relatively straightforward adaptation to a variety of different Affymetrix array applications including the SNP5.0, SNP6.0 and DMET Plus arrays, in addition to some model organism arrays and the next-generation ligation-based genotyping assay. BRLMM-P performs genotyping using three subcomponents derived from the "BRLMM" method: generation of tentative genotypes from either reference data or the DM methodology, creation of cluster models from the tentatively labeled data points and prior information, and the application of the cluster models to yield genotypes. BRLMM-P uses the same underlying structure, but generates the tentative genotypes directly from the data. The first subcomponent generates tentative genotypes for the data points based on a 1-dimensional Gaussian mixture model. The likelihood model includes several special features: a Bayesian prior, which allows incorporation of previous information, a penalty for disagreeing with reference data, which allows for errors in training data, and isotonic regression, which prevents clusters from occurring in incorrect orders. These exposed features of the likelihood are "affordances" which simplify training. The second sub-component takes tentative genotypes and updates a Bayesian prior normal-inverse-Wishart mixture model resulting in a posterior mixture model of the same distributional form. Because the prior and posterior have the same form, an output posterior from one run of the code can serve as a prior in another run. The third sub-component utilizes the mixture model to make genotype calls based on the likelihood that a data point belongs to a specific cluster. This component can be run in "single-sample" mode, in which there has been no update of the mixture model, and we are only interested in generating genotype calls. BRLMM-P has been successfully used over multiple generations of products and completely different assays, not because it has the optimal clustering designed for any particular application, but because it has affordances allowing the full cycle of training to take place quickly and accurately. This makes it a useful research tool as well as a useful genotyping method.

## 1780/T/Poster Board #329

**The PhenX Toolkit - get the most from your measures.** *C. Hamilton[1], I. Strader[1], J. Pratt[1], J. Hammond[1], T. Hendershot[1], W. Huggins[1], D. Jackman[1], R. Kwok[1], D. Maiese[1], D. Nettles[1], H. Pan[1], D. Wagener[1], M. Zmuda[1], H. Junkins[2], R. Li[2], E. Ramos[2], W. Harlan[3], J. Haines[4].* 1) RTI International, Res Triangle Park, NC; 2) NHGRI, Bethesda, MD; 3) Retired, NIH; 4) Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

Despite the vast potential for cross-study comparisons, the lack of standardized or comparable phenotypic and environmental measurements has limited the ability to combine data from GWAS and other genomic studies. To enhance cross-study analyses, RTI International and the National Human Genome Research Institute (NHGRI) are collaborating on a three- year project called PhenX (consensus measures for Phenotypes and eXposures). The goal of PhenX is to identify 15 high-priority, well-established, measures in each of 20 research domains. Working Groups (WGs) of domain experts select these measures via a consensus-building process that also considers input from the broader scientific community. The measures selected by the WGs are made publicly available via the PhenX Toolkit. Researchers will want to visit the PhenX Toolkit to select measures as they plan a new study or to add measures to an existing study. Thus, the Toolkit provides a common currency for investigators who want to be able to effectively combine and/or compare their data with data from other studies. The Toolkit makes it easy for investigators to broaden their study by adding measures that are outside of their primary research focus. Visitors can search or browse the Toolkit to view PhenX measures, and then add measures of interest to a Cart. As measures are chosen, the Toolkit prompts the User to review other measures that are essential or related. Registered Users may name and save their Cart(s), and then come back later to review and/or revise. Registered Users will also have the option of sharing their Cart(s) with other Registered Users. For each PhenX measure the Toolkit provides a brief description of the measure, the rationale for including the measure in the Toolkit, protocol(s) for collecting the measure, supporting information and references. The User can generate a report that incorporates all of this information. By the end of 2009, the PhenX Toolkit is expected to include measures that were selected by 11 WGs, including Demographics, Anthropometrics, Alcohol, Tobacco and Other Substances (ATOS), Cardiovascular, Nutrition and Dietary Supplements, Environmental Exposures, Oral Health and Cancer. Broad acceptance and use of PhenX measures should greatly facilitate cross-study analysis. You can visit the PhenX Toolkit at https://www.phenxtoolkit.org/. Supported by: NHGRI, Award No. 1U01 HG004597-01.

## 1781/T/Poster Board #330

**A new PAGE in understanding complex traits: study design for analysis of Population Architecture using Genomics and Epidemiology.** *T.C. Matise[1], J.L. Ambite[2], S.A. Cole[3], D.C. Crawford[4], C.A. Haiman[5], C. Kooperberg[6], L. Le Marchand[7], T.A. Manolio[8], K.E. North[9], U. Peters[6], M.D. Ritchie[4], L.A. Hindorff[8], J.L. Haines[4] for PAGE.* 1) Dept Genetics, Rutgers Univ, Piscataway, NJ; 2) Information Sciences Institute, Univ of Southern California, Los Angeles, CA; 3) Dept Genetics, Southwest Foundation for Biomedical Research, San Antonio, TX; 4) Center for Human Genetics Research, Vanderbilt Univ, Nashville, TN; 5) Keck School of Medicine, Univ of Southern California, Los Angeles, CA; 6) Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA; 7) Cancer Research Center, Univ of Hawaii, Honolulu, HI; 8) Office of Population Genomics, NHGRI, NIH, Bethesda, MD; 9) Dept Epidemiology, Univ of North Carolina, Chapel Hill, NC.

By relating hundreds of thousands of genotypes to only a few phenotypes, mostly in individuals of one ancestry, genome-wide association (GWA) studies are identifying a rapidly growing number of associations. The Population Architecture using Genomics and Epidemiology (PAGE) Study is designed to further characterize the most promising variants along an epidemiological dimension that is substantial in its sample size, ethnic diversity, breadth of phenotypes, and exposures. PAGE includes scientists and population samples from large ongoing cohort studies: CALiCo (Causal Variants Across the Life Course, a consortium of ARIC, CARDIA, CHS, HCHS/SOL, Strong Heart Cohort Study, Strong Heart Family Study), EAGLE (Epidemiologic Architecture for Genes Linked to Environment, based on 3 National Health and Nutrition Examination Surveys (NHANES)), MEC (Multiethnic Cohort) and WHI (Women's Health Initiative), with logistical and scientific support contributed by a Coordinating Center and the NHGRI Office of Population Genomics. These studies combined include over 290,000 participants, and populations represented include Asian Americans, African Americans, European Americans, Hispanic Americans, Native Hawaiians and American Indians. Health outcomes and traits of interest are prioritized, followed by replication of trait-genotype associations and generalization of their effects across population groups and environmental contexts. The first round of genotyping focused on 256 high-profile SNPs having replicated associations with phenotypes related to diabetes, obesity, cardiovascular disease, lipids, inflammation and autoimmunity that are being genotyped in over 90,000 participants, as available for trait-specific analyses. Subsequent genotyping will examine new variants in these and other traits such as cancers. SNP genotyping, quality control and population-specific association analyses are performed within each cohort, followed by meta-analyses using harmonized phenotypes and standardized analytic methods. Novel display tools are being developed to facilitate exploration and dissemination of the large number of association tests being conducted. Individual-level or summary data will be deposited to dbGaP. PAGE will contribute context-specific population level annotation for promising variants from GWAS, addressing gene-gene and gene-environment interactions and intermediate outcomes. More information at http://www.pagestudy.org.

## 1782/T/Poster Board #331

**Assessing the accuracy of ancestry reported in a biorepository linked to electronic medical records for genetic association studies.** *M.D. Ritchie[1,2], L. Dumitrescu[1], K. Brown-Gentry[1], J. Pulley[3], M. Basford[3], J. Denny[4,5], J.R. Oksenberg[6], D.M. Roden[3,5,7], J.L. Haines[1,2], D.C. Crawford[1,2].* 1) Department of Molecular Physiology and Biophysics, Vanderbilt University, Nashville, TN; 2) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 3) Office of Personalized Medicine, Vanderbilt University, Nashville, TN; 4) Department of Biomedical Informatics, Vanderbilt University, Nashville, TN; 5) Department of Medicine, Vanderbilt University, Nashville, TN; 6) Department of Neruology, University of California at San Francisco, San Francisco, CA; 7) Department of Pharmacology, Vanderbilt University, Nashville, TN.

The Vanderbilt DNA Databank (BioVU) is a biorepository of >57,000 DNA samples linked to electronic medical records in Nashville, TN. While BioVU is a valuable source of samples and phenotypes for genetic association studies, it is unclear whether administratively assigned race/ethnicity in BioVU is accurate in describing genetic ancestry for association studies. Previous studies suggest that self-reported ancestry is highly concordant with genetic ancestry. In contrast, there is much variation in the accuracy of observer-reported ancestry, and this variability can be highly dependent on the study, site, and method of interview. To characterize the accuracy of observer-reported ancestry compared with self-reported ancestry, we genotyped 360 SNPs on the Illumina DNA Test Panel containing ancestry informative markers (AIMs) in 1910 BioVU samples with observer-reported ancestry [1503 European-American (EA), 201 African-American (AA), 62 other, and 144 missing data] and 384 samples from the Multiple Sclerosis Genetics Group with self-reported ancestry (192 EA and 192 AA). After filtering for minor allele frequency (MAF<1%), deviations from Hardy-Weinberg expectations (p<10-4), and genotyping efficiency (<95%), 294 SNPs in the samples with self-reported ancestry were clustered by ancestry using STRUCTURE 2.2. After assuming K=3 and allowing 50,000 iterations and 10,000 burn-in cycles, 95.7% of the self-reported EA DNA samples were assigned to one cluster. After implementing similar quality control measures and STRUCTURE settings, 341 SNPs were used to cluster the observer-reported DNA samples. Similar to the self-reported clustering results, 96.9% of the EA observer-reported samples clustered together. For AA, 89.2% and 89.7% of samples with self-reported and observer-reported ancestry, respectively, clustered together. Among the BioVU samples with missing data, 90.1% clustered with EA samples and 9.30% clustered with AA samples. Using a two-sample test of proportions, we determined that the concordance rate of observer-reported ancestry was not significantly different from the concordance rate of self-reported ancestry in either population (z=-0.885, p=0.376 in EA and z=-0.161, p=0.872 in AA). This finding suggests that for EA and AA populations in BioVU, observer-reported ancestry is highly correlated with genetic ancestry determined by AIMs and thus probably sufficient for use in genetic association studies.

**A multi-stage genome-wide association study detects a novel risk locus near *IRS1* for type 2 diabetes, insulin resistance, and hyperinsulinemia.** *S. Cauchi[1], J. Rung[2,3], A. Albrechtsen[4], G. Rocheleau[2,5,6], C. Cavalcanti-Proença[1], A. Vaag[7,8], O. Pedersen[9,10], P. Froguel[1,11], R. Sladek[2,5,12], The IRS1 consortium.* 1) CNRS-UMR-8090, Institute of Biology and Lille 2 University, Pasteur Institute, F-59019 Lille, France; 2) McGill University and Génome Québec Innovation Centre, Montréal, Canada H3A 1A4; 3) European Bioinformatics Institute, Hinxton, Cambridge, CB10 1SD United Kingdom; 4) Department of Biostatistics, University of Copenhagen, DK-1014 Copenhagen K, Denmark; 5) Department of Human Genetics, Faculty of Medicine, McGill University Montreal, Canada H3A 1B1; 6) Prognomix Inc., Montreal, Canada H1Y 3L1; 7) Steno Diabetes Center, DK-2820 Gentofte, Denmark; 8) Unit of Diabetes and Endocrinology, Department of Clinical Sciences, Malmö University Hospital, Lund University, Malmö, Sweden; 9) Hagedorn Research Institute and Steno Diabetes Center, DK-2820 Gentofte, Denmark; 10) Department of Biomedical Sciences, University of Copenhagen, DK-2200 Copenhagen N, Denmark; and Faculty of Health Sciences, University of Aarhus, DK- 8000 Aarhus C, Denmark; 11) Centre and Department of Genomic Medicine, Hammersmith Hospital, Imperial College London, W12 0NN, London, UK; 12) Department of Medicine, Faculty of Medicine, McGill University, Montreal, Canada H3A 1A4.

Genome-wide association studies (GWAS) have identified a number of robust associations between specific chromosomal loci and type 2 diabetes (T2D). To fully utilize the GWA data that we had obtained in 1,376 French individuals (Sladek and colleagues, Nature, 2007), we designed a large stage 2 study to capture other possible association signals. From our existing datasets, we selected 16,360 SNPs nominally associated with T2D and genotyped these in an independent set of 4,977 French normoglycemic and T2D subjects. Based on their association strength, we selected 28 SNPs for replication in 7,698 Danish individuals and identified four SNPs showing strong association with T2D. Three of these represent signals in known loci and one is in a novel risk locus adjacent to the insulin receptor substrate 1 gene (*IRS1*: rs2943641, $p = 9.3 \times 10^{-12}$, OR = 1.19). IRS1 plays a key role in transmitting signals from the insulin and insulin-like growth factor-1 receptors to intracellular PI3K/Akt and Erk MAP kinase pathways. Unlike previously reported T2D risk loci, which predominantly associate with impaired beta-cell function, the C-allele of rs2943641 is associated with insulin resistance and hyperinsulinemia in 14,358 French, Danish and Finnish non-diabetic participants from population-based cohorts. Importantly, this risk allele is also associated with reduced basal levels of IRS1 protein and decreased insulin-induction of IRS1-associated PI3-kinase activity in human skeletal muscle biopsies. In conclusion, our stage 2 design and analysis approach allowed us to identify, for the first time, a novel T2D risk locus associated with whole body insulin resistance, hyperinsulinemia and impaired insulin signalling. Our study emphasizes the importance of using different strategies for genome-wide discovery of genetic loci related to T2D.

**Evaluation of Factors Associated with Occurrence of Congenital Malformations in an Area Close to a Large Municipal Dump Site in Cali, Colombia.** *C. Isaza[1], F. Mendez[2], Y. Ariza[2], N. Benitez[2], Y. Orejuela[2], H. Pachajoa[1].* 1) Dept Morphology, Univ del Valle, Cali Valle, Colombia; 2) Dept Epidemiology, Universidad del Valle, Cali, Valle, Colombia.

Objective: A hospital based surveillance system was established since 2004 in Cali, Colombia, and geographical analysis of cases distribution showed malformations are clustered in poorer areas which are close to the main river of the city. This river is polluted by contaminants from the municipal waste disposal site and agricultural pesticides. A study is developed to evaluate environmental factors potentially associated to occurrence of clusters of congenital malformations in this area. Materials and Methods: We have collected information to describe routes and pathways of exposure to contaminants. Specifically, water, soil and air samples were analyzed. In addition, to understand population believes and practices which may facilitate intake of pollutants, we developed a survey among 380 women. Results: Neural tube defects and vascular disruption defects are among the most frequent malformations in the area (5 to 10 times higher occurrence as compared with similar surveillance systems in other cities of the world). Ground water and soil samples demonstrated presence of metals, particularly cadmium, lead and mercury. These contaminants and other pollutants, including pesticides, can reach pregnant women by several routes and pathways, including fish and crops in diet (oral) and also indoor exposure to batteries of vehicles and other chemical products (inhalation and dermal contact). Conclusions: Multiple routes and pathways allow exposure of women to pollutants and explain clustering of congenital malformations in this area. Indoor exposures and behavioral factors, as fish consumption during pregnancy, need to be considered to understand causes of congenital malformations.

**Genome-wide studies of complementary designs identify coagulation and fibrinolytic loci and variants potentially implicated in venous thromboembolism.** *F. Gagnon[1], G. Antoni[1,2,3], N. Saut[4], Y. Luo[1], A. Tuite[1], P.S. Wells[5], J. Emmerich[6], P.E. Morange[4,7], D.A. Tregouet[2,3].* 1) School of Public Health, Univ of Toronto, Toronto, ON, Canada; 2) INSERM, UMR_S 937, F-75013, Paris, France; 3) UPMC Univ Paris 06, UMR_S 937, F-75013, Paris, France; 4) INSERM, URM_S 626, F-13385, Marseille, France; 5) Ottawa Health Research Institute, Ottawa, ON, Canada; 6) INSERM U765, Universite Paris-Descartes, France; 7) Universite de la Mediterranee, F-13385, Marseille, France.

A multi-stage/multi-design strategy is being used to identify new loci and variants that would contribute to venous thromboembolism (VTE) susceptibility by modulating coagulation and fibrinolytic factors known to be implicated in thrombosis and hemostasis. Linkage analyses of 26 quantitative traits were first performed on 5 extended French-Canadian families ascertained on a single proband with both VTE and the F5L variant. These analyses included 261 individuals genotyped for 1079 microsatellites. Using Bayesian MCMC-based oligogenic methods, we identified a total of 25 loci for 14 quantitative traits with Bayes Factors (logBF) >1.5 (strong evidence for linkage). Anti-coagulant and other treatment effects were taken into account in follow-up analyses. These regions were then validated by *in silico* association analysis of published GWAS data on VTE with the aim of narrowing the linkage signals by focusing on candidate regions for VTE. Among the results, the replication of the FXII chromosome (chr) 5 locus previously identified in the GAIT (Genetic Analysis of Idiopathic Thrombosis) study, and a novel locus on chr 8, with logBF of 2.9 and 1.9, respectively. One and two SNPs for chr 5 and 8, respectively, were associated with VTE at $p<10^{-4}$ in the GWAS. Prioritized analyses investigating their association with FXII in the Stanislas cohort, a sample of 123 French nuclear families, and with VTE in two independent French case-control studies, are underway. In conclusion, using a multi-stage approach based on pedigree linkage analysis of quantitative traits, followed by a GWAS of VTE in an independent sample, was critical in identifying putative variants involved in the susceptibility to VTE, as well as providing clues into the underlying mechanisms.

### 1786/T/Poster Board #335

**Effect of Genetic Architecture on Prediction of Complex Diseases.** *D. Hu[1, 2, 3], E. Ziv[1, 2, 3].* 1) Dept Medicine, Univ California, San Francisco, CA; 2) Institute for Human Genetics, Univ California, San Francisco, CA; 3) Hellen Diller Family Comprehensive Cancer Center, University of California, San Francisco, CA.

A common model of complex diseases, the “common disease common variant” model, suggests that by identifying common variants that have modest effects on disease, geneticists will be able to combine these to introduce accurate disease prediction tools. In contrast, rare variants that substantially increase risk have traditionally been considered minimally useful from a public health perspective. We relate the allele frequency, the number of loci, the population attributable risk and area under the curve of the ROC curve. Using these relationships we demonstrate that rare variants with a strong effect on disease are actually more useful in a public health setting than common variants with modest effects. Furthermore, we demonstrate that under many plausible circumstances, most of the disease prediction potential in the genome is actually in the rare allele frequency. Finally, we consider the practical sample size limitations on discovery for both rare and common variants related to disease and, at what point, disease prediction potential in the genome has been optimally reached. Our results have several important consequences for study design and for clinical practice: (1) Study designs may have currently reached or are close to reaching the limit of common variants useful for disease prediction. In contrast, the majority rare variants with disease prediction potential remain undiscovered. (2) Designing clinical prediction tools to optimally take advantage of the disease prediction potential of the genome will require sequencing individual patients at some genetic loci.

**Families versus unrelateds: An empirical comparison of gene mapping power based on genetic analysis of expression profile data.** *H.H.H. Göring, E.I. Drigalenko, M.A. Carless, J.E. Curran, M.P. Johnson, S.A. Cole, T.D. Dyer, L. Almasy, M.C. Mahaney, E.K. Moses, J. Blangero.* Dept. of Genetics, Southwest Foundation for Biomedical Resesarch, San Antonio, TX.

More than a decade ago, Risch and Merikangas suggested that association analysis is more powerful for identification of complex trait genes than linkage analysis. However, linkage versus association is a false dichotomy, because families permit joint usage of both strategies. A more fundamental question is the performance of study designs based on families versus unrelated individuals. It is now apparent that the genetic variants discovered in singleton-based GWAS explain only a small proportion of the estimated heritability. A possible explanation is that rarer variants are cumulatively responsible for a substantial portion of the genetic risk. Family-based studies are expected to be more powerful to detect such variants since rare variants, if present in a sample, are more likely to be found in multiple copies amongst related individuals. Additionally, linkage power is a function of the cumulative effects of functional variants across a larger genomic interval. To address these questions, we have performed an empirical power comparison between singleton- and family-based study designs, focusing on gene expression phenotypes. Our study has two key strengths: 1) it is not based on simulation and its dependence upon unknown parameters, and 2) the true state of nature is known, namely that proximal (*cis*) genetic regulation is common. Focusing on autosomal RefSeq transcripts, we have performed proximal linkage and joint linkage/association analyses in families, and association analysis on a subset of unrelated individuals. Our sample is the San Antonio Family Heart Study, where lymphocyte-derived expression profiles (Illumina WG-6 Series I BeadChip) and SNP genotypes (Illumina HumanHap 550 BeadChip) are available for 858 individuals. At a 5% FDR, we identified >1,000 proximally regulated transcripts using linkage analysis alone, and >5,000 such transcripts in joint linkage/association analysis. A comparison between association analysis on unrelated individuals and joint linkage/association on the same number of individuals in large families shows that in the presence of linkage evidence, joint tests can exhibit superior power to localize causal genes. In the absence of linkage evidence, little power tends to be lost relative to association in unrelateds. Our results suggest that joint linkage/association analysis in families represents a rational strategy that is not dependent upon prior assumptions regarding the frequency spectrum of functional variants.

## 1788/T/Poster Board #337

**A design of multi-source samples as a shared control for association studies in genetically stratified populations.** *Y. He[1], S. Xu[1], C. Jia[2], J. Li[1,2].* 1) Computational Genomics Department, CAS-MPG Partner Institute for Computational Biology, SIBS, CAS, Shanghai 200031, China; 2) MOE Key Laboratory of Contemporary Anthropology, School of Life Sciences, Fudan University, Shanghai 200433, China.

Statistical power is one of the key issues in study design of GWAS. Having a larger sample size of normal controls and cases is usually considered in achieving higher statistical power in association studies. Shared control for different studies, or common control, is a possible cost effective solution to achieve a larger sample size. However, this design may be impeded by the presence of population stratification in the samples. Since most of the patient samples, i.e., cases, were pre-collected from large hospitals in cosmopolitan areas, it is sensible to assume that they often come from mixed sources or subpopulations. Population stratification is known to exist in Chinese populations across geographic area. Principles in a better, if not optimal, design for shared controls in Chinese could benefit association studies in all countries and areas. In this study, performance of different designs for shared controls in Chinese was evaluated with genetic parameters from real data. A better design is expected to yield higher power for a given sample size, which was calculated using a simulation algorithm throughout this study, given a predefined type I error (0.05) and other population parameters including sample size. The simulation algorithm incorporated a hierarchical model to address genetic divergence in multi-source scenarios. For risk allele frequencies at 0.1 and 0.3, we showed that power increases with increasing sources of controls, and the single-source control yields the lowest power. Another question of great importance is whether the shared control could benefit future association studies in which the diversity of the sources of samples is expected to increase. Our results showed that the multi-source designs gain more power than the single-source designs when cases increase. We also observed that the power continually improves with increasing sources of control subjects for both types of designs. But, the power increase was nearly stopped for the single-source control design when number of studies is more than 3, while the multi-source control design continues to gain more statistical power. To summarize, this study showed that a good design of shared control for populations with genetic heterogeneity should include samples from multiple sources. A good multi-source design wills not only benefit GWAS study using the existing cases but also the future studies when more patient samples are added.

## 1789/T/Poster Board #338

**Rapid inexpensive genome-wide association using pooled whole blood.** *S. Macgregor[1], A. Hewitt[2,3], A. McMellon[2], A. Henders[1], L. Ma[2], L. Wallace[1], S. Sharma[2], K. Burdon[2], P. Visscher[1], G. Montgomery[1], J. Craig[2].* 1) Genetics and Population Health, Queensland Inst Med Res, Brisbane, Australia; 2) Department of Ophthalmology, Flinders University, Adelaide, SA, 5046, AUS; 3) Centre for Eye Research Australia, Melbourne University, Melbourne, VIC, 3002, AUS.

Genome-wide association studies (GWAS) have now successfully identified important genetic variants associated with many human traits and diseases. The high cost of genotyping arrays in large datasets remains the major barrier to wider utilization of GWAS. Previously we have shown it is possible to reduce the genotyping cost by pooling DNA samples for genotyping. Here we have developed a novel method in which whole blood from cases and controls respectively is pooled prior to DNA extraction for genotyping. We demonstrate proof of principle by clearly identifying using blood pooling based GWAS the associated variants for eye color, age-related macular degeneration and pseudoexfoliation syndrome in cohorts not previously studied. Blood pooling has the potential to reduce GWAS cost by several orders of magnitude and dramatically shorten gene discovery time. This method has profound implications for translation of modern genetic approaches to a multitude of diseases and traits yet to be analysed by GWAS, and will enable developing nations to participate in GWAS.

## 1790/T/Poster Board #339

**Design of Association Studies with Pooled Next-Generation Sequencing Data.** *S. Kim.* Integrative Biology, University of California, Berkeley, CA.

Most of the common hereditary diseases in humans are complex and multifactorial. Large scale genome-wide association studies based on SNP genotyping, have only identified a small fraction of the heritable variation of these diseases. One explanation may be that many rare variants (a minor allele frequency, MAF > 5%), which are not included in the common genotyping platforms, may contribute a substantial portion of the genetic variation of these diseases. Next-generation sequencing, which would allow the analysis of rare variants, is now becoming so cheap that it provides a viable alternative to SNP genotyping. In this paper, we present cost-effective protocols for using next-generation sequencing in association mapping studies based on pooled and un-pooled samples, and identify optimal designs with respect to total number of individuals, number of individuals per pool, and the sequencing coverage. We perform a small empirical study to evaluate the pooling variance in a realistic setting where pooling is combined with exon capturing. To test for associations, we have developed a likelihood ratio statistic that accounts for the high error rate of next-generation sequencing data. We also perform extensive simulations to determine the power and accuracy of this method. Overall, our findings suggest that with a fixed cost, sequencing many individuals at a more shallow depth with larger pool size achieves higher power than sequencing a small number of individuals in higher depth with smaller pool size, even in the presence of high error rates. Our results provide guidelines for researchers who are developing association mapping studies based on next-generation sequencing.

## 1791/T/Poster Board #340

**Genomic and genealogic investigation of the French Canadian founder population structure.** *M.-H. Roy-Gagnon[1,2], C. Moreau[1], C. Bherer[1], P. St-Onge[1], D. Sinnett[1,3], C. Laprise[4], H. Vézina[5], D. Labuda[1,3].* 1) Sainte-Jusine Hospital Research Center, Montreal, QC, Canada; 2) Dept. of Social and Preventive Medicine, University of Montreal, QC, Canada; 3) Dept. of Paediatrics, University of Montreal, QC, Canada; 4) Dept. of Fundamental Sciences, Université du Québec à Chicoutimi, QC, Canada; 5) GRIG, Université du Québec à Chicoutimi, QC, Canada.

It is thought that genetic epidemiological studies in founder populations may have greater power to identify genes for complex diseases due in part to greater genetic homogeneity. A relatively large number (~3,300) of original founders contributed to the majority of the contemporary French Canadian (FC) gene pool and subsequent regional founder effects also occurred. Hence, the extent of genetic homogeneity in the FC population is unclear. In this study, we investigated genome-wide variation and structure in 143 individuals from 7 FC sub-populations characterized by different demographic histories. We also situated our FC samples among the HapMap samples and the French samples of the Human Genome Diversity Panel (HGDP-CEPH). An important advantage of the FC population is the availability of major population registers, such as the BALSAC register, allowing the reconstruction of ascending genealogies going back over four centuries. We used both genealogic data and genome-wide SNP data (Illumina 650K) to characterize genetic variation and structure in the FC population. Principal components analysis on a subset of genome-wide SNPs spaced at least 500kb apart yielded 4 FC sub-populations (Tracy-Widom p-value < 0.02), 3 of which are geographically close but culturally different. Genomic inflation factors between pairs of these 4 sub-populations (assuming study cases come from one and controls from another) ranged from 1.2 to 1.4, while they were greater than 1.09 for all sub-populations pairs. We observed higher numbers and longer extended runs of homozygosity when within-population relatedness was higher. We also observed higher median linkage disequilibrium (LD) levels and proportions of SNPs in high LD in the FC sub-populations compared to HapMap CEU and French HDP-CEPH. Information on relatedness and inbreeding calculated from genealogies (14 generations) supports and complements our genomic-based findings. Our results highlight the need to consider both geographical and cultural origin of FC participants in association studies. Our study also provides insights on approaches to exploit both genomic and genealogic data in the search for disease genes in the FC founder population. These approaches may be especially relevant for the identification of rare variants.

**Analysis of Genetic Substructure of Han Chinese Using Genome-Wide SNP Arrays: Implication for Association Studies.** *S. Xu[1], S. Li[2], W. Jin[1], H. Lou[1], L. Yang[1], X. Gong[2], X. Zhang[3], X. Yin[3], Y. He[1], Y. Yang[2], Y. Wang[2], W. Fu[2], Y. An[2], J. Tan[2], J. Wang[2], J. Qian[2], X. Zhang[2], H. Wang[2], B. Wu[2,4], L. Jin[1,2,5].* 1) Chinese Academy of Sciences and Max Planck Society (CAS-MPG) Partner Institute for Computational Biology, Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, Shanghai 200031, China; 2) State Key Laboratory of Genetic Engineering and Ministry of Education (MOE) Key Laboratory of Contemporary Anthropology, School of Life Sciences and Institutes of Biomedical Sciences, Fudan University, Shanghai 200433, China; 3) Institute of Dermatology and Department of Dermatology at No.1 Hospital, Anhui Medical University, Hefei, Anhui 230022, China; 4) Children's Hospital Boston, Harvard University, Boston, MA 02115, USA; 5) China Medical City (CMC) Institute of Health Sciences, Taizhou, Jiangsu 225300, China.

China will start this year a $30 million effort of genome-wide association studies (GWAS) of common diseases in Chinese populations which have been largely underrepresented in the similar effort worldwide. A general concern is population stratification (ancestry differences) among subpopulations which can cause false positive associations. Han Chinese is the largest ethnic group in the world, however, its population substructures are often expected and yet well characterized. In this study, we examined population substructures in a diverse set of >1,700 Han Chinese samples collected from 26 regions, each genotyped with at least 160K single nucleotide polymorphisms (SNPs). Our results showed that: (a) Han Chinese population is complicatedly substructured, with the main observed clusters roughly corresponding to northern Han, central Han and southern Han; (b) Han Chinese samples collected from large cities, such as Shanghai, Beijing and Guangzhou, show diverse source of ancestries including three aforementioned clusters; (c) HapMap samples (CHB & CHD) and HGDP samples (Han & Han-NChina) deliver a limited representation of Han Chinese people. Building on the above insights, we investigated false positive rates and statistical power in various study designs using both empirical and simulated data. We further explored sample collection strategies and public data usage for future association studies.

## 1793/T/Poster Board #342

**A common variant of tumor necrosis factor-alpha gene and pregnancy-induced hypertention in Japan.** *G. Kobashi[1,4], K. Ohta[1,2,3], H. Yamada[2], A. Hata[3], H. Minakami[2], N. Sakuragi[2], H. Tamashiro[4], S. Fujimoto[5], Hokkaido PIH Epidemiological Study Group.* 1) Research Center for Charged Pa, National Institute of Radiological Sciences, Chiba, Japan; 2) Dept. of Obstetrics and Gynecology, Hokkaido University Graduate School of Medicine; 3) Dept. of Public Health, Chiba University Graduate School of Medicine; 4) Dept. of Global Health and Epidemiology, Hokkaido University Graduate School of Medicine; 5) Sapporo Maternity-Women's Hospital.

Pregnancy-induced hypertention (PIH), major cause of maternal morbidity and mortality, is considered to be a multifactorial disease resulting from an interaction among several factors including endothelial injury. Tumor necrosis factor-alpha (TNF-A) fundamentally effects on the endothelial cells by several pathways, such as oxidant/anti-oxidant balances, changing patterns of prostaglandin production and expression of cell surface components. Some recent studies have reported that an association between a common variants in promoter region (G-308A) of the TNF-A gene and PIH in some racial population, however, it has been yet confirmed. In the present study, we genotyped and analyzed the variant and other genetic and environment risk factors in order to confirm the association in the Japanese subjects. One hundred forty Japanese patients with PIH including preeclampsia, protein uric type of PIH, were matched with 280 Japanese normal pregnant controls according to age and parity. Informed consent for the study was obtained from every subject. Genotypings of variants including G-308A of the TNF-A gene were carried out using PCR-RFLP methods after extraction of genomic DNA from 1.0 ml of whole blood samples. Differences were statistically analyzed by the chi-square test (degree of freedom=1). Fisher's exact test was used when an observed number was ≤ 5. In the subgroup analysis with other genetic and environment risk factors, the values with a p<0.0125 were considered to be significant, using the Bonferroni's correction for multiple comparison in order to reduce the probability of the alpha-error. In the allelic frequencies of A-308 a mutant type of the TNF-A gene, there were no significant differences between the cases and controls (2.2% in severe PIH, 1.5% in moderate PIH and 1.7% in controls). Furthermore, no significant differences were found in the subgroup analyses using the other PIH risk factors such as maternal age, parity, prepregnancy body mass index, family history of hypertension, M235T of angiotensinogen gene, Glu298Asp of the endothelial nitoric oxide synthase gene and some lifestyle factors. The present result suggests that the G-308A variant of TNF-A gene is not associated with PIH in the Japanese women.

## 1794/T/Poster Board #343

**Epidemiologic Architecture for Genes Linked to Environment (EAGLE): Characterizing genome-wide association study variations associated with inflammation in the National Health and Nutrition Examination Surveys.** *D.C. Crawford, L. Dumitrescu, K. Brown-Gentry, K. Spencer, J.A. Canter, D. Murdock, J.L. Haines, M.D. Ritchie.* Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

C-reactive protein (CRP), one of several serum inflammatory markers, is associated with obesity and cardiovascular disease, and its causal role is controversial. Several candidate gene and now genome-wide association (GWA) studies have identified variations associated with CRP levels, some of which are also associated with clinical outcomes. While many of the candidate gene studies have been performed in diverse populations, the GWA-identified variations have yet to be tested in diverse samples. Also, some previous association studies predated the high-sensitivity (hs) CRP assay. To characterize these candidate gene and GWA-identified variants in diverse samples with hs-CRP, we, as part of the Population Architecture using Genomics and Epidemiology (PAGE) Study, are genotyping samples collected for the National Health and Nutrition Examination Surveys (NHANES), a cross-sectional survey of Americans representing three major groups: non-Hispanic **w**hites (n=3974), non-Hispanic **b**lacks (n=1334), and **M**exican-**A**mericans (n=1877). To date, four *CRP* SNPs previously associated with CRP levels have been genotyped in NHANES 1999-2002. In preceding candidate gene and GWA studies, these SNPs explained a relatively small proportion of observed trait variability: ~3% for any one SNP. Assuming a significance threshold of 0.01, NHANES 1999-2002 has 80% power to detect small effect sizes (0.3%, 0.9%, and 0.6% in **W**, **B**, and **MA**, respectively). Using linear regression and an additive genetic model, SNPs were tested for an association with CRP levels among adults adjusting for age, sex, and body mass index. Three SNPs were significantly associated with CRP levels in all three groups in the same direction: rs1205 was associated with decreased levels (**W**: $\beta$=-0.24, p<0.001; **B**: $\beta$=-0.23, p=0.0001; **MA**: $\beta$=-0.21, p<0.001), rs1417938 was associated with decreased levels (**W**: $\beta$=-0.14, p<0.0001; **B**: $\beta$=-0.18, p=0.015; **MA**: $\beta$=-0.13, p=0.003), and rs1800947 was associated with increased CRP levels (**W**: $\beta$=0.34, p<0.0001; **B**: $\beta$=0.60, p=0.007; **MA**: $\beta$=0.31, p=0.013). *CRP* rs3093058, which is rare in **W** (minor allele frequency = 0.05%), was associated with increased CRP levels in **B** ($\beta$=0.48; p<0.0001) and **MA** ($\beta$=0.59; p=0.002), consistent with previous reports. Overall, these SNPs explained 0.1% (rs1800947) to 3.7% (rs3093058) of the variability observed in CRP levels in NHANES 1999-2002.

## 1795/T/Poster Board #344

**From association to disease risk prediction: an optimistic view from genome-wide association studies on type 1 diabetes.** *H. Zhang[1], K. Wang[1], Z. Wei[2], H. Qu[3], J. Bradfield[1], C. Kim[1], E. Frackleton[1], C. Hou[1], J.T. Glessner[1], R. Chiavacci[1], C. Stanley[4], D. Monos[5], S.F. Grant[1,6], C. Polychronakos[3], H. Hakonarson[1,6].* 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA 19104; 2) Department of Computer Science, New Jersey Institute of Technology, Newark, NJ 07102; 3) Departments of Pediatrics and Human Genetics, McGill University, Montreal H3H 1P3, Québec, Canada; 4) Division of Endocrinology, Department of Pediatrics, The Children's Hospital of Philadelphia, Philadelphia, PA 19104; 5) Department of Pathology and Laboratory Medicine, The Children's Hospital of Philadelphia, Philadelphia, PA 19104; 6) Division of Genetics, Department of Pediatrics, The Children's Hospital of Philadelphia, Philadelphia, PA 19104.

Genome-wide association studies (GWAS) have been fruitful in identifying previously unsuspected disease susceptibility loci for several common diseases. A remaining question is whether we can predict and quantify the individual disease risk based on genotype data, to facilitate decision making on personalized prevention and treatment. Previous studies, using a limited number of confirmed genuine susceptibility loci, typically failed to achieve satisfactory performance and convey pessimistic view on disease risk prediction. Here we propose that sophisticated machine-learning approaches on a large ensemble of markers, which contain unconfirmed disease susceptibility variants, may improve the performance of disease risk prediction. We applied a Support Vector Machine (SVM) algorithm on an Affymetrix-typed GWAS data set for type 1 diabetes (T1D) with 1,963 cases and 1,480 controls, and optimized a risk prediction model with hundreds of SNP markers. We subsequently tested this prediction model on a second Illumina-typed GWAS data set on T1D (1,008 cases, 1,000 controls) with whole-genome imputed genotypes, as well as a third Affymetrix-typed GWAS data set on T1D (1,529 cases and 1,458 controls), achieving AUC (area under ROC cuve) scores of ~0.83 in both data sets. In contrasts, poor performance was achieved when using dozens of known susceptibility loci in the SVM prediction model, or using logistic regression model for risk prediction, with AUC scores of ~0.65. Our study suggests that improved risk prediction can be achieved by using sophisticated algorithms that take into account of interaction effects on a large ensemble of SNP markers. We are optimistic that whole-genome genotype based disease risk prediction is clinically feasible and useful, at least for diseases where notable proportion of the risk has been captured by SNP arrays.

**Harnessing the Information Contained Within Genome-wide Association Studies to Improve Individual Prediction of Complex Disease Risk.** *D. Evans[1], P. Visscher[2], N. Wray[2], The TASC Consortium.* 1) Soc Med, Univeristy Bristol, Bristol, United Kingdom; 2) Genetic Epidemiology and Queensland Statistical Genetics, Queensland Institute of Medical Research, Australia.

The current paradigm within genetic diagnostics is to test individuals only at loci known to affect risk of disease- yet the technology exists to genotype an individual at thousands of loci across the genome. We investigated whether information on thousands of SNPs from genome-wide association studies could be harnessed to improve discrimination of complex disease affection status. We employed genome-wide data from the Wellcome Trust Case Control Consortium to test this hypothesis. Each disease cohort together with the same set of controls were split into two samples- a "Training Set", where thousands of SNPs that might predispose to disease risk were identified, and a "Prediction Set", where the discriminatory ability of these SNPs was assessed. Genome-wide scores consisting of, for example, the total number of risk alleles an individual carries were calculated for each individual in the prediction set. Case-control status was regressed on this score and the area under the receiver operator characteristic curve (AUC) estimated. In most cases, a liberal inclusion of SNPs in the genome-wide score improved AUC compared to a more stringent selection of top SNPs, but didn't perform quite as well as selection based upon established variants. More importantly, the addition of genome-wide scores to known variant information produced an increase in discriminative accuracy being most effective in the case of bipolar disorder, coronary heart disease and type II diabetes where AUC increased by eleven, five and three units respectively. We are currently expanding these methods in a large cohort of individuals with Ankylosing Spondylitis- the only complex disease where it is currently possible to perform genetic tests with very high sensitivity and specificity (i.e. > 90%). It is likely that the diagnostic and predictive utility of genome-wide scores will further increase as the size of training sets expand.

## 1797/T/Poster Board #346

**Individual etnic admixture in a brazilian western amazonian city (Monte Negro-RO)and effects on malaria episodes.** *F.A.B. Santos[1,2], R.G.M. Ferreira[1,2], L.M. Garrido[1,2], C.E.M. Kawamata[1,2], L.M.A. Camargo[1,2], H. Krieger[1,2].* 1) Parasitologia, Universidade de São Paulo, São Paulo, São Paulo, Brazil; 2) INAGEMP - Instituto Nacional de Genética Médica Populacional.

Several studies on population ethnic admixture proportions were done in Brazil: Krieger et al, in 1965 (Ann. Hum. Genet. 19:113-125), Culpi and Salzano (Int. J. of Hum. and Med. Gen., v. 34, n. 2, p. 388-392) are some examples. There are also more studies in Brazil or other countries using classical genetic, mitochondrial and molecular markers. A previous admixture analysis estimating ethnic proportions was done in this region by Ferreira et al in 2002 (Hum. Biol 74/4:607-614) based on a gene frequencies algorithm as recommended by Krieger et al (op. cit.). Individual admixture follows the same methodology, however some adaptations were made. Numeric calculations were performed using TC 3.0 software. After individual ethnic proportions being determined, a correlation analysis was perfomed between the corrected logarithm number of malaria episodes by each individual and ancestral proportions. A weak correlation (r = -0.068, P<0.05)was obtained for Europeans and a strong significant correlation was observed for Africans (r = 0.116, P<0.05). Knowing that this result could be partly explained by negative Duffy individuals, an analysis was built in order to exclude this component. Newer results revealed that the weak European correlation disappeared (r = -0.058, P>0.05), while the strong correlation observed for Africans remained (r = 0.104, P<0.05). This results suggests that other genetics mechanisms of malaria resistance or susceptibility evolved in Africa and may be detectable in african descendents in the New World. Sponsored by CAPES,CNPq.

**Genetic Mechanisms for Venous Thromboembolism (VTE).** *J. Heit[1], T. Petterson[2], S. Armasu[2], E. Jeavons[2], J. Larson[2], J. Cunningham[3], M. de Andrade[2].* 1) Internal Med/Hematology Res, Mayo Clinic College of Medicine, Rochester, MN; 2) Biomedical Statistics and Informatics, Mayo Clinic College of Medicine, Rochester, MN; 3) Laboratory Medicine and Pathology, Mayo Clinic College of Medicine.

VTE consists of deep vein thrombosis (a blood clot occluding the lumen of large veins, usually in the leg or pelvis) and its complication, pulmonary embolism (a dislodged DVT which obstructs one or more arteries to the lung). We conducted a candidate gene association study from 780 genes in four pathways (anticoagulant, procoagulant, fibrinolytic and innate immunity) relevant to the pathogenesis of VTE using a haplotype tagging algorithm that incorporated Illumina's design score for iSelect. A total of 12,313 SNPs and 2331 unique individuals (1166 VTE and 1165 controls) were available for the analysis. From those, 261 individuals were removed due to the study exclusion criteria (82), genotype issues (150), race (22), and relatedness (13). A total of 2070 individuals were used for the association analysis (49% VTE subjects; 48% males). The analyses were performed with PLINK using an additive genetic model and adjusted for age, sex, state of residence, and prior myocardial infarction or stroke (yes/no). The most significant results included two SNPs in the F5 (procoagulant Factor V) gene including the Factor V Leiden mutation (rs6025, OR=3.36, p-value=1.38x10-16), five SNPs in the ABO gene including blood group type (rs8176719, OR=1.57, p-value=2.22x10-11) and one SNP in the F2 (procoagulant prothrombin) gene (rs1799963 [prothrombin G20210A], OR=2.51, p-value=3.44x10-5). These results remained significant when the analysis was stratified by sex. We also performed an analysis stratified on F5 carrier, F2 carrier, and blood type O status (yes/no). Significant results identified for F5 non-carriers mutation were SNPs in the ABO, F2, and IL4R genes; for F2 non-carriers mutation SNPs in ABO and F2 genes, and for non-O blood type carriers SNPs in the F5 and PLSCR1 genes. In conclusion, SNPs within the F5 (including Factor V Leiden), F2 (prothrombin G20210A) and ABO genes are susceptibility variants for VTE, and the joint population-attributable risk of the most significant risk alleles from F5, ABO and F2 was 0.21. The F2 and ABO variants appear to act independently of Factor V Leiden status.

## 1799/T/Poster Board #348

**Association between 5' region of *NFKBIA* and TNFα receptors in Hispanic Americans: The IRAS Family Study.** *M.R. Miller[1], W. Zhang[1], C.D. Langefeld[2], D.W. Bowden[2], S.M. Haffner[3], J.I. Rotter[4], Y.I. Chen[4], J.M. Norris[1], T.E. Fingerlin[1].* 1) Colorado School of Public Health, University of Colorado Denver, Aurora, CO; 2) Wake Forest University Health Sciences, Winston-Salem, NC; 3) University of Texas Health Sciences Center at San Antonio, San Antonio, TX; 4) Cedars-Sinai Medical Center, Los Angeles, CA.

The IKKβ/NF-κB pathway is known to play an important role in inflammatory response. We have shown a relationship between SNPs in the gene that codes for IκBα (*NFKBIA*) with both insulin resistance and diabetes status. SNPs in this gene have also been implicated in diseases with a strong inflammatory component, such as carotid artery disease (CAD), Crohn's disease (CD), and multiple sclerosis (MS). Based upon these prior findings, we also investigated the association of several SNPs in the *NFKBIA* gene with other markers of inflammation, Tumor Necrosis Factor-α receptors 1 and 2 (TNFr1 and TNFr2). We typed 25 SNPs spanning 20 kb including *NFKBIA* in two Hispanic samples of the IRAS Family Study: 619 individuals from 30 families in the San Luis Valley in Colorado (SLV) and 649 individuals in 60 families in San Antonio, Texas (SA). At least one typed SNP had an $r^2 > 0.90$ with all known common variants in the gene. Soluble TNFRr1 and TNFr2 were measured from stored plasma samples. Individuals with type 2 diabetes were excluded from the analysis. We tested for association between each SNP and TNFr1 or TNFr2 using a variance components measured genotype approach as implemented in SOLAR. We identified a SNP in the 5' region of the *NFKBIA* gene that was significantly associated with both TNFr1 and TNFr2, adjusting for age, gender, and admixture. SNP rs762009 (G→A) was associated with levels TNFr1 and TNFr2 in the SA sample under a recessive model ($p = 7.01 \times 10^{-4}$, and $p = 2.02 \times 10^{-3}$, respectively). Individuals in the SA sample with two copies of the A allele for rs762009 had ~8% lower TNFr1 and TNFr2 levels than individuals with at least one copy of the G allele. In the SLV sample, the association was not significant ($p = 0.871$ and $p = 0.761$), and levels of TNFr1 and TNFr2 were not changed for people with genotype AA versus AG or GG. Adjustment for BMI did not change the evidence for association in either the SA or SLV sample (SA: $p = 1.90 \times 10^{-3}$ and $p = 4.66 \times 10^{-3}$; SLV: $p = 0.700$ and $p = 0.640$). As this SNP is one of the most 5' of any of the SNPs typed, studies to refine the apparent association at rs762009 with levels of TNFr1 and TNFr2 are ongoing. These results further support the role that IκBα may play in inflammatory response and may have important consequences for inflammatory related diseases such as obesity, insulin resistance, and cardiovascular disease.

## 1800/T/Poster Board #349

**Evidence of age-dependent genetic effects on tooth decay: heritability estimates suggest genes influencing dental caries differ between primary and permanent dentitions.** *J.R. Shaffer[1], X. Wang[2,3,4], R.J. Weyant[3,5], K.T. Cuenco[2,3,4], R. Crout[6], D.W. McNeil[7], M.L. Marazita[1,2,3,4,8].* 1) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA,15261; 2) Center for Craniofacial and Dental Genetics, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA, 15219; 3) Center for Oral Health Research in Appalachia, University of Pittsburgh, Pittsburgh, PA, 15261 and West Virginia University, Morgantown, WV, 26506; 4) Department of Oral Biology, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA, 15261; 5) Department of Dental Public Health and Information Management, University of Pittsburgh, School of Dental Medicine, Pittsburgh, PA,15261; 6) Department of Periodontics, School of Dentistry, West Virginia University, Morgantown, WV, 26506; 7) Practice and Rural Health, West Virginia University, Morgantown, WV, 26506; 8) Clinical and Translational Sciences Institute, and Department of Psychiatry, School of Medicine, University of Pittsburgh, Pittsburgh, PA, 15261.

Dental caries (tooth decay) is a common disease, affecting children and adults in both the primary and permanent dentitions. Although it is well established that genetic factors are important for this disease, the degree to which genes contribute to the development of dental caries, and whether these genes differ between primary and permanent dentitions, is largely unknown. Using family-based likelihood methods, we assessed the heritability of caries scores for both children and adults in over 2300 participants from 701 families. We found that caries scores for primary dentition were highly heritable with genes accounting for 39% to 66% of variation (p-values < 0.01). The heritability of caries scores in permanent dentition was also substantial (15% to 55%; p-values < 0.01), although lower than analogous phenotypes in the primary dentition. Assessment of the genetic correlation between primary and permanent caries scores indicated that 26% of the covariation in these traits was due to common genetic factors (p-value < 0.01). Therefore, dental caries are likely to be partly attributable to different suites of genes and/or genes with different effects in primary vs. permanent teeth. Sex and age explained much of the phenotypic variation in permanent, but not primary, dentition. Furthermore, adding pre-cavitated white-spot lesions to the caries scores contributed substantially to the heritability of dental caries. In summary, our results show that dental caries are heritable, and that genes affecting susceptibility to dental caries in primary dentition may differ from those in permanent teeth. Moreover, metrics for quantifying caries that incorporate white-spot lesions may be better suited for genetic studies of the causes of tooth decay. In conclusion, dental caries may serve as an example phenotype in which genes that influence trait variation during childhood development may (partly) differ from those during adulthood. ## 1801/T/Poster Board #350

**Kinship Analysis of Inflammatory Bowel Disease.** *M.S. Williams[1], G.M. Wood[2], G. Mineau[3], R. Pimentel[4], K. Thompson[5], S.L. Guthery[5].* 1) Director, Intermountain Healthcare Clinical Genetics Inst, Salt Lake City, UT; 2) Intermountain Healthcare Clinical Genetics Inst, Salt Lake City, UT; 3) Department of Oncological Sciences and Huntsman Cancer Institute, University of Utah, Salt Lake City, UT; 4) Huntsman Cancer Institute, University of Utah, Salt Lake City, UT; 5) Department of Pediatrics Division of Pediatric Gastroenterology, Hepatology, and Nutrition, University of Utah and Primary Children's Medical Center, Salt Lake City, UT.

The inflammatory bowel diseases (IBD), including Crohn's disease (CD) and ulcerative colitis (UC), are debilitating disorders without a cure. Several genetic risk factors have been identified, but even in aggregate, do not account for the observed heritability. Alternative study designs, such as extended pedigree studies, would compliment genome wide association studies in identifying new risk factors for IBD. To assess the utility of the Utah Population Database (UPDB) as a resource for IBD gene mapping studies, we determined the IBD risk to family members of affected individuals, and disease distribution within pedigrees. Cases were identified from the Intermountain Healthcare (IH) and University of Utah Health Sciences Center (UUHSC) electronic data warehouses (EDW) using ICD-9 codes 555.x or 556.x. for CD and UC respectively. Cases were probabilistically linked into UPDB. Multiple controls, matched on birth year, sex, and birth state were randomly selected for each of the patients. Relative risks (RR) for classes of kinship were computed using Conditional Logistic regression. Results. 4935 CD cases, 5448 UC cases, and 10,830 IBD cases (these represent patients who had encounters with 555.x, 556.x or both, hence are counted twice. These individuals were included in analyses for both CD and UC as well as IBD) were present in UPDB. The RR to a first-degree relative of a CD-affected proband was 5.72 compared with 3.92 for UC. There was a statistically significant increased RR for second-degree relatives (CD 1.64; UC 1.45) and first cousins (CD 1.53, UC 1.29), but no increased risk to second cousins. The relative risks to first-degree relatives, second-degree relatives, and first cousins of an IBD-affected individual were 3.37, 1.64 and 1.29 respectively, all statistically significant. Multiple high-risk IBD kindreds were identified, including some kindreds with more than 15 times the expected number of IBD cases. In conclusion this population-based study confirms the familiality of CD, UC, and IBD, and validates the Utah Population Database for targeting high-risk IBD pedigrees for genetic studies.

## 1802/T/Poster Board #351

**Genetic variations in CNTNAP2 gene are associated with Adolescent Idiopathic Scoliosis (AIS) progression.** *J. Gu, L. Nelson, R. Chettier, K. Ward.* Axial Biotech, Inc., Salt lake City, UT.

Adolescent Idiopathic Scoliosis (AIS) is a complex, familial disorder characterized by a lateral deformity of the spine, affecting school age children between 9 and 15 globally, which etiology remains elusive. Our genome wide association studies and linkage analysis in affected families have implicated contactin associated protein-like 2 (CNTNAP2), a neuronal specific gene, involved in the etiology of AIS. CNTNAP2 is a member of the neurexin superfamily, which functions as cell adhesion molecules and receptors in the myelinated axons of the central nervous system (CNS). This gene is one of the largest genes in the human genome and encompasses almost 1.5% of chromosome 7. Recent studies have reported CNTNAP2 mutations in a number of neurological disorders, including focal epilepsy, Gilles de la Tourette syndrome, autism spectrum disorder and nonsyndromic deafness. The purpose of this study is to identify genetic variants in CNTNAP2 associated with AIS progression. Genomic DNA samples from 188 severe AIS patients and 92 controls were used for bi-directional sequencing of exonic regions of CNTNAP2. Results were analyzed using Sequencher 4.9 program (Gene Code). Many known SNPs as well as novel genetic variants were identified. Interestingly, we found a known in-del rs35167289 [OR= 1.5 (0.89-2.52)], which happens to be in LD with a novel in-del [OR= 0.58 (0.3-1.1)], located 3 base pairs downstream of rs35167289. There was no evidence of deviation from HWE (p>0.01) among severe AIS patients and control population. In addition, SNP rs34738210 [OR= 1.3 (0.76-2.2)] was also found associated with the severe AIS phenotype. Currently, we are pursuing haplotype analysis on the in-del as well as the SNP. Our results provide first evidence of CNTNAP2, a neuronal specific cell adhesion molecule, involved in AIS etiology and progression. Since CNTNAP2 plays an important role in axon differentiation during CNS development, this study facilitates the understanding of the CNS function in the onset of AIS.

## 1803/T/Poster Board #352

**Genome-wide association study identified novel susceptibility loci for type 2 diabetes and related traits in a cohort of African Americans.** *G. Chen, A. Adeyemo, A. Doumatey, J. Zhou, S. Daniel, H. Huang.* CRGGH/NHGRI, NIH, Bethesda, MD.

We sought for genetic variants underlying type 2 diabetes (T2D) and related traits (fasting glucose and insulin, Insulin Resistance -IR, Beta-cell Function -BCF, and triglyceride/HDL ratio - TG/HDL) by conducting a genome wide association study in African Americans (AAs), a population group that are disproportionately affected by diabetes and related complications. A total of 2024 persons were genotyped using the Affymetrix 6.0 fixed SNPs array. 1082 unrelated T2Ds and controls were selected for T2D and TG/HDL traits, 927 unrelated non T2Ds for glucose, insulin, IR, BCF, and Homa traits analysis. After quality filters, the analysis focuses on experimentally determined 806,047 autosomal SNPs. We then search for novel variants for T2D and attempted to replicate previously reported GWAS findings for 47 SNPs. We identify novel associations in or near several genes including the CADPS (rs833662), KLHDC6 (rs13066860), GARNL4 (rs1079530), SLC10A6 (rs10050311), SC4MOL (rs17046216), PPTG2/1 (rs1895320), GPC6 (rs9524298) and CTDP1 (rs3786228) with T2D and related traits at a p value < 5x10-6. Interestingly, we replicated 15 of 47 SNPs previously reported to be associated with T2D and related traits at a p values < 0.05 in this study of African Americans.

## 1804/T/Poster Board #353

**Epidemiologic Architecture for Genes Linked to Environment (EAGLE): Characterizing genome-wide association study variations associated with lipid traits in the National Health and Nutrition Examination Surveys.** *L. Dumitrescu, K. Brown-Gentry, K. Spencer, D. Murdock, J.A. Canter, J.L. Haines, M.D. Ritchie, D.C. Crawford.* Department of Molecular Physiology and Biophysics, Center for Human Genetic Research, Vanderbilt University, Nashville, TN 37232.

Low-density lipoprotein cholesterol (LDL-C), high-density lipoprotein cholesterol (HDL-C), and triglyceride (TG) levels are well known independent risk factors for cardiovascular disease. Lipid-associated SNPs are being discovered in genome-wide association (GWA) studies in samples of European descent, but little data exist in diverse cohorts. To characterize these GWA-identified variants, we, as part of the Population Architecture using Genomics and Epidemiology (PAGE)Study, are genotyping samples collected for the National Health and Nutrition Examination Surveys (NHANES), a cross-sectional survey of Americans representing at least three major groups: non-Hispanic whites (n=3,974), non-Hispanic blacks (n=1,334), and Mexican-Americans (n=1,877). To date, 13 SNPs previously associated with lipids have been genotyped in NHANES 1999-2002. In preceding GWA studies, these SNPs explained a relatively small proportion of trait variance, with a maximum of about 5%. Assuming a significance threshold of 0.01, NHANES 1999-2002 has 80% power to detect small effect sizes (0.3%, 0.9%, and 0.6% in W, B, and MA, respectively). Using linear regression, SNPs were tested for an association with transformed lipid traits adjusting for age, sex, and body mass index on fasting adults not on lipid-lowering medication. Among all 13 SNPs examined, only *PCSK9* rs11591147 was significantly associated with its corresponding lipid trait, LDL-C, in all three groups ($\beta$=-0.112, p=0.0090 in W; $\beta$=-0.757, p=0.0152 in B; and $\beta$=-0.165, p=0.0371 in MA). This nonsynonymous (R46L) variant explained ~0.6% of the variability in LDL-C in NHANES and was associated in the same direction as previous findings. In contrast, seven SNPs replicated in W but were not associated in B and/or MA. For example, among the five SNPs tested for association with HDL-C, *LIPC* rs1800588 and *LPL* rs328 were associated with increased levels in W ($\beta$=0.037; p=0.0002 and $\beta$=0.027; p=0.0373, respectively) and in MA ($\beta$=0.031; p=0.0027 and $\beta$=0.069; p=0.0014, respectively), but not in B ($\beta$=0.003; p=0.8380 and $\beta$=0.039; p=0.1735, respectively). This finding suggests that either population differences exist for these SNPs or that the causal SNP has not yet been identified. Overall, these post-GWAS data demonstrate the importance of characterizing replicated associations using large, diverse, population-based cohorts such as NHANES to help direct the next generation of genetic association studies.

## 1805/T/Poster Board #354

**A multi-stage analysis of *CIITA*, *DRB1*1501* and multiple sclerosis (MS).** *P.G. Bronson[1], P.P. Ramsay[1], S. Caillier[2], S.L. Hauser[2], J.R. Oksenberg[2], L.F. Barcellos[1], International Multiple Sclerosis Genetics Consortium.* 1) Department of Epidemiology, Barcellos Lab, University of California, Berkeley, CA, USA; 2) Department of Neurology, University of California, San Francisco, CA, USA.

An association between major histocompatibility complex (MHC) genes, particularly those in the human leukocyte antigen (HLA) class II region, and multiple sclerosis (MS) is well established. The primary genetic risk factor within this region is the *HLA-DRB1*1501* allele. The MHC class II transactivator gene (*CIITA*) recently emerged as the most important transcription factor regulating gene required for HLA class II MHC-restricted antigen presentation. A multi-stage investigation of *CIITA*, *DRB1*1501* and MS was undertaken. A total of 23 *CIITA* SNPs were initially genotyped in 1,343 MS cases and 1,379 independent controls with >90% European ancestry (EA) (N= 2,722). All individuals were characterized for the *DRB1*1501* allele. Allelic tests were conducted with Fisher's exact test in PLINK. Global haplotype tests of 5 haplotype blocks (encompassing 15 SNPs) were conducted by estimating haplotype probabilities and using score statistics in HAPLOSTATS. The strongest association between *CIITA* and MS was observed for the +1614G/C missense mutation (rs4774) (OR=1.19, 95% CI=1.05 to 1.33, P=4.8x10-3), and was restricted primarily to *DRB1*1501*+ cases (OR=1.59, 95% CI=1.29 to 1.96, P=1x10-4). Second, the rs4774 SNP was genotyped in 894 independent EA families (676 trios and 491 DSPs) and tested for association using the pedigree disequilibrium test. Rs4774*C* was associated with increased MS risk in the *DRB1*1501*+ families (P=0.025). Third, rs4774 was tested for association in the combined case-control and family sample with the allelic likelihood ratio test in UNPHASED. Rs4774*C* was over-represented in *DRB1*1501*+ MS patients (24.4%) compared to *DRB1*1501*+ controls (16.2%) (OR=1.67, 95% CI=1.31 to 2.14, P=2.5x10-5). The presence of both *DRB1*1501* and rs4774*C*, compared to their absence, was strongly associated with MS in the combined cases (55%) vs controls (20.5%) (OR=4.76, 95% CI 3.82 to 5.96, P<2x10-16), and interaction between rs4774 and *DRB1*1501* was present and statistically significant (OR=1.41, 95% CI=1.12 to 1.78, P=3.7x10-3). The previously reported -168A/G promoter polymorphism (rs3087465) was not associated with MS. Our results provide for the first time, evidence for association between rs4774 and MS, particularly in the presence of the MS-associated *DRB1*1501* allele, and also for effect modification of the *DRB1*1501* allele by variation at *CIITA* (rs4774).

## 1806/T/Poster Board #355

**Incorporating causality into genetic models: insights about familial aggregation.** *A.M. Madsen[1], S.E. Hodge[2,3], R. Ottman[1,4,5].* 1) Department of Epidemiology, Mailman School of Public Health, Columbia University, New York, NY 10032; 2) New York State Psychiatric Institute, New York, NY 10032; 3) Department of Biostatistics, Mailman School of Public Health, Columbia University, New York, NY 10032; 4) G.H. Sergievsky Center, Columbia University, New York, NY 10032; 5) Department of Neurology, College of Physicians and Surgeons, Columbia University, New York, NY 10032.

**Background:** Most genetic models start from mathematical assumptions rather than causal assumptions, i.e., from a hypothetical model of causation. This has the disadvantage that the validity of genetic models for answering questions of causation is unproven. For example, Risch uses multiplicative and additive penetrance models to derive expected patterns of increased recurrence risk among siblings ($\lambda_S$) or other relatives ($\lambda_R$) of affected individuals, compared with the general population, and the $\lambda_R$-1 ratio between relatives with increasing degrees of relationship to a proband (e.g., parents to grandparents). Determining whether these patterns correspond to causal models of gene-gene interaction (GGI) or genetic heterogeneity (GenHet) requires a comparison with a model based on causal assumptions. Here we assume a sufficient-component cause model (SCCM) of disease causation to determine patterns of familial aggregation resulting from two-locus GGI and GenHet under the SCCM framework. **Methods:** From a SCCM we derive a two-locus penetrance matrix that depends on: allele frequency, proportion-susceptible, phenocopy frequency, genetic heterogeneity, and gene-gene interaction. From this we determine disease prevalence in the population and in relatives of affected individuals, using the IBS distribution. We calculate expected $\lambda_R$ and $\lambda_R$-1 ratios for representative combinations of parameter frequencies in the SCCM framework. **Results:** The $\lambda_R$-1 ratio is slightly less than 2 when two genes cause disease independently. Increasing the number of independently-acting variants further decreases the $\lambda_R$-1 ratio. Under our assumptions, a $\lambda_R$-1 ratio < 2 indicates causal GenHet, whereas $\lambda_R$ -1 ratios > 2 indicate causal GGI. But, we find the $\lambda_R$ -1 ratio decreases with decreasing $\lambda_S$, so a $\lambda_S$<2 and $\lambda_R$-1 ratio ≈ 2 does not imply lack of interaction. When $\lambda_S$ > 2, interaction is unlikely if the $\lambda_R$-1 ratio ≈2. **Conclusion:** Patterns of familial aggregation can help distinguish whether disease is caused by gene-gene interaction or by genetic heterogeneity, but under some conditions the familial patterns of diseases caused by GGI, GenHet and a single locus are indistinguishable.

## 1807/T/Poster Board #356

**Susceptibility of premature infants to retinopathy through mutant endothelial nitric oxide synthase VNTR genotypes.** *J.G. Aryama[1], K. Yanamandra[1], D. Napper[1], H. Chen[1], S.A. Ursin[1], A. Pramanik[1], J.A. Bocchini Jr.[1], R. Dhanireddy[2].* 1) Pediatrics, LSU Health Sciences Center, Shreveport, LA; 2) Dept Pediatrics, UT Health Sciences Center, Memphis, TN.

Very low birth weight infants (VLBW) have immature retina and are susceptible to Retinopathy of prematurity (ROP). Problems associated with the immature vasculature lead to disorganized vasculature leading to scarring of retinal tissue and detachment in extreme cases. Several researchers have put forward various genetic markers in the etiology of ROP. Earlier, we have reported an association of mutant vascular endothelial growth factor (VEGF) genotypes with ROP in premature infants . We are presently studying the role of endothelial nitric oxide (eNO) synthase (eNOS) genes in the etiology of ROP. Endothelial nitric oxide serves as a vasodilator, relaxes smooth muscle, prevents platelet aggregation, and facilitates improved blood flow, vascular tonicity. Reduced nitric oxide levels result in vasoconstriction and weak tone leading to decreased blood flow and hypoxia, hypertension and thrombosis. Mutant eNOS genotypes result in reduced nitric oxide levels by decreasing the enzyme activity. Presently, we are investigating the role of eNOS polymorphism in infants with ROP. We have collected peripheral blood specimens consecutively from 144 premature infants from our NICU facility. We have studied VNTR 27bp repeat (*a/b*) polymorphism in the intron 4 region of eNOS gene by microplate PCR genotyping. Common allele *b* carries 5 repeats and rare variant allele *a* carries 4 repeats. The present data revealed a higher frequency of allele *a* in the ROP patients as compared to that in the control infants (0.25 vs. 0.14 with an odds ratio of 2.03). The data suggest that allele *a* may be a risk factor in the etiology of ROP. Previous reports have shown that allele *a* results in the decreased production of nitric oxide than the common *b* allele. Thus, we strongly believe that allele *a* through the insufficient levels of nitric oxide in the premature infants may lead to genesis of retinopathy and supplementation of either inhaled nitric oxide or L-arginine could reduce the risk of retinal detachment in severe cases in these infants. Clinical data, genotype frequencies in various ethnicities and their significance will be presented.

## 1808/T/Poster Board #357

**Comparison of genotype frequencies in Toll-like receptor genes in Ugandans, South Africans, and African HapMap populations.** *A.R. Baker[1], A.K. Randhawa[2], M.S. Shey[3], M. de Kock[3], G. Kaplan[4,6], M. Adams[5,6], W.A. Hanekom[3,6], W.H. Boom[6], T.R. Hawn[2,6], C.M. Stein[1,6].* 1) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland OH, USA 44106; 2) Department of Medicine, University of Washington, Seattle, WA, USA 98195; 3) South African Tuberculosis Vaccine Initiative, Institute for Infectious Diseases and Molecular Medicine, University of Cape Town, South Africa; 4) Laboratory of Mycobacterial Immunity and Pathogenesis, Public Health Research Institute, Newark, NJ, USA 07103; 5) Department of Genetics, Case Western Reserve University, Cleveland OH, USA 44106; 6) Tuberculosis Research Unit, Case Western Reserve University, Cleveland OH; Clinical Epidemiology Unit, Makerere University School of Medicine, Kampala, Uganda.

It has been suggested by several recent studies that susceptibility to tuberculosis (TB), a continual global health threat, is related to genes in the toll-like receptor (TLR) pathway. Single nucleotide polymorphism (SNP) data for TLR genes are available through the HapMap Project, but very little is known about how these data relate to other global populations, particularly African populations, which have an older population history, possibly subject to selective pressure. To examine the similarity in genotype frequency and linkage disequilibrium structure between HapMap populations and our study populations, we conducted full-exon resequencing of TLR genes in unrelated individuals from Uganda and South Africa. The TLR genes of interest included TLR2, TLR4, TLR6, and an adaptor-like protein involved in TLR4 signal transduction, toll/interleukin 1 receptor domain-containing adaptor protein (TIRAP). The 48 Ugandan individuals were all of Black African descent; of the South African individuals, 8 were Black Africans and 33 were Mixed Race. 7 South Africans were of Caucasian descent, however, these individuals were not analyzed in depth as Caucasians were not anticipated to be enrolled in future studies. In comparing genotype frequencies, the Ugandan population tended to show fewer differences from the Kenyan populations than the Yoruba population; most differences in the Ugandan population were seen in TLR6 where the Ugandan frequencies were dramatically different. Interestingly, the South African Blacks were very similar to both the Yoruba and Kenyan populations. The South African mixed population showed the fewest differences from the Yoruba and Southwest US African ancestry population. Comparisons of linkage disequilibrium patterns are ongoing. These results suggest that HapMap data provide a good starting point for the selection of SNPs, however, follow-up analyses using resequencing may also be required.

**On the construction of a Naïve Bayes classifier from Genome Wide Association data.** *R.W. Davies, A.F.R. Stewart, L. Chen, R. Roberts, G.A. Wells.* Univ Ottawa Heart Inst, Ottawa, ON, Canada.

Objective: We sought to develop a classification algorithm using whole genome DNA microarray data from cardiovascular Genome Wide Association (GWA) studies. Methods: We adopted a Naïve Bayes framework which assumes independence between the SNPs involved in the construction of the classifier, and constructed classifiers based on four inputs: the probability of being a case; an nSNPx3 matrix of probabilities of being a case given a genotype at a SNP; an nSNPx1 vector of the probability that a SNP is associated with disease; and a threshold for association, which can be scaled to generate Receiver Operating Characteristic curves. We considered the probability of being a case given a SNP was linear (additive) or independent (exact) with respect to genotype, and based the probability of association on p-values (Cochran-Armitage Test for Trend, Fisher's Exact Test) for the respective inheritance model corrected for multiple testing using stringent (Bonferonni style (Hochberg)), lenient (False Discovery Rate (FDR)) or no correction. We therefore considered 6 classifiers in total. Results: Two cardiovascular GWAs were looked at, the Ottawa Heart Genomics Study (OHGS) (training set) and the Wellcome Trust Case Control Consortium (WTCCC) Coronary Artery Disease (CAD) dataset (test set). OHGS consists of 1542 cases and 1455 controls genotyped on either Affymetrix 5.0 or 6.0 arrays. 482,251 SNPs common to both platforms were analyzed. Quality Control (QC) was synchronized with the WTCCC approach with the additional removal of MAF<1%. An $r^2$ filter was then used to select a subset of SNPs from OHGS which tagged the QC SNPs with minimum $r^2$=0.8, leaving 237,602 OHGS SNPs; WTCCC SNPs were taken as those which passed WTCCC QC and OHGS $r^2$. The constructed Naïve Bayes classifiers gave similar results; the following values are for the additive FDR model. Cross Validation (CV) gave sensitivity and specificity of (0.68,0.68). However, results seemed to be inflated by having run genotype calling algorithms by plate with plates being uniformly cases or controls; removing this bias by running CV by plate gave (0.64,0.65). Results on the WTCCC dataset were more modest, (0.55,0.51). Conclusions: The results on the test set were less than stellar. Next steps would be to better accommodate the independence assumption using haplotypes and to further evaluate the effects of by-plate genotype bias.

**Worldwide distribution of MYH9 risk haplotype for HIV-associated nephropathy, focal segmental glomerulosclerosis, and hypertension-associated ESRD in human populations.** *T. Oleksyk[1], G. Nelson[2], J. Kopp[3], C. Winkler[2].* 1) University of Puerto Rico, Puerto Rico; 2) SAIC, NCI-Frederick, Frederick, MD; 3) NIDDK, NIH, Bethesda, MD.

*MYH9* was shown to be main effect gene for focal segmental glomerulosclerosis (FSGS) and HIV-associated nephropathy (HIVAN) (OR≈5-7, p<10-8) and a risk factor for hypertension-associated end stage renal disease (OR≈3, p<10-8). Four risk alleles (rs4821480, rs2032487, rs4821481 and rs3752462) defined the risk haplotype (E1) that was extremely common in Americans with African ancestry (AA) (≈60%) and rare in European Americans (EA) (<4%), thus explaining a major USA health disparity. The protective haplotype (E2) was most frequent in EA (69%) and less frequent in AA (21%). The worldwide distribution, selective, and demographic factors maintaining *MYH9* risk alleles in human populations remain relatively unexplored. We reconstructed *MYH9* haplotypes involved in kidney disease by combining the data available for the HapMap and the Human Genetic Diversity Panel (HGDP) and by genotyping SNPs defining the risk haplotype in the HGDP. We analyzed the continental distribution of renal disease haplotypes and examined the extent of linkage disequilibrium for four tagging SNPs among world populations. There are substantial differences between the human populations in frequencies of risk and protective E haplotypes indicated by high FST values among continental populations, suggestive of natural selection. The risk E1 haplotype for non-diabetic kidney disease is very frequent in Sub-Saharan Africa (69%) and much less frequent outside Africa. European and Middle East feature the protective haplotype (E2) (62% and 52%, respectively) while populations in South and East Asia as well as Oceania are dominated by neutral haplotypes, with a near-complete loss of the risk E1 haplotype. The E1 risk haplotype in Africa and E2 protective haplotype in Europe both show high FST, high frequencies and extended length compared to each other, specifically in Yorubans (iHs=2.7). The Yoruban haplotypes are unique among African populations, since the extent of LD in this population is greater than in the neighboring populations within Africa. The increased risk of kidney disease in African-ancestry populations relative to their non-African counterparts is nearly completely explained by the high frequency of the *MYH9* E1 haplotype in African populations and its relative infrequency outside of Africa. There are suggestions that the E1 risk and the protective E2 haplotypes may have been maintained by balancing selection but this warrants further investigation.

## 1811/T/Poster Board #360

**A method to estimate the sharing of eQTLs between tissues, with application to skin and lymphoblastoid cells.** *J. Ding[1], J.E. Gudjonsson[2], L. Liang[1], P.E. Stuart[2], W. Chen[1], R.P. Nair[2], J.T. Elder[1], G.R. Abecasis[2].* 1) Department of Biostatistics and Center for Statistical Genetics, University of Michigan, Ann Arbor, MI; 2) Department of Dermatology, University of Michigan, Ann Arbor, MI.

Gene transcript levels can serve as an intermediate phenotype that bridges genotypes and more complex organismal phenotypes, including common diseases. Genome-wide association studies of gene expression in several human tissues have identified thousands of genetic loci impacting the expression of specific transcripts. Each of these loci is called an expression quantitative trait locus (eQTL). Although it is expected that many eQTLs will be tissue specific, the exact proportion of eQTLs that are tissue specific or shared between tissues remains unknown.

A simple measure of the tissue specificity of eQTLs can be obtained by examining the overlap of eQTL lists from two different tissues. Unfortunately, this naïve approach will always underestimate the true proportion of overlapping signals. We have developed a more accurate method. Our multi-step procedure first generates a list of potential eQTLs and then uses unbiased estimates for QTL effect sizes to estimate the expected number of replicating eQTLs for a specific sample size. The proportion of overlapping eQTLs can then be interpreted in this context. When applied to compare cis-eQTLs detected in an analysis of 57 skin biopsies and in a panel of ~400 lymphoblastoid cell lines, our method shows that 70-80% of eQTLs are shared between tissues, a much larger proportion than the naïve estimate of 30-40%.

Our results provide guidance to researchers contrasting eQTL results across tissues and a specific means to accurately estimate the proportion of overlapping eQTLs between tissues.

## 1812/T/Poster Board #361

**Genome-wide association study of leprosy defines HLA and previously unidentified loci.** *F. Vannberg[1], S. Wong[1], S. Gochhait[2], D. Malhotra[2], R. Bamezai[2], A. Hill[1].* 1) Wellcome Trust Human Genetics, Univ Oxford, Oxford, United Kingdom; 2) National Centre of Applied Human Genetics, School of Life Sciences, Jawaharlal Nehru University, New Delhi 110067, India.

Genome-wide association studies (GWAS) have been successful at identifying common variants associated with common diseases. Using GWAS methodology we here report a screen for leprosy susceptibility in an Indian cohort based in New Delhi. The highest ranking SNP in this screen was rs9270650, p=6.44x10-10, OR=2.43, which tags an HLA-DRB allele previously known to associate with leprosy. We also identify novel loci with SNPs that rank in the top 99th percentile of associated SNPs, including the loci 3q21.3, 4p14 and 15q21.1, with each loci having multiple SNPs associated with leprosy in the range of 1.17x10-6 to 1.85x10-7. Replication efforts are now underway in additional leprosy case control populations to attempt to confirm these findings. In addition, ex-vivo PBMCs from 96 healthy individuals were stimulated with LPS and tested for TNF protein expression (pQTL). We demonstrate an overlap between the 3p21.3 loci in the leprosy association screen and TNF production pQTL, suggesting that SNPs that cause differential TNF production may promote differential susceptibility to infectious disease.

## 1813/T/Poster Board #362

**A mixture model for the analysis of allelic expression imbalance.** *R. Xiao, M. Boehnke, L. Scott.* Dept Biostatistics, Univ Michigan, Ann Arbor, MI.

Genetic polymorphisms that regulate gene expression account for major phenotypic diversity in human, and may also predispose to complex diseases and determine variability in quantitative traits. Polymorphisms affecting gene expression in cis will cause differentiated expression levels depending on which of the two alleles of the gene are present. Such an allelic expression imbalance (AEI) can be detected in individuals heterozygous for the transcribed SNP. The use of AEI is complementary to testing for SNP-gene expression association and has the advantage of testing both alleles within the same environment in each individual. To detect the association of the SNP with the AEI, we propose a mixture model and corresponding expectation-maximum (EM) algorithm that is robust to the linkage disequilibrium (LD) structure between the rSNP and the transcribed SNP.

**Multifactor Dimensionality Reduction 2.1: Open-Source Genetic Analysis Software for Embracing the Complexity of Common Human Diseases.** *P. Andrews, J.H. Moore.* Department of Genetics, Dartmouth College, Lebanon, NH.

Multifactor dimensionality reduction (MDR) was designed as a nonparametric and genetic model-free approach to identifying, characterizing and interpreting gene-gene interactions in genetic and epidemiologic studies of common human diseases. The kernel of the MDR algorithm uses constructive induction to combine two or more polymorphisms into a single predictor that captures interaction effects. This general approach has been validated in numerous simulation studies and has been applied to a wide-range of different human diseases including asthma and allergy, autoimmune diseases, cancer, cardiovascular diseases, diabetes and metabolic syndrome, Mendelian diseases, pharmacogenetics and psychiatric diseases, for example. We describe here version 2.1 of the open-source MDR software package that has been made freely available to the genetic epidemiology and bioinformatics communities since February of 2005. Over this time period MDR has been downloaded more than 20,000 times. This new version of MDR has been significantly updated to allow users to load and analyze genome-wide associations study (GWAS) data. Improved data loading procedures and memory management techniques make it possible to carry out an MDR analysis on a GWAS data set. We expect this new version of MDR will open the door to routine epistasis analysis with GWAS data when combined with stochastic search methods such as the included estimation of distribution algorithm (EDA) that has the important ability to use expert knowledge in the form of prior statistical evidence (e.g. LOD scores, ReliefF) or biological evidence (e.g. chromosomal location, KEGG pathway, Gene Ontology) to probabilistically select polymorphisms for consideration in an MDR model.

## 1815/T/Poster Board #364

**Computationally efficient ReliefF-based algorithms for detecting epistasis in genome-wide association studies.** *C.S. Greene, J. Kiralis, J.H. Moore*. Department of Genetics, Dartmouth College, Lebanon, NH.

The detection of epistasis in genome-wide association study (GWAS) data is an enormous computational challenge due the combinatorial nature of the problem. We have previously shown that the ReliefF family of algorithms is able to detect epistasis in GWAS data without the need for a combinatorial algorithm. We previously developed an improved Relief algorithm called Spatially Uniform ReliefF (SURF) that significantly increases the power to detect interacting attributes in this domain. Here we provide a novel alternative to the nearest neighbor approach that instead uses all instances and weights genetic variants differently depending on whether each instance (i.e. subject) is close to or far away from the instance in question. We show using simulated genome-wide data that this new algorithm (SURF*) significantly outperforms ReliefF and SURF for genetic analysis in the presence of gene-gene interactions across a wide range of heritabilities (0.025 to 0.4) and sample sizes (800 to 3200). For example, the power of ReliefF, SURF and SURF* to rank two interacting genetic variants in the top 95% of 1000 total variants is 5%, 10% and 80%, respectively, for an epistatic model with a heritability of 0.2 and a sample size of 1600 subjects. This study provides for the first time a computationally efficient algorithm that can detect epistatic loci in genome-wide data in a non-combinatorial manner.

## 1816/T/Poster Board #365

**Discovery of Causal Relationships between Gene Expressions by Local Causal Feature Estimation.** *E. Kang[1], I. Shpitser[2], E. Eskin[1].* 1) UCLA, Los Angeles, CA; 2) Havard University, Cambridge, MA.

The availability of high throughput microarray data has encouraged several genetical genomics studies where researchers have identified genomic locations correlated with expression quantitative traits in the form of linkages or associations. Various statistical approaches have been applied to these results to tease out the underlying biological networks that govern how genes regulate and interact with each other. Extracting causal relationships from these networks is a challenging but important step to understanding the complex diseases and phenotypes under perturbation. Our goal of the project is to discover the presence and absence of causal relationships between gene expressions of yeast data and gene expressions collected from various tissues of F2 mice data. Causal discovery is challenging in our case because our domain has many thousands of variables, while our number of samples is very limited. In particular, most conventional conditional independence tests are not reliable in the small sample case, since conditioning severely reduces the power of the test. In addition, sequential conditional independence test with few samples results in complex cascading of errors in traditional constraint-based methods, and as a result we cannot infer independence with high confidence. In this project, we develop new types of causal discovery algorithm that does not suffer from these problems. The key idea behind our algorithm is that we represent a causal graph by set of “causal features” which define the causal graph and predict these features from data independently. Our approach is flexible and robust in that it allows us to predict the presence or absence of “causal features” which gets enough support from given data so that we can only identify the confident region of causal graph. We apply our algorithm to discover the causal relationships between gene expressions of yeast data and gene expressions collected from various tissues of F2 mice data.

## 1817/T/Poster Board #366

**A computational evolution system for open-ended automated learning of complex genetic relationships.** *J.H. Moore, D. Hill, C.S. Greene.* Department of Genetics, Dartmouth College, Lebanon, NH.

The failure of genome-wide association studies to reveal the genetic architecture of common diseases suggests that it is time that we embrace, rather than ignore, the complexity of the genotype-to-phenotype mapping relationship that is characterized by epistasis, plastic reaction norms, heterogeneity and other phenomena such as epigenetics. The extreme complexity of the problem suggests that simple linear models and other approaches that assume simplicity are unlikely to capture the full spectrum of genetic effects. To this end, we have developed an open-ended computational evolution system (CES) that makes no assumptions about the underlying genetic model and can learn through evolution by natural selection how to solve a particular genetic modeling problem. This is accomplished by providing the basic mathematical building blocks (e.g. +, -, *, /, LOG, <, >, =, AND, OR, NOT etc.) for models that can take any shape or form and the basic building blocks for algorithmic functions (e.g. ADD, DELETE, COPY, etc.) that can manipulate genetic models in a manner that is dependent on expert statistical and biological knowledge or prior modeling experience. We have previously demonstrated that our CES approach has excellent power to detect epistatic relationships in genome-wide data across a wide-range of heritabilities and sample sizes (Moore et al. 2008, 2009). We have also previously shown that this system can learn to utilize one of many sources of expert knowledge thus providing an important clue as to how the system solves the problem (Greene et al. 2009). Here, we introduce an additional layer to our CES approach that introduces noise into the training data (5%, 10%, 15% and 20%) to drive the discovery process toward models that are more likely to generalize. We show using simulated epistatic relationships in genome-wide data that the CES leads to significantly smaller models ($P<0.001$) thus reducing false-positives and overfitting while maintaining a power of 97% to 100%. These results are important because they show how introduced noise in the data can yield more parsimonious models and reduce overfitting without the need for computationally expensive cross-validation. This study is an important step towards a paradigm of genetic analysis that makes few assumptions about a genetic architecture that is very complex.

**Expert Knowledge from Protein - Protein Interaction Databases to Guide Genome-Wide Genetic Analysis of Common Human Diseases.**
*K. Pattin, J. Gui, J. Moore.* Gen, Dartmouth, Lebanon, NH.

With the recent availability of high-throughput technology, the feasibility to map millions of single-nucleotide polymorphisms (SNPs) has allowed us to begin to explore the depths to which genomic variation contributes to disease susceptibility. Discovering epistatic, or gene-gene, interactions in high dimensional datasets is a problem due to the computational complexity that results from the analysis of all possible combinations of SNPs. Since one of the strongest demonstrations of the functional relationship between genes is protein-protein interactions, thus we may be able to exploit the expert knowledge from protein-protein (PPI) interaction databases to facilitate the analysis of genome-wide studies. The PPI database STRING integrates a number of PPI databases as well as PubMed abstracts to comprise a large PPI interaction network where each interaction is given a confidence score based on the evidence provided for that interaction. We use this confidence score to develop and evaluate metrics by which we can prioritize SNPs in pseudo-artificial bladder cancer datasets derived from a real bladder cancer data set. Our data sets were simulated to have two functional SNP interactions where the SNPs represent a diversity of interaction scenarios and a range of confidence scores from lower to higher including zero confidence interactions according to the confidence score in STRING. We evaluate a total of 5 metrics to see which metric(s) allow us to reduce gene list of the data set significantly while retaining the two functional SNPs. We observed that there was correlation between confidence score and the gene list size for all metrics, yet no consistent trend showing that all higher confidence scores were included in increasingly smaller subsets. The metric MAX-SUM is a measure of genes prioritized by their maximum confidence score and then subsequently by the sum of the confidence scores of all interactions per gene. We find that by Wilcoxon comparison, MAX -SUM reduced the data sets significantly more than metrics AVE, MAX, and MAX-AVE (p=0.03, 0.05, 0.03). Comparison to metric SUM showed no significance. While overall this metric was most effective at reducing the gene list in a majority of scenarios, other metrics were more effective for certain interaction scenarios. We plan to implement these metrics in a bioinformatics tool that will allow us to preprocess genome-wide data on the basis of expert knowledge from protein-protein interactions.

## 1819/T/Poster Board #368

**No evidence that gene-gene interaction contributes substantially to the missing heritability of adult height, a model complex trait.**

Weedon[1], The GIANT consortium.* 1) Genetics of Complex Traits, Peninsula Medical School, Exeter, UK; 2) Department of Genome Sciences, University of Washington, Seattle, Washington, USA; 3) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK; 4) Department of Cardiovascular Science, University of Leicester, Glenfield Hospital, Leicester, UK; 5) The Genome Centre, William Harvey Research Institute, Barts and The London School of Medicine and Dentistry, Queen Mary University of London, London, UK; 6) Department of Haematology, University of Cambridge, Long Road, Cambridge, UK; 7) MRC Centre for Causal Analyses in Translational Epidemiology, Department of Social Medicine, University of Bristol, Bristol, UK; 8) Medical Research Council (MRC) Epidemiology Unit, Addenbrooke's Hospital, Cambridge, UK; 9) Metabolic Disease Group, Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK; 10) Department of Internal Medicine, Erasmus MC, Rotterdam, The Netherlands; 11) Department of Medical Genetics, University of Lausanne, Lausanne, Switzerland; 12) Medical Genetics/Clinical Pharmacology and Discovery Medicine, GlaxoSmithKline, King of Prussia, Pennsylvania, USA; 13) Program in Medical and Population Genetics, Broad Institute of Harvard and Massachusetts Institute of Technology, Boston, Massachusetts, USA; 14) Montreal Heart Institute (Research Center), Université de Montréal, Montréal, Québec, Canada; 15) Program in Molecular and Genetic Epidemiology, Harvard School of Public Health, Boston, Massachusetts, USA.

Genome-wide association (GWA) studies have resulted in the identification of >200 variants involved in complex traits and diseases. Despite this success, these variants typically only explain a small proportion of the heritability for many of these traits. Adult height is an ideal model trait to start to locate the "dark matter" of human genome variation involved in complex traits. Height is highly heritable (>80%) and accurately measured, but common variants to date explain <5% of the population variance of the trait. In this study we used GWAS data from ~10,500 individuals genotyped on the Affymetrix 500K chip and replication data from 4 additional datasets (total replication N ~16,000) to test the hypothesis that pairwise non-additive interactions between SNPs contribute to the missing heritability of adult height. We used 3 different approaches to test for interaction (Y= b0+b1.A+b2.B+b3.AB+e; Test of b3 = 0). First, we assessed 44 previously robustly associated height loci against all other SNPs in the genome. Second, we tested for interaction in the subset of SNPs with a main effect P<0.01. From these analyses, we took forward any SNPs with an interaction P<1x10-5 into replication. Third, we exhaustively tested all possible SNP pair combinations across the genome using a full 8 d.f model. From this analysis we took forward any SNPs with a full model P<1x10-8 and an interaction P<1x10-5 into replication. No more significant interactions were observed than would be expected by chance. For example, for the analysis of the 44 robustly associated variants against the rest of the genome we observed 157 SNP pairs with a P<1x10-5, when we would have expected 134 by chance. Similarly, for the analysis of SNPs showing some evidence of main effects, the respective numbers were 121 observed vs. 131 expected. Of the 401 SNP pairs that were taken forward into replication, none showed strong evidence of replication (top $P_{Replication}$ = 0.01; top $P_{Overall}$ = 1x10-6; N~26,000). Using height as a model polygenic trait, this study does not provide any evidence that gene-gene interaction explains a large proportion of the missing heritability in complex trait genetics.

## 1820/T/Poster Board #369

**A learning classifier system approach to detecting and modeling genetic heterogeneity in the presence of epistasis.** *R. Urbanowicz, J.H. Moore.* Department of Genetics, Dartmouth College, Lebanon, NH.

Genetic heterogeneity (GH) refers to the presence of different underlying genetic risk factors that result in the appearance of the same or similar disease phenotype. While some methods have been suggested to “side-step” this problem, (i.e. clustering and data stratification) these methods often rely on arbitrary cutoffs and lead to an inherent loss of power. The complexity of underlying GH makes the expectation of an accurate and comprehensive single model unrealistic. To address this problem we propose the development, application and evaluation of Learning Classifier Systems (LCS). LCS combine machine learning with evolutionary computing and other heuristics to produce an adaptive system that simultaneously learns to solve different parts of a particular problem. The solution evolved by an LCS is represented as a population of independent rules or models which are utilized collectively to make decisions or predictions. We selected LCS for study here due to their inherent focus on multiple models that each explain different subsets of the data but collectively form a solution to the problem. Three LCS algorithms of differing architectures (XCS, MCS, and GALE) were implemented, evaluated and compared using simulated genetic heterogeneity data in the presence of epistasis. We specifically compared (1) the power to correctly detect predictive polymorphisms, (2) classification accuracy on testing data, (3) computational time, and (4) model generality. This analysis indicated than an LCS is able to achieve better than 80% power to detect all of the attributes involved in the underlying GH model. Additionally, XCS was demonstrated to significantly outperform the other tested LCS methods ($p < 0.001$). The results of this study demonstrate the potential of utilizing an LCS algorithm to address the problem of GH and highlights architectural components of the algorithm best suited to the GH problem domain.

**Expression analysis confirms candidate genes found in a genome wide interaction analysis with HLA-DRB1 shared epitope alleles in Rheumatoid Arthritis.** *M. Ronninger[1], E. Lundström[1], M. Seddighzadeh[1], L. Klareskog[1], L. Alfredsson[2], L. Padyukov[1].* 1) Dept of Medicine, Karolinska Inst & Hosp, Stockholm, Sweden; 2) Dept of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden.

**Background** Several risk factors were previously found to interact with HLA-DRB1 shared epitope (SE) alleles, which is the best known risk factor in development of RA, in the Swedish EIRA study of ACPA-positive rheumatoid arthritis (RA). Both previously known (PTPN22 and C5) as well as novel RA risk genes are pending independent replication and functional confirmation. **Objectives** We hypothesize that polymorphisms connected through interaction with the HLA-DRB1 SE may have an effect on expression regulation that can lead to a change in the phenotype. **Methods** For the top ten best scoring candidates that interact with HLA-DRB1 SE alleles, we performed dense fine mapping in a cohort of ca 4000 RA cases and controls (EIRA study). We also measured mRNA expression in PBMC from 88 RA cases and controls with known genotypes by RT-qPCR. **Results** All tested genes were found to be significantly up-regulated in individuals with RA. For the gene MAP2K4 we detected an association of the mRNA expression with genotypes. A detailed study of the MAP2K4 loci demonstrated an additional variation close to the third exon in strong association with MAP2K4 expression ($p=0.004$). **Conclusions** Our data confirm previously known and reveals several new candidate genes for RA. The strategy to use the SE risk factor for finding new disease markers is a novel approach, which indicates new pathways for the disease development. We present an integration of genetic association studies with expression analysis for specific genes providing possible directions for future functional experiment in the study of RA.

## 1822/T/Poster Board #371

**A survey of epistatic effects among four candidate genes in myocardial fatty acid metabolism in hypertensive heart disease.** *L. de las Fuentes[1], J.M. Juang[1], S. Climer[1,2], V.G. Davila-Roman[1], C.C. Gu[2].* 1) Department of Medicine, Cardiovascular Division; 2) Division of Biostatistics, Washington University, St. Louis, MO.

Alterations in myocardial metabolism are implicated in hypertensive heart disease (HHD) traits in humans and in animals. Collective actions of multiple genetic factors play an important role in modulating complex traits such as HHD. In the present study, SNPs (single-nucleotide polymorphisms) covering four candidate genes involved in fatty acid metabolism and transport were tested for epistatic interactions associated with HHD-related traits. A latent HHD trait was extracted from race/sex-adjusted residuals of measured phenotypes (i.e., ultrasound indices of LV structure/function and carotid artery intima media thickness) using independent component analysis; and was used to represent the HHD trait in subsequent analyses. SNPs in PPARGC1A, PPARA, PPARG, and CD36 were tested in Caucasian (CA, n= 611) and African-American (AA, n=229) adults. Individual SNP associations were tested by race-specific linear regression analysis; and pair-wise interactions were assessed using the epistasis model implemented by PLINK (v. 1.05). In both ethnic groups, epistatic effects involving PPARGC1A SNPs were common, representing 94% and 95% of the cross-gene SNP-SNP interactions in CA and AA, respectively. Interactions between PPARGC1A and PPARA SNPs were most frequent in CA, whereas those between PPARGC1A and CD36 SNPs were most common in AA. These results are consistent with the role of PPARGC1A as a coactivator of PPARA and PPARG which in turn regulate the expression of fatty acid metabolism and transport genes including CD36. In fact, further analyses of networks formed by significant SNP-SNP interactions identified prominent pivotal nodes (SNPs) connecting clusters of interacting variants in determining HHD. In CA, we identified 5 pivotal nodes (3 PPARGC1A and 2 PPAR$\alpha$) in a network of 24 interacting SNPs; in AA, 6 nodes (4 PPARGC1A, 1 PPARG, and 1 CD36 SNPs) were identified in a network of 31 interacting SNPs. Notably, none of the pivotal SNPs in AA or CA, and only one of the other interacting SNPs in AA, was marginally associated with the HHD phenotype. Therefore, an evaluation of epistatic effects may identify meaningful associations that would go unrecognized in analyses restricted to main effects.

## 1823/T/Poster Board #372

**On the simulation of realistic samples with complex human diseases.** *B. Peng, Y. Xu, C.I. Amos.* Dept Epidemiology, Univ Texas MD Anderson CA Ctr, Houston, TX.

Simulated datasets with known disease predisposing loci have been widely used to evaluate the power of statistical methods to detect genes that are responsible for human genetic diseases. In response to the rapid adoption of genome-wide association studies, a few simulation methods have been proposed to simulate realistic samples with high-density markers over long chromosomal regions. To evaluate the performance of these methods, we used four simulation methods, GWAsimulator, Hapgen, HapSample, and a forward-time approach to simulate a large number of datasets using markers with different densities over different chromosomal regions. The quality of simulated datasets was assessed in terms of their resemblance to a reference HapMap population, using criteria such as per-locus allele frequency, short and long range linkage disequilibrium, heterozygosity and distribution of pairwise differences between sequences. Among other properties, samples simulated by these methods have varying levels of linkage disequilibrium which lead to varying effect sizes of disease predisposing loci. For example, under identical simulation conditions, four case-control samples simulated by GWAsimulator, Hapgen, HapSample and the forward-time approach have, respectively, 57, 133, 87 and 85 significant markers (single-locus $\chi^2$ tests at the 0.05 significance level) out of 1000 simulated markers. While HapSample is recommended for simple simulations due to its overall performance, the forward-time method remains the most flexible choice for more complex simulations. We extended these methods to simulate complex human diseases with multiple interacting genetic and environmental factors and gave an example using lung cancer as a model disease.

## 1824/T/Poster Board #373

**Genome-wide interaction analysis of coronary artery disease.** *Y. Liao[1], H. Dong[1], G. Peng[2], Y. Zhu[2], M. Xiong[1].* 1) Biostatistics, University of Texas School of Public Health, Houston, TX; 2) School of Life Science , Fudan University, Shanghai, China.

Numerous studies have been carried out to try to better understand the genetic predisposition for cardiovascular disease. Although it is widely believed that multifactorial diseases such as cardiovascular disease is the result from effects of many genes which working alone or interact with other genes, most genetic studies have been focused on identifying of cardiovascular disease susceptibility genes and usually ignore the effects of gene-gene interactions in the analysis. We argue that interaction holds a key to dissecting the genetic architecture of complex diseases. Although genetic interactions on a genomic scale have been investigated and genetic interaction networks have been constructed for yeast, genome-wide studies of genetic interactions in humans have not been conducted. To construct genome-wide interaction networks, minimum requirement is to assess the pair-wise interaction between SNPs. However, the number of combinations of SNPs to be evaluated will be extremely large. An exhaustive evaluation of all combinations of more than two SNPs is impossible even if we use a large supercomputer. The current study applies a novel linkage disequilibrium based statistic for testing all possible pair-wise interactions between A total of 53,394 SNPs among 501 biochemical pathways assembled from BioCarta and KEGG PATHWAY database using data from Wellcome Trust Case Control Consortium (WTCCC) Coronary Artery Disease (CAD) studies. WTCCC dataset consisted a total of 469,612 SNPs typed in 1926 CAD cases and 2938 controls. A total of 8,644 interactions are found to be significant with p-values less than $3.5\times10^{-11}$ and formed several interaction networks. Among the 8,644 significant interactions, 111 contain at least one SNP that is in the previously identified cardiovascular disease susceptibility genes. The SNP with the largest number of interaction is rs3785579, which is in CACNG1 (calcium channel, voltage-dependent, gamma subunit 1) gene and has 57 interactions with known cardiovascular disease susceptibility genes. This SNP is also found to be significant from the single SNP association test. The SNP with the second largest number of interaction is rs642298, which is in IL3RA (interleukin 3 receptor, alpha) gene and has 16 interactions with known cardiovascular disease susceptibility genes. This SNP shows marginal significance in the single SNP association test ($P=1.84\times10^{-6}$).

**Studying gene-by-environment interaction using case-control-parent tetrads.** *D.M. Umbach, M. Shi, C.R. Weinberg.* Biostatistics Branch, NIEHS, Research Triangle Park, NC.

Several proposed methods for examining haplotype-by-exposure interactions use data from affected individuals and their parents. Unfortunately, that design cannot assess the effects of exposure on risk, limiting the interpretability of identified interactions. We propose a new design that supplements the case-parents design with an unaffected sibling who is not genotyped but provides exposure data. If, in the population at large, inheritance is Mendelian and haplotypes do not influence propensity for exposure, then this case-control-parent tetrad structure permits study of haplotype effects, exposure effects and haplotype-by-exposure interactions. We describe omnibus permutation tests of no haplotype-by-exposure interaction. We base our test statistics on covariances between exposure and a score that reflects transmission. We consider two different permutation schemes; both involve interchanging exposures of sibs and one involves additional permutations among families within strata defined by sums of unphased parental genotypes. Our test can accommodate many SNPs, e.g., representing a multi-gene functional pathway, and can handle sporadically missing SNP genotypes and missing individuals. It is robust to exposure-involved population stratification and requires no distributional assumptions about the exposures under study. We characterize our test's performance through simulations. Preliminary findings are somewhat unexpected. In many scenarios, the tetrad design provides much better power than does the triad design for detecting haplotype-by-exposure interaction. We describe application of this tetrad design to the Two Sister Study, an ongoing study of families affected by breast cancer under age 50.

## 1826/T/Poster Board #375

**African ancestry-tobacco interaction accelerates lung function decline among African Americans.** *M.C. Aldrich[1], S. Kritchevsky[2], B. Meibohm[3], T. Leak[4], T. Harris[5], R. Kumar[6], E. Ziv[1], E.G. Burchard[1] for the Health ABC Study.* 1) Department of Medicine, UCSF, San Francisco, CA; 2) Sticht Center on Aging, Wake Forest School of Medicine, Winston-Salem, NC; 3) College of Pharmacy, University of Tennessee Health Science Center, Memphis, TN; 4) Department of Epidemiology, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 5) Laboratory of Epidemiology, Demography and Biometry, Intramural Research Program, National Institute on Aging, Bethesda, MD; 6) Children's Memorial Hospital, Department of Pediatrics, Northwestern University Feinberg School of Medicine, Chicago, IL.

African Americans have significantly lower lung function compared to Caucasians and Mexican Americans. However, African Americans are a genetically heterogeneous admixed population with contributions from several ancestral populations of continental origin. Moreover, while tobacco smoke exposure is an established risk factor for decreased lung function, African Americans have lower clearance of cotinine from cigarette smoke compared to Caucasians. To understand disease mechanisms, it is crucial to examine genetic factors influencing racial/ethnic differences in smoking-related diseases. We sought to identify whether African genetic ancestry modifies the association between tobacco smoke exposure and decreased lung function among 936 African Americans (68-81 years) enrolled in the Health, Aging and Body Composition Study. Genetic ancestry was estimated using 1229 ancestry informative markers and the Bayesian software program STRUCTURE. Only pulmonary function tests meeting American Thoracic Society criteria for acceptability and reproducibility were included in analyses. Multivariable linear regression analyses of forced expiratory volume in one second ($FEV_1$) revealed a greater decrease in $FEV_1$ per pack-year smoking among African Americans having greater than the median (80.9%) African ancestry (-6.5 ml $FEV_1$/ smoking pack-year) compared to African Americans having less than the median African ancestry (-5.0 ml in $FEV_1$/ smoking pack-year). There was a significant interaction between African genetic ancestry and smoking (p-value = 0.03). Significant African ancestry*smoking interactions were also observed for the pulmonary function measures, forced vital capacity (FVC) and $FEV_1$/FVC (p-value = 0.02 for each measure). These results suggest individuals with greater African ancestry may have greater risk of smoking-related lung function decline. Efforts examining interactions between admixture and smoking on rate of lung function decline are ongoing. These results highlight the importance of studying admixed populations for understanding disease. This research was supported by the Intramural Research Program of the NIH, National Institute on Aging, National Heart, Lung, and Blood Institute (R01 HL74104), contracts N01-AG-6-2101, N01-AG-6-2103, N01-AG-6-2106 and by the Flight Attendants Medical Research Institute.

## 1827/T/Poster Board #376

**A Likelihood Based Approach to Detecting Gene-Gene Interactions for Nuclear Families.** *X. Cui, HS. Chen.* Mathematical Sci, Michigan Technological Univ, Houghton, MI.

Common complex human diseases are the result of interactions of several genes instead of the effect of a single gene. To detect gene-gene interactions, we propose a novel likelihood based combinatorial method which modifies and extends the MDR method (Multifactor-Dimensionality Reduction, by Ritchie et al. 2001). Our approach can deal with nuclear families of any size, and improve computational efficiency by incorporating likelihood scores. In the simulations, a variety of different models have been investigated. Under these models we demonstrate that our method has correct type I errors and uniformly better powers than the other method, PGMDR (Lou et al., 2008). We also compared our method with the MDR-PDT (Martin et al., 2006). Under some circumstances our method performed better, and in other cases, both methods performed equally well. In summary, to detecting gene-gene interactions, we propose a novel likelihood based method, which can deal with nuclear family of any size and gain better or equal power than the other two popular methods.

**SAFARI: A software package for genome-wide interaction studies.** *B. Ding[1], H. Källberg[1], L. Padyukov[2], L. Klareskog[2], L. Alfredsson[1].* 1) Ins. of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden; 2) Rheumatology Unit, Department of Medicine, Karolinska Institutet, Sweden.

The most common human diseases have a complex etiology involving both genetic and environmental factors. Genome-wide association studies (GWAS) has recently become a popular method for identifying susceptibility loci. However, for most diseases the genetic variants discovered so far account for only a small portion of the genetic influence, indicating that there still are many genes or loci with small effects yet to be discovered. There exists the possibility that a gene's effect is more easily detected within a framework that accommodates gene-environment interactions. This pinpoints the need of developing a computation tool for detecting gene-environment interactions in a genome-wide fashion. We developed a software package SAFARI (statistical assessment of factors related to interaction) that incorporates concepts of both statistical interaction referring to departure from the underlying form of a statistical model and biologic interaction defined as departure from additivity of the disease rates. In the program, statistical interaction is estimated by inclusion of an interaction term in a logistic regression model while the estimation of biological interaction is based on the attributable proportion due to interaction (AP) as described by Rothman (2002). We have applied this software to our Swedish Epidemiologic Investigation of Rheumatoid Arthristis (EIRA) GWAS data (Illumina 317K) and successfully identified several novel disease susceptibility loci that are modified by the environmental factor smoking. SAFARI has two packages: SAS package (coded in SAS 9.1) for SAS users and R (coded in R 2.7.2) for R users. A copy of the software is available upon request.

## 1829/T/Poster Board #378

**Gene-environment interaction testing in family-based association studies with phenotypically ascertained samples: A causal inference approach.** *D.W. Fardo[1], D.L. DeMeo[2], E.K. Silverman[2], S. Vansteelandt[3].* 1) Biostatistics, UK College Pub Hlth, Lexington, KY; 2) Channing Laboratory, Brigham and Women's Hospital and Harvard Medical School, Boston, MA; 3) Applied Mathematics and Computer Science, Ghent University, Gent, Belgium.

It is well accepted that the interplay of genetic and environmental factors can form an important part of the biological foundation of common diseases. Detecting, and more importantly understanding, these gene-environment (G x E) interactions, thus, plays a crucial role in solving the puzzle of disease-phenotypic variation.

The class of family-based association tests (FBATs; Laird et al, 2000) provides strategies for testing main genetic effects that are robust to undetected/unaccounted for population substructure. Conditioning on parental/founder genotypes (or the corresponding sufficient statistics when parental genotypes are missing; Rabinowitz and Laird, 2000) insulates these testing strategies from the bias due to ancestry-driven confounding. However, once a main genetic effect must be estimated, as in the case of testing for G x E and gene-gene (G x G) interactions, ascertainment conditions for sample recruitment must appropriately be taken into account.

The calculus of directed acyclic graphs (DAGs), specifically rules of d-separation (Pearl, 2000; Robins, 2001), helps identify estimating equations that can properly incorporate ascertainment criteria. We employ the concept of principal stratification (Frangakis and Rubin, 2002) and G-estimation techniques (Robins et al, 1992) to estimate main genetic effects consistently and are able, then, to test for gene-environment interactions.The resulting test maintains robustness to population stratification, avoids assumptions on the phenotypic and allele frequency distributions and accounts for sample ascertainment. We assess the performance of this test empirically through extensive simulation studies. To illustrate the approach in practice, we also apply these new techniques to a study of chronic obstructive pulmonary disease (Silverman et al, 1998).

**Detecting Gene-Gene Interactions via Optimally Weighted Markers.** *J. He[1], K. Wang[2], A. Edmondson[3], A. Rader[3,4], C. Li[5], M. Li[1].* 1) Department of Biostatistics and Epidemiology, University of Pennsylvania; 2) Center for Applied Genomics, Children's Hospital of Philadelphia; 3) Institute for Translational Medicine and Therapeutics, University of Pennsylvania School of Medicine; 4) Cardiovascular Institute, University of Pennsylvania School of Medicine; 5) Department of Biostatistics, Vanderbilt University.

Gene-gene interactions play an important role in complex human diseases. Detection of gene-gene interactions has long been a challenge due to their complexity. The standard method that aims at detecting pairwise interactions between genetic markers may be inadequate since it does not model linkage disequilibrium (LD) among markers in the same gene and may lose power due to a large number of pairwise comparisons. To improve power, we describe a gene-based interaction test in which information of markers within a gene is optimally combined. A unique feature of our method is its ability to incorporate LD information provided by a reference dataset such as the HapMap. We analytically derive the optimal weight for both quantitative and binary traits. We then use principal components to summarize information for each gene, and test the interactions between the principal components of two genes under consideration. To evaluate the performance of our method, we conducted extensive simulations under various settings. We compared our method with several approaches, including the maximum pairwise interactions approach, which reports the maximum test statistic among all pairwise interaction test statistics, and a straightforward principal components analysis (PCA) based approach without optimal weighting. Our results show that when a single locus in the first gene interacts with a single locus in the second gene, the maximum pairwise interactions approach is the most powerful, followed by our method, but when there are two loci in the first gene interact with two loci in the second gene, then our method yields the greatest power, followed by the PCA-based approach. In general, our method performs better than the other two approaches under more complicated interaction mechanism, for example, when each of the two genes involve several disease loci and when not all disease loci are directly genotyped. In addition to simulations, we also applied our method to a HDL dataset which consists of 1,231 individuals genotyped using the ITMAT/Broad/CARe vascular disease 50K SNP array. Our method detected significant interactions between genes CETP and BCAT1. Given the complexity of human disease etiology, our method should prove useful in unraveling disease susceptibility genes for complex human diseases.

## 1831/T/Poster Board #380

**A general framework for studying genetic effects and gene-environment interactions with missing data.** *Y.J. Hu, D.Y. Lin, D. Zeng.* Dept Biostatistics, Univ North Carolina, Chapel Hill, NC.

Missing data arise in genetic association studies when genotypes are unknown or when haplotypes are of direct interest. We provide a general likelihood-based framework for estimating genetic effects and gene-environment interactions with such missing data. We allow genetic and environmental variables to be correlated while leaving the distribution of environmental variables completely unspecified. We consider three major study designs --- cross-sectional, case-control, and cohort designs --- and construct appropriate likelihood functions for all common phenotypes (e.g., case-control status, quantitative traits, and potentially censored ages at onset of disease). The likelihood functions involve both finite- and infinite-dimensional parameters. The maximum likelihood estimators are shown to be consistent, asymptotically normal, and asymptotically efficient. EM algorithms are developed to implement the corresponding inference procedures. Extensive simulation studies demonstrate that the proposed inferential and numerical methods perform well in practical settings. Illustration with a genome-wide association study of lung cancer is provided.

**Association of BFSP2 for age-related cortical cataract is modulated by cigarette smoking.** *G. Jun[1], B.E.K. Klein[2], R. Klein[2], T. Joshi[1], K.E. Lee[2], T.D. Spector[3], T. Andrew[3], C.J. Hammond[3], R.C. Elston[1], S.K. Iyengar[1,4,5].* 1) Epidemiology and Biostatistics, Case Western Reserve University School of Medicine, Cleveland, OH; 2) Ophthalmology and Visual Sciences, University of Wisconsin School of Medicine and Public Health, Madison, WI; 3) King's College London, St Thomas' Hospital Campus, Twin Research & Genetic Epidemiology Unit, London, UK; 4) Genetics, Case Western Reserve University School of Medicine, Cleveland, OH; 5) Ophthalmology, Case Western Reserve University School of Medicine, Cleveland, OH.

Age-related cortical cataract is a multifactorial disease influenced by both genetic and environmental risk factors. We studied two family-based cohorts (twin study: 185 individuals from 172 families, population-based study: 1401 individuals in 494 families) for age-related cortical cataract. We examined four variants in the gene for beaded filament structural protein 2 (BFSP2) because it is known to be associated with juvenile cataract. We also examined gene-environment interactions between SNPs in BFSP2 and two known environmental risk factors: cigarette smoking and alcohol intake. A quantitative measure, the percent of the lens affected, was adjusted for covariates and transformed before the analysis. Under the additive model, rs2078262 was the most significant in the twin cohort ($P = 7 \times 10^{-9}$), but was not significant in the population-based cohort or in a meta-analysis of both. However, rs9289447 was significant using a regression model with the interaction term (INT) between the SNP and cigarette smoking (COV) in both datasets. The joint model (JOINT) including the interaction, the SNP, and the smoking covariate was the best model for the cortical cataract trait in the population-based cohort (SNP = 0.190, COV = $3 \times 10^{-5}$, INT = $2 \times 10^{-5}$, JOINT = $4 \times 10^{-8}$) and the twin cohort (P values: SNP = 0.024, COV = 0.218, INT = $1 \times 10^{-5}$, JOINT = $6 \times 10^{-6}$); the combined P value of the joint model was $3 \times 10^{-6}$. We have thus demonstrated that development of age-related cortical cataract is modulated by exposure to cigarette smoking in later life and genetic predisposition at the BFSP2 gene.

**Gene Set Analysis based on Gene Interactions for Microarray Expression Data.** *J. Li[1], J. Zhang[2], H. Deng[2,3,4].* 1) Dept Info Med Person Hlth, Univ Missouri-Kansas City, Kansas City, MO; 2) Depts Orthopedic Surgery and Basic Medical Science, Univ Missouri-Kansas City, Kansas City, MO; 3) 3. The Key Laboratory of Biomedical Information Engineering of Ministry of Education and Institute of Molecular Genetics, School of Life Science and Technology, Xi'an Jiaotong University, Xi'an, Shaanxi 710049, P. R. China; 4) Laboratory of Molecular and Statistical Genetics, College of Life Sciences, Hunan Normal University, Changsha, Hunan 410081, P. R. China.

Gene set analysis is an important tool in analyzing microarray data of complex human diseases. It allows the inclusion of knowledge from established gene sets, such as gene pathways, and potentially improves the power of detecting differentially expressed genes, even when the expression changes of individual genes are modest. However, conventional methods of gene set analysis ignore the information of gene interactions which may contribute to variation of complex human diseases. In this study, we propose a method that uses knowledge of predefined gene sets (e.g. gene pathways) and identifies those gene sets, in which gene interactions are enriched and associated with the phenotype of interest. The utility of our method is demonstrated through analyses on two publicly available microarray datasets. The results show that our method identifies several sets of genes that show strong gene interaction enrichments that are associated with the studied phenotypes. The enriched gene interactions identified by our method may provide clues to new gene regulation pattern which are not already accounted for through known pathway identification or classical gene set analyses. In summary, our method can give researchers the ability to extract potentially disease-related genes from microarray data, and thus is helpful to delineate the sophisticated knowledge of relevant molecular pathways of disease pathogenesis. Our method can be a useful complement to classical gene set analysis which only considers single genes in a gene set.

## 1834/T/Poster Board #383

**Contribution of smoking and known susceptibility variants to the increased risk of urinary bladder neoplasms in individuals with a familial cancer history.** *J. Lorenzo Bermejo[1,2], J. Lascorz[2], K. Hemminki[2,3].* 1) Institute of Medical Biometry , University Hospital Heidelberg, Heidelberg, Germany; 2) Division of Molecular Genetic Epidemiology, German Cancer Research Center, Heidelberg, Germany; 3) Center for Primary Health Care Research, University of Malmö, Malmö, Sweden.

The aim of our study was to quantify the contribution of smoking and known genetic susceptibility variants to the increased risk of urinary bladder neoplasms in individuals with a familial cancer history. Gene variants, genetic parameters and reference values for smoking were retrieved from meta-analyses and from genome-wide association studies. This information was combined using epidemiological models and simulation.

Under the investigated domain of parameter values, the contribution of smoking to the clustering of lung and bladder cancers in families was limited to a familial relative risk (FRR) of 1.11. Daughters of women affected by lung cancer showed a FRR=1.81 of bladder cancer. In other words, the FRR explained by smoking represented 0.11/0.81=16.6% of the familial excess. Brothers of laryngeal cancer patients showed a FRR=2.93 and the proportion attributable to smoking was 5.2%. The contribution of smoking to the clustering of two cases of bladder cancer in the same family was 8.3% for sons of affected fathers and 3.5% for mother-daughter pairs.

The attributable risks of known common susceptibility variants are extensively narrowed by their conferred penetrances (genotype relative risks (GRRs) under 1.5). For example, the increased risk of stomach cancer (GRR=1.3) and bladder cancer (GRR=1.4) in *GSTM1* null genotypes, assuming a phenotype frequency of 56% and a recessive penetrance model, translated into FRR=1.03. Brothers of men affected by stomach cancer showed a FRR=2.00 of bladder tumours. Thus, *GSTM1* contributed with a 3% to the familial excess. If known risk alleles in *XRCC3*, *NAT2*, *GSTM1*, *GSTP1* and *NQO1* interacted multiplicatively on bladder cancer susceptibility, they would result in FRR=1.09. The contribution of these five variants to the aggregation of two cases of bladder cancer in one single family was 15% for sons of affected fathers and 6.3% for mother-daughter pairs.

Our results suggest that, in addition to gender and smoking history, future association studies may benefit from familial histories of other malignancies than bladder cancer. Even under the assumption that smoking and known susceptibility variants interact multiplicatively, the aetiology of a large proportion of familial cases remains still unknown.

## 1835/T/Poster Board #384

**A Bayesian hierarchical model with gene and environment interaction in a matched case-control metabolic syndrome study.** *S. Wang[1,2], C. Hsiao[1,3], L. Chuang[4], P. Liu[1,2], K. Chien[2,5], S. Lin[6], W. Chen[1,2,3].* 1) Institute of Epidemiology, College of Public Health, National Taiwan University, Taipei, Taiwan; 2) Genetic Epidemiology Core Laboratory, Division of Genomic Medicine, Research Center for Medical Excellence, National Taiwan University, Taipei, Taiwan; 3) Department of Public Health, College of Public Health, National Taiwan University, Taipei, Taiwan; 4) Department of Internal Medicine, College of Medicine and National Taiwan University Hospital, National Taiwan University, Taipei, Taiwan; 5) Institute of Preventive Medicine, College of Public Health, National Taiwan University, Taipei, Taiwan; 6) Bureau of Health, Taoyuan County Government, Taoyuan, Taiwan.

Genes, environment, and the interaction between them are known to play important roles in metabolic syndrome. Environmental influences include individual-level effects, such as personal characteristics and life styles, and group-level effects, usually called contextual effects. To explore the interaction between genes and contextual factors, it requires a formulation of hierarchical statistical models. In this study, we adopted a Bayesian hierarchical mixed-effects model for a matched case-control study, where each selected case was matched with one to two controls by sex, age, education level, ethnicity, and a contextual covariate. There were 326 matched pairs, a total of 738 persons. Five SNPs located on genes LEP (H1328082 and G2548A), APM1 (A-10066G and G-7950T), and PPARG (Pro12Ala) were genotyped. Meanwhile, availability in exercise facility in an area was treated as the contextual covariate. We evaluated the gene and environment interactions by examining if the allelic effect differs among various contextual levels. The magnitude of the corresponding variability indicates the heterogeneity of this allelic effect among areas. Under non-informative Gaussian priors on the pair and individual specific random effects and inverted Gamma priors on variance components, we performed the statistical analysis based on posterior samples obtained from the software WinBUGS version 1.4.3. For the SNP Pro12Ala, the posterior means of effects on the logit scale were 1.3, -0.7, and -0.1, respectively, for the three levels in exercise facility availability, indicating a substantial difference among areas. In addition, the posterior mean and median of the corresponding variance were 1.3 and 1.1, indicating the gene effect could be modified by the contextual factor. With regard to other SNPs, their effects on metabolic syndrome were similar across areas, all with small posterior variances. We also carried out the sensitivity analysis to examine the effect of prior specifications and the results were robust. In summary, this Bayesian hierarchical mixed-effect model provides an alternative approach to inference on the interaction between genes and a contextual variable.

## 1836/T/Poster Board #385

**A Comparison of Sample Size and Power in Case-only Association Studies of Gene-Environment Interaction.** *G.M. Clarke, A.P. Morris.* Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom.

Assuming continuous environmental and categorical genotype variables, the authors compare six case-only tests of association for gene-environment interaction. Novel tests modelling the environmental exposure as response, a non dominant coding of the genetic exposure as response, as well as the traditional test with its dominant coding of the genetic exposure as response, are included. The authors show that tests imposing the same genotypic pattern of inheritance perform similarly regardless of whether genotype is modelled as response or predictor. These novel tests with genetic exposure as response are advantageous as they are robust to non-normally distributed environmental exposures. Dominance deviance, deviation from additivity in the main or interaction effects, is key to test performance: when zero or modest, tests that search for a trend with increasing risk alleles, are optimal; when large, tests for genotypic effects are optimal. However, the authors show that when testing at a proxy locus, common in genome-wide association studies, a large dominance deviance is rare and so genotypic, as opposed to trend, tests are not generally recommended. Traditional tests assuming a dominant pattern of inheritance can suffer from serious losses of power in the presence of any recessive, or modest dominant, effects.

## 1837/T/Poster Board #386

**Insulin resistance related expression quantitative trait network: Application of linkage analysis to directed genetic network construction.** *K. Kim[1], J. Min[2], G. Kwon[3], J. Sung[1], S. Cho[1].* 1) School of Public Health, Seoul National University; 2) Institute of Health and Environment, Seoul National University; 3) Department of Preventive Medicine, School of Public Health, Seoul National University.

**Introduction** Insulin resistance is a knwon cause of endocrine-metabolic disorders, and the pathologic or epidemiologic characteristics were continually investigated, including the genetics. In this study, we suggest a novel, intuitional method to construct the expression quantitative trait (eQT) network related to insulin resistance syndrome using LOD scores and the peak loci for eQTs based on gene-gene interaction concept. **Materials and Methods** Data were from 15th Genetic Analysis Workshop, Problem 1. The data included 194 individuals in 14 three-generation families. Phenotypes were expression levels of 3554 genes in lymphoblastic cells. Of those, we selected 50 eQTs related to insulin resistance. Genotype data were available for 2884 SNP markers across the genome. Variance component linkage analysis was performed to explore the expression loci of each of the eQTs. The linkage peak loci were investigated, and the “support zone” was defined within the bounds to 0.5 LOD score from the peak. In order to explore gene-gene interactions, we investigated the relationships between all possible pairs among 50 genes. If one gene was located within the “support zone” of the peak loci for the eQT of another gene, the relationship was considered as a potential “directed causal pathway” from the former to the latter gene. Merlin 1.1.2 software was used for the analysis. **Results** We identified linkage peaks with >2.0 LOD scores for 13 eQTs, and 6 of them showed >2.5 LOD scores. SNP markers under the linkage peaks or within the support zone were searched in the database to identify the genes at the loci. 8 genes were identified on the peak, and 31 genes were identified in the support zone. 9 genes were included among the selected 50 eQTs. Gene network was constructed with those eQTs. 2 groups of gene network were formed, each around IRS2 and UGCGL2 genes; IRS2 with 3 genes, ASCL3, IDE, and IGFBP2; UGCGL2 with 4 genes, APOL3, APOL6, LEPR, and UGP2. **Conclusion** This study supported the evidence of gene networks among the genes related to insulin resistance syndrome. Use of linkage analysis enabled construction of causal directed networks. The methodology of our study showed that characterizing and locating eQTs can provide an effective way to construct genetic network model.

## 1838/T/Poster Board #387

**ReliefF Methods for Gene-Gene Interactions Including Covariate Information: Application to Antibody Response/Adverse Events Following Anthrax Vaccine Adsorbed Vaccination.** *N. Pajewski[1], V. Srinivasasainagendra[1], S. Parker[1], R. Kaslow[1], H. Tiwari[1], B. McKinney[2].* 1) University of Alabama at Birmingham, Birmingham, AL; 2) University of Tulsa, Tulsa, OK.

Interactive effects, both gene by gene and gene by environment, may play a role in the development of complex traits. Due to the high-dimensional nature of current genetic studies, comprehensive yet powerful searches for these effects require computationally efficient approaches. Machine learning methods, such as ReliefF, Multifactor Dimension Reduction, and different variations of neural networks have been popularized as one such set of approaches. However, the need to account for covariate information with these methods is an issue that has not been fully explored. As an example, our work was motivated by a Centers for Disease Control sponsored clinical trial investigating immunogenicity and reactogenicity of a reduced-dose schedule and intramuscular injection of Anthrax Vaccine Adsorbed (AVA). We aimed to identify variations within 154 candidate immune response genes (densely genotyped with 7800 SNPs) that might influence anti-PA IgG concentrations and/or local/systemic adverse events within the AVA trial population. The population included a ethnically diverse group (Caucasians, African-Americans, and others), recruited from 6 clinical sites, distributed widely by age (18 to 61 years) and equally by sex, who were randomized to reduced dose schedules or to intramuscular versus subcutaneous injections. Because machine learning algorithms are not cast within the usual linear model statistical framework, most do not directly offer an option to adjust for phenotypic effects attributable to covariates such as those mentioned above. Herein, we focus on ReliefF, which is a filter capable of reducing genome-wide datasets while respecting the structure of any gene-gene interactions inherent in the data. Using data from the AVA trial and simulations based on Phase 3 of the International HapMap Project, we first illustrate the deleterious impact of ignoring this covariate information upon applying the ReliefF interaction filter. In particular, we illustrate that ReliefF is just as susceptible to spurious results from population stratification as the usual practice of single marker hypothesis testing. We then introduce a modified ReliefF filter that incorporates stratification/group information, thus allowing for powerful detection of interactive effects while alleviating covariate induced confounding.

## 1839/T/Poster Board #388

**Finding that Elusive Gene-Environment or Gene-Gene Interaction: Prioritizing SNPs for Quantitative Trait Interaction Testing.** *G. Pare[1,2], N.R. Cook[2], P.M. Ridker[2], D.I. Chasman[2].* 1) McMaster University, Hamilton, ON, Canada; 2) Brigham and Women’s Hospital, Boston, MA, USA.

Whole genome association studies have identified many common genetic determinants of complex traits. However, few gene-gene and gene-environment interactions have been identified and validated. One of the main obstacles to interaction testing stems from multiple hypothesis testing. In this report, we show that under plausible interaction scenarios, the variance of a quantitative trait is expected to differ between the three possible genotypes of a biallelic SNP. Leveraging this observation with Levene’s test of equality of variance, we propose a novel method to prioritize SNPs for subsequent gene-gene and gene-environment testing. Prioritization is independent of subsequent interaction testing and substantially reduces the burden of multiple hypothesis testing. We first use simulations to demonstrate that our method has increased power over conventional ones. Then, using data from our ongoing genome scan (n=20,628) of two inflammatory markers, C-reactive protein and soluble ICAM-1, we successfully apply our method to identify two novel interactions which replicate (combined P-values of $4.2 \times 10^{-10}$ and $4.4 \times 10^{-8}$, respectively). Both C-reactive protein and soluble ICAM-1 are plasma markers used in the prediction of cardiovascular disease and diabetes. The first interaction involves the leptin receptor SNP rs12753193 and body mass index in the prediction of C-reactive protein. The second interaction involves the PNPLA3 SNP rs738409 and body mass index in the prediction of soluble ICAM-1. This second interaction is particularly interesting because 1) it would not have been identified using conventional methods and 2) the PNPLA3 SNP rs738409 has recently been associated with fatty liver disease, a phenotype tightly linked to both insulin resistance and inflammation.

## 1840/T/Poster Board #389

**Risk of tuberculosis (TB) among close contacts to TB patients: role of SLC11A1 and Interleukin-10 promoter polymorphisms.** *M. Reichler[1], C.C. Luo[1], B. Chen[1], E. Sigman[1], F. Maruri[2], T. Sterling[3] for the TB Epidemiologic Studies Consortium.* 1) Div TB Elimination, Centers Disease Control, Atlanta, GA; 2) Tennessee Department of Health, Nashville, TN; 3) Vanderbilt University, Nashville, TN.

**Background:** Single nucleotide polymorphisms (SNPs) in the SLC11A1 gene have been implicated in susceptibility to TB, possibly through regulation of the immunosuppressive cytokine interleukin-10 (IL-10). **Methods:** We enrolled US-born contacts with latent TB infection or active TB disease with >180 hours of exposure to smear+ TB patients at 9 sites. Blood was collected and genotyped for SLC11A1 gene SNP 3'UTR and IL-10 gene SNPs -592C/A, -819C/T and -1082A/G and epidemiologic data collected by contact interview. Pair-wise analysis was conducted for gene SNPs singly and in combination using chi2 tests with homozygous wild genotype as the referent group. This analysis is limited to contacts of Black race/ethnicity. **Results:** Among 663 contacts, 17 had active TB and 646 had a positive tuberculin skin test (TST+). Compared with TST+ contacts, contacts with active TB were more likely to have the homozygous mutant genotype for SLC11A1 3'UTR in combination with the homozygous mutant genotype for IL-10 -1082A/G (OR=9.09, P<.001), IL-10 -819C/T (OR=10.05, P<.001), or IL-10 -592C/A (OR=15.50, P<.001), but equally likely to have the homozygous mutant genotype for each individual SNP (OR=2.13, P=.33 for SLC11A1 3'UTR; OR=1.24, P=.75 for IL-10 -592C/A; OR=1.17, P=.81 for IL-10 -819C/T; OR=1.96, P=.20 for IL-10 -1082A/G). **Conclusions:** In this U.S. population, active TB in contacts after exposure to *M. tuberculosis* was associated with homozygous mutant genotype for SLC11A1 in combination with homozygous mutant genotype for three IL-10 SNPs. These findings suggest that the risk of active TB after M. tuberculosis exposure may be modulated by gene combinations rather than single genes, and that synergy between SLC11A1 3'UTR and IL-10 gene SNPs may exist.

## 1841/T/Poster Board #390

**Test for gene-gene interaction from case-control data: A study using a combination of non-parametric methods.** *A. Sengupta Chatterjee[1,2], C.C Chang[1], L.B Lian[4], C.S.J Fann[1,3].* 1) Department of Biostatistics, Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 2) Department of Life Sciences, Institute of Biomedical Informatics, National Yang-Ming University,Taipei, Taiwan; 3) Department of Life Sciences, Institute of Genome Sciences, National Yang-Ming University, Taipei, Taiwan; 4) Department of Mathematics, National Changhua University of Education, Changhua,Taiwan.

A major goal of genetic epidemiology is to determine the genetic architecture of common human diseases. Identification and characterization of susceptibility genes influencing such diseases remains a computational challenge since the effect of any single genetic variant on a complex disease may be dependent on other genetic variants through gene-gene interactions. To address this situation, statisticians have developed novel methods over the years. Presently, no single method is recognized as the best in this direction. Hence a combination of methods with the aim of balancing their specific strengths may be an optimal approach for obtaining significant results, minimizing the probability of producing false positives. Nonparametric methods have gained increased interest for their ability to handle high dimensional data. In this study we propose to include three non-parametric approaches to detect gene-gene interactions, on case-control datasets, namely (a) GINI criteria (used in CART decision trees) ,(b) a naïve Bayesian approach (A sum of absolute differences in probability of finding cases and controls) and (c) an entropy based method (based on Shannon's information entropy). We use each of these methods to score and rank 2-way Single Nucleotide Polymorphism (SNP) interactions, and subsequently obtain a summary score based on the above three scores to rank the SNP combinations. To evaluate the power we simulate 100 datasets, each for 6 different two locus epistasis models. Each dataset consists of 200 SNP markers with 900 cases and 1000 controls. Our approach produces high power (81%) to detect two-way SNP interactions for SNPs with main-effects (false positive = 1%) and shows moderate power (39%) to detect interactions for SNPs without main-effects (false positive = 3.5%). We also compare our results with Multifactor Dimensionality Reduction (MDR) method to obtain comparable results in terms of power (78% for SNPs with main-effects and 28% for SNPs without main-effects) with slightly better type I error rates than MDR. Although both the methods show less power for SNPs without main-effects, our method seems to perform slightly better than MDR for both, SNPs with and without main-effects.

## 1842/T/Poster Board #391

**RAPID detection of pairwise epistatic interactions in Genome wide association.** *V. Bafna[1], D. Brinza[1], G. Tesler[3], D. O' Connor[2].* 1) Computer Science & Engineering, UC San Diego, La Jolla, CA; 2) Department of Medicine, UC San Diego, La Jolla, CA; 3) Department of Mathematics, La Jolla, CA.

Significant challenges remain in GWA studies. In complex disorders, many independently evolving loci might interact to confer disease susceptibility, with only a modest effect at each locus. Detecting interactions in GWAS on large populations is computationally challenging. A test involving all pairs of m markers, with a case-control population of n individuals, involves nm^2 computations. For GWAS (n=1000,m=1M), this implies 10^(15) computations. Further, a straightforward (bonferroni-like) correction for the multiple tests results in significant loss of sensitivity. Our algorithm, RAPID, scales linearly with m SNPs, with no loss of sensitivity. The algorithm is based on a two-stage, iltering model. In the first stage (the filter stage), we discard a vast majority of the locus pairs, while retaining the truly interacting pairs. The filtering stage is guarenteed to be (a) fast; (b) efficient (Most candidate pairs are discarded), and (c) sensitive (truly interacting pairs are admitted). The second stage scores the remaining candidate pairs using standard tests of association. Previous filtering strategies (Marchini et al.) are based on the assumption that interacting pairs of loci should also show a marginal effect at each locus. Empirical results on simulated models of interaction show that there is a clear loss of power by employing these filters. By contrast, our method provides explicit guarantees on power of detecting interactions. There are two key ideas in RAPID. The first is a mapping of loci to a high-dimensional Euclidean metric so that statistical correlation between two loci corresponds to distance in the Euclidean space. The second is the use of a randomized technique, Locality Sensitive Hashing (LSH), in which the loci are independently projected to random hyperplanes while preserving distance between loci. Simulations show that RAPID outperforms previous approaches in speed and power. We also applied our method to the WTCCC hypertension data-set, which is particularly challenging case for GWAS, as a number of genes of modest effect define disease etiology. In a fast (10 hrs. on a PC) computation designed to uncover the most significant interactions, we identified ~30 pairs with un-adjusted p-values ranging from 10^{-10} to 10^{-11}. The gene X gene interactions reveal insights into this complex disease.

## 1843/T/Poster Board #392

**A Powerful Genome-Wide Association Study of Multiple SNPs considering Interlocus Interactions.** *R. Nakamichi, T. Tsunoda.* Center for Genomic Medicine, RIKEN, Yokohama, Kanagawa, Japan.

By the success of International HapMap Project, half million of tag SNPs covering whole genome were selected, and genome-wide association study (GWAS) to identify disease-related genes is realized. In the case of multi factorial disease, pathogenic factors are commonly observed among the population, and the contribution of each factor is relatively small. Therefore, case/control study is the mainstream to analyze multi factorial disease. Since the detection power is not enough because of small sample number, the current study is mainly focused on the analysis between a trait and a single locus. However even a binary trait, to which case/control analysis is applicable, is often controlled by multiple genes, and is difficult to analyze each locus separately, especially when the interaction exists between genes. Simple chi-squared analysis is not enough to analyze these situations. Therefore, we need more powerful statistical model. When considering gene interactions mentioned above, multiple comparison is an important problem. Bonferroni correction is too conservative when linkage disequilibrium is observed among target SNPs. Permutation test is another approach which can achieve practical correction when linkage disequilibrium exists, however is computationally heavy. For this problem, rapid association test (RAT) was proposed. It uses importance sampling to approximate permutation test, and succeeded in drastic reduction of calculation in the association study on the basis of simple chi-squared test. In this study, we extend RAT to multiple SNP model and discuss feasibility of GWAS considering gene interaction. We implemented extended RAT as fast permutation test based on logistic regression and likelihood ratio test to analyze a pair of SNPs associated to disease by interaction. We performed simulations for GWAS reflecting actual linkage disequilibrium under 2SNP interaction model, and we showed that extended RAT can effectively analyze a set of two SNPs with interaction within practical calculation time. Actually, GWAS is performed as case/control study using a few thousands of samples and limited in the single SNP analysis because of detection power. In the future, sample size may increase to tens of thousands, and we can expect to perform the analysis of combination of two or more SNPs because of increase of detection power. And then, we expect our extended RAT will effectively contribute to analyze huge data at that time.

## 1844/T/Poster Board #393

**Gene-gene interaction on selected pathways.** *S. Eyheramendy[1], S. Sober[2], E. Org[2], M. Laan[2].* 1) Statistics Department, Pontificia Univ Catolica de Chile, Santiago, Chile; 2) Department of Biotechnology, Institute of Molecular and Cell Biology, University of Tartu, Tartu, Estonia.

In genetic association studies of complex diseases, the discovery of gene-gene interactions is of great interest because most complex disorders are thought to be caused by numerous genes and environmental factors, a subset of which may act synergistically. Gene-gene interactions are hard to detect because there are thousands of genes and millions of SNPs that might be interacting in an unknown manner. Statistically, it is hard to detect epistasis because of the sparseness of data in higher dimensions, which results in that exponentially larger datasets are needed to reliably estimate the interacting models. We address this difficulty by grouping SNPs according to the pathway that they belong to and then do a gene-gene interaction analysis within (and also between) pathways for a few selected pathways. We select a handful of pathways among the ones that show the highest level of association with the phenotype. In this way we decrease the dimensionality problem by reducing the number of pair-wise tests that need to be performed while at the same time attempting not to loose valuable genetic functionality information. Hence, this approach generates a list of candidate interactions that can be empirically tested. We use the KORA 500k Affymetrix genotype data to illustrate this methodology on blood pressure traits. Our study shows that poulation genetic data can be used to perform genome-wide searches for gene-gene interactions, generating interesting gene pairs that can be further probed for their contribution to phenotypic variation in comptex traits.

## 1845/T/Poster Board #394

**A model for family-based case-control studies of genetic imprinting.** *T. Liu[1], R.L. Wu[2].* 1) Genome Inst Singapore, Singapore, Singapore; 2) Departments of Public Health Sciences and Statistics, Pennsylvania State University.

Genetic imprinting has been recognized to play an important role in the formation and pathogenesis of human diseases. In this study, we present a statistical model for testing the effect of genetic imprinting (or parent-of-origin) on a human disease in case-control studies with family structure. For each subject sampled from a case and control population, we not only genotype its own single nucleotide polymprohisms (SNPs), but also collect its parents' genotypes. By tracing the transmission pattern of alleles from parental to offspring generation, the model allows the characterization of genetic imprinting effects based on chi-squared tests of a contingency table. The model is expanded to test the interactions between imprinting effects and additive, dominant, and epistatic effects in a complex web of genetic interactions. Statistical properties of the model are investigated and its practical usefulness is validated by a real data analysis.

## 1846/T/Poster Board #395

**Characterization of Gene Interaction and Assessment of LD Matrix Measures for the Analysis of Biological Pathway Association.** *D.R. Crosslin[1], X. Qin[2], E.R. Hauser[2].* 1) Department of Biostatistics, University of Washington, Seattle, WA; 2) Center for Human Genetics, Duke University Medical Center, Durham, NC.

Complex diseases will have multiple functional sites, and it will be invaluable to understand this LD interaction between those sites (epistasis) in addition to the haplotype-LD effects. We investigated the statistical properties of a class of matrix-based statistics to assess epistasis. These statistical methods include three LD contrast tests (Zaykin et al. 2006, Wang et al. 2007) and partial least squares regression (Wang et al. 2008). To estimate Type 1 error rates and power, we simulated multiple two-variant disease models using the SIMLA software package. SIMLA allows for the joint action of up to two disease genes in the simulated data, with all possible multiplicative interaction effects between them. Our goal was to detect an interaction between multiple disease-causing variants by means of their linkage disequilibrium (LD) patterns with other markers. While the disease variants were not included in the correlation matrices assessed, we measured the effects the marginal disease effect size in terms of relative risk (RR) (1.0, 1.5 and 3.0), haplotype LD, disease prevalence and minor allele frequencies (MAF) have on cross-locus interaction (epistasis) that we specified though RR (1.0, 3.0 and 10.0). We evaluated 3 categories of null epistasis models: 1. No marginal effects and no LD; 2. Marginal effects and no LD; and 3. LD and no marginal effects. We evaluated 3 categories of alternative models: 1. No epistasis in the presence of marginal effects and LD; 2. Epistasis in the presence of LD and no marginal effects; and 3. Epistasis in the presence of marginal effects and LD. We simulated the data using a multiplicative disease model. We calculated the correlation between the two disease variants to evaluate the underlying evidence for the interaction disease models. In the setting of strong allele effects and strong interaction, the correlation between the two disease genes was weak (r=0.2). In a complex system with multiple correlations (both marginal and interaction), it was difficult to determine the source of a significant result. Despite these complications, the partial least squares approach maintained adequate power to detect the epistatic effects; however, for many of the analyses we often could not separate interaction from a strong marginal effect. While we did not exhaust the entire parameter space of possible models, we do provide guidance on the effects that population parameters have on cross-locus interaction.

## 1847/T/Poster Board #396

**Investigating the interactive effects of RHD and ABO blood group loci on human fitness.** *W.K. Meyer[1], G.H. Perry[1], M. Caliskan[1], R.S. Smith[2], C. Lee[2,3], R.R. Hudson[4], C. Ober[1,5], M. Przeworski[1,4].* 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Department of Pathology, Brigham & Women's Hospital, Boston, MA; 3) Harvard Medical School, Boston, MA; 4) Department of Ecology & Evolution, University of Chicago, Chicago, IL; 5) Department of Obstetrics and Gynecology, University of Chicago, Chicago, IL.

We considered the functional interaction between the RHD and ABO blood group systems in an evolutionary framework. The RHD negative phenotype is recessive, most often the result of homozygous deletion of the entire *RHD* gene. Prior to the availability of the clinical preventive treatment Rho(D) immune globulin in 1968, some pregnancies involving RHD positive children of RHD negative mothers resulted in miscarriage, stillbirth, or infant mortality due to hemolytic disease of the newborn (HDN). Following an initial "sensitizing" pregnancy of a RHD positive child, which exposed the mother to the RHD antigen at birth and initiated anti-RHD production, subsequent RHD positive offspring could develop HDN. Studies estimate that RHD sensitization was prevented in 55 to 90% of susceptible pregnancies if the child also carried a foreign ABO antigen, as determined by the *ABO* gene. The *RHD* and *ABO* genes are thus involved in an indirect biological interaction resulting in differential selective pressures according to maternal and child genotypes. We investigated the selective effects of different alleles of these genes in a sample of 841 Hutterites, a founder population of European descent. We hypothesized that there might be a statistical association between *RHD* and *ABO* genotypes in the Hutterites due to differential survival and reproductive potential among two-locus genotypes. We used a chi-square test of homogeneity among genotypes to provide preliminary evidence of such an association. Because the Hutterites are related through a common 1650 person, 13 generation pedigree, we assessed the significance of the association by allele dropping down this pedigree. The chi-square statistic calculated from the true data was marginally significant ($p<0.1$) when evaluated against 10,000 allele-dropping simulations. We also compared number of offspring and inter-birth interval among families with different genotype combinations before the use of Rho(D) immune globulin. These analyses reveal selection against RHD positive children of negative mothers, but with incomplete penetrance. Modeling the effects of *RHD* and *ABO* on fitness indicates that, given plausible parameters, this interaction could have played a role in maintaining appreciable frequencies of *RHD* deletion alleles. We are now extending this work by developing a statistical framework to identify other genetic interactions of potential evolutionary and biological importance.

## 1848/T/Poster Board #397

**Selecting multiple epistatic models using MB-MDR.** *T. Cattaert[1], V. De Wit[1], J.M. Mahachie John[2], K. Van Steen[1].* 1) Montefiore Institute - Bioinformatics, University of Liege, Liège, Belgium; 2) Department of Oto-rhino-laryngology, Ghent University, Ghent, Belgium.

When searching for epistasis, parametric regression approaches have severe limitations when there are many independent variables compared to the number of observed outcome events. Alternatively, the non-parametric Multifactor Dimensionality Reduction method[3] can be applied. It handles the dimensionality problem by pooling multi-locus genotypes into two groups of risk: high and low. This method and its numerous extensions are all extremely computer-intensive. Best models are evaluated on the basis of cross-validation and prediction accuracy measures, and only one such best model is proposed and its significance assessed through permutations.

We recently proposed FAM-MDR,[2] a novel unified MDR strategy for genetic interaction association analysis that can handle both unrelateds and families of any structure, different outcome types (e.g. categorical, continuous or survival type), and allows adjustment for lower order effects or confounding factors. By relying on the flexible Model-Based MDR,[1] a semi-parametric MDR method to detect epistasis in unrelated individuals, we obtain a less computationally intensive method. Association tests are applied to identify multi-locus risk cells and on the final one-dimensional construct.

In the present research, we focus on allowing multiple clusters of markers to be proposed as showing significant association with the outcome under investigation. In this light, improvement of the identification of high and low multi-locus risk cells is discussed also. Optimal definitions may substantially improve the power of our method and may dramatically impact computation time. This epistasis detection method will be evaluated and validated via a simulation study, by computing power and type I error under a variety of scenarios, including heterogeneity.

## 1849/T/Poster Board #398

**Allelic based Gene-Gene Interaction in longitudinal data.** *J. Jung.* Med & Molec Gen, Indiana Univ Sch Med, Indianapolis, IN.

In longitudinal data where repeated measures are present, there is lack of statistical methods to identify genetic association through interaction caused by multiple single nucleotide polymorphisms (SNPs) within a gene as well as by SNPs at unlinked genes contributing to risk of a disease. A novel statistical approach is proposed to detect the gene-gene interactions at the allelic level under semiparametric framework. With a new allelic score inferred from the observed genotypes at two or more unlinked SNPs, we derive profiled score statistics which are unbiased and asymptotically efficient using profile likelihood function. By testing for the association, the interaction can be assessed both in cases where the SNP association can be detected and cannot be detected as a main effect in single SNP approach. The analytical power and type I error rates over 6, two-way interaction models are investigated based on simulation study. Simulation studies demonstrate that (1) the profiled score statistic follows chi-square distribution on three degrees of freedom in two unlinked genes and (2) the allelic based method provides higher power than a genotypic based methods.

## 1850/T/Poster Board #399

**Detection of SNP-SNP Interactions in Case-Parent Trios.** *I. Ruczinski[1], Q. Li[1], TA. Louis[1], MD. Fallin[2], AE. Pulver[3].* 1) Department of Biostatistics, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 2) Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 3) Department of Psychiatry and Behavioral Sciences, Johns Hopkins Bloomberg School of Medicine, Baltimore, MD.

Statistical approaches to detect higher order SNP-SNP (and possibly SNP-environment) interactions are critical in genetic association studies, as susceptibility to complex disease is likely related to the interaction of multiple SNPs (and environmental factors). We present a novel method to detect SNP-SNP interactions in trios with affected probands. The interactions are assessed in a regression framework, and become part of the model search space. The approach accounts for the linkage disequilibrium (LD) structure in the genotype data, and accommodates missing genotypes via haplotype-based imputation. We present a case study using case-parent trios from a study of schizophrenia and schizo-affective disorder, which revealed a genotype-phenotype association that includes an allele without marginal effect. We also introduce the open source software, which includes an efficient algorithm to simulate case-parent trios where genetic risk is determined by epistatic interactions.

## 1851/T/Poster Board #400

**TSLP Polymorphisms are Associated with Asthma in a Sex-Specific Fashion.** *G. Hunninghake[1, 2, 4], H. Kim[2, 4], M. Soto-Quiros[5], J. Lasky-Su[1, 4, 6], L. Avila[5], N. Rafaels[7], K. Barnes[7], J. Wilk[8], G. O'Connor[8], W. Gauderman[9], J. Baurley[9], F. Gilliland[9], S. Sharma[1, 2, 4], B. Himes[1, 3, 10], E. Israel[2, 4], B. Raby[1-4], A. Bush[11], A. Choi[2, 4], S. Weiss[1, 2, 4], J. Celedon[1-4].* 1) Channing Laboratory, Boston, MA; 2) Division of Pulmonary and Critical Care Medicine. Brigham and Women's Hospital, Boston, MA; 3) Center for Genomic Medicine, Boston, MA; 4) Harvard Medical School, Boston, MA; 5) Division of Pediatric Pulmonology, Hospital Nacional de Niños, San José, Costa Rica; 6) Department of Biostatistics, Harvard School of Public Health, Boston, MA; 7) Division of Allergy and Clinical Immunology, Department of Medicine, Johns Hopkins University, Baltimore, MD; 8) The National Heart, Lung, and Blood Institute's Framingham Heart Study, Framingham, MA, Boston University School of Medicine, Boston, MA; 9) Department of Preventive Medicine, University of Southern California, Los Angeles, CA; 10) Harvard-MIT Division of Health Sciences and Technology, Cambridge, MA; 11) Paediatric Respirology, Imperial School of Medicine at National Heart and Lung Institute, Royal Brompton Hospital, London, United Kingdom.

Rationale: We recently demonstrated a sex-specific association between single nucleotide polymorphisms (SNP) in thymic stromal lymphopoietin (TSLP) and IgE. There has been no previous study of association between TSLP and asthma. Methods: We conducted regular and sex-stratified analyses of association between SNPs in TSLP and asthma in families of asthmatic children in Costa Rica. Significant findings were replicated in white and African-American participants in the Childhood Asthma Management Program, in African Americans in the Genomic Research on Asthma in the African Diaspora study, in a population of mixed ethnicity from the Children's Health Study, and in white subjects from the Framingham Heart Study (FHS). Results: The minor alleles of two SNPs in TSLP (rs1837253 and rs2289276) were inversely associated with asthma in a combined analysis of all subjects (p values of 5x10-5 and 7x10-5, respectively). In all studies, the direction of association was consistent and the combined result was significant after adjustment for multiple testing. In a sex-stratified analysis, the minor allele (T) of SNP rs1837253 was significantly associated with a reduced risk of asthma in all males (p= 3x10-6) but not in females. Alternately, the minor allele (T) of SNP rs2289276 was significantly associated with a reduced risk of asthma in all females (p= 2x10-4). Findings for SNP rs2289276 were consistent in girls but not in adult females in the FHS. Conclusions: TSLP variants are associated with asthma in a sex-specific fashion.

## 1852/T/Poster Board #401

**Quantifying epistasis between two sets of signaling pathway genes by canonical correlation analysis.** *B.H. Yip, C.S. Tang, S.S. Cherny, P.K. Tam, E.S. Elly, M.M. Garcia-Barcelo, P.C. Sham.* Psychiatry, Hong Kong University, Hong Kong.

This paper focuses on three aspects related to the conceptualization and application of canonical correlation analysis (CCA) as a statistical model in genetic study: 1) partial canonical correlation analysis to control the effect of population stratification, 2) epistasis analysis for case control study and 3) backward or stepwise canonical analysis to provide more insight into the dynamics of the complex genetic network. We applied these methods to simulated data and to a genetic pathway study of Hirschsprung disease. The results suggest the DLL3 gene from the NOTCH pathways interacted with the PTCH1 gene from the SHH pathway. The first canonical correlation is 0.444 (p-value from the Wilks Lamda test is 8.40E-06) among the cases and 0.157 (p-value 0.236) among the control. The difference between the correlations is significant (p-value 0.00011), after Fisher z transformation.

**Penetrance of *CDKN2A* mutations estimated using population-based Australian families.** *M. Jenkins[1], A.E. Cust[1], D. Schmidt[1], E. Makalic[1], E.A. Holland[2], H. Schmid[2], R.F. Kefford[2], G.G. Giles[3], B.K. Armstrong[4], J.F. Aitken[5], G.J. Mann[2], J.L. Hopper[1], the Australian Melanoma Family Study.* 1) Centre for MEGA Epidemiology, University of Melbourne, Melbourne, Australia; 2) Westmead Institute for Cancer Research and Melanoma Institute of Australia, University of Sydney at Westmead Millennium Institute, Sydney, Australia; 3) Cancer Epidemiology Centre, The Cancer Council Victoria, Melbourne, Australia; 4) School of Public Health, University of Sydney, Sydney, Australia; 5) Viertel Centre for Research in Cancer Control, The Cancer Council Queensland, Brisbane, Australia.

**Background**: Germline mutations in the CDKN2A gene increase risk of melanoma. For example, previous estimates of the cumulative risk (i.e. penetrance) of melanoma for *CDKN2A* mutation carriers were 30% by age 50 (95% CI: 12 to 62%) and 67% (95% CI: 31 to 96%) by age 80 when using multiple-case families, and 14% (95% CI = 8 to 22%) by age 50 and 28% (95% CI: 18 to 40%) by age 80 when using population-based families limited to first-degree relatives with unverified melanoma histories. **Methods**: The Australian Melanoma Family Study is a population-based case-control-family study which included probands with incident, histopathologically-confirmed, first-primary cutaneous melanoma diagnosed before age 40 recruited from Brisbane, Sydney and Melbourne and their first- and second-degree relatives. Of the 595 probands with DNA samples, we identified 12 with pathogenic or suspected pathogenic *CDKN2A* mutations for whom there were data for first- and second-degree relatives. The hazard ratio (HR) of melanoma incidence for carriers relative to that for the general population, and hence penetrance, were estimated using a modified segregation analysis that incorporates both genotyped and ungenotyped relatives and conditions on ascertainment to produce unbiased estimates. **Results**: Based on reports of melanoma for relatives, the HR was greater for females than males (HR = 34.2 and 9.9, respectively; p=0.02). There were no statistically significant differences in HR by age group or city of recruitment, although the power of these subgroup analyses was limited by small numbers. Combining males and females, the estimated penetrance of melanoma for *CDKN2A* mutation carriers was 18% (95% CI: 11 to 27%) by age 50, and 60% (95% CI: 43 to 77%) by age 80. For females, the penetrance estimates were 29% (95% CI: 17 to 48%) by age 50, and 70% (95% CI: 47 to 90%) by age 80, and for males they were 9% (95% CI: 4 to 20%) by age 50, and 43% (95% CI: 22 to 73%) by age 80. Restricting the reports of melanoma to the 50% that could be confirmed through official records resulted in an approximate halving of the HRs from 19.5 to 8.4 for males and females combined. **Conclusion**: Our population-based estimates of melanoma risk to age 80, which apply to the *CDKN2A* mutations identified in early-onset cases of melanoma, appear to be higher than previous population-based estimates from studying the families of cases unselected for age at onset, and were higher for females than males.

## 1854/T/Poster Board #403

**Risks of cancer for *MLH1* and *MSH2* mutation carriers.** *J.G. Dowty[1], A.K. Win[1], D. Buchanan[2], S.N. Thibodeau[3], G. Casey[4], N. Lindor[5], S. Gallinger[6], L. LeMarchand[7], R. Haile[4], P. Newcomb[8], J.L. Hopper[1], M.A. Jenkins[1], the Colon Cancer Family Registry.* 1) Centre for Molecular, Environmental, Genetic and Analytic Epidemiology, The University of Melbourne, Parkville, Victoria, Australia; 2) Familial Cancer Laboratory, Queensland Institute of Medical Research, Brisbane, Queensland, Australia; 3) Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, Minnesota; 4) Department of Preventive Medicine, University of Southern California, Los Angeles, California; 5) Departments of Medical Genetics, Mayo Clinic, Rochester, Minnesota; 6) Mount Sinai Hospital, University of Toronto, Toronto, Ontario, Canada; 7) University of Hawaii Cancer Research Center, Honolulu, Hawaii; 8) Cancer Prevention Program, Fred Hutchinson Cancer Research Center, Seattle, Washington.

**Background** Germline mutations in the DNA mismatch repair genes MLH1 and MSH2 are associated with a substantially increased risk of some cancers. Due to the rarity of these mutations, previous studies have been underpowered to provide precise estimates of age- or gene-specific risks. **Methods** We identified 307 families of MLH1 (n=133) and MSH2 (n=174) mutation carriers (probands) from the Colon Cancer Family Registry (163 from Australasia, 93 from USA and 51 from Canada). These were ascertained either because they had a family history of cancer (n=262) or from cancer registries independently of family history (n=45). MLH1 and MSH2 mutation status, sex, age and history of cancer, polypectomy and hysterectomy were sought from 13,226 probands and their relatives. Hazard ratios (HR) of cancer incidence for mutation carriers relative to those for the general population, and hence age-specific cumulative risks (penetrance), were estimated using a modified segregation analysis that incorporated both genotyped and ungenotyped relatives and conditioned on ascertainment to produce unbiased estimates. **Results** The HR for colorectal cancer did not differ by gene (p=0.9). Under a log-linear model, the HR for males was 141 at age 40 yrs and decreased with age by 8% per yr; for females, the HR was 43 at age 40 yrs and decreased with age 6% per yr. For mutation carriers from USA, the cumulative risks of colorectal cancer to age 70 yrs were estimated to be 67% (95%CI 55-79) for males and 30% (95%CI 20-45) for females. For females, the HR for endometrial cancer was higher for MSH2 mutation carriers than for MLH1 mutation carriers (16.8 versus 2.8; p=0.01). The cumulative risk to age 70 yrs was estimated to be 25% (95% 12-49) for MSH2 mutation carriers and 5% (95%CI 2-13) for MLH1 mutation carriers. Male and female MLH1 and MSH2 mutation carriers were at increased risk of other Lynch cancers (HR = 7.3 for males and 12.6 for females). The cumulative risks to age 70 yrs were estimated to be 15% (95%CI 7% - 30%) for males and 24% (95%CI 15-38) for females. There was no evidence that mutation carriers were at increased risk of non-Lynch cancers (p=0.8). **Conclusions** This international study shows that MLH1 and MSH2 germline mutations are associated with the same multiplicative increase in colorectal cancer risk, which is greater for males and greater at younger ages. MSH2 mutations are associated with a greater endometrial cancer risk than MLH1 mutations.

## 1855/T/Poster Board #404

**Disease associated polymorphisms and all cause mortality in a population cohort.** *D.S. Cross, C.A. McCarty.* Center for Human Genetics, Marshfield Clinic Research Foundation, Marshfield, Wi.

**Background**: While there have been many studies to determine alleles associated with disease, there have been few studies to determine if the alleles are associated with mortality in a population. Here we used the Personalized Medicine Research Project cohort, a population of approximately 20,000 adult individuals in 19 zip codes surrounding Marshfield Wisconsin, that have agreed to provide DNA, serum and plasma with a linked dynamic medical record for medical research. The average age at enrollment was 48, with 57% of the cohort female and 98% Caucasian. We genotyped 36 polymorphisms in the entire population to determine if disease associated polymorphisms were associated with mortality in the population. **Methods**: 36 polymorphisms with at least 1 association with a disease in two independent populations and at least 20% minor allele frequency in a Caucasian population were chosen to investigate the association of disease polymorphisms with death. All cause mortality was determined by known deaths in the population between the time of enrollment and 2008. We also stratified the population by sex to determine if there were differences in alleles associated with death by gender. **Results**: Four polymorphisms were associated with mortality in the population at the 0.05 level, rs1042031 (APOB), rs7493 (PON2), rs6313 (HTR2A), and rs688 (LDLR). Of these rs688 and rs1042031 were associated with mortality only in males when stratified by sex, and rs6313 was associated with mortality in both males and females. For rs6313 (HTR2A) there was a strong linear trend in both women alone (Mantel-Heanszel $\chi 2 = 0.0037$) and men and women combined Mantel-Heanszel $\chi 2 = 0.0053$). **Conclusions**: We provide suggestive evidence that disease associated polymorphisms may also be associated with all cause mortality, particularly alleles that are associated with cardiovascular disease such as rs1042031 and rs688 in males. In females there was a greater tendency toward mortality in a linear fashion with a greater number of T alleles for rs6313 (HTR2A). Interestingly, the C allele of this polymorphism has been associated with extraversion personality traits and the TT allele has been associated with increased tendency toward depression and suicide.

## 1856/T/Poster Board #405

**Evidence of polymorphisms of *Xpo1* as a biomarker for susceptibility to anti-tuberculosis drug-induced hepatotoxicity in Japanese patients with tuberculosis.** *T. Mawatari[1], A. Nakaura[1], N. Higuchi[2], S. kondo[1], K. Tsukamoto[1].* 1) Dept Pharmacotherapeutics, Nagasaki Univ Grad Sch, Nagasaki, Japan; 2) Dept Pharmacy, Nagasaki Univ Hosp.

**Objective**: Tuberculosis (TB) is a re-emerging infectious disease. TB care involves serious problems including the occurrence of adverse effects of anti-TB drugs, especially hepatotoxicity. Recent studies suggest that hepatotoxicity is induced by reactive oxygen species derived from isoniazid metabolites. Thus, we investigated whether polymorphisms of the exportin 1 gene (*Xpo1*), which regulates transcription of antioxidant enzymes, are associated with anti-TB drug-induced hepatotoxicity in Japanese patients with pulmonary TB.

**Methods**: This study subjects comprised 100 Japanese patients with pulmonary TB treated at least with isoniazid and rifampicin-containing regimen for six or nine months. The three tag single-nucleotide polymorphisms (SNPs) in *Xpo1* were detected by PCR-restriction fragment length polymorphism or PCR-direct DNA sequencing method. Subsequently, haplotypes were constructed from two tag SNPs, which were located within a common linkage disequilibrium block. The frequencies of alleles, genotypes, haplotypes, and diplotypes were compared between TB patients with and without hepatotoxicity by a chi-square test or a logistic regression analysis using SPSS 17.

**Results**: The frequency of an A/A genotype of an intron SNP site in *Xpo1* in TB patients with hepatotoxicity was significantly higher in comparison to that in patients without it [$P = 0.030$, odds ratio (OR) = 3.20]. Moreover, the frequencies of a Hap 3 haplotype and its homozygous Hap 3/Hap 3 diplotype in TB patients with hepatotoxicity were significantly increased as compared with those in patients without it [$P = 0.016$, OR = 3.08 and $P = 0.019$, OR = 16.2, respectively].

**Conclusion**: The present study is the first report to demonstrate the association between *Xpo1* polymorphisms and susceptibility to anti-TB drug-induced hepatotoxicity. Therefore, having the Hap 3/Hap 3 diplotype in *Xpo1* may be useful as a new biomarker for identifying high-risk TB patients with anti-TB drug-induced hepatotoxicity.

## 1857/T/Poster Board #406

**COMPARATIVE STUDY OF AMELIORATIVE ACTION OF CURCUMIN AND KALMEGH ON MERCURIC CHLORIDE INDUCED GENOTOXICITY.** *M.V. Rao, T.A. Patel.* Human Genetics Division, Department of Zoology, University School of Sciences, Gujarat University, Ahmedabad, India - 380009.

Heavy metals, particularly through their wide commercial use, pose environmental problems which may ultimately threaten human health. Mercury, one of the heavy metals, has xenobiotic and deleterious effects on public health for many decades. Mercury is released into the environment through various natural geological processes, such as volatilization of rocks, dissolution, and volcanic eruption as well as due to some anthropogenic activities like combustion of fossil fuels, incineration of waste, mining and industrial discharge. Curcumin and kalmegh are very well known antioxidants and have been used in medicine as natural remedies for the various health problems. The objective of the present study was to determine the protective effect of curcumin and kalmegh against mercuric chloride induced genotoxicity in human peripheral blood lymphocyte cultures (PBLC). Cultures were treated with two different doses of mercuric chloride 2.6 $\mu$M and 10.5 $\mu$M for two different time exposures and genotoxic indices including chromosomal aberrations, sister chromatid exchanges and proliferative index were scored and their percent frequencies were also calculated. Curcumin (3.8 $\mu$M) and kalmegh (0.4 $\mu$M) of plant products were used alone and in combination along with the higher dose of mercuric chloride. Results of the present study showed that the mercuric chloride treatment gradually increased these genotoxic indices. Supplementation of these herbal products reduced the metal exerted genotoxicity in cultures. In conclusion both herbal products viz., curcumin and kalmegh diminished mercuric chloride induced increase in genotoxic endpoints revealing their ameliorative property.

## 1858/T/Poster Board #407

**Gene-dosage effect of GSTM1 contributes to development of Rheumatoid Arthritis.** *E. Lundström[1], T. Hartshorne[2], K. Li[2], L. Alfredsson[3], L. Klareskog[1], L. Padyukov[1].* 1) Medicine, Rheumatology Unit, Stockholm, Stockholm, Sweden; 2) Applied Biosystems, Foster City, CA, USA; 3) Stockholm Center for Public Health and Environmental Medicine, Cardiovascular Epidemiology Unit, Stockholm, Sweden.

Objective. Copy number polymorphisms (CNPs) are important contributors to the diversity in human genome and the functional consequences of CNPs are not well studied. Glutathione-S-transferases (GSTs) have an important role in tobacco smoke detoxification and approximately 50% of individuals in most human populations completely lack the gene GSTM1 due to common CNP. Our goal was to investigate the impact of GSTM1 CNP in rheumatoid arthritis (RA) and its interaction with smoking and HLA-DRB1 shared epitope (SE) status, which are the two best known risk factors in development of RA. Methods. qPCR was performed using TaqMan copy number variation assays (Applied Biosystems) for 2426 incident cases and 1257 controls from the Swedish EIRA study. To quantify GSTM1 number, the software CopyCaller v0.99 was used. DAS28 was assessed for 1426 cases. Odds ratio (OR) together with 95% confidence intervals (CI) was calculated and used as a measure for risk of developing disease. Results. No association between RA and GSTM1 CNP could be found when analyzing whole study population. However, we found that the presence of GSTM1 appears to be a significant risk factor for autoantibody positive RA in females 60 years or older in absence of smoking and SE alleles (OR: 5.33 95% CI: 1.26-22.57) compared to females not carrying GSTM1, never smokers and without the SE. The presence of GSTM1 does not influence the baseline activity of RA and this CNP does not interact with SE alleles. Conclusion. For the first time in a case-control study we assessed the exact number of GSTM1 gene copies in relation to development and severity of RA. Our data suggest that presence of GSTM1 is a risk factor for a certain subgroup with probable gender effect in development of this disease.

## 1859/T/Poster Board #408

**Relation of Genetic Variants in Fatty Acid Binding Protein-4 (FABP4) and Clinical Diabetes Risk in the Women's Health Initiative Observational Study.** *K.K. Chan[1,7], Y. Song[2], Y. Hsu[3], N.Y. You[1,7], L. Tinker[4], S. Liu[1,5,6,7].* 1) Program on Genomics and Nutrition, Department of Epidemiology, University of California-Los Angeles, Los Angeles, CA; 2) Divison of Preventive Medicine, Department of Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, MA 02215; 3) Molecular and Integrative Physiological Science Program, Department of Environmental Health, Harvard School of Public Health, Boston, MA 02215; 4) Fred Hutchinson Cancer Research Center, Seattle, WA 98109; 5) Department of Medcine, David Geffen School of Medicine, UCLA, Los Angeles, CA 90095; 6) Johnson Comprehensive Cancer Center, David Geffen School of Medicine, UCLA, Los Angeles, CA 90095; 7) Center for Metabolic Disease Prevention, UCLA.

Adipocypte fatty acid binding protein (FABP4/aP2) may play a central role in energy metabolism and inflammation. In animal models, genetic defects of the FABP4 gene partially protected against the development of obesity-related insulin resistance, dyslipidemia, and atherosclerosis. However, it is unclear whether common genetic variation in FABP4 gene contributes to risk of type 2 diabetes (T2D) or diabetes-related metabolic traits in humans. We comprehensively assess the genetic associations of variants in the FABP4 gene with T2D risk and diabetes-associated biomarkers in a nested case-control study of 1,529 cases and 2,147 controls from postmenopausal women aged 50-79 years enrolled in the Women's Health Initiative Observational Study (WHI-OS). We selected and genotyped a total of 11 haplotype-tagging single nucleotide polymorphisms (tSNPs) spanning 41.3 kb across FABP4 in all samples. None of the SNPs and their derived haplotypes showed significant association with T2D risk. Neither were there any significant associations between SNPs and plasma levels of inflammatory and endothelial biomarkers (including CRP, TNF, IL-6, E-selectin, and ICAM-1). Among African American women, several SNPs were significantly associated with lower levels of vascular cell adhesion molecule-1 (VCAM-1), especially among those with incident T2D. On average, plasma levels of VCAM-1 were significantly lower among carriers of each minor allele at rs1486004(C/T) (-1.08 ng/mL; P=0.01), rs7017115(A/G) (-1.07 ng/mL, P= 0.02), and rs2290201(C/T) (-1.12 ng/mL, P=0.002) as compared with the homozygotes of the common allele, respectively. After adjusting for multiple testing, carriers of the rs2290201 minor allele remained significant association with decreasing levels of plasma VCAM-1 in these women (p=0.02). In conclusion, our finding from a multiethnic cohort of postmenopausal women did not support the notion that common genetic variants in the FABP4 gene may confer increased risk of T2D, although the observed significant association between reduced VCAM-1 levels and FABP4 genotypes in African American women requires further confirmation.

## 1860/T/Poster Board #409

**Variants in Neuropeptide Y Receptor 1 and 5 Are Associated with Nutrient-Specific Food Intake and Are Under Recent Selection in Europeans.** *C.C. Elbers[1,2], C.G.F. de Kovel[1], Y.T. van der Schouw[2], J.R. Meijboom[1], F. Bauer[1,2], D.E. Grobbee[2], G. Trynka[4], J.V. van Vliet-Ostaptchouk[3], C. Wijmenga[1,4], N.C. Onland-Moret[1,2].* 1) Complex Genetics Section, Department of Biomedical Genetics, University Medical Center Utrecht, Utrecht, Netherlands; 2) Julius Center for Health Sciences and Primary Care, University Medical Center Utrecht, the Netherlands; 3) Department of Pathology and Laboratory Medicine, University Medical Center Groningen, University of Groningen, the Netherlands; 4) Department of Genetics, University Medical Center Groningen, University of Groningen, the Netherlands.

ABSTRACT There is a large variation in caloric intake and macronutrient preference between individuals and between ethnic groups, and these food intake patterns show a strong heritability. The transition to new food sources during the agriculture revolution around 11,000 years ago probably created selective pressure and shaped the genome of modern humans. One major player in energy homeostasis is the appetite-stimulating hormone neuropeptide Y, in which the stimulatory capacity may be mediated by the neuropeptide Y receptors 1, 2 and 5 (NPY1R, NPY2R and NPY5R). We assess association between variants in the NPY1R, NPY2R and NPY5R genes and nutrient intake in a cross-sectional, single-center study of 400 men aged 40 to 80 years, and we examine whether genomic regions containing these genes show signatures of recent selection in 270 HapMap individuals (90 Africans, 90 Asians, and 90 Caucasians) and in 846 Dutch bloodbank controls. Our results show that derived alleles in NPY1R and NPY5R are associated with lower carbohydrate intake, mainly because of a lower consumption of mono- and disaccharides. We also show that carriers of these derived alleles, on average, consume meals with a lower glycemic index and glycemic load and have higher alcohol consumption. One of these variants shows the hallmark of recent selection in Europe. Our data suggest that lower carbohydrate intake, consuming meals with a low glycemic index and glycemic load, and/or higher alcohol consumption, gave a survival advantage in Europeans since the agricultural revolution. This advantage could lie in overall health benefits, because lower carbohydrate intake, consuming meals with a low GI and GL, and/or higher alcohol consumption, are known to be associated with a lower risk of chronic diseases.

## 1861/T/Poster Board #410

**Novel mutations in the *ABCA4* gene in French-Canadian patients affected by Stargardt disease.** *M-K. Gauthier[1], E. Deilhes[1], S. Dubois[1], P. Belleau[1], R. Arseneault[1], M-A. Rodrigue[1], M. Malenfant[2], Y. Tardif[2], G. Lalonde[2], P. Turcotte[2], V. Raymond[1,2].* 1) Biology of Sensory Systems, Laboratory of Genetics and Genomics, CREMOG, Laval University Hospital (CHUL) Research Center, Québec City, PQ, Canada; 2) Department of Ophthalmology, Laval University, Québec City, PQ, Canada.

Among 250 forms of hereditary blindness, 15 are severe monogenic macular dystrophies. The most prevalent is Stargardt disease, usually beginning between the age of 7 and 12. This autosomal disease can be either recessive (AR) or dominant, and is associated with *ABCA4*, *ELOV4* or *CNGB3*;*ABCA4* being the sole gene for AR Stargardt. We initiated a program to determine the prevalence of mutations causing Stargardt disease in the French-Canadian population. Here, we present our first study on 13 Stargardt families. Ophthalmologic examinations were performed on 22 patients. Six microsatellite markers overlapping *ABCA4* (6,9 Mb) were genotyped to establish disease haplotypes. Mutational screening was performed in the AR kindreds by sequencing all of *ABCA4* 50 exons and splicing junctions. Splicing mutations were predicted using *Automated Splicing Mutations* software and confirmed by RT-PCR. Among the 10 families which showed AR inheritance, 18 subjects were diagnosed with Stargardt. These patients harbored 25 disease haplotypes. Mutational screening of *ABCA4* revealed 12 non-synonymous amino-acid (AA) changes and one splicing mutation. Five of these AA changes, N96H, R537C, R943Q, G1961E and L2027F, have been reported as mutations. Three families, harboring the same disease haplotype, carried G1961E, the most frequent mutation worldwide. The other 6 AA changes, R212H, H423R, L1250P, A1773E, N1861I and S2255I, have been previously categorized either as disease-causing mutations or as non-disease associated polymorphisms. Interestingly, we found 2 novel mutations. These were the F56S AA change and the intron IVS37-2ΔA deletion. The F56S AA variation causing a major AA change within a mutational hot spot, we considered it as a mutation. The IVS37-2ΔA deletion was also considered a mutation as it caused the complete and/or partial deletion of exon 38, generating a troncated protein. Mutations in the 12 remaining disease haplotypes are still to be identified. In conclusion, we report 2 novel *ABCA4* mutations. Our screening also revealed at least 1 *ABCA4* mutation in 10 of our 18 Stargardt patients. In 3 of these patients, both disease-causing alleles were identified, whereas only 1 was observed in 7 patients. Founder mutations have been frequently observed in the French-Canadian population. However, the present study does not support major founder effects in *ABCA4* in our population, probably due to the vast number of exons favoring DNA rearrangements in the gene.

## 1862/T/Poster Board #411

**Multiple genetic factors (*MC1R*, *GSTT1*, *XPD*) modify melanoma risk in melanoma-prone families segregating *CDKN2A* mutations.** *V. Chaudru[1], C. Balanan[2], H. Mohamdi[1], C. Marian[3], E. Corda[1], K. Laud[4], M. Barrois[2], M-F. Avril[5], B. Bressac-de-Paillerets[2], F. Demenais[1].* 1) INSERM U946, CEPH, Paris, France; 2) Service de Genetique and FRE2939 CNRS, Institut Gustave Roussy, Villejuif, France; 3) Cancer Genetics and Epidemiology Division, Georgetown University Medical Center, Washington DC; 4) INSERM U830, Institut Curie, Paris, France; 5) AP-HP Hopital Cochin, Universite Rene Descartes Paris 5, Paris, France.

**Objectives:** The effect of *CDKN2A*, the major high-risk melanoma susceptibility gene, has been shown to be modified by melanoma-associated phenotypes and variants of *MC1R* gene. Genes implicated in DNA repair (such as *ERCC2/XPD*) or in detoxification of metabolites after UV exposure (such as Glutathione S-transferase (*GST*s)) are also candidates as modifiers of *CDKN2A* penetrance. Few case-controls studies have investigated the effect of *GST*s or *XPD* on melanoma risk, and have led to controversial results while these genes have not yet been studied in families segregating *CDKN2A* mutations. Our aim was to study potential genetic modifiers of *CDKN2A*, namely *GSTT1*, *GSTM1*, *GSTP1* and *XPD*, in the presence of *MC1R* gene variants in 34 French melanoma-prone pedigrees with *CDKN2A* mutations.

**Methods:** Logistic regression analyses, adjusted for age, sex, *CDKN2A* and *MC1R*, and taking into account correlations among family members, were applied to 212 subjects genotyped for all investigated genes. These analyses were also conducted by stratifying on melanoma-associated phenotypes.

**Results:** We found a significant protective effect of the null *GSTT1* allele (OR=0.26 [0.12-0.56]), confirming a previous result obtained in a subset of our families. A borderline significant protective effect of the null *GSTM1* allele was also detected (OR=0.45 [0.20-1.03]). The effect of *GSTP1* (p.I105V, p.A114V) or *XPD* (p.K751Q, p.D312N) variants on melanoma risk did not reach significance. However, stratifying on melanoma-associated phenotypes led to an increase in melanoma risk in blond/red haired subjects carrying at least one p.K751Q (OR=8.76 [1.97-38.94]) or p.D312N (OR= 7.67 [1.90-30.96]) variant of *XPD*. Multiple logistic regression conducted in the whole sample showed that the factors modulating independently the melanoma risk associated with *CDKN2A* mutations were: *MC1R* and dysplastic nevi (increasing the risk) and *GSTT1* (decreasing the risk). In red/blond hair subjects, the genetic modifiers of *CDKN2A* penetrance included *MC1R*, *GSTT1* and *XPD*.

**Conclusions:** This study shows the multiplicity of genetic pathways predisposing to melanoma.

## 1863/T/Poster Board #412

**The role of reduced folate as a risk factor for nondisjunction in chromosome 21.** *N. Hollis, L. Bean, A. Locke, S. Sherman.* Human Genetics, Emory University, Atlanta, GA.

The folate pathway is important for DNA synthesis, protein synthesis and cellular methylation. It has been hypothesized that a decrease in folate and subsequent increase in homocysteine may lead to DNA hypomethylation during meiosis. In turn, this may result in chromosome instability and abnormal chromosome segregation during oocyte formation. Supporting evidence comes from studies that show an increased frequency of variants in genes known to reduce folate metabolism, such as C677T MTHFR, or increased levels of homocysteine among case mothers who had a child with trisomy 21 compared to control mothers who had a child without trisomy 21. However, other studies have failed to find such associations. We tested this hypothesis further by comparing folate supplementation prior to conception (i.e., during resumption of meiosis I) among case mothers (n=1084) and control mothers (n=987). Dietary supplementation of folate can help maintain normal homocysteine levels and remethylation. We used logistic regression to examine the use of preconception folate supplementation adjusting for race/ethnicity, education, smoking, and maternal age. There was no significant difference in folate use between case and controls. We have just completed genotyping 21 SNPS in four genes of the folate pathway including MTHFR, MTR, MTRR, and CBS to further test this hypothesis. We will include these variables in our model and examine the interaction of these folate pathway variants with folate intake around conception to better understand the influence of reduced folate on nondisjunction. We will also incorporate our data on recombination along the nondisjoined chromosomes 21. For example, we can test the hypothesis that reduced folate may increase hypomethylation of centromeric DNA and increase the risk for a pericentromeric recombinant event, a known predisposing factor for abnormal chromosome segregation.

## 1864/T/Poster Board #413

**Genomewide Linkage and Association Study of Onset Age of LRRK2-related Parkinson's Disease.** *J.C. Latourelle[1], N. Pankratz[2], A.E. Hendricks[3], J.B. Wilk[1], A.L. DeStefano[1,3], T. Foroud[2], R.H. Myers[1], the PSG -PROGENI and GenePD Investigators, Coordinators and Molecular Genetic Laboratories.* 1) Boston University School of Medicine, Department of Neurology,Boston, MA; 2) Indiana University, Indianapolis, IN; 3) Boston University School of Public Health, Department of Biostatistics, Boston, MA.

Mutations in the leucine-rich repeat kinase 2 gene (LRRK2) located at 12q12, are the most common known genetic causes of Parkinson's Diseases (PD). The most frequently seen LRRK2 mutation, Gly2019Ser (G2019S), is associated with approximately 5 to 6% of familial PD cases and 1 to 2% of idiopathic cases. Studies of LRRK2 mutation carriers have shown incomplete and age-dependent penetrance of the disease. In addition, greater lifetime penetrance has been seen in unascertained parents of PD affected siblings compared to parents of sporadically ascertained LRRK2 cases, suggesting that inherited susceptibility factors may modify the penetrance of LRRK2 mutations. In this study, genotyping from an Illumina HumanCNV370Duo array was used to examine linkage and association to age of onset of PD in a sample of 99 LRRK2 PD cases from 59 families. The sample consisted of 54 men and 45 women, with an average age of onset of 62.6 years (StDev = 9.8, range: 41-88). Linkage analysis was performed using two methods: (1) non-parametric quantitative trait linkage (QTL) and (2) a robust score statistic based on variance components (RSS). Association to onset age for each SNP was tested under an additive mode of inheritance, using a linear mixed effects model to account for the familial relationships. The top LOD score observed for the QTL method was 2.43 and for the robust score statistic method was 1.94, both located in the region 1q32.1, within the gene neuron navigator 1 (NAV1). Moderate linkage peaks were also identified at 16q12.1 for both methods (QTL LOD=1.58, RSS LOD=1.10). In the association analyses, no SNPs reached a genomewide level of significance. Restricting the SNP association results and controlling for multiple comparisons only under the linkage peaks, also revealed no statistically significant SNP associations. The top association observed was at 19q12 between the hypothetical genes LOC148189 and LOC148145, with a p-value of 4x10-6. Additional association analyses that account for covariates and population substructure will also be presented. Further investigation of regions identified by linkage or association may provide insight into understanding the penetrance and progression of LRRK2 related PD.

## 1865/T/Poster Board #414

**Frequencies of C282Y and H63D Alleles in the HFE Gene among Various Ethnic Jewish Groups in Israel: A Change of Concept Required.** *O. Reish[1], N. Shefer-Kaufmann[2], D. Chapman Shimshoni[1], P. Renbaum[3], A. Orr-Urtreger[2], H. Steiner[3], E. Levy-Lahad[3], G. Altarescu[3].* 1) Genetic Institute, Assaf Harofeh Med Ctr, Zerifin, Israel; 2) Genetic Institute, Sourasky Medical Center, Tel Aviv, Israel; 3) Shaare Zedek Medical Center, Jerusalem, Israel.

Background: Hereditary Hemochromatosis (HHC) is a leading cause for iron overload due to increased absorption of dietary iron from the GI tract resulting in multiorgan dysfunction. Ninety percent of HHC patients are homozygous for the HFE-C282Y, 5-7% are compound heterozygotes for the C282Y and HFE-H63D and less than 2% are H63D homozygotes. Allele frequencies of these 2 mutations are highly variable among different populations in the world. There is a lack of knowledge regarding affected patients with HHC in the variable ethnic Jewish groups and allele frequency has not been well established except for the Ashkenazi group. Aim: We ascertained 3 HHC non related families of North African Jews with the C282Y/C282Y genotype, which led to frequency evaluation of C282Y and H63D alleles among the different ethnic Jewish groups in Israel, focusing on the North African one. Methods: Participants were healthy individuals from the relevant ancestries. The genotype of C282Y and H63D alleles was assessed using RFLP . Data was collected from 3 Israeli Medical centers, Assaf Harofeh, Sourasky and Shaare Zedek. This cohort included individuals from North African, Oriental, Yemenite and Sephardic Jews. Results: 586 chromosomes derived from North African individuals were evaluated: 6 alleles carried the C282Y genotype and 81 the H63D, leading to allele frequencies of 1.02% and 13.92% respectively. From the Oriental, Yemenite and Sephardic groups, 304, 94 and 118 chromosomes were evaluated. Allele frequency of C282Y was 0 in these groups but H63D frequency was 11.6%, 14.9% and 9.3% respectively. Discussion & conclusions: The detection of 3 families with HHC along with carrier frequencies of 1/50 and 1/8 for C282Y and H63D respectively, represents an under-detection of this disorder among the North African Jews in Israel even though penetrance is estimated at 1-4%. As to the Oriental, Yemenite and Sephardic groups, although no C282Y heterozygotes were detected, the H63D carrier frequency was relatively high. An aggravation of the abnormal iron metabolism has been associated with the co-inheritance of H63D genotype with other iron metabolism modifier conditions, such as the beta-thalassemia trait. As both conditions are relatively frequent in Oriental and Yemenite ethnic groups, further medical attention should be given when detected, and evaluation of the H63D allele should be considered to enable further medical attention and possible preventive care.

## 1866/T/Poster Board #415

**Meta analysis of *filaggrin* polymorphisms in eczema and asthma: robust risk factors in atopic disease.** *E. Rodríguez[1], HJ. Baurecht[2,3], E. Herberich[3], S. Wagenpfeil[3], S.J. Brown[4,5], H.J. Cordell[5], A.D. Irvine[6,7], S. Weidinger[1,8].* 1) Division of Environmental Dermatology and Allergy, Helmholtz Zentrum Munich and ZAUM-Center for Allergy and Environment, Technische Universität München, Munich, Germany; 2) Department of Epidemiology, Helmholtz Zentrum Munich, Neuherberg, Germany; 3) Institute for Medical Statistics and Epidemiology IMSE, Technische Universität München, Munich, Germany; 4) Department of Dermatology, Royal Victoria Infirmary, Newcastle upon Tyne, United Kingdom; 5) Institute of Human Genetics, Newcastle University, Newcastle upon Tyne, United Kingdom; 6) Department of Paediatric Dermatology, Our Lady's Children's Hospital, Crumlin, Dublin, Ireland; 7) Department of Clinical Medicine, Trinity College Dublin, Ireland; 8) Department of Dermatology and Allergy Biederstein, Technische Universität München, Munich, Germany.

The discovery of null mutations in the gene encoding the key epidermal protein filaggrin (*FLG*) as a major risk factor for eczema and related asthma represents a milestone towards the understanding of an important genetic mechanism in these complex diseases. However, studies published to date demonstrate differences concerning study design and strength of associations. In addition, studies on the impact of *FLG* in asthma have reported apparently conflicting results. The aim of this study was to provide a general and overall measure of effect size based on all available association studies on *FLG* in eczema and asthma respectively. We also carried out a sensitivity analysis by grouping the studies based on characteristics like definition of eczema, study size and power and source of controls. We conducted a meta-analysis of 24 studies on common *FLG* mutations and eczema involving 5791 cases, 26454 controls and 1951 eczema families as well as 17 studies involving 3138 cases, 17164 controls and 4 family studies including 1511 affected offspring on asthma. In both case-control and family studies strong associations with eczema were observed. Case-control studies were heterogeneous and odds ratios (ORs) ranged from 1.69 to 11.56 with an overall OR of 3.39 (95%CI=2.73-4.23), while family studies showed more homogeneous results with an overall OR of 2.03 (95%CI=1.77-2.34). Random effects meta-analysis after combining both study types showed that overall *FLG* haploinsufficiency increases the odds of eczema by more than 3-fold. *FLG* mutations are also significantly associated with asthma with an overall OR of 1.62 (95%CI=1.36-1.93). However, while strong effects for the compound phenotype "asthma + eczema" with an OR of 3.45 (95%CI= 2.74-4.34) were observed, there appears to be no significant association with asthma in the absence of eczema. This meta-analysis summarizes the strong evidence for a high risk for eczema conferred by *FLG* null mutations, one of the largest ever observed in the genetics of complex diseases. The results of this extensive analysis refine the risk profiles of *FLG* null alleles and suggest an association with both more severe and dermatologist diagnosed disease. The results also clearly indicate that *FLG* loss-of-function mutations are a robust risk factor in determining genetic predisposition to asthma, and suggest that FLG deficiency might help define the endophenotype of asthma linked with eczema.

## 1867/T/Poster Board #416

**Performance of gene signature-based predictions: effect of gene selection, gene numbers, and sample size.** *L.-Y. Wang, W.-C. Lee.* Institute of Epidemiology, College of Public Health, National Taiwan University, Taipei, Taiwan.

With the advance of microarray technology, gene signature-based prediction is becoming a hot topic. Researchers try to make use of gene signature to predict the outcome of treatment or certain cancers. The prediction performance varies mainly due to the heterogeneity among studies, such as sample size, gene numbers, and different selection algorithms. It's very interesting to know how these factors influence the prediction performance. We used three microarray data of cancers. One is Golub's leukemia dataset with 7129 genes and 72 subjects. The other is Armstrong's leukemia dataset with 12582 genes and 44 subjects. The last one is Alon's colon cancer dataset with 2000 genes and 62 subjects. We then did some experiments on these datasets. For example, we added noise genes to the pre-existent genes and gradually curtail sample sizes of the training datasets. Simple linear regression and univariate testing with significance level $\alpha$ is used to examine the effect of different selection criteria. All genes, no matter significant or not, are ordered by means of their $p$ values. The prediction performance increases as the gene number increases, and quickly reaches its peak (e.g., AUC =0.95 or 0.98). Later, the performance decreases due to the harm of noise genes. However, as the gene number gets larger (e.g., >2000 genes, depending on individual dataset), the prediction performance starts rising again and finally achieve the same performance as the initial peak. We found that the reduction of the sample size in the training datasets will postpone the initial peak time and decrease the corresponding prediction performance. The prediction model seems to be very resistant to the considerable number of new added noise genes because the highest performance is still >0.95 when all genes are put into the model. Also, we showed an optimal gene selection strategy depending on signal-to-noise ratio and signal strength given a fixed sample size. There exists a no-selecting zone where any gene selection procedure within the zone will only jeopardize prediction performance. We conclude that the sample size in the training dataset is influential to the initial peak prediction performance. The gene selection in some occasions may not benefit the prediction performance. We suggest the further studies of these no selecting zones may be as important as that of gene selection procedures.

## 1868/T/Poster Board #417

**candidate gene pharmacogenetics study of mGlu 2/3 agonist LY2140023.** *W. Liu, P. Chen, J.E. Brandt, R. Njau, L. Munsie, B. Kinon, A. Downing, L. Nisenbaum.* Lilly Research Laboratories, Indianapolis, IN.

LY2140023 is the oral prodrug of LY404039, a selective agonist for metabotropic-glutamate 2/3 (mGlu) receptors. LY2140023 is currently under development for the treatment of schizophrenia. mGlu2/3 agonism by LY2140023 has the potential to introduce a novel mechanism of action for oral antipsychotics, as all other commonly prescribed medications target monoaminergic activity. The primary goal of the current pharmacogenetics effort is to identify genetic markers that are predictive of patients' response to LY2140023 that could be used in future trials to target specific subpopulations of patients. This study examined genetic variants in eight candidate genes related to the mechanism of action of LY2140023 or the atypical antipsychotic olanzapine. Single nucleotide polymorphisms (SNPs) were genotyped in DNA samples collected as part of the Phase II proof of concept trial, H8Y-MC-HBBD, which was a 28-day, randomized, double-blind, placebo controlled study of LY2140023 in the treatment of patients with schizophrenia. Statistical analysis was conducted on 193 Caucasian patients treated with either placebo, LY2140023 or olanzapine. Associations between LY2140023 response and genotypes were identified for SNPs within the HTR2A and NRG1 genes. Three SNPs (1 in NRG1, 2 in HTR2A) were statistically significantly associated with LY2140023 response at 28 days as measured by Positive and Negative Syndrome scale (PANSS) Total change from baseline. All three SNPs had unadjusted p-values less than 0.001 (FDR=0.114) at 28 days. Twenty-three SNPs had unadjusted p-values less than 0.01 (FDR<0.2) in the LY2140023 arm at 28 days and 16 of them were in HTR2A, - all in tight linkage disequilibrium based on HapMap data. Top LY2140023 HTR2A and NRG1 SNPs showed similar results in PANSS Positive, Negative, and Clinical Global Impressions-Severity analyses. In conclusion, these data suggest that a genetic association may exist between SNPs in two genes and response to LY2140023 treatment. These findings will need to be examined in additional clinical trials to gain a better understanding of the clinical utility of these genetic markers.

## 1869/T/Poster Board #418

**Disease model distortion and effect size underestimation in association studies.** *D. Vukcevic, E. Hechter, C. Spencer, P. Donnelly.* Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom.

Most GWAS findings are consistent with the simplest disease model, in which each additional copy of the risk allele increases disease risk by the same multiplicative factor, in contrast to recessive or dominant effects. Using theoretical and empirical results we show that LD markedly distorts these effects, with the power to detect dominant or recessive effects dropping off extremely quickly. For example, power to detect departures from the simplest model decays as a function of $r^4$, where $r^2$ is the usual correlation between the causal and marker loci. This is in contrast to the the well-known result that power to detect a multiplicative effect decays as function of $r^2$. Similar results apply to the detection of interactions between distinct GWAS loci. Using replicated findings for breast cancer, Crohn's disease and type 2 diabetes, we examine the consequences of these results for prediction of individual disease risk. Disease model distortion can also account for much of the missing heritability in common diseases.

## 1870/T/Poster Board #419

**The cholesterol 7 alpha-hydroxylase gene susceptible to the severe progression of primary biliary cirrhosis in Japanese patients.** *S. Higa[1], T. Inamine[1], F. Noguchi[1], A. Kawauchi[1], H. Hashiguchi[1], S. Kondo[1], M. Nakamura[2], H. Ishibashi[2], K. Omagari[3], K. Tsukamoto[1].* 1) Dept Pharmacotherapeutics, Nagasaki Univ Grad Sch Biomed Sci, Nagasaki, Japan; 2) Clin Res Center, Natl Hosp Organi Nagasaki Med Center, Nagasaki, Japan; 3) Dept Nutr, Fac Nurs Nutr, Univ Nagasaki, Nagasaki, Japan.

**Purpose**: Primary biliary cirrhosis (PBC) is a chronic liver disease characterized by destruction of the bile ducts and inflammation, resulting in the accumulation of bile acids, thus leading to hepatic damage. Here, we focused on the cholesterol 7 alpha-hydroxylase gene (*CYP7A1*), which is a rate-limiting enzyme of bile acid synthesis, and examined an association between polymorphisms of this gene and susceptibility to the severe progression of PBC.

**Methods**: The study subjects comprised 149 unrelated Japanese patients with PBC. Patients were classified into two different stages based on the findings of liver biopsy and clinical manifestations. Jaundice stage was defined as any Scheuer's stage with persistent jaundice. While, non-jaundice stage was defined as any Scheuer's stage without persistent jaundice. The five tag single-nucleotide polymorphisms (SNPs) in *CYP7A1* were detected by PCR-restriction fragment length polymorphism or by PCR-direct DNA sequencing method. Subsequently, haplotypes were constructed from two SNPs, which showed a significant association of the severe progression of PBC. The frequencies of alleles, genotypes, haplotypes, and diplotypes were compared between subgroups of PBC patients by a chi-square test or a logistic regression analysis using SPSS 17.

**Results**: The frequency of a Hap 3 haplotype and a Hap 1/Hap 3 diplotype were significantly increased in jaundice stage in comparison to that in non-jaundice stage [$P = 0.0152$, odds ratio (OR) = 3.348 and $P = 0.0040$, OR = 8.370, respectively].

**Conclusion**: These results suggest that the abilities of bile acid biosynthesis may be accelerated in PBC patients possessing the Hap 1/Hap 3 diplotype, resulting in the accumulation of toxic bile salts, and leading to the severe progression of PBC. Thus, *CYP7A1* appears to be a genetic determinant of the progression of PBC in Japanese patients. Genetic polymorphisms of *CYP7A1* may be useful as a biomarker for identifying high-risk PBC patients.

## 1871/T/Poster Board #420

**Diplotype polymorphisms of the bile salt export pump gene are associated with susceptibility to the severe progression of primary biliary cirrhosis in Japanese patients.** *T. Inamine[1], S. Higa[1], F. Noguchi[1], A. Kawauchi[1], H. Hashiguchi[1], S. Kondo[1], M. Nakamura[2], K. Omagari[3], H. Ishibashi[2], K. Tsukamoto[1].* 1) Dept Pharmacotherapeutics, Nagasaki Univ Grad Sch Biomed Sci, Nagasaki, Japan; 2) Clin Res Center, Natl Hosp Organi Nagasaki Med Center, Nagasaki, Japan; 3) Dept Nutr, Fac Nurs Nutr, Univ Nagasaki, Nagasaki, Japan.

Purpose: Primary biliary cirrhosis (PBC) is a chronic liver disease characterized by destruction of the bile ducts and inflammation, resulting in the accumulation of bile acids, thus leading to hepatic damage. Here, we focused on the bile salt export pump gene (*BSEP, ABCB11*), whose polymorphisms and mutations are associated with intrahepatic cholestasis of pregnancy, and examined an association between polymorphisms of *ABCB11* and susceptibility to the progression of PBC.

Methods: The study subjects comprised 145 unrelated Japanese PBC patients. Patients were classified into two different stages based on the findings of liver biopsy and clinical manifestations. Jaundice stage was defined as any Scheuer's stage with persistent jaundice. While non-jaundice stage was defined as any Scheuer's stage without persistent jaundice. The twenty-two tag single nucleotide polymorphisms (SNPs) in *ABC11* were detected by PCR-restriction fragment length polymorphism or PCR-direct DNA sequencing method. Subsequently, haplotypes were constructed from two tag SNPs, which showed a significant association of the severe progression of PBC. The frequencies of alleles, genotypes, haplotypes, and diplotypes were compared between subgroups of PBC patients by a chi-square test or a logistic regression analysis using the SPSS 17 statistical program package.

Results: The frequency of a Hap3/Hap4 diplotype was significantly increased in patients in jaundice stage in comparison to that in patients in non-jaundice stage ($P = 0.038$, odds ratio = 4.831). Inversely, all of the PBC patients having another Hap2/Hap3 diplotype were observed only in non-jaundice stage, but not in jaundice stage, although statistical analysis could not be carried out.

Conclusion: Our results suggest that the diminution of the bile acid efflux activities due to *ABCB11* polymorphisms, especially having the Hap3/Hap4 diplotype, may accelerate the accumulation of bile acid, eventually leading to the severe progression of PBC. Therefore, *ABCB11* appears to be a genetic determinant of the severe progression of PBC in Japanese.

## 1872/T/Poster Board #421

**Haplotype and diplotype polymorphisms of *HNF-4α* as a genetic biomarker for susceptibility to the severe progression of primary biliary cirrhosis in Japanese patients.** *F. Noguchi[1], T. Inamine[1], S. Higa[1], A. Kawauchi[1], H. Hashiguchi[1], S. Kondo[1], M. Nakamura[2], H. Ishibashi[2], K. Omagari[3], K. Tsukamoto[1].* 1) Dept Parmacotherapeutics, Nagasaki Univ Grad Sch Biomed Sci; 2) Clin Res Center, Natl Hosp Organi Nagasaki Med Center; 3) Dept Nutr, Fac Nurs Nutr, Univ Nagasaki.

**Objective:** Primary biliary cirrhosis (PBC) is a chronic liver disease characterized by destruction of the bile ducts and inflammation, resulting in the accumulation of bile acids, thus leading to hepatic damage. Here, we focused on the hepatocyte nuclear factor-4 alpha gene (*HNF-4α*), which regulates the expression of a set of genes related to bile acid synthesis and metabolism in the liver as a transcription factor, and examined an association between polymorphisms of this gene and susceptibility to the progression of PBC.

**Methods:** The study subjects comprised 149 unrelated Japanese patients with PBC. Patients were classified into two different stages based on the findings of liver biopsy and clinical manifestations. Jaundice stage was defined as any Scheuer's stage with persistent jaundice. While, non-jaundice stage was defined as any Scheuer's stage without persistent jaundice. The six tag single-nucleotide polymorphisms (SNPs) in *HNF-4α* were detected by PCR-restriction fragment length polymorphism method. The frequencies of alleles, genotypes, haplotypes, and diplotypes were compared between subgroups of PBC patients by a chi-square test or a logistic regression analysis using the SPSS 17 statistical software package.

**Results:** The frequencies of a Hap 6 haplotype and its heterogenous Hap 2/Hap 6 diplotype, which were constructed from three tag SNPs showing a significant association of the severe progression of PBC, were significantly increased in jaundice stage as compared with those in non-jaundice stage [$P = 0.0020$, odds ratio (OR) = 11.0 and $P = 0.0096$, OR = 13.0, respectively].

**Conclusion:** The present study is the first report to demonstrate that *HNF-4α* appears to be a genetic determinant of the severe progression of PBC, and may be useful as a new DNA-based diagnostic biomarker for identifying high-risk PBC patients. Furthermore, HNF-4α may be good target molecule for the development of novel drugs in the future.

## 1873/T/Poster Board #422

**Genetic risk score for systemic lupus erythematosus is associated with age of onset and autoantibody production.** *K. Taylor[1], S. Chung[1], R. Graham[2], W. Ortmann[2], A. Lee[3], C. Langefeld[4], C. Jacob[5], M. Alarcón-Riquelme[6], B. Tsao[7], K. Moser[6], P. Gaffney[6], J. Harley[6], M. Petri[8], S. Manzi[9], P. Gregersen[3], T. Behrens[2], L. Criswell[1].* 1) Division of Rheumatology, University of California San Francisco, San Francisco, CA; 2) Genentech, Inc., South San Francisco, CA; 3) Feinstein Institute for Medical Research, Manhasset, NY; 4) Wake Forest University Health Sciences, Winston-Salem, NC; 5) University of Southern California, Los Angeles, CA; 6) Oklahoma Medical Research Foundation, Oklahoma City, OK; 7) University of California at Los Angeles, Los Angeles, CA; 8) Johns Hopkins University School of Medicine, Baltimore, MD; 9) University of Pittsburgh, Pittsburgh, PA.

Systemic lupus erythematosus (SLE) is a genetically complex disease with heterogeneous clinical manifestations. Recent studies have greatly expanded the number of established SLE risk alleles, but the distribution of multiple risk alleles in cases versus controls and their relationship to SLE subphenotypes has not been studied. We define a genetic risk score (GRS) for SLE as the number of risk alleles from 11 established SLE susceptibility polymorphisms in 10 genes: *HLA-DRB1* (*HLA-DR3* and *HLA-DR2* alleles), *PTPN22, STAT4, IRF5, TNFAIP3, FCGR2A, ITGAM, KIAA1542, PXK,* and *BLK*. We studied the GRS of 1919 SLE cases from 9 independent Caucasian SLE case series and 4813 independent controls. We also studied associations with clinical manifestations for the cases, namely age of onset, the 11 American College of Rheumatology (ACR) classification criteria, and anti-double-stranded DNA autoantibodies (anti-dsDNA), a subset of the ACR immunologic criterion. These manifestations strongly influence disease severity and outcome. This expands our previous work by the addition of 624 cases, principal components analysis for intra-European ancestry adjustment, and the addition of a *TNFAIP3* risk allele. The mean number of SLE risk alleles was 7.77 (SD ± 2.04) for cases versus 6.70 (SD ± 1.91) for controls, linear trend in log odds ptrend=$2.5 \times 10^{-87}$. The odds ratio for SLE risk comparing 9 or greater (22%) versus 5 or fewer (23%) risk alleles was 4.33 (95% CI 3.64-5.14). After adjustment for significant terms among sex, disease duration, cohort, and ancestry, each single-allele increase in the GRS was associated with increased risk of anti-dsDNA autoantibody production (OR=1.14, p=$6 \times 10^{-7}$) and the immunologic criterion (OR=1.12, p=0.00001), decreased risk of oral ulcers (OR=0.93, p=0.002), and a 9-month earlier age of onset (p=$10^{-6}$). Furthermore the GRS was more significant than any single SNP effect for these subphenotypes. In contrast, renal disease was most significantly associated with the *HLA-DR3* tag SNP (OR=1.34, p=0.004), arthritis with *ITGAM* (OR=0.71, p=0.001), serositis with *BLK* (OR=1.23, p=0.010), the hematologic criterion with *HLA-DR3* (OR=1.22, p=0.04), and anti-nuclear autoantibodies with *IRF5* (OR=2.14, p=0.010). Other clinical manifestations, such as photosensitivity and malar rash, were not associated with any genetic predictors.

## 1874/T/Poster Board #423

**A haplotype polymorphism of *FUT1* is associated with susceptibility to pulmonary emphysema in the Japanese population.** *R. Uemura[1], M. Taniguchi[1], Y. Naka[1], T. Inamine[1], S. Kondo[1], K. Nakatomi[2], S. Kohno[2], K. Tsukamoto[1].* 1) Dept Pharmacotherapeutics, Nagasaki Univ Grad Sch Biomed Sci, Nagasaki, Japan; 2) Second Dept Int Med, Nagasaki Univ Sch Med, Nagasaki, Japan.

**Objective**: Pulmonary emphysema (PE) is a multifactorial disorder characterized by destruction of alveolar septa, loss of lung elasticity, and enlargement of alveolar airspaces. Although the precise etiology of PE remains unknown, not only environmental factors such as cigarette smoking, but also genetic factors may contribute to the pathogenesis of PE. In this study, we focused on the alpha1,2-fucosyltransferase gene (*FUT1*), which down-regulates the expression of sialyl-Lewis x in neutrophils as well as the binding of neutrophils to E-selectin in the lung epithelial cells, and eventually inhibits the transfer of neutrophils to the site of inflammation in the lungs. Thus, we examined an association between polymorphisms of *FUT1* and susceptibility to PE.

**Methods**: The study subjects comprised 72 Japanese patients with PE and 72 age- and gender-matched healthy control subjects. All participants were former or current smokers. The three tag single-nucleotide polymorphisms (SNPs) in *FUT1* were detected by PCR-restriction fragment length polymorphism method. Subsequently, haplotypes were constructed from these SNPs. The frequencies of alleles, genotypes, haplotypes, and diplotypes were compared between PE patients and control subjects by a chi-square test or a logistic regression analysis using the GraphPad Prism 4 or SPSS 17 statistical software packages.

**Results**: The frequency of a Hap 1 haplotype of *FUT1* was significantly increased in PE patients as compared with that in control subjects [$P$ = 0.013, odds ratio = 1.815].

**Conclusion**: Our results suggest the possibility that the Hap 1 haplotype polymorphism may lead to the loss-of-function of FUT1, resulting in a decrease in both the transfer of neutrophils into the lungs and the prevention of alveolar destruction due to smoking. Therefore, *FUT1* appears to be a genetic determinant of susceptibility to PE. Furthermore, the haplotype polymorphism of *FUT1* may be useful as a DNA-based diagnostic biomarker for identifying Japanese individuals at high-risk for PE.

## 1875/T/Poster Board #424

**Polymorphic Glutathione S Transferase P (GSTP) as genetic risk factor for myopia in Indians Ch.Hema Bindu Gokaraju Rangaraju Institute of Engineering and Technology, JNTU, Hyderabad, India.** *c. HemaBindu.* Biotechnology, GRIET, Hyderabad, India, India.

Purpose : Myopia or short sightedness is the most common human eye disorder affecting 30% of world population. Genetic and environmental factors are implicated in the onset of myopia. Environmental causes include mechanical factors, oxidative stress, nutritional factors etc. Oxidative stress can arise due to intrinsic or extrinsic factors. Oxidation reduction mechanism has special importance in many tissues, including lens. Oxidative damage can result in number of molecular changes that contribute to the development of myopia. Crystallins and other protein in lens fiber cells do not turn over and must serve the lens for the life time of persons. thus, lens must have efficient reducing and detoxification system. GSTP are one of the Enzyme thought to be important in the protection of the eye from oxidative damage. our aim is to investigate the association of GSTP gene polymorphism with myopia in Indian patients. Methods: GSTP gene polymorphism were detected in 320 myopic patients and 320 control individuals by using Polymerase chain reaction and genotyping was done. Results: Results were compared with 320 cases of age and sex matched controls. The frequency of GSTP val/val genotype is case of disease is (3.40%) than in control (2%). When the data on myopia was sub grouped with respect to different parameters, interesting results were obtained. Frequency of val/val genotype in case of familial is (4.10%) when compared with nonfamilial (1.9%).patients with age at onset greater than 10 years have higher Val/Val genotype frequency (3.7%) when compared with early at onset. Further myopia patients having refractive error greater than 2 diopter have higher frequency of val/val genotype (4.03%) when compared with refractive error less than 2 diopter . there is an elevation in the val/val genotype frequency in case of females (4.40%) when compared that of males(2.7%). Conclusions : These results indicates that there is an elevation of val/val genotype in myopia patients which indicate that inefficient detoxification system to combat the accumulation of free radicals might be responsible for the onset of myopia . There was no association of GSTP gene polymorphism with parental consanguinity.

## 1876/T/Poster Board #425

**Is Familial Mediterranean Fever Prevalent and Undiagnosed in Ethiopia?** *L. Kogleck[1], C. Plaster[1], A. Tarekegn[2,1], E. Bekele[2], L. Yepiskosyan[3], A. Harutyunyan[3], N. Bradman[1], M.G. Thomas[1].* 1) Research Department of Genetics, Evolution and Environment (G.E.E), University College London, London, United Kingdom; 2) Addis Ababa University, Addis Ababa, Ethiopia; 3) Institute of Man, Yerevan, Armenia.

Familial Mediterranean Fever (FMF) is a hereditary auto-inflammatory disease prevalent in Armenian, Turkish, Arab and non-Ashkenazi Jewish populations. The gene responsible for this disorder, MEFV, has been mapped to chromosome 16p13.3 and most common mutations associated with the disease are located in exon 10. An additional less common mutation, A744S, has been reported in 2% (n=3) of Tunisian FMF patients (n=139), 2% (n=3) of Syrian patients (n=153) and 1% (n=16) of Turkish patients (n= 1201). Consequently, although computer modelling using PolyPhen predicts the A744S amino acid change to be benign, the presence of the mutation in patients, both as a simple heterozygote and as a compound heterozygote with more common exon 10 non synonymous mutations, suggests that it may be a cause of FMF. Archaeological, linguistic and genetic data suggest substantial migration into Ethiopia from the Arabian Peninsula over the past few thousand years. It is therefore reasonable to anticipate that mutations present in exon 10 of MEFV associated with the disease might be present in Ethiopians. To investigate this possibility we sequenced the whole of exon 10 in general population sample sets comprising individuals unrelated at the paternal grandfather level from five geographically separated Ethiopian ethnic groups (Amhara, Semitic speakers; Afar and Oromo, Cushitic speakers; Maale, Omotic speakers; and Anuak, Nilo-Saharan speakers, n= 187). A744S was identified in all four non Nilo-Saharan speaking groups being present in a heterozygous state in 5.4% of individuals. If, as with common exon 10 mutations, homozygous or compound heterozygous individuals are prone to FMF, as many as one in 1,500 Ethiopians may be at risk of suffering from the disease. This may be of medical importance since Ethiopians, in Ethiopia as well as in the UK, USA and Israel (all three of which have accepted many Ethiopian migrants during the past few decades), may have periodic fevers misdiagnosed and consequently receive inappropriate and potentially harmful healthcare. Clinical investigation to establish the presence or otherwise of FMF in Ethiopians is warranted.

## 1877/T/Poster Board #426

**Personalized Decomposition of the Genetic Variance Using Probabilistic Conjoint Measurement (PCM) Models.** *N.J. Markward.* Pennington Biomedical Research Center, Baton Rouge, LA.

Drawing on the intimate relationship between measurement theoretic reliability and genetic heritability, this project outlines how probabilistic conjoint measurement (PCM) models can be used to personalize decomposition of the phenotypic variance and, in turn, to extract haplotype- and individual-specific estimates of disease propensity, pharmacologic response, and environmental susceptibility. Example calculations are presented and discussed in the context of both large-scale candidate gene and genome wide association (GWA) studies.

## 1878/T/Poster Board #427

**Multiple loci associated with prostate cancer susceptibility on 8q24.** *A. Amin Al Olama[1], R.A. Eeles[2,3], Z. Kote-Jarai[2], G.G. Giles[4], G. Severi[4], M. Guy[2], J. Hopper[5], D. Leogamornlert[2], M. Tymrakiewicz[2], E. Saunders[2], J. Morrison[1], D. Easton[1].* 1) Cancer Research UK Genetic Epidemiology Unit, Department of Public Health & Primary Care, University of Cambridge, Strangeways Laboratry, Worts Couseway, Cambridge, CB1 8RN, United Kingdom; 2) The Institute of Cancer Research, 15 Cotswold Road, Sutton, Surrey, SM2 5NG, United Kingdom; 3) The Royal Marsden NHS Foundation Trust, Downs Road, Sutton, Surrey, SM2 5PT, and Fulham Road, London SW3 6JJ, United Kingdom; 4) Cancer Epidemiology Centre, The Cancer Council Victoria, 1 Rathdowne street, Carlton VIC 3053, Australia; 5) Centre for Molecular, Environmental, Genetic and Analytic Epidemiology, The University of Melbourne, 723 Swanston street, Carlton VIC 3053, Australia.

Previous studies have identified multiple loci associated with prostate cancer on 8q24[1-4]. To provide a comprehensive analysis of common alleles associated with prostate cancer risk, we analysed two large case-control studies for SNPs across the 1.2Mb 'desert' region on between FAM84B and C-MYC[5] : (1) 1,854 individuals with clinically detected prostate cancer diagnosed below age 60 years or with positive family history, and 1,894 population screened controls, genotyped for 322 SNPs from the Illumina 550k array (2) 3,650 cases and 3,940 controls from UK and Australia, genotyped for 427 SNPs from the Illumina 1M array[6]. We also genotyped five additional SNPs (rs13254738, rs6983561, rs16901979, rs7000448 and rs10090154) previously associated with prostate cancer risk. 39 SNPs were associated with prostate cancer at $P(trend)<10^{-5}$, eight of which were independently associated with risk. These included three establish SNPs: rs6983561 ($P=10^{-11}$); rs6983267 ($P=6x10^{-23}$) and rs10090154 ($P=7x10^{-24}$), together with 5 additional SNPs ($P=4x10^{-6}$ to $P=10^{-12}$). All SNPs were associated in both stages but the per-allele ORs effects were all higher in stage 1. The combined effects of all SNPs were consistent with a multiplicative model, and imply a twofold difference in risk between the top 1% and bottom 1% of the population based on 8q24 genotypes. ## 1879/T/Poster Board #428

**Functional dbSNP rs28493229 of the ITPKC gene is not associated with Kawasaki disease in Taiwanese children.** *H. Chi[1,3,5], F.-Y. Huang[1,4], M.-R. Chen[1,5], N.-C. Chiu[1,5], H.-C. Lee[1,4], S.-P. Lin[1,2,5,6], W.-F. Chen[2], C.-L. Lin[2], H.-W. Chan[2], H.-F. Liu[2], M. Lin[2], L.-M. Huang[3], Y.-J. Lee[1,2,4].* 1) Pediatrics, Mackay Memorial Hosp. 92, Section 2, Chung Shan North Road, Taipei 10449, Taiwan; 2) Department of Medical Research, Mackay Memorial Hospital, 45, Min-Sheng Rd., Tamshui, 25115 Taipei, Taiwan; 3) Graduate Institute of Clinical Medicine, National Taiwan University College of Medicine, Taipei, Taiwan; 4) Department of Pediatrics, Taipei Medical University, Taipei, Taiwan; 5) Mackay Medicine, Nursing and Management College, Taipei, Taiwan; 6) Department of Infant and Child Care, National Taipei College of Nursing, Taipei, Taiwan.

Kawasaki disease (KD) is an acute febrile illness with considerable geographic and racial variability. Vasculitis is the pathologic lesion underlying most of the clinical findings and 15-25% of untreated KD patients are complicated by the development of coronary artery lesions (CALs). The etiology and pathogenesis remain unknown and a suggestive mechanism of its onset would be a genetically determined exaggerated immune response triggered by several different unknown microbial agents. T-cell activation and cytokines play an important role in the pathogenesis of vascular endothelial cell injury by eliciting proinflammatory in the onset of KD. Inositol 1,4,5-trisphosphate (IP3) is a second messenger in various types of cells involved in the pathogenesis of KD. ITPKC is a kinase of IP3 and serves as a negative regulator of the Ca2+/ nuclear factor of activated T-cells signaling pathway in T cells. The C allele of dbSNP rs28493229 of the ITPKC gene contributes to immune hyper-reactivity that affects susceptibility to KD and leads to CALs among Japanese and US KD patients. The aim of this study was to investigate whether the single-nucleotide polymorphism (SNP) was associated with susceptibility to KD or with occurrence of CALs in Taiwanese children. We collected 168 unrelated Taiwanese children (99 boys and 69 girls) with KD including 65 patients had CALs. The mean age of the patients was 1.8 ± 1.6 years (0.1- 7.4). THE dbSNP rs28493229 was genotyped in children with KD and 1147 ethnically matched healthy controls using the TaqMan Allelic Discrimination Assay. No significant differences in genotype, allele, and carrier frequencies of the three SNPs were found between healthy controls and children with KD or those with CALs (p = 0.34 and p = 0.41, respectively). In conclusion, we did not find statistically significant association between the functional dbSNP rs28493229 of the ITPKC gene and KD or CALs in Taiwanese children. The discrepancy might be due to difference in ethnicity.

## 1880/T/Poster Board #429

**Potential clinical validity of germline genomic profiling for colorectal cancer screening and risk prediction.** *S. Hawken, J. Little.* Epidemiology & Community Med, Univ Ottawa, Ottawa, ON, Canada.

The heritability of colorectal cancer (CRC) has been estimated to be 25-35%, with 2-6% of cases attributed to specific genetic syndromes. Common, low-penetrance variants could play a substantial etiological role and in combination have potential utility in targeting individuals at elevated risk for preventive interventions, such as enhanced screening. Although mass CRC screening in average risk people aged 50+ has been implemented in several jurisdictions, uptake is low except in people with a family history of CRC. If uptake in response to a positive genetic test improved to that observed for people with elevated familial risk, then a substantial number of additional CRC cases might be detected early. We used statistical modeling in empirical and in simulated data to assess the potential value of genomic profiling in the context of CRC screening. 1. Empirical modeling in the ARCTIC case-control data: we defined a panel of 80 genetic variants associated with CRC, by conducting a systematic review of original research and meta-analyses. This *a priori* list of variants was then used to develop and test risk prediction models in a data obtained from genome-wide genotyping of 1200 CRC cases, and 1200 population-based controls. We report model building for ~30 SNPs in the panel that were covered directly or by LD. Allele frequencies ranged from 1%-50%. Univariate OR per allele ranged from 0.8 to 1.4. Counting the number of risk alleles per person, the risk increase was 8% for each additional risk allele (OR 1.08 95% CI 1.05-1.11); the OR for persons with 30+ alleles compared those with ≤20 was 2.26 (95% CI 1.27-4.04). The cross-validated area under the ROC curve was <60%, suggesting that many more risk alleles would be needed to constitute a genomic profile useful in screening. 2. Simulation work: We examined possible scenarios that could lead to a genomic test that could concentrate 80% of CRC cases in the top 50% of test scores, constrained to a maximum of 30% of CRC cases being attributable to genetic factors. For an average risk allele prevalence of 20% and per allele OR of 1.2 between 100 and 200 risk alleles with would be required. We estimate that such a genomic test could result in several thousand more cancers being detected for every one million people targeted for screening.

**SNP association study of Behcet's disease to unravel the genetic susceptibility and pathoetiology.** *R. Kurata[1], H. Nakaoka[1], A. Tajima[1], T. Saito[1], K. Hosomichi[1], T. Shiina[1], A. Meguro[2], N. Mizuki[2], H. Inoko[1], I. Inoue[1].* 1) Dept. of Molecular Lifescience, Tokai University School of Medicene; 2) Dept. of Ophthalmology, Yokohama City University School of Medicine.

Behcet's disease (BD) is a chronic inflammatory disorder characterized by recurrent oral and genital ulcers, skin legions, uveitis, arthritis, and neurological manifestations. Human Leukocyte Antigen (HLA) has been analyzed as a candidate region of BD, because of the autoimmunity nature. It has already reported that *HLA-A26* and *-B51* are the strong genetic factor responsible for BD. Because patients who harbor *HLA-A26*, *-B51* and both are 48 %, 35 % and 29 %, respectively, among Japanese, *HLA-A26* and *-B51* are not the absolute causes of BD and the functional causality is not still unclear. We speculated a possibility that other susceptible genes contributing to BD exist in HLA region. We screened the entire HLA region with microsatellite markers and could narrow the susceptible region down to *HLA-A* to *-E*. Then, we carried out SNP association study in the region to identify a novel susceptible gene. We genotyped 384 Japanese patients with BD and 384 controls for 192 SNPs covering the *HLA-A* to *-E* using BeadXpress system (illumina). 19 SNPs are associated (P<0.0001) with BD, and the logistic regression analysis showed 2 SNPs were associated (P=0.0005) with BD independently of *HLA-A26* and *HLA-B51*. In conclusion, we identified the 2 SNPs as new genetic factors to BD that are independent of the previous HLA association and one of the SNP showing amino acid substitution may have a functional relevance to BD.

## 1882/T/Poster Board #431

**Coclustering genes and common diseases.** *N. Tanaka[1], M. Muramatsu[2], T. Arai[3], M. Sawabe[3].* 1) Dept Biostatistics, Harvard Sch Pub Hlth, Boston, MA; 2) Dept Molecular Epidemiology, Medical Research Institute, Tokyo Medical and Dental Univ, Tokyo, Japan; 3) Dept Pathology, Tokyo Metropolitan Geriatric Hospital, Tokyo, Japan.

Several genetic polymorphisms have been linked to more than one disease, for example, polymorphisms in the ACE, APOE, and TGF-β gene. However, most of the study are focusing on only one disease and does not shed light on disease-disease relationship. It has been well established that the proportion of people with multiple diseases may vary from 30% in the general population to over 50% in people aged 60 years and older. Interestingly, many people have both any cardiovascular diseases and any cancers before they die, whereas some people have none of any common diseases throughout their lives. We focused on this disease-disease relationship and the susceptible multiple common genetic risks, and have developed algorithms that perform simultaneous clustering on the row (diseases) and column (SNPs) dimensions to find the subgroups of genes and the subgroups of diseases. We apply the co-clustering method and demonstrate that a specific combination of genes results in a specific combination diseases using a consecutive autopsy study data.

**Multiple Subsampling of Dense SNP Data Localizes Disease Genes with Increased Precision.** *A.L. Peljto, W.C.L. Stewart, D.A. Greenberg.* Division of Statistical Genetics, Biostatistics Dept, Columbia University, New York, NY.

Genome-wide linkage studies routinely use genotypes sampled at hundreds of thousands of single nucleotide polymorphisms (SNPs) to look for disease-related genes. However, linkage disequilibrium (LD) between neighboring SNPs can distort the information about trait location. We present an efficient method for trait location estimation that accounts completely for LD and yields narrow, high-resolution candidate gene regions (CGRs). Our method is freely available, and is implemented in the software package EAGLET (Efficient Analysis of Genetic Linkage: Estimation and Testing).

Existing linkage methods either: (1) ignore LD; (2) approximate the LD-related correlation; or, (3) analyze a single, uncorrelated subset of the original dense data. By contrast, our method makes efficient use of all available data by averaging location estimates obtained from random subsamples of the original dense SNP data. We use pairwise LD estimates to ensure that the SNPs within each subsample are approximately uncorrelated; and, we use the nonparametric bootstrap procedure to construct 95% confidence intervals (i.e. CGRs) for the true trait location. To assess the performance of our method in comparison to the three existing methods, we analyzed simulated dense SNP linkage data in the presence of LD, as well as the real data of 15 families with pulmonary hypertension.

RESULTS: Based on simulated data, we show that the existing approaches to dense SNP linkage analysis (described above) can yield biased and/or inefficient estimation depending on the underlying LD pattern. With respect to mean squared error, our estimator outperforms the single random subsample approach, and is at least as good as, and usually better than, methods that ignore or approximate LD. Furthermore, using the dense SNP data from 15 hypertension families, the CGR estimated by EAGLET is 47.5% shorter than the CGR estimated by the common approach, which uses a single random subsample.

CONCLUSION: Our method completely accounts for LD, and is the best available tool for constructing high-resolution CGRs. Furthermore, it is not limited to the analysis of small families, and can be used to inform deep sequencing projects.

## 1884/T/Poster Board #433

**Model-free Linkage Analysis of QT Interval Duration in the Jackson Heart Study.** *S. Buxbaum[1], K. Lewis[2], S. Tribune[2], L. Ekunwe[1].* 1) Jackson Heart Study, Jackson State Univ, Jackson, MS; 2) Tougaloo College, Jackson, MS.

The QT interval is measured in electrocardiograms and prolonged QT intervals are associated with ventricular arrhythmias. QT interval has been shown to be heritable, with an estimate of 35% in the Framingham Heart Study and 41% in the Jackson Heart Study, a study of African Americans in Jackson, Mississippi. Findings of polygenic effects (multiple loci with small effects) have previously been reported in genome wide association studies. A complex segregation analysis in the JHS data suggested the existence of a major gene or genes. Following on this work, a model-free multipoint linkage analysis of the QT interval, adjusted for age, sex, the RR interval, body mass index (BMI), coronary heart disease, use of diuretics, hypertension, plasma potassium levels, the QRS interval, and Sokolow-Lyon voltage was conducted, using 374 autosomal microsatellite markers. Two regions with strong linkage signals for QT were found using the weighted square trait sum and difference of QT between sibs in the SIBPAL program in the S.A.G.E. package. 772 sib pairs, comprising 159 half sibs and 613 full sibs, were analyzed. One peak was on chromosome 10q23, with a nominal p-value less than 1.0 x 10-7 (LOD > 5.9) and another on chromosome 11q11, with a nominal p-value of 3.5 x 10-6 (LOD 4.4). Power transforms of QT (log QT and square root QT) were analyzed with similar results. Using a reduced model of QT adjusted for sex, age, BMI and the RR interval resulted in less missing phenotype data, but also less power. Using the reduced model, analysis of 800 sib pairs, comprising 177 half sibs and 634 full sibs, gave similar results at the same loci, although less strong: p-value = 1.31 x 10-5 (LOD 3.8) and p-value = 2.84 x 10-4 (LOD 2.4), respectively. Hence, the full regression model with additional adjustment for coronary heart disease, use of diuretics, hypertension, plasma potassium levels, QRS interval and Sokolow-Lyon voltage had more power to detect linkage. Previous genome wide association studies (GWAS) with large Caucasian samples have reported 15 loci that explain a small percentage of QT variance; however, there is no overlap with these two loci found by linkage analysis in this African American sample.

This research from the Jackson Heart Study is supported by NIH contracts N01-HC95170, N01-HC-95171, and N01-HC-95172 provided by the national Heart, Lung and Blood Institute and the National Center for Minority Health and Health Disparities.

## 1885/T/Poster Board #434

**A new strategy for linkage analysis under epistasis taking into account genetic heterogeneity.** *A. Bureau[1,2], C. Mérette[1,3], J. Croteau[1], A. Fournier[1], Y.C. Chagnon[1,3], M.-A. Roy[1,3], M. Maziade[1,3].* 1) Centre de recherche Université Laval - Robert-Giffard, Québec, Québec, Canada; 2) Département de médecine sociale et préventive, Université Laval, Québec, Québec, Canada; 3) Département de psychiatrie, Université Laval, Québec, Québec, Canada.

Epistasis, the biological interaction of multiple genes modulating their individual effects, is likely omnipresent in complex diseases, and modelling epistasis in linkage studies can help detect loci with little marginal effect and detect epistatic effects themselves. We propose a complete three-step strategy for parametric linkage analysis under epistasis and heterogeneity in extended pedigrees. 1) Loci most likely involved in epistatic interactions are pre-screened using two-locus one-marker analyses. 2) Among selected loci, linkage to each locus is evaluated conditionally on linkage information at another locus under two-locus epistatic models. Linkage statistics are maximized over a space of epistatic models to avoid misspecification of model parameters. 3) Families linked to the conditioning locus are selected to deal with heterogeneity between pairs of epistatically interacting loci and other unlinked loci. Properties of conditional linkage statistics prevent the introduction of bias. Simulations reveal important gains in power to detect a locus with weak marginal effect involved in epistatic interaction. Application of our methods to schizophrenia and bipolar disorder in Eastern Quebec kindreds suggests epistasis between three locus pairs for bipolar disorder: 8p11-16p13, 15q11-16p13 and 18q12-15q11. These results suggest that the proposed strategy is powerful for tackling complex phenotypes involving epistasis and heterogeneity.

## 1886/T/Poster Board #435

**EAGLET: A Powerful New Tool for Analyzing Dense SNP Linkage Data.** *E.N. Drill, W.C.L. Stewart, D.A. Greenberg.* Division of Statistical Genetics, Biostatistics Department, Columbia University Mailman School of Public Health, New York, NY.

Linkage disequilibrium (LD), the non-random distribution of alleles at different loci, can be a serious problem for the analysis of dense SNP linkage data when the genotypes of founders are unavailable and families are enriched for affected individuals. If ignored, LD can bias estimates of trait location, inflate the Type I error, and reduce the power to detect linkage. We developed the ALOD, a test for linkage that uses all available SNP data, and accounts completely for LD. It is based on the average of multiple lod score curves calculated from random subsamples of the original dense data, and uses pairwise estimates of LD to ensure that each subsample has approximately uncorrelated SNPs. Our test has power comparable to, but often better than, alternative approaches, and is implemented in the software package EAGLET (Efficient Analysis of Genetic Linkage: Estimation and Testing). We examine the performance of four different methods: the ALOD, the MLOD, MERLIN, and a naïve approach that ignores LD using all SNPs to calculate the Kong & Cox LOD. The MLOD is another multiple subsampling approach; however, the SNPs in each subsample are chosen on the basis of physical distance, not absence of LD. MERLIN models the alleles of highly correlated SNPs as non-recombining haplotypes (or clusters) in the founders. Each cluster is then assumed to be independent. Both MERLIN and MLOD have been shown to increase power relative to single subsampling methods.

RESULTS: Using dense SNP data simulated with LD but without linkage, we show that relative to the approach that ignores LD, the ALOD reduces bias in the evidence for linkage by at least 72% across the different simulation scenarios that we considered. For example, based on simulated data involving 100 affected sibling pairs (ASPs), with a high-LDlow-LDhigh-LD pattern in three 33 cM blocks, the percent reductions in bias for the ALOD, MLOD, and MERLIN were 76, 69, and 59, respectively. Moreover, assuming a linked dominant trait and incomplete penetrance, we simulated dense SNP data for the same number of ASPs, LD pattern, and map. The percent powers for the ALOD, MLOD, and MERLIN were 29, 19.5, and 30.5.

CONCLUSIONS: The maximum ALOD accounts well for LD, and is more powerful than the MLOD, with comparable power to MERLIN. Furthermore, it is twice as fast as MERLIN, and is not limited to the analysis of small families.

## 1887/T/Poster Board #436

**Robust Score Statistics for QTL Linkage Analysis Using Extended Pedigrees.** *C. Kuo[1], D. Weeks[1, 2], N. Mukhopadhyay[2], S. Bhattacharjee[3], E. Feingold[1, 2].* 1) Dept Biostatistics, Univ Pittsburgh, Pittsburgh, PA; 2) Dept Human Genetics, Univ Pittsburgh, Pittsburgh, PA; 3) Division of Cancer Epi and Genet, National Cancer Institute, NIH, Dept Health and Human Services, Bethesda, MD.

Score statistics for QTL linkage analysis have been proposed by many authors as an alternative to variance components and/or Haseman-Elston type methods because they have high power and can be made robust to selected samples and/or non-normal traits. But most literature exploring the properties of these statistics has focused on nuclear families. There are a number of computational complexities involved in implementing the score statistics for extended pedigrees, primarily having to do with computation of the statistic variance. In our work, we propose several different practical methods for computing this variance in general pedigrees, some of which are based only on relative pairs and some of which require working with the overall pedigree structure, which is computationally more difficult. We evaluate the performance of these different score tests using various trait distributions, ascertainment schemes, and pedigree types.

## 1888/T/Poster Board #437

**Estimation of trait parameters in human QTL mapping under different ascertainment schemes.** *I. Mukhopadhyay[1], E. Feingold[2], D.E. Weeks[2].* 1) Human Genetics Unit, Indian Statistical Institute, Kolkata, WB, India; 2) Department of Human Genetics & Biostatistics, University of PIttsburgh, Pittsburgh, PA, USA.

In almost all the regression-based statistics and the score statistics methods of QTL mapping, usually it is assumed that the trait parameters (segregation parameters) ? (=(?, ?$^2$)) are known. This is rarely so unless one has a very good idea about ? from a previous study. Through simulation, Sham et al (2002), T.Cuenco et al (2003a, 2003b) and Szatkiewicz and Feingold (2005) studied the effect of misspecification of the segregation parameters considering a few values, which differs from the true values of the parameters, for population samples and selected samples. They showed that departure from the true values of ? results in substantial loss of power. In view of this it becomes important to develop a proper estimation procedure of the segregation parameters involved in regression-based statistics and score statistics. In this work, we propose some estimation methods for ? based on population samples as well as selected samples. We discuss our proposed methods of estimation under several ascertainment schemes e.g. affected concordant sib-pair, discordant sib-pair, discordant and concordant sib-pair etc. Through simulation, we evaluated the performance of several test statistics by calculating probability of Type I error and power under several genetic models. Keeping the probability of Type I error at the desired level, the power of the statistics using our proposed method is very close to the power that can be obtained assuming the true values of the segregation parameters.

## 1889/T/Poster Board #438

**Kinship testing goes linkage.** *M. Nothnagel, M. Krawczak.* Institute of Medical Informatics and Statistics, University of Kiel, Germany.

Practical applications of kinship testing in humans so far have largely ignored linkage. This is mainly due to the fact that, until quite recently, genetic markers routinely used for identification purposes were not (closely) linked. Furthermore, over 95% of kinship cases in humans involve a disputed paternity in a trio of mother, child, and alleged father. Here, inter-marker linkage is indeed computationally irrelevant in the absence of linkage disequilibrium. However, with the introduction of a substantial number of novel markers into forensic practise, linkage has become an issue in kinship testing. Furthermore, the availability of more comprehensive markers sets has rendered increasingly more complex kinship cases tractable with fewer individuals tested, eventually involving only pairs of supposed relatives. We performed extensive simulations of genotypes for the 34 autosomal STRs widely used in forensic practise today to assess the current limits of the resolution of pair-wise kinship testing, the effects of an appropriate consideration of linkage between STRs on the ensuing likelihood ratios, and the potential gain in power from expanding the current marker set by a realistic amount. The results reveal a clear-cut difference between the power of the 34 STRs to resolve first degree and second degree relatedness. Expanding the marker set improved the chance of distinguishing second degree relatives from unrelated individuals, but at the same time intensified the need to take inter-marker linkage appropriately into account.

## 1890/T/Poster Board #439

**Deciphering The Genetic Architecture Of Alcohol Dependence: The Success Of Multivariate Phenotypes.** *S. Ghosh[1], L. Bierut[2], Collaborative Study On The Genetics Of Alcoholism.* 1) Human Genetics Unit, Indian Statistical Inst, Kolkata, India; 2) Department of Psychiatry, Washington University School of Medicine, St. Louis, MO.

Using the clinical end-point of alcoholism as a linkage phenotype in the Collaborative Study On The Genetics Of Alcoholism (COGA) project has failed to identify chromosomal regions harboring potential genes for the complex trait. This has motivated analyses of quantitative endophenotypes correlated with alcoholism, which capture greater variation within trait genotypes compared to the end-point binary trait. However, a single quantitative trait is unlikely to be a powerful surrogate of the end-point trait and it may be more prudent to use a correlated multivariate phenotype for linkage analyses. We propose along the lines of Sham et al. (2002), a linear regression formulation in which the traditional response variable, that is, some function of the multivariate phenotype and the explanatory variable, that is, the genetic similarity between sib-pairs are interchanged. The major advantage of the method is that it neither requires specification of any probability model for the quantitative trait values nor any data reduction technique like principal components. Hence, the method is more robust to violations in distributional assumptions compared to likelihood based methods. On the other hand, linkage inferences based on the proposed method are more meaningful compared to data reduction methods. Moreover, the method can incorporate both quantitative as well as qualitative traits within the multivariate phenotype vector. Based on simulations, we find that the proposed method is more powerful than analyses based on the first principal component of the correlated phenotypes and the end-point binary trait. We perform a genome-wide linkage scan of a multivariate phenotype comprising three alcohol related quantitative traits: number of drinks in a day, Beta 2 electroencephalogram and count of externalizing symptoms associated with anti-social behavior using the proposed regression approach and identify chromosomal regions on Chromosomes 1,4,5 and 15 exhibiting significant linkage. We find that these regions harbor potential genes for alcoholism like the GABRA receptor, the ADH cluster and CHRNA7. We follow up the significant linkage findings using a novel association approach based on logistic regression, which can analytically shown to be statistically equivalent to the binary TDT (Spielman et al. 1993) and have been able to obtain significant evidence of association in the regions exhibiting linkage.

## 1891/T/Poster Board #440

**Optimally Discovering cis eQTLs Across Multiple Tissues.** *C. Ye[1], B. Han[2], T. Choi[3], E. Eskin[4,5].* 1) Bioinformatics Program, University of California, San Diego, San Diego, CA; 2) Department of Computer Science, University of California, San Diego, San Diego, CA; 3) Predictive Biology, Inc., San Diego, CA; 4) Department of Computer Science, University of California, Los Angeles, CA; 5) Department of Human Genetics, University of California, Los Angeles, CA.

Recent technological improvements and cost decreases in gene chips have led to a growing accumulation of gene expression studies in different tissues across the same genetic gradient in both human and mouse. Current methods for comparing eQTLs across tissues are qualitative in nature, often reporting a set of significant eQTLs specific to one tissue or shared between several tissues based on the results of analyzing the tissues independently. This approach faces two major challenges that significantly reduce the power we have at identifying cross tissue and tissue specific eQTLs. Intuitively, one would like to use information about the similarities between tissues, for example between two homogeneous brain regions, to help detect shared eQTLs. In this work, we develop a new multiple hypothesis testing procedure, Multi-dimension Decision Procedure (MDP) that utilizes similarities between tissues in terms of shared status of test statistics to detect tissue specific and cross tissue eQTLs. We present two simple approaches for estimating our procedure in practice. Using simulated data, we show that MDP outperforms traditional eQTL approaches if there's sharing of tests between tissues. It performs as well as traditional approaches if there's no sharing. We then applied our method to one of the first systematic genetical genomics studies of different tissues from F1-backcrossed mice. We studied four datasets, including two populations collected in liver, two similar tissues (cortex and hippocampus), two different tissues (cortex and liver) and across four tissues (cortex, liver, heart and spleen). In all cases, our method outperforms traditional approaches in terms of discovering more cis-eQTLs at the same FDR cutoffs. Not only did we discover proportionally more cross tissue cis -eQTLs, we also discover more tissue specific cis-eQTLs because we directly optimize for the FDR. Using the results across four tissue types with unmatched individuals, we present one of the first cross tissue cis-eQTL maps identifying genomic loci with tissue specific or cross tissue effects on gene expression. We hypothesize that with denser genotyping data, we can apply our method to construct denser cross tissue eQTL maps to identify regulatory components. Combined with additional phenotype data, we can begin to understand how tissue specificity affect the way regulatory components interact to give rise to complex phenotypes.

## 1892/T/Poster Board #441

**How common is hypophosphatasia?** *M.E. Nunes[1], J-L. Serre[2], E. Mornet[2,3].* 1) Dept Genetics/Pediatrics, Kaiser Permanente, San Diego, CA; 2) Universite de Versailles-Saint Quentin en Yvelines, Versailles, France; 3) Laboratoire SESEP, Centre Hospitalier de Versailles, Le Chesnay, France.

Hypophosphatasia is characterized by defective bone mineralization with highly variable clinical expression, caused by mutations in the tissue-nonspecific alkaline phosphatase (*TNSALP*) gene. To date, 204 novel mutations have been reported. 44 of these represent insertions, deletions, splice site, and nonsense mutations resulting in haploinsufficiency and predicting severe effect. 160 are *TNSALP* missense mutations, of which an estimated 75% affect a functional protein domain. The severity of many of these missense mutations has been evaluated by clinical phenotype in carrying patients, 3D protein modeling, and in select cases site-directed mutagenesis. This has allowed for characterization of mutations as “wildtype”, “moderate”, and “severe” alleles reflecting normal, reduced, and absent serum alkaline phosphatase activity. Six clinical forms of hypophosphatasia are currently recognized. Patients with odontohypophosphatasia reflect specific genotype/phenotype correlations. A prenatal benign form probably reflects a specific maternally inherited missense mutation. Perinatal lethal, infantile, childhood, and adult hypophosphatasia are recognized as a clinical spectrum by age at diagnosis, the first two transmitted as autosomal recessive disorders and the latter two milder forms as autosomal recessive or dominant. Thus, genetic counseling with several possible phenotypes within a family remains complex, predicting the population carrier frequency for marriage into a segregating kindred a challenge. The birth prevalence of severe hypophosphatasia (perinatal lethal and infantile forms) in Ontario 50 years ago was estimated to be 1/100,000, which has been used to suggest a carrier frequency of 1/150 by the Hardy-Weinberg principle. We expanded this analysis assuming three alleles: p (wildtype), q (moderate), and r (severe). Assuming a continuous phenotypic spectrum attributable to allele affect on serum alkaline phosphatase activity, adult cases are represented by $(2pr + q^2)$, childhood $(q^2 + 2pq)$, infantile (2qr), and perinatal lethal $(2qr + r^2)$. The original estimate of birth prevalence (1/100,000) thus becomes $2qr + r^2$. Assuming 80% of alleles are severe, r = 4q. The model predicts r = 1/387, q = 1/1548, childhood hypophosphatasia “common” at 1/750, adult cases more common at 1/200. Clinical and laboratory ascertainment thresholds combine with allelic heterogeneity to explain why dominant forms of hypophosphatasia are less commonly recognized.

**Heritability of mammographic density in Korean twin and family: the Healthy Twin study.** *YM. Song[1], J. sung[2], KY. Lee[3], S. Kim[1].* 1) Department of Family Medicine, Samsung Medical Center and Center for Clinical Research, Samsung Biomedical Research Institute, Sungkyunkwan University School of Medicine, 50 Irwondong, Gangnamgu, Seoul, Korea; 2) Department of Epidemiology, the Graduate School of Public Health and Institute of Health and Environment, Seoul National University, 27 Yeongeon-dong, Chongro-gu, Seoul, Korea; 3) Department of Family Medicine, Busan Paik Hospital, Inje University, College of Medicine, 633-165, Kaegum-dong, Busan Jin-Gu, Busan, Korea.

Background: Mammographic density, a known risk factor of breast cancer, has been found to have a high heritability in White women. However, little was known about the mammographic density in Asian women. This study was conducted to determine the heritability of the components of mammographic density and to examine the genetic correlation between dense and nondense areas in Korean women. Methods: Study subjects were 730 women composed of twins and their first degree relatives, who came from the Healthy Twin study. Mammographic density was measured using a computer-assisted method. Interclass correlations of residual variance of each component of mammographic density were calculated between twin pairs, mother-daughter pairs, and sibling pairs. Quantitative genetic analysis was done using computer program the Sequential Oligogenic Linkage Analysis Routines (SOLAR) ver. 2.0 Results: Interclass correlation of age-adjusted residual variance of dense area, nondense area, and percent dense area (PDA) was highest between monozygotic pairs (0.78, 0.78, 0.73) and it was the second highest between dizygotic pairs (0.55, 0.47, 0.64), the third highest sibling pairs (0.31, 0.44, 0.34), and the lowest between mother-daughter pairs (0.02, 0.28, 0.15). When we further adjusted for age and other covariates, interclass correlation of residual variance attenuated only slightly. Age-adjusted heritability coefficients for dense area, nondense area, and PDA were 0.77, 0.74, and 0.71, and were slightly reduced to 0.75, 0.68, and 0.67 when age, age2, and other covariates were adjusted. There were significant inverse genetic correlations between dense area and nondense area and it reduced only slightly when covariates were fully adjusted. Conclusion: Given that mammographic density is associated with an increased risk of breast cancer, genes that have opposite effects on dense and nondense mammographic area and are responsible for familial genetic correlation in PMD need to be elucidated.

## 1894/T/Poster Board #443

**Genetic epidemiology of Montenegro skin test in a Western Amazonian Population.** *A.P. Fioretti[1,2], R.G.M Ferreira[1,2], C.E.M Kawamata[1,2], L.M. Garrido[1,2], A. La Luna[1,2], F.A.B. Santos[1,2], L.M.A. Camargo[1,2], H. Krieger[1,2].* 1) Parasitology, Universidade de São Paulo, São Paulo, São Paulo, Brazil; 2) INAGEMP - Instituto Nacional de Genética Médica Populacional.

Familial distribution of the response to an antigenic extract of Leishmania (Montenegro test) was analyzed by genetic epidemiologic methods. Montenegro skin tests were used to measure the human response to a Leishmania antigen. The present study tested a sample of 313 individuals from Monte Negro (10° 15’ S, 63° 18’ W), a Brazilian small rural county in Rondônia state located at the Amazonian region. The objective was to ascertain the relative importance of genetic components to establish the expression of the phenotype. Statistical analyses were performed using SPSS program and complex segregation analysis was made using POINTER program (Lalouel, J. M. et al., 1983, Am. J. Hum. Genet., 35: 816-826). Stepwise multiple regression suggests that age and gender affects significantly the Montenegro phenotype. Correlations between pairs within families suggested the existence of a significant familial aggregation with a strong genetic component since no significant correlation was found between parents. This familial aggregation was confirmed by complex segregation analysis, which showed that the best model to explain the phenotype transmission in the Monte Negro population was the recessive one, since its likelihood ratio is significantly lower than the sporadic model, while it was not different from the general mixed one (CAPES, CNPq).

**A major gene controls leprosy susceptibility in a hyper-endemic isolated population from the Brazilian Amazon.** *M. Mira[1], F.P. Lazaro[1], R.I. Werneck[1], C.C.O. Mackert[1], F.C. Prevedello[1], R.P. Pimentel[1], G.M.M. Macedo[2], M.A. Eleutério[1], G. Vilar[1], L. Abel[3,4], M.B. Xavier[2], A. Alcais[3,4].* 1) Graduate Program in Health Sciences, Pontifical Catholic University of Paraná, Curitiba, Paraná, Brazil; 2) Tropical Medicine Core, Federal University of Pará, Belém, Brazil; 3) Laboratoire de Génétique Humaine des Maladies Infectieuses, Institut National de la Santé et de la Recherche Médicale, INSERM U550, Paris, France; 4) Université Paris René Descartes, Faculté Médecine Necker, Paris, France.

Leprosy is a chronic infectious disease caused by Mycobacterium leprae that affects 250.000 new individuals worldwide every year. Genetic analysis has been successfully applied to the identification of host genetic factors impacting on susceptibility to leprosy; however, a consensus regarding its mode of inheritance is yet to be achieved. We conducted a Complex Segregation Analysis (CSA) on leprosy using data from the Prata Colony, an isolated, highly endemic former leprosy located at the outskirts of Brazilian Amazon presenting large multiplex, multigenerational leprosy pedigrees. Our enrollment strategy was complete ascertainment leading to the inclusion of the whole colony, totalizing 2005 individuals (225 affected) distributed in 112 pedigrees. CSA was performed using REGRESS, which specified a regression relationship between the probability of being affected and a set of explanatory variables. CSA identified a best fit co-dominant model, with a major gene accounting for the entire familial effect observed. The frequency of predisposing allele was estimated at 0.22. Penetrance for homozygous individuals for the predisposing allele older than 30 years old ranged from 55% to 90%, depending of gender and race, with higher values for black males. Results suggest that the Prata population may be particularly suitable for leprosy gene identification studies.

**Evaluation of the IBS method in relationship analysis from short tandem repeat data.** *M. Osawa[1], R. Kimura[2], T. Tamura[3], M. Soda[1], F. Satoh[1], I. Hasegawa[1], I. Sato[3].* 1) Dept Forensic Medicine, Tokai Univ Sch Medicine, Kanagawa, Japan; 2) Trasdisciplinary Research Organization, Subtropical and Island Studies, University of the Ryukyus, Okinawa, Japan; 3) Forensic Biology Unit, Scientific Crime Laboratory, Kanagawa Prefectural Police, Kanagawa, Japan.

For paternity test and personal identification, multiplex analysis of short tandem repeat (STR) has been widely employed. Identifiler® system consists of 15 CODIS STR loci that exhibit extensive polymorphism with the heterozygosity of more than 0.7. In this study, relationships between pairs of Japanese individuals have been estimated by the method based on identical by state (IBS) upon the data of DNA profiling in our department. Probabilities of sharing 0, 1, and 2 IBS alleles (zi) were calculated for each locus on basis of allele frequencies reported for the Japanese; 0.11, 0.52 and 0.37 of z0, z1 and z2, respectively, in full sib pairs, for instance. Then, distribution of the number of loci having 0, 1, and 2 IBS alleles (li) in the set of 15 loci was accomplished by listing all possible combinations of IBS probabilities, zi, in the loci. The expected values of l1 and l2 (E(l1) and E(l2)) for parent-child pair were calculated to be 11.7 and 3.3, respectively. E(l0), E(l1), and E(l2) were 1.6, 7.7 and 5.7 for full sib pair, 3.2, 9.6 and 2.2 for 2nd degree relatives, 6.1, 7.5 and 1.3 for non-related pair, respectively. In DNA profiles of real identification cases, the distribution of li was consistent with the theoretical one. Since the distributions between different categories of relationship considerably overlapped, the total number of 15 loci seemed to be too small to judge biological relationship between arbitrary pairs. Even in testing sib relationship, the total number of 15 loci is clearly small because no significant relationship can be obtained in approximately 25%. The exact method generally displays higher likelihood ratio than the IBS method. However, the merits of the IBS method are its conciseness in calculation and the ability to exclude incidental effects of rare alleles, of which involvement is inevitable in examination to more number of STR loci. Therefore, the IBS method, being alternative to the exact method, would be useful in applied genetics and forensic investigation.

## 1897/T/Poster Board #446

**Statistical methods to detect viral integration site hotspots.** *A.P. Presson[1,2], S. Kim[3], Y. Xiaofei[4], I.S.Y. Chen[3].* 1) Dept Biostatistics, Univ California, Los Angeles, Los Angeles, CA; 2) Dept Pediatrics, Univ California, Los Angeles, Los Angeles, CA; 3) Dept Microbiology, Immunology and Molecular Genetics, Univ California, Los Angeles, Los Angeles, CA; 4) Dept Statistics, Univ California, Los Angeles, Los Angeles, CA.

Modern gene therapy methods suffer from insufficient control over where a therapeutic viral vector inserts into the host genome. Viral integration patterns vary by vector type and often prefer regions containing genes, so that the probability of an integration event varies by location. Since integration can activate local gene expression, it is important to characterize insertion patterns of potential gene therapy vectors. Currently, viral integration hotspots are defined by a minimum density of events (2-4 within a 36-104kb region). While this guideline may be useful for some data sets, it relies on the number of observed integration sites. This is problematic for comparing hotspots among different vectors or collections of experiments where the number of observed integration sites can vary substantially. Furthermore, this definition targets small genomic regions. As the definition of viral integration hotspots is essential to understanding their mechanism and safety, an accurate and more general definition is warranted. We propose a Bayesian change point (bcp) framework to estimate integration hotspots from consecutive changes in integration rate along a chromosome. We identify change points using both a) a traditional bcp model and b) a modified version that samples the number of change points as a proposal in the Markov chain. We test these models on 1) our data from rhesus macaque animals transplanted with hematopoietic stem cells containing lentivirus vectors (LV), 2) published LV data, 3) published retrovirus data and 4) control data from pre-transplant stem cells containing LV. Preliminary results identified 35 hotspots in our LV transplant data (1). While the LV control data (4) contained four times the number of integration sites observed in (1), the bcp method identified only two additional hotspots. In comparison, a definition of ≥2 insertions within a 100kb region identified 43 hotspots in (1) and 150 in (4). The published transplant data sets (2-3) also suggest preferential integration. The average hotspot size in our LV data was about 850kb. Bayesian change point models effectively distinguish true hotspots from random integration events. Statistical models that can reliably define hotspots will allow us to compare integration preferences among different vector types and assess their safety and efficacy for gene therapy trials.

## 1898/T/Poster Board #447

**Sensitive and accurate detection of copy number variants using depth of coverage.** *S. Yoon[1], Z. Xuan[1], K. Ye[2], J. Sebat[1].* 1) Cold Sprg Harbor Lab, Cold Sprg Harbor, NY; 2) Albert Einstein College of Medicine, Bronx, NY.

Methods for the direct detection of copy number variation (CNV) genome-wide have become effective instruments for identifying genetic risk factors for disease. The application of next generation sequencing platforms to studies of disease promises to improve sensitivity to detect CNVs as well as inversions, indels and SNPs. New computational approaches are needed to detect these variants. Existing approaches for CNV detection are primarily based on paired-end read mapping (PEM). Due to limitations of this approach, some classes of CNVs are difficult to ascertain, including large insertions and variants located within complex genomic regions. To overcome these limitations, we developed a method based on analyzing depth of coverage. Event-wise testing (EWT) is a method based on significance testing. In contrast to standard segmentation algorithms which typically operate by performing likelihood estimation for every point in the genome, EWT works on intervals of probes, rapidly searching for specific classes of events. Overall false-positive rate is controlled by testing the significance of each possible event and adjusting for multiple testing. Deletions and duplications detected in an individual genome by EWT are examined across multiple genomes to identify polymorphism between individuals. We estimated error rates using simulations based on real data, and we applied EWT to the analysis of chromosome 1 from paired-end shotgun sequence data (30X) on three individuals obtained by participation in the 1000 genomes project (www.1000genomes.org). Our results suggest that analysis of read depth is an effective approach for the detection of CNVs, and it captures structural variants that are refractory to established PEM-based methods.

## 1899/T/Poster Board #448

**Automated High Resolution HLA Typing of Class I & II Alleles Using the SBT Method.** *W. Dong[1], C. Carozza[1], E. Pimpinella[1], J. Barone[1], S. Hsu[1], N. Flaherty[2], L. Tack[2].* 1) Histocompat/Molecular Genetics, American Red Cross Penn-Jersey Region, Philadelphia , PA; 2) PerkinElmer, Inc, 2200 Warrenville Rd, Downers Grove, IL.

Human Leukocyte Antigen (HLA) matching is a critical element for solid organ or bone marrow transplantation success. The HLA Lab of the PJ Region of the American Red Cross provides allelic level HLA typing supporting bone marrow transplantation to hospitals and also carries out DNA-based typing of unrelated donors and cord blood units as a contract lab for the National Marrow Donor Program. We screen for HLA polymorphisms using molecular methods such as Sequence Specific Oligonucleotide Probing (SSOP) and Sequencing-based Typing (SBT) methods. Our strategy is to use the SSOP method as an intermediate resolution testing process along with SBT for higher resolution typing. High resolution typing using the more informative “Gold Standard” SBT method is common for successful bone marrow and stem cell transplantation. SBT also allows the detection and identification of new alleles, not possible with most other techniques. The AlleleSEQR SBT kits from Celera are used for testing both Class I (HLA-A, B, C) and Class II (HLA-DRB1, DQB1 and DPB1) loci and requires setting up hundreds of PCR reactions, making this procedure an ideal candidate for automation. Our lab processes more than 1000 samples/week for HLA typing. To meet the turn around time of 3 to 9 days for clinical purposes, we used a JANUS Liquid Handling Workstation from PerkinElmer to automate the SBT typing process. The JANUS workstation sets up (1) primary PCR amplification plates, and (2) SBT cycle sequencing reactions using forward and reverse sequencing primers to detect polymorphic sequences in both Class I and Class II regions. Amplified dye-terminator labeled reaction products are analyzed using an ABI Prism 3730XL DNA Analyzer. Sequence files are imported into the Assign-SBT data analysis software and electropherograms aligned. Data for each sample template analyzed is compared to known alleles in the library for identification. Automation, by increasing SBT throughput, shortens turnaround time, reduces the potential for manual procedural errors, and maintains consistency between runs.

**Systematic identification of loci controlling gene co-regulation.** *K.S. Kompass, J.S. Witte.* Department of Epidemiology and Biostatistics, University of California-San Francisco, San Francisco, CA, USA.

In normal tissues, genes in *trans* that participate in similar biological processes, such as encoding components of the same pathway or a larger protein complex, are often co-regulated in clusters. When gene clusters are transcriptionally regulated, much of this organization is determined by *cis* acting sequences, as genes with common regulatory elements are more likely to be bound by the same transcription factors. Experimental work has shown that polymorphic sequence changes in the *cis*-regulatory elements of individual genes can greatly alter the affinity of coordinate transcription factor binding and lead to aberrant transcription, and regulatory changes in upstream transcription factors that bind regulatory elements of many target genes are key components in the development of certain cancers (Pittman et al., Genome Research 2009). We performed a preliminary study to systematically identify loci that interact with multiple promoters in *trans* using publicly available data (NCBI GEO GSE14860; Salvesen et al., PNAS 2009). To this end, we modified an existing rank-based gene biclustering algorithm (Owen et al., Genome Research 2003) to generate high-quality, stable clusters of genes by recursively minimizing the algorithm's cross-validation error. Using this method, we generated 875 unique clusters of genes from 33 human samples from GSE14860 and tested their association with genotype using Affymetrix 100k SNP arrays. Approximately 25 *trans* loci were identified that significantly interact ($p<10^{-7}$) with clusters of co-regulated genes. The most significant interaction identified was between a region at 8q.22.1 containing PGCP and a cluster of genes containing CFL1, MYH9, SRM, and GNB2. Another cluster containing HLA-DRB1, CUX1, HLA-DPB1, HLA-DRB5, MTMR14, and HLA-DQB1 interacted significantly with a region at 9q33.1 containing PAPPA. Further studies will incorporate other publicly available data to systematically identify *trans* loci that interact with distant regulatory elements to exert broad regulatory control over the genome. These studies should allow for improved genetic identification of pathways, improved functional predictions for unstudied transcripts, and improved detection of regulatory aberrations in disease.

## 1901/T/Poster Board #450

**A comprehensive resequence analysis of the KLK3 gene region on chromosome 19q13.33.** *H. Parikh[1], Z. Deng[1,2], J. Boland[1,2], C. Mathews[1,2], I. Collins[1], J. Jia[1], A. White[1], L.A. Burdett[1,2], A. Hutchinson[1,2], M. Yeager[1,2], J. Ahn[1], S. Berndt[1], L. Qi[1,2], R. Hoover[1], G. Thomas[1], D. Hunter[3], R. Hayes[1,4], S. Chanock[1,2], L. Amundadottir[1].* 1) Division of Cancer Epidemiology and Genetics, National Cancer Institute, National Institutes of Health, Bethesda, MD 20892; 2) Core Genotyping Facility, Advanced Technology Program, SAIC-Frederick, Inc., NCI-Frederick, Frederick, MD 21702; 3) Program in Molecular and Genetic Epidemiology, Department of Epidemiology, Harvard School of Public Health, Boston, MA 02115, USA; 4) Division of Epidemiology, Department of Environmental Medicine, New York University School of Medicine, New York, NY 10016.

Prostate cancer is the most commonly diagnosed non cutaneous cancer in men in the U.S. The PSA test, a widely used test for prostate cancer screening, is based on measuring prostate specific antigen (PSA) levels in serum as they are often increased in men with prostate cancer. However, elevated levels of PSA can also be caused by nonmalignant conditions such as BPH and prostatitis. Although the PSA test has led to the diagnosis of earlier stage prostate cancers it has serious limitations because of low sensitivity and specificity. A recent genome wide association study (GWAS) of prostate cancer described single nucleotide polymorphisms (SNPs) in the vicinity of the KLK3 gene that associate with an increased risk of prostate cancer. The SNP most significantly associated with prostate cancer risk is rs2735839 (P value $1.5x10^{-18}$). In contrast, our analysis of tag SNPs from the KLK3 gene region in subjects from the Prostate, Lung, Colon and Ovarian (PLCO) Cancer Screening Trial indicated that the variants associate with altered PSA levels but not with prostate cancer risk unless control subjects are restricted to those with very low PSA levels. As a first step in resolving the question whether genetic variation in the KLK locus associates with prostate cancer, PSA levels or both, we set out to thoroughly characterize common genetic variation in the region. We conducted a next-generation sequence analysis in 78 individuals of European background to characterize common (minor allele frequency over 1%) genetic variation in a 56 kb region on Chr19q13.33 (Chr19:56,019,829-56,076,043 bp). This region is centered on the KLK3 gene but also includes the KLK2 and KLK15 genes. Sequence depth was on average about 70 fold. Four HapMap families (CEU and YRI) were included for quality assessment of genotypes (99.8%; concordance). We identified 555 polymorphic loci including 298 novel SNP and indel polymorphisms not in db-SNP. Twenty variants are predicted to alter exons or 5'/3'UTR sequences of the KLK3 gene including five non-synonymous amino acid changes. In the neighboring genes KLK15 and KLK2, there were 7 and 15 coding SNPs, respectively. We have also begun to correlate SNPs in region with expression levels of KLK2, KLK3 and KLK15 in the NCI60 cell line dataset. The detailed map of genetic variation in the region will aid in selecting tag SNPs for fine mapping the association signal and determine its relevance to prostate cancer risk and regulation of PSA expression.

## 1902/T/Poster Board #451

**A method to analyze extreme quantitative trait data attributable to rare variants: application to the analysis of next generation sequence data.** *D.W. Covarrubias[1,2], B. Li[1], S.M. Leal[1,2].* 1) Dept. Molecular and Human Genetics, Baylor College Medicine, Houston, TX; 2) Dept. Statistics, Rice University, Houston, TX.

It has been demonstrated that rare variants are involved in etiology of quantitative traits. It is now possible to identify rare variants which influence quantitative trait loci (QTL) using next generation sequencing. For the analysis of QTL, one strategy which is often used is to only analyze individuals with extreme quantitative trait values (QTVs). Although methods which are used to detect associations with common variants that influence QTL can be used to analyze rare variants, they are underpowered. We extended the combined multivariate collapsing (CMC) method to analyze quantitative traits; the CMC method was originally developed to test for associations with rare variants in case-control data. The quantitative CMC (QCMC) method can be used to analyze data for which either all individuals regardless of their QTVs are sequenced or only individuals with extreme QTVs are sequenced. In order to evaluate the power and robustness of the QCMC method, sequence data was simulated via coalescence theory using parameters estimated from population genetic data and the QTV distributions were based-upon clinically relevant quantitative trait data. It was shown in most situations that there was only a slight gain in power when the complete sample was sequenced and analyzed, compared to when only those individuals with extreme QTVs in the upper and lower 25% were analyzed. When only individuals with extreme QTVs are sequenced and analyzed it is advantageous to analyze their QTVs instead of dichotomizing and implementing the CMC method, since power loss can be substantial. The QCMC is robust to misclassification (e.g. inclusion of non-causal variants and exclusion of causal variants). In conclusion, implementing extreme QTV sampling is a beneficial strategy to reduce sequencing cost and the power of the study design can be greatly increased by analyzing full QTVs. The QCMC method can easily be implemented to analyze rare variant quantitative trait data obtained from candidate genes or whole exome sequencing.

## 1903/T/Poster Board #452

**A novel adaptive method for the analysis of next generation sequencing data to detect complex trait associations with rare variants due to gene main effects and interactions.** *S.M. Leal[1,2], D.J. Liu[1,2].* 1) Dept. Molecular and Human Genetic, Baylor Col Med, Houston, TX; 2) Dept Statistics, Rice University, Houston, TX.

Increasing evidence suggests complex traits may not only be due to common variants but also be due to rare variants which have stronger phenotypic effects than variants with higher frequencies. Next generation sequencing technologies make it possible to carry out direct association studies of rare variants for complex traits. Although statistical methods developed for the analysis of rare variant sequence data have been shown to be more powerful than applying methods commonly used to analyze common variants; analysis of rare variants is still problematic, especially in the presence of variant misclassification (i.e. inclusion of non-causal variants and exclusion of causal variants) and unknown patterns of gene interactions. Working in a novel framework to address the problems of rare variant analysis, the Kernel Based Adaptive Clustering (KBAC) method was developed. The KBAC combines variant classification and association testing in a coherent framework. This method not only exhibits robustness against variant misclassification errors, but also allows for flexible disease models. In order to evaluate the power and robustness of the KBAC method, sequence data was simulated via coalescence theory using parameters estimated from population genetic data and realistic disease models with and without gene interactions were generated based-upon Hirschsprung's Disease and Breast Cancer. It was demonstrated especially in the presence of variant misclassifications and gene interactions that the KBAC method has superior power and robustness over other methods, such as combined multivariate and collapsing, Hotelling T^2 and minimum p-value.
