Coronary artery disease is one of leading causes of morbidity and mortality in developed countries and strong associations have been established between lipoprotein levels and coronary heart disease. High levels of low-density lipoprotein cholesterol (LDL-C) and genotypes increased with high LDL-C levels are associated with increased risk of coronary heart disease. Our previous studies of >8,000 individuals through genome-wide association scans identified a number of loci associated with LDL-C levels, including previously reported and also newly implicated loci. To further understand the genetic contributions of both common and rare variants to the LDL-C level, we sequenced exons of 9 genes in associated loci in 256 unrelated Sardinian individuals with either extremely low or high LDL-C levels, along with 120 HapMap samples. Among all variants identified, 71% (81/121) nonsynonymous and 56.3% (40/71) synonymous mutations have frequency below 1%. In addition, two frame shift (in *APOB*) and two truncation mutations (in *PCSK9*) were identified. Comparisons between high LDL-C and low LDL-C groups showed that rare coding variants are enriched in one of the two groups for a set of genes (*APOB*, *LDLR*, *PCSK9*, *SORT1*). To increase power of detecting associations of variants in coding regions with LDL-C levels, we are using imputation to extend our findings to additional genotyped individuals in our 6148 sample Sardinian cohort. Equipped with this larger amount of data after imputation, fine mapping and evaluation of potential functional variants should be achieved with greater power.

## 1905/T/Poster Board #454

**Difference in Estimators of Population Parameter between Data I and Data II in 1000 Genomes Project Pilot 1.** *Z. Hou[1,2], H. Siu[1,2], P. Hu[1,2], F. Yu[4], Y. Fu[3], L. Jin[1,2], M. Xiong[1,3].* 1) Laboratory of Theoretical Systems Biology, School of Life Science, Fudan University, Shanghai, 200433, China; 2) State Key Laboratory of Genetic Engineering and MOE Key Laboratory of Contemporary Anthropology, School of Life Sciences and Institutes of Biomedical Sciences, Fudan University, Shanghai, 200433, China; 3) Human Genetics Center, University of Texas School of Public Health, Houston, TX 77225; 4) Human Genome Sequencing Center, Molecular and Human Genetics Department, Baylor College of Medicine, Houston, TX 77030.

The 1000 genomes project provides the high density sequencing data in pilot1, and the data release in two versions (Data I with 210 chromosomes in Feb. and Data II with 344 chromosomes in Apr.). Number of segregation sites in Data II is increased over twice than that in Data I. We contrast the frequencies of derived alleles with the theoretic model, and obtain the mean errors between the observed allele frequencies and theoretic allele frequencies in three populations (Data I: ASI.I{23.2%}, CEU.I{16.9%} and YRI.I{13.4%}; Data II: ASI.II{11.1%}, CEU.II{14.3%} and YRI.II{9.7%}). It is clear that the estimated sequencing error in data I is large than that in Data II. We calculate several common statistics of $\theta$-estimators in a sliding window set (100kb), and obtain the average population parameter as shown in Table 1. We can see the $\theta$-estimators in Data II are greater than those in Data I. We also observe the differences between Tajima's estimator and Watterson's estimator are relatively small. This demonstrates that sequence error rates are not large. Using Fu and Li's method and ignoring the mostly sequencing errors which are from singletons, we can reduce the differences in both mean values and variances among the estimators of $\theta(\pi\text{-}\xi)$, $\theta(S\text{-}\xi)$, $\theta(\pi\text{-}\eta)$ and $\theta(S\text{-}\eta)$. Furthermore, we observe that $\theta(\pi\text{-}\xi)$ is same as $\theta(\pi\text{-}\eta)$ and $\theta(S\text{-}\xi)$ is same as $\theta(S\text{-}\eta)$ in both datasets. This shows that impact of sequencing errors in high-frequency mutation on $\theta$-estimators is small. If the errors of the estimates of population parameter are mostly from singleton, Fu and Li's correction is an efficient method to estimate the population parameter $\theta$. Changing the width of the sliding window from 100 kb to 10kb we obtain the similar results.

## 1906/T/Poster Board #455

**Functional Principal Component Analysis for Testing Association of Full Spectrum of DNA Variation.** *L. Luo, E. Boerwinkle, M. Xiong.* Human Gen Ctr, Univ Texas, Houston, Houston, TX.

Although great progress in GWAS has been made, the identified significant SNP associations account for only a few percent of the genetic variation. More disease risk variants remain to be identified. Next-generation DNA sequencing technologies will detect millions of rare variants. Most traditional statistical methods are difficult to be applied to rare variants due to the low frequency and high genotyping error. Functional Data Analysis (FDA) techniques are ideally suited for association analysis of next-generation sequencing data. A genotype profile of each individual can be viewed as a realization of the Poisson process and hence as a function of genomic location. They use data reduction techniques to compress the signal into a few components by Functional Principal component analysis (FPCA), which in turn can reduce both false positive and negatives. FPCA can also decorrelate dependent functional data, where many traditional statistics for independent variables can be easily applied. We develop a novel FPCA-based statistic for testing association of full spectrum of genetic variants within a gene ranging from rare variants to common SNPs. Its type 1 error rates were not appreciably different from the nominal levels by simulation studies. The proposed statistic was applied to association studies of Psoriasis. The best SNP P-values, adjusted for multiple testing, of two MHC class genes MICA and HLA-DMA are 3.2E-6 and 1.6E-4, respectively. Their P-values by gene-based linear combination test are 3.4E-4 and 1.9E-4, respectively. While their P-values by new statistic are respectively,1.4E-7 and 2E-7. We also applied the FPCA approach to the next-generation sequencing data of gene ANGPTL4 in the Dallas Heart Study where we compared the number of sequence variants in the top and bottom quartiles of the distribution to examine the genetic effects of sequence variants. After excluding variants with MAF greater than 0.03, FPCA approach declared the significant association of gene ANGPTL4 with three phenotypes: BMI (P-value: 6.03E-05), Triglycerides (P-value: 0.0035) and VLDL (P-value: 0.0148). However, Fisher exact test declared no significant association of gene ANGPTL4 (BMI, 0.21, Triglycerides,0.87, and VLDL,0.94). These examples demonstrate that the FDA-based statistic is powerful for testing association of entire spectrum of genetic variants. FDA is expected to emerge as a major analytic tool for association studies of next-generation sequencing data.

## 1907/T/Poster Board #456

**Assessing the utility of imputation for fine-mapping in association studies via simulations.** *S.R. McGee[1], D.A. Nickerson[1], C.S. Carlson[2,3], T. Bhangale[1,4].* 1) Department of Genome Sciences, University of Washington, Seattle, WA; 2) Department of Epidemiology, University of Washington, Seattle, WA; 3) Division of Public Health Prevention, Fred Hutchinson Cancer Research Center, Seattle, WA; 4) Department of Biostatistics, University of Washington, Seattle, WA.

Hundreds of associations for common human diseases/traits have been established via genome-wide association studies (GWAS). This is rapidly moving variation analysis towards the discovery of the underlying causal variant(s) to provide a greater understanding of human phenotypic variation. Imputation has been widely applied in association analysis but could be of great utility in fine mapping causal variation as well. The advent of the Thousand Genomes Project (TGP) is expected to provide considerable new information for alleles with lower minor allele frequencies (MAF < 10%) and greater insights into the patterns of linkage disequilibrium (LD) within and among human populations. In this study, we used simulations to characterize the extent to which imputation from the HapMap and TGP data will aid in uncovering the causal variation in human association studies. To explore causal variant mapping we simulated sequence variation among samples using a neutral model for two major founder populations (African-descent and European-descent). We then trimmed the simulated variation data to match the densities of the Phase II HapMap and TGP as well as commercially available genotyping arrays. Causal variants were picked to cover a wide range of MAFs and effect sizes. The locations of significantly associated variants were then detected using 1) genome-wide arrays, 2) after imputation with simulated HapMap, and 3) TGP data. We then assessed the probability of discovering the true causal variant within a distance-range defined by a set of the most significantly imputed variants. For example, TGP-based imputation can provide a three-fold increased probability of locating the causal variant (with MAF < 5%) within a 20 kb window defined by the most significantly associated variants, compared to HapMap-based imputation. Furthermore, when simulating an African population, imputation with TGP-based data identified the causal variant as the most significantly associated variant approximately 20% of the time. Our approach can be used to set confidence limits on the search windows for follow-up resequencing to identify causal variations in human association studies.

## 1908/T/Poster Board #457

**Clustering binary sequences and inferring haplotype sequences from genotypes using modal expectation-maximization (MEM).** *X. Mao[1], B. Lindsay[1], S. Chen[2].* 1) Dept Statistics, Penn State Univ, State College, PA; 2) School of Math. and Stat. Sci., Arizona State University, Tempe, AZ.

DNA sequences are widely used in biomedical research and other fields. Many methods are developed to study the variation within sequences, to infer haplotype from genotypes, to quantify the differences between sequences, to cluster sequences and further to infer the cause of the physiological changes. The proposed method is a modal expectation-maximization (MEM) method for clustering DNA haplotype sequences. First we define a kernel density estimator for the sequences and use it to define a weight function for each sequence. Then we start from each data sequence and examine all other sequences along with the weight function to find the nearest mode of the density. We may cluster the sequences that share the same mode. We can create a hierarchical clustering of all the sequences by adjusting the tuning parameters in the kernel density function. We generalize this method to create a new tool for the haplotype inference problem. We define a density estimator for the genotype sequences and find the objective function that needs to be maximized. By adjusting the tuning parameters, one may also obtain modes for the sequences as the ancestor (as in haplotype) for the genotypes or obtain the haplotype configuration for the genotype sequences. We only present the method for inferring the haplotypes. Both methods are tested on large datasets with the comparison to the available methods such as Phase, fastPhase and others . It shows that the methods yield similar results as they require less or equal amount of computational time and they provide some advantages of statistical inference.

## 1909/T/Poster Board #458

**DNA Sequence-based Analysis Via Regression Modeling that Leverages Genomic Annotations.** *O. Libiger, A. Torkamani, N.J. Schork.* The Scripps Translational Science Inst, Scripps Health and The Scripps Research Inst, La Jolla, CA.

Recent whole genome association studies (GWAS) yielded unequivocal statistical associations between a number of common single nucleotide polymorphisms (SNPs) and a variety of diseases. However, each of these SNPs only accounts for a very small proportion of the incidence of the associated disease. Possible explanations are that structural variants or rare single nucleotide variants not captured by the variation assayed in the GWAS are important genetic determinants of complex diseases. It could also be the case that many loci contribute to the manifestation of a disease either in isolation or through epistatic interactions. We devised a novel approach to assessing associations between groups of variants and disease based on high-dimensional regularized regression models. Our approach can accommodate the analysis of the full range of genomic variations identified by DNA sequencing assays, and addresses locus heterogeneity and interaction effects by leveraging genomic annotations for collections of variations. We have assessed the utility of the method through analytical and simulation studies and showcase its application in a number of empirical studies including studies of complete mtDNA sequences obtained on individuals with cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) as well as two genes sequenced in their entirety for a study of obesity.

## 1910/T/Poster Board #459

**Bayesian network model for SNP calling in shallow sequencing with haplotype based prior.** *D. Zhi, N. Liu.* Section on Statistical Genetics, Dept Biostatistics, Univ Alabama, Birmingham, Birmingham, AL.

Traditionally, deep sequencing (e.g., >30X for solexa short-reads) of individuals' genome is conducted to ensure high quality ascertainment of genetic variations. Alternatively, shallow (low-coverage) sequencing approach allows for affordable survey of genetic variation with large samples, even the genotype of each individual may not be accurately ascertained. This approach is adopted by the 1000 Genomes Project (1KG, http://www.1000genomes.org/page.php) to sequence 1200 individuals at 4X coverage which promises to deliver the most complete catalogue of single-nucleotide polymorphisms (SNPs) with minor allele frequency >1%. While the large sample size in 1KG warrants accuracy of SNP calling, leveraging haplotype information would improve SNP calls further. Moreover, phased sequences for 1KG individuals would be invaluable for genetic research, such as for untyped marker imputation. Recently, hidden Markov models (HMMs) are used to efficiently describe individuals as mosaic of reference or ancestral haplotypes. However, current HMM-based approaches do not consider information about mate pairs, which carry essential clues for haplotyping. In this study we set forth to develop a Bayesian network model which generalizes existing HMM models to include mate pair information and sequencing error models. Our preliminary results indicate that our model significantly improves upon current HMM-based approaches, especially when sequencing coverage is relatively low.

## 1911/T/Poster Board #460

**SERPING1 Mutation rs2511989 is Variably Associated with Macular Degeneration and Not Associated with Severity of Disease.** *C. Ramsden[1,4], M. Cooper[2], A. Tan[2,3,4], L. McDougall[4], B. Longville[2,3,4], J. Xiao[2,3,4], D. Mackey[4], I. Constable[4], L. Palmer[2].* 1) Department of Ophthalmology, Sir Charles Gairdner Hospital, Nedlands, WA 6009, Australia; 2) Centre for Genetic Epidemiology and Biostatistics, University of Western Australia, Nedlands, WA 6009, Australia; 3) Western Australian Institute for Medical Research, Centre for Medical Research, University of Western Australia, Nedlands, WA 6009, Australia; 4) Lions Eye Institute, Centre for Ophthalmology and Visual Science, University of Western Australia, Nedlands, WA 6009, Australia.

Background: Age Related Macular Degeneration (AMD) is the most common cause of blindness in developed countries occurring in over 10% of individuals aged over 60. There is a spectrum of disease, from early to late, late being further divided into geographic atrophy and choroidal neovascularisation. A plethora of robust research has implicated the alternative and classical complement pathways of innate immunity in causing AMD. C1 esterase inhibitor, coded by the SERPING1 gene, an inhibitor of the classical pathway has been variably reported to be associated with AMD. We intended to test this association and that of SERPING1 with the severity of disease. Methods: A single nucleotide polymorphism rs2511989 was genotyped in 1013 individuals from a cohort of patients with recorded AMD from the Western Australian Macular Degeneration Study (WAMDS) and analysed for disease association against 4 control populations previously described in the UK and US using R. Further analysis was conducted comparing early disease to late. Multivariate analysis considered age, sex, smoking, hypertension, dyslipidaemia and the use of alcohol, non-steroidal anti inflammatory drugs and antioxidants. Results: Of the 1013 patients 74% had late AMD. SERPING1 minor allele genotype of rs2511989 AA occurred at a frequency of 18.2%, GA at 45.6%, GG at 36.2%. Genotyping was successful in 97% of samples. In comparison to four established control groups, taken from previously published work by other groups, rs2511989 was variably associated with AMD. A GG genotype association with AMD was only shown with one UK control population ($p = 0.003$) and not in three US control population ($p = 0.36$, 0.30 and 0.66). This relationship did not alter when late AMD was compared to the control populations. Within the WAMDS population, rs2511989 genotype variation was not associated with late disease in comparison to early ($p=0.61$). There was no association with any genotype and visual acuity, retinal detachment, haemorrhage, lesion size or lesion characteristic in the neovascular subgroup. Conclusion: Our results suggest that SERPING1 mutation rs2511989 is not associated with severity in macular degeneration, but is variably associated with the occurrence of disease when compared to previously described control populations.

**A Scalable Information Content-Based Approach for Genomewide-Association Studies.** *S. Bolte[1,3], E. Luczkowski[2], P. Jailwala[2], M. Serafin[2], K. Stamm[3], T. Wang[4], S. Twigger[5], S. Ghosh[2], C. Struble[3].* 1) GE Healthcare, Wauwatosa, WI; 2) The Max McGee National Research Center for Juvenile Diabetes and The Human and Molecular Genetics Center, Department of Pediatrics at the Medical College of Wisconsin and the Children's Research Institute of the Children's Hospital of Wisconsin, Milwaukee; 3) Department of Mathematics, Statistics & Computer Science, Marquette University, Milwaukee, WI; 4) Division of Biostatistics, Department of Population Health, Medical College of Wisconsin, Milwaukee, WI; 5) Department of Physiology, Medical College of Wisconsin, Milwaukee, WI.

Complex, common diseases such as Type 1 Diabetes, inflammatory bowel disease, coronary artery disease, depression and allergic disorders have strong genetic components. Understanding the etiology of complex diseases will help develop new strategies for prevention and cure. Recent genome-wide association (GWA) studies for complex diseases using single nucleotide polymorphisms(SNPs) have yielded important pathogenesis regions. To date, these studies have mostly employed single-marker analytical tools that do not fully exploit the information available from multiple markers. An approach to multiple marker analysis is information content (IC), a measure of variability, of SNP typing data. Instead of several haplotype frequencies to compare between cases and control subjects, we gain power by incorporating the underlying haplotype information into one IC score, allowing for a single statistical test to be performed. Chromosomal intervals differing in IC between cases and control subjects potentially harbor susceptibility genes. Nevertheless, multiple marker analysis increases the computational complexity beyond the capabilities of single desktop workstations. In this study, we present our IC-based framework as a means for identifying disease genes. The flexible framework allows for a variety of GWA studies. Adjustable parameters such as window size & structure of genomic regions for IC calculations, bootstrap sample size, and number of cases & controls balance statistical power and computational time. No assumptions are made about the location of potential associated variations, analyzing available SNP data for non-coding and coding regions. Furthermore, our framework does not depend on identifying haplotype blocks or tag SNPs as a preprocessing step. Our framework is implemented using the previously developed tagsnps program of Nicolas et al and Condor, middleware for high-throughput computation, from the University of Wisconsin--Madison. Early results analyzing the human MHC indicate the framework is scalable on our modest sized computational resources, a 42-core Macintosh grid. An analysis of 971 cases and 937 controls completed in under 10 minutes representing an over 10-fold speedup in computational time compared to a single machine. To understand the impact of framework parameters, power studies are presented for two simulated data sets. We conclude by applying the framework to two real-world data sets.

## 1913/T/Poster Board #462

**Extreme Point Methods in Calculating Power Function of Any Test of HWE in Multi-Allelic Markers.** *R. Chakraborty, M. Rao, S. Venkatesan.* Ctr Genome Infor/Env Hlth, 108, Univ Cincinnati, Cincinnati, OH.

In the 58th ASHG Annual Meeting, a poster was presented outlining how the power function of any test of the Hardy-Weinberg Equilibrium (HWE) can be calculated explicitly in the case of bi-allelic markers using extreme point methods (Abstract 2351, 2008). The goal of this presentation is to extend the methodology to multi-allelic markers. For simplicity, let us assume that we have a tri-allelic marker with alleles $A_1$, $A_2$, and $A_3$ with population frequencies $p_1$, $p_2$, and $p_3$, respectively. Let the distribution of the genotypes $A_1A_1$, $A_1A_2$, $A_1A_3$, $A_2A_2$, $A_2A_3$, and $A_3A_3$ be cast in the form of a Wright's model (1977) with inbreeding coefficient '$\theta$.' Testing HWE is equivalent to testing '$\theta$' equal to zero. Let T be any test of HWE built on data collected on the genotypes. Using extreme point methods, we give an explicit formula for the power function of T. The underlying convex set is the set of all genotype distributions with '$\theta$' ranging over the permissible values of '$\theta$.' This convex set has only two extreme points. The power function formula is built on these extreme points. Some illustrations of the computations are provided.

## 1914/T/Poster Board #463

**Hypothesis Mining: A web based query tool utilizing relational databases to mine GWAS results.** *Q.D. Gibson, P.F. McArdle.* Univ Maryland Sch Medicine, Baltimore, MD.

Since ambiguous temporality is not an issue in genetic epidemiology, cross sectional study designs are a cost effective approach. Once a GWAS design has been selected, genotype costs remain fixed and thus overall efficiency increase as the number of phenotypes in the study increases. Assuming association analyses have been conducted for a genome wide set of markers and multiple phenotypes, we propose a data mining application to help distinguish true positive associations from false positive ones. Our application relies on storage of association results in a relational database. The application allows the researcher to input a hypothesis through a user interface that then queries the database to identify data that is consistent with the hypotheses. This approach allows researchers to identify markers consistent with a biological pathway, even though the individual association results were not among the top signals or reach "genome wide significance". The pathway mining application allows for greater utility of the data thereby provide added value to the cost of each study.

## 1915/T/Poster Board #464

**An immersive 3-D visualization environment for exploring high-dimensional genetic analysis results.** *D. Hill, R. Cowper, J.H. Moore.* Department of Genetics, Dartmouth College, Lebanon, NH.

This is an exciting time in biomedical research due to the availability of technology that allows us to measure tremendous amounts of information about genes, proteins and other biomolecules that play an important role in the molecular pathology of disease. However, it is also a challenging time due to the bioinformatics needs associated with storing, managing, analyzing and interpreting 'omics' data. While we have made great progress in developing the databases and data analysis tools for measuring statistical relationships in high-dimensional datasets, the bioinformatics methods for knowledge discovery in the large volumes of statistical results generated from 'omics' analyses are in their infancy. To address this interpretation challenge, we have developed an innovative three-dimensional (3-D) visualization approach to the exploration of statistical analysis results from genome-wide association studies (GWAS) that capitalizes on the power of human visual perception and our evolved ability to recognize complex patterns. The overall goal of this study is to replace the traditional approach of sifting through thousands of rows of p-values in an Excel spreadsheet with an innovative and unconventional visual approach that presents the results in an interactive 3-D graphical format that makes important local and global patterns much easier to identify by the user. To implement this we have harnessed the power of cutting-edge computer graphics technology in the form of fast Graphical Processing Unit (GPU) video card hardware and sophisticated 3-D video game engine software (Unity3D) that is designed for real time rendering of 3-D visual environments and animation. Here, we map multiple different analytical results for each gene onto a 3-D structure such a tree or a tropical fish, for example. This allows the user to visually explore forested landscapes or schools of tropical fish for visually interesting patterns that reflect important multivariate information that would otherwise not be revealed in an Excel spreadsheet. This immersive and interactive 3-D virtual environment puts the user in a visually appealing environment that enhances scientific discovery.

## 1916/T/Poster Board #465

**PHENOMIM: an OMIM-based secondary database with a controlled vocabulary.** *X.L. Ji[1,2], C.X. Liu[3], Y. Fang[1], S.Q. Liu[2], Y.Y. Zhao[4], D.Y. Zhao[1], J. Li-Ling[1,3,4].* 1) Sino-Dutch Biomedical and Information Engineering School, Northeastern University, Shenyang 110003, China; 2) Laboratory for Conservation and Utilization of Bio-Resources & Key Laboratory for Microbial Resources of the Ministry of Education, Yunnan University, Kunming 650091, China; 3) Department of Gynecology and Obstetrics, Liaoning Center for Prenatal Diagnosis, Shengjing Hospital of China Medical University, Shenyang 110003, China; 4) Department of Medical Genetics, China Medical University, Shenyang 110001, China.

It has been recognized that phenotype analysis may provide crucial information for gaining insights into molecular interactions underlying various diseases. However, so far few attempts have been made to systematically carry out analyses at the phenotype level, mainly owing to lack of a unified system of phenotype descriptors. Here we present a secondary database, PHENOMIM, for presenting the clinical synopses (CS) from the Online Mendelian Inheritance in Man (OMIM) database with a structured and controlled vocabulary. The OMIM-based phenotype vocabulary has combined medical knowledge and mechanisms of embryonic development. A web interface has also been developed for visualization of the hierarchical structure of the vocabulary and related information from the OMIM database. Our downloaded OMIM databank contained over 18,000 detailed entries about human genes and genetic disorders, of which 4,741 entries have a CS field that lists the clinical features of a given disease. Through text parsing, a total of 58,075 clinical features were retrieved. The data were then sorted according to a hierarchical ontological system designed based on human embryology and clinical knowledge. To assess the value of PHENOMIM, a simple statistical test has been performed to evaluate the vocabulary. OMIM entries were compared to each other based on their phenotypic maps. The OMIM entry pairs with most similar phenotypic mapping were identified. Interestingly, besides variants of a same syndrome, e.g., Cockayne syndromes type A (OMIM 216400) and type B (OMIM 133540), many entries with drastically different labels (e.g., OMIM 170995 and 214110; OMIM 194190 and 601803, etc.) were found to have very similar maps. Since such pairs maybe either clinically or genetically related, our phenotypic analysis may provide crucial information for underlying genetic interactions. Availability and Implementation: Freely available on the web at http://yunda.org:8080/test/phenomim/index.php. Website implemented in PHP, MySQL and Apache, with all major browsers supported. Contact: li-ling@mail.cmu.edu.cn Supplementary Information: Detailed documentation is available at http://yunda.org:8080/test/phenomim/index.php.

## 1917/T/Poster Board #466

**Classifying Clinical Outcomes in Rare Renal Diseases Using Molecular Markers: Optimal Feature Selection When Features Are Rare, Weak and Correlated.** *J. Jin[1], P. Song[2].* 1) Statistics, Carnegie Mellon University, Pittsburgh, PA; 2) Statistics, University of Michigan, Ann Arbor, MI.

We consider two types of rare renal diseases: Membranous Nephropathy (MN) and Focal and Segmental Glomerulosclerosis and Minimal Change Disease (FSGS/MCD). Data are collected from 450 patients, roughly half in each of the two types. For each patient, over 20,000 genetic features (i.e. gene expression levels) are measured through microarray experiments on renal biopsy tissues, accompanied with dozens of auxiliary features such as histopathology, laboratory, clinical, treatment variables. The main interest is, based on both molecular and auxiliary features, to predict patient's primary clinical outcome as to be either {em complete/partial remission} or {em no remission} of urinary protein excretion. We model the feature vector $X = (Y, W)'$ as samples drawn from a high dimensional Gaussian distribution, where $Y$ and $W$ correspond to genetic features and auxiliary features, respectively. We model the covariance matrix as $Lambda + H$, where $Lambda$ is a diagonal matrix and $H$ is a low-rank matrix characterizing the correlation between $Y$ and $W$. In addition, the $Y$ component is highly sparse, and the $W$ component is relatively dense. We propose a new approach for feature selection in the $W$, and apply the recent innovation of Higher Criticism Thresholding (Donoho and Jin (2008), Proc. Natl. Acad. Sci.) to select features in the $Y$. We show that the feature selection approach for the $W$ is optimal when useful features are weak but relatively dense, and that the feature selection approach for the $Y$ is optimal when useful features are both weak and rare. These two approaches complement with each other in different sparsity regimes. In addition, we find that the correlation matrix $H$ plays an important role in the power determination for a classifier. We derive an explicit formula on how matrix $H$ affects feature weights in a classifier. Results on both simulations and applications to rare renal diseases are reported. This is joint work with Peter Song, Department of Biostatistics, University of Michigan.

## 1918/T/Poster Board #467

**Software for designing and forming predictive genetic tests.** *Q. Lu[1], C. Ye[1,2], J. Zhu[2], R.C. Elston[3].* 1) Department of Epidemiology, Michigan State University, East Lansing, MI; 2) Institute of Bioinformatics, Zhejiang University, Zhejiang, P. R. China; 3) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH.

Early disease prediction capitalizing on genetic loci and clinical risk factors holds great promise for improving health care and is anticipated to change health care from treatment to prevention. However, linking the genetic and clinical risk factors, including those from genome-wide association studies, into individual genotype/clinical profiles to predict an individual's risk of disease (i.e., forming a predictive genetic test), remains a challenge. To facilitate this kind of translational research, we develop a graphical user interface package, PredTest, in R. This package is built for both designing and analyzing predictive genetic tests. In the design stage, it provides an estimated classification accuracy of the test using essential information gained from public resources and/or previous studies, and determines the sample size required to verify this accuracy. In the analysis stage, it adopts a robust and powerful method for forming predictive genetic tests. The package is developed based on the optimality theory of the likelihood ratio and, therefore, theoretically could form a test with the highest performance. It can be used to incorporate a relatively large number of genetic and clinical predictors, with consideration of their possible interactions, and so is particularly useful for forming predictive genetic tests under the common complex diseases scenario.

## 1919/T/Poster Board #468

**GWAMA: software tool for meta-analysis and visualization of whole genome association data.** *R. Magi[1,2], A.P. Morris[2].* 1) Oxford Centre for Diabetes, Endocrinology and Metabolism, University of Oxford, Oxford OX3 7LJ, UK; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford OX3 7BN, UK.

Genome-wide association (GWA) studies have proved to be extremely successful in identifying moderate genetic effects contributing to complex human phenotypes. However, to gain insights into increasingly more modest signals of association, samples of many thousands of individuals are required. One approach to overcome this problem is to combine the results of GWA studies from closely related populations via meta-analysis, without direct exchange of genotype and phenotype data. We have developed the GWAMA (Genome-Wide Association Meta-Analysis) software to perform meta-analysis of the results of GWA studies of binary or quantitative phenotypes. Fixed-effects meta-analyzes are performed for both directly genotyped and imputed SNPs using estimates of the allelic odds ratio and 95% confidence interval for binary traits, and estimates of the allelic effect size and standard error for quantitative phenotypes. The software incorporates error trapping facilities to identify strand alignment errors and allele flipping, and performs tests of heterogeneity of effects between studies. Comprehensive log files of all errors and warnings are composed with unique error codes for each exception. This allows researchers to quickly and easily discover all problems in their data set. The software package also includes R scripts for creating publication quality Manhattan- and QQ-plots from the output data to summarize results. Both Manhattan- and QQ-plots can be drawn for illustrating the results. GWAMA is an open source software package and can be downloaded from http://www.well.ox.ac.uk/gwama/. A userguide and example files are provided with the software.

## 1920/T/Poster Board #469

**Sparsity Pruning with Random Forests.** *A.E. Hubbard[1], B.A. Goldstein[1], A. Cutler[2], L.F. Barcellos[3].* 1) Division of Biostaitsics, University California Berkeley, Berkeley, CA; 2) Department of Mathematics & Statistics, Utah State University, Logan UT; 3) Division of Epidemiology, Univ of California, Berkeley, CA;.

One of the significant challenges in genome wide association (GWA) studies is to separate the few true effects (signals) from the rest of the data (noise). Many machine learning techniques are available for dealing with such sparse data. Random Forests (RF) is a flexible algorithm that has seen growing application in genetic studies. The algorithm produces a series of categorization trees using a large set of predictor variables and a specified outcome. The collection of trees can be used to predict an outcome, cluster observations, and calculate variable importance measures. In a recent application to GWA data, we found that by recursively removing sparse data, SNPs associated with disease can more effectively be discovered. However, little work has been done to characterize the effectiveness of sparsity pruning using RF. Using simulated GWA data, the effectiveness of sparsity pruning and filtering techniques is examined. We define the sparsity of the final forest through the two main RF tuning parameters: mtry (the number of variables to search over at a node) and ntree (the number of trees in the forest). Different genetic causal models are explored with a focus on epistatic and heterogeneous effects, as well as dominant and recessive effects. The power of such sparsity pruning to retain a true association is examined, revealing that most true associations are retained while the dimension size is decreased. Power is strongest to detect main effects, though still more than capable of isolating interactions as well as heterogeneous effects. This dimension reduction subsequently allows one to effectively analyze GWA data for causal effects with more targeted parameters.

## 1921/T/Poster Board #470

**Some Strategies of Testing Hardy-Weinberg Equilibrium in Tri-Allelic Markers.** *M. Rao[1], R. Chakraborty[1], S. Venkatesan[1], R. He[2].* 1) Environmental Health, University of Cincinnati, Cincinnati, OH; 2) Novartis Consumer Health, Inc., 200 Kimball Drive, Parsippany, NJ.

The focus of the presentation is testing the Hardy-Weinberg Equilibrium (HWE) in tri-allelic markers. Let $A_1$, $A_2$, and $A_3$ be the alleles with population frequencies $p_1$, $p_2$, and $p_3$, respectively. Let the resultant genotype distribution be cast in the form of a Wright's model (1977) with inbreeding coefficient $\theta$. The Wright's model has four parameters: the allele frequencies and the inbreeding coefficient. Testing HWE is equivalent to testing $\theta = 0$. One could use a likelihood ratio test based on the sample genotype frequenices to test HWE. One could use Mathematica for the optimization work involved in the likelihood ratio test. In spite of spending hours and hours on Mathematica, no solution is forthcoming on certain data sets. There is a way out. Let us reduce the genotype distribution into three 2x2 genotype distributions stemming from $A_1$ versus not $A_1$, $A_2$ versus not $A_2$, and $A_3$ versus not $A_3$ with respective inbreeding coefficients $\theta_1$, $\theta_2$, and $\theta_3$, respectively. It can be shown that $\theta_1 = \theta_2 = \theta_3 = \theta$. One can then easily test HWE in each of the 2x2 set-ups using any one of the tests available in the literature. One can then string all these three tests together to test HWE in the 3x3 case. We will also show how to compute the power function of such a test. Computations will be illustrated using some examples.

## 1922/T/Poster Board #471

**A software tool for scoring CNVs and runs of homozygosity using linkage results.** *R. Karlsson, L. Graae, M. Lekman, D. Galter, A. Carmine Belin, S. Paddock.* Neuroscience, Karolinska institutet, Stockholm, Sweden.

**Background:** High-density SNP platforms can reveal copy number variants in the human genome that have previously been difficult to discover. Linkage studies have been performed for many diseases, however resolution is low, and follow-up was prohibitively expensive. Thus interesting but broad linkage peaks may have been left uninvestigated. Family-based DNA samples that were collected for linkage studies can now be re-genotyped relatively cheaply on genome-wide SNP platforms, where software (e.g. PennCNV) can be used to call CNVs with high confidence. The high resolution of modern SNP genotyping together with the inheritance information available in family-based samples can lead to new insights. We therefore suggest scoring CNVs using linkage data to find candidate CNVs for complex diseases. **Methods:** We present a simple approach to linkage-based CNV scoring. The genome is segmented so that every start or end of a CNV in any individual becomes a segment breakpoint. CNVs are counted and summarized for each individual and each pedigree. Filters for inclusion can be applied, for example on copy number or minimum CNV count per family and region (to exclude singleton de novo events). CNVs that pass the filters are scored by the sum of average family-wise linkage scores over the segment for all families that have a CNV in that specific chromosomal segment. Input files can be derived from parametric or non-parametric linkage analyses. We have implemented this analysis in a freely available software package. Our implementation supports output from Merlin for linkage, and PennCNV for CNV analysis, but can easily be extended to accept other popular file formats. It is also possible to score other individual-based chromosomal segments by this method. One alternative, implemented in our tool, is to replace CNVs by runs of homozygosity output from PLINK and perform an analogous scoring. **Results:** In a preliminary study we applied our method to a 47 pedigree, 277 individual subsample of the NIMH genetics initiative repository of DNA from families affected by bipolar disorder. The sample was re-genotyped on the Illumina HumanHap610 platform. Using nonparametric linkage data, regions 2p25, 15q21, and 12p12 got the highest scores. Using parametric linkage scores identified a candidate region on 3p14. These CNVs will be validated using qPCR and further investigated by re-sequencing and functional assays to assess their significance in the etiology of bipolar disorder.

## 1923/T/Poster Board #472

**Modelling Single SNP and Haplotype Mendelian Randomisation in R.** *G. Cadby, PA. McCaskie, LJ. Palmer.* Centre for Genetic Epidemiology and Biostatistics, University of Western Australia, Perth, Western Australia, Australia.

One aim of epidemiology is to discover modifiable disease exposures and translate this knowledge into public health for the prevention of disease. Researchers often rely on observational studies to find associations between exposure and disease as randomised controlled trials (RCTs) are not always feasible, however many observational epidemiology results have not been replicated in RCTs. This may be as the reported associations are due to artefacts of the study design, including confounding, selection bias and reverse causation.

If it is possible to identify a genetic variant (or instrument) which is associated with the exposure, then due to the random assortment of alleles from parents to offspring, this variant should not be associated with confounding factors or subject to selection bias or reverse causation. If an association is detected between the variant and disease, we can assume the exposure is causally related to disease. This is referred to as Mendelian Randomisation (MR) and is a form of Instrumental Variables (IV) analysis.

Several software packages implement IV methods, however none of these are designed specifically for a genetic association analytic framework. As such, they can accommodate the inclusion of simple single nucleotide polymorphism (SNPs) as instruments, however they do not allow the inclusion of imputed haplotypes. We have designed a MR software application in R which models epidemiological relationships using either SNPs or haplotypes as instruments. Both SNP and haplotype MR analyses use Generalised Method of Moments and Two Stage Least Squares. In addition, a multiple-imputation approach to haplotypic analysis, identical to that utilized in the program SimHap, is used to estimate the phase of the haplotype instrument.

The use of MR modeling in the genetic epidemiological framework will assist in the detection of casual relationships between exposures and disease, which will in turn lead to improved health interventions acting on modifiable environmental exposures, resulting in better health outcomes.

**PATH2: Analysis of Genetic Pathways Incorporating Prior Information From Electronic Databases.** *D. Daley, B. Tripp, D. Zamar.* i-CAPTURE Ctr, Univ British Columbia, Vancouver, BC, Canada.

Statistical models are becoming more complex as we seek to better understand biologic disease pathways. For complex diseases, susceptibility may be the result of interactions (gene-gene or gene-environment) and statistical models need to be able to incorporate these interactions. Hierarchical models provide a framework to tackle many of the problems encountered in the genetic analysis of common complex diseases, as they allow for the incorporation of prior information into the statistical model. In the "information age" there is a vast quantity of knowledge that can be mined from electronic databases, but the challenge is how to automate data retrieval and appropriately incorporate this information into the statistical model. We have developed Path (Path: a tool to facilitate pathway-based genetic association analysis), to aid researchers in the incorporation of prior information in statistical analyses, the software can be freely obtained from http://genapha.icapture.ubc.ca/index.php/research/software/. Path is designed to help researchers interface their data with biological information from several bioinformatics resources. Path brings together currently available information from nine online bioinformatics resources including the National Center for Biotechnology Information (NCBI), Online Mendelian Inheritance in Man (OMIM), Kyoto Encyclopedia of Genes and Genomes (KEGG), UCSC Genome Browser, Genetic Association Database, the Single Nucleotide Polymorphism database (dbSNP). Path allows users to view KEGG pathway diagrams and to search for genetic pathways by gene name, or by rs number. Path displays KEGG pathway diagrams and indicates the genes that have been genotyped in the pathway, allowing users to build custom association graphs, plots of interest, and to test for interactions. Path has been incorporated in the Genapha website (http://genapha.icapture.ubc.ca/). We are currently expanding Path to include additional data sources and hierarchical model structure, to guide users in the incorporation of prior information gathered from external sources. These models will be applied to an asthma dataset with 98 candidate genes and 5,565 individuals from Canada and Australia, in order to better understand the contribution of gender, genes, and environment and their complex interactions in the development of asthma. We have published our primary results (Daley, D et al (2009) Hum Genet 125, 445-59). Hierarchical model results will be presented.

## 1925/T/Poster Board #474

**An Application of Random Forests to a MS GWA dataset: Methodological Considerations & New Findings.** *B.A. Goldstein[1], A.E. Hubbard[1], F.B.S. Briggs[2], A. Cutler[3], L.F. Barcellos[2], IMSGC.* 1) Division of Biostatistics, Univ California, Berkeley, Berkeley, CA; 2) Division of Epidemiology, Univ of California, Berkeley, CA;; 3) Department of Mathematics & Statistics, Utah State University, Logan UT.

As computational power improves, the application of more advanced machine learning techniques to the analysis of large GWA datasets becomes possible. While most traditional statistical methods of analysis can only elucidate main effects of genetic variants on risk for disease, machine learning approaches are particularly suited to discover higher order and non-linear effects. One such approach is the Random Forests (RF) algorithm. In brief, the algorithm produces a series of categorization trees using a large set of predictor variables. Each tree serves as a weak predictor for a chosen outcome. After growing a series of trees, the results are aggregated to create a robust predictor. The algorithm computes an importance score for each predictor variable considered. While recent years have seen a growth in the use of RF for SNP discovery in complex diseases, most work has focused on small datasets or simulation studies which are limited. Using a multiple sclerosis (MS) case-control dataset comprised of 500K SNP genotypes characterized across the genome, we outline an approach and several considerations for optimally tuning RF based on the empirical dataset. For large GWA data, it is found that the default values typically used for RF analyses are not appropriate, particularly the mtry (the number of variables to search over at a node) value. Furthermore, prediction and inference notably improve after recursively sub-sampling the data, and after removing very strong effects (predictors) from the analysis. The RF results obtained in this study are compared to previously published and replicated GWAS results using the same dataset. RF is able to replicate the positive findings for SNPs within EVI5 (Chr 1), KANK1 (Chr 9), and IL2RA (Chr 10). Moreover, SNPs within four new loci are identified as important for distinguishing between MS cases and controls: PHACTR2 (Chr 6), IL7 (Chr 8), CTNNA3 (Chr 10), and MPHOSPH9 (Chr 12). This study represents one of the first applications of a machine learning algorithm to a GWA dataset and demonstrates the utility of RF to reveal novel genetic associations.

## 1926/T/Poster Board #475

**A Bonferroni procedure using weights accounting for Hardy-Weinberg disequilibrium information in genome-wide association studies.** *G. Kang, G. Gao.* University of Alabama at Birmingham, Birmingham, AL.

In genetic case-control studies, traditional tests for detecting association between a single marker and a disease include Pearson's Chi-square allelic test and genotypic test, and Cochran-Armitage trend test (for additive model). These tests can be powerful for additive (ADD) and multiplicative (MUL) disease models, but are less efficient for dominant (DOM) and recessive (REC) disease models. In addition, testing for Hardy-Weinberg disequilibrium (HWD) has been used for detecting association between a single marker and a disease. The HWD methods can be powerful for DOM and REC models, but have very low or no power for ADD and MUL models. Recently, Song and Elston proposed a method combining the Cochran-Armitage trend test and a measure of HWD to create an approach powerful for the four models discussed above. When the methods described above for testing association for a single marker are applied to genome-wide association studies (GWAS) that test hundreds of thousands of single nucleotide polymorphisms (SNPs), the Bonferroni procedure is often used to control family-wise error rate (FWER), the power of GWAS can be low. In this study, we adapt a generalized sequential Bonferroni (GSB) procedure of Holm to GWAS. The GSB assigns a weight to each test (or marker) according to prior information instead of treating each marker equally and assigning the same significance threshold to each marker as in the Bonferroni procedure. We propose to calculate a weight for each marker by using information of HWD among cases, and then to incorporate the weights for all markers into the allelic association tests used for GWAS. We refer to this GSB procedure with HWD weight as GSB-HWD procedure. Simulation results show that our GSB-HWD method: 1) controls FWER quite well, 2) always has much higher power in GWAS than the traditional association tests with Bonferroni correction under DOM and REC models, 3) can have power very comparable to the traditional association tests with Bonferroni correction in GWAS under ADD and MUL models, and 4) generally outperforms Song and Elston's method with Bonferroni correction in multiple testing under the four models described above. We applied our GSB-HWD procedure to GWAS of a coronary artery disease dataset with about 340K SNPs and to GWAS of a hypertension dataset with about 350K SNPs. Our GSB-HWD procedure identified more significant SNPs than the traditional association tests with Bonferroni correction.

## 1927/T/Poster Board #476

**Analyses and Comparison of Imputation-based Association Methods.** *Y. Pei[1,2], J. Li[2], L. Zhang[1,2], H. Deng[1,2,3].* 1) Key Laboratory of Biomedical Information Engineering, Ministry of Education and Institute of Molecular Genetics, School of Life Science and Technology, Xi'an Jiaotong University, Xi'an 710049, P. R. China; 2) School of Medicine University of Missouri-Kansas City, 2411 Holmes Street Kansas City, MO 64108, USA; 3) College of Life Sciences and Engineering, Beijing Jiaotong University, Beijing, China.

Genotype imputation methods have become increasingly popular for recovering untyped genotype data. An important application with imputed genotypes is to test genetic association with complex traits. Association testing with imputed genotypes can provide additional insight beyond what is provided by testing on only typed tagging SNPs in genome-wide association studies. Many sophisticated imputation-based association methods have been proposed and proven to be effective. However, their performances are affected by a variety of genetic factors, which have not been well studied. In this study, using both simulated and real data sets, we investigated the effects of LD, MAF of untyped causal SNP and imputation accuracy rate on the performances of five popular imputation-based association methods, MACH, IMPUTE, SNPTEST, BIMBAM and SNPMStat, and compared their relative performances. Results show that: 1). all the methods investigated could boost signals and improve power under medium and high LD levels, and the power increased with increasing level of LD; 2) the power increased with higher MAF of untyped causal SNPs; 3). high imputation accuracy rate could not guarantee an improvement in power; 4). among the methods, SNPTEST performed best under most scenarios for both quantitative and qualitative traits. Our results are helpful in guiding the applications of imputation-based association methods in empirical data.

**Robust Score Tests for Multivariate Linkage Analysis.** *N. Morris, Y. Song, R. Elston, C. Stein.* Epidem/Biostatistics, Case Western Reserve Univ, Cleveland, OH.

There have been numerous papers discussing robust score tests for univariate quantitative trait linkage. In this work we suggest several robust tests for multivariate linkage analysis. While previous investigations have been hampered by inaccurate knowledge of the distribution of the multivariate linkage test statistic, we show how recent advances can solve this problem. Our tests include a transformation method and several empirical variance estimators. We perform a simulation study to determine the power and validity of these tests in terms of type I error. We also derive theoretical approximations to the power curve for one of these score tests. This theoretical approximation is used to further investigate how the power of these test is influenced by the model parameters, and when multivariate linkage is likely to be beneficial. Our method for linkage analysis has been implemented in the program RELPAL in the S.A.G.E. software suite.

## 1929/T/Poster Board #478

**Mitochondrial Sequence Data Analysis Tool.** *M. Schmidt, J. McCauley.* Miami Inst Human Genomics, Miller School of Medicine, Univ Miami, Miami, FL.

With the increasing ability to sequence mitochondrial DNA (mtDNA), the need for a flexible multi-purpose analysis tool arises. We have developed software to aid in examining mitochondrial variation for the purposes of genetic studies. Using this tool, one can complete various tasks which include quality control, detection of insertions/deletions, detection of single-nucleotide polymorphisms (SNPs), classification of haplogroups, and other data analyses. Analysis starts with a reference sequence and descriptor files for things such as gene location, amino acid coding, haplogroup classifications, and other user defined labels that can describe regions or sequence of interest. Using the quality control feature, one is able to compare sample data to a user provided reference sequence (e.g. the Revised Cambridge Reference Sequence (rCRS)), providing a summary about missing data, variant calls, or understanding sequence irregularities that may result as an artifact of the sequencing process. This tool is not limited to human mtDNA but could be adapted for analysis of any species' mitochondrial DNA sequence provided a user defined reference sequence and descriptor files. The overall focus of this application is to detect and summarize SNP variation along with insertions and deletions in sample data. All deviations from the reference are reported. For all positions in the mtDNA, base and affection status are tallied and provided in the summary for further consideration. Base changes leading to amino acid (i.e. non-synonymous) changes may be of particular interest when comparing mitochondrial sequences between cases and controls in a disease study. These and other variations may be subjected to a chi-square test with the summary file reporting significance values. In addition to examination of single SNPs this software also considers the collective variation across the mtDNA genome or within each gene (or other user defined regions). It tallies this variation, again by affection status, with the ability to perform additional tests for association. Haplogroups are also reported and analyzed for association through use of a defined descriptor file. This software is written in C++ and runs on Windows and Linux. Included with the distribution are the C++ source files for the program and a set of descriptor files for human mtDNA, including a haplogroup defined descriptor file utilizing the simplified mtDNA lineages found at mitomap.org.

## 1930/T/Poster Board #479

**Performance of population stratification correction: a simulation study using observed genotypes from a large European Reference Panel.** *E. Genin[1,2], M-C. Babron[1,2,3,4], R. Kazma[4,1], G.M. Lathrop[5,6], S. Heath[5,6].* 1) INSERM UMRS-946, PARIS, France; 2) Univ Paris-Diderot, Paris, France; 3) Inserm UMRS-535, Villejuif, France; 4) Univ Paris-Sud, Villejuif, France; 5) Centre National de Génotypage, CEA, Evry, France; 6) Fondation Jean Dausset/CEPH, Paris, France.

With the development of high density SNP-arrays spanning the whole human genome, genome-wide association studies have become a reality. In these studies, large samples of several hundreds of cases and controls are required to keep reasonable power after accounting for multiple testing. This is usually only feasible through multi-centric collaborative studies and stratification issues are likely to arise. Indeed, even within Europe, SNP allele frequency and disease prevalence variations exist that can lead to false positive results in association studies. Different methods have been proposed to account for stratification in association tests. One of the most widely used is the principal-component (PC) corrected chi-square implemented in Eigenstrat (Price et al., 2006) which computes association statistics using ancestry-adjusted genotypes and phenotypes. Simulations have shown that the method performs very well in keeping type-one error rates at the expected sizes while maintaining good power to detect association. In the different simulation studies however, power rates are usually computed using simulated genotype data and not observed ones and global type-one error rates are reported; i.e. without any account of markers that give false-positive results. In this study, we explored the performance of the Eigenstrat method using a large panel of 5,811 individuals from 13 European countries genotyped on Illumina 317K or 370K chips (Heath et al., 2008). We simulated case-control statuses (with 2,000 cases and 3,811 controls) of the 5,811 individuals from the sample assuming different disease gradients within Europe and different genetic models for the disease predisposition with different SNPs involved (3 among the most stratified ones and 3 among the less stratified ones). We compared the results obtained with Eigenstrat using corrections based on different numbers of PCs and PCs computed with different densities of markers to those obtained with the Cochran-Mantel-Haenszel (CMH) test after stratification on the individual reported country of origin. Although the different SNPs chosen as disease susceptibility loci had similar average allele frequencies over Europe, the impact of the PCs used to correct for stratification is not the same both in terms of power and type-one error rates. The CMH tests is shown to perform relatively well with a correct size and a limited lack of power compared to Eigenstrat.

## 1931/T/Poster Board #480

**Comparison of methods for the analysis of genetic association studies with very rare variants.** *S. Bacanu, M.R. Nelson, J.C. Whittaker.* GlaxoSmithKline, Res Triangle Park, NC.

Recent genome wide association studies of complex traits have been very successful and are predicted to detect the majority of common genetic variants of moderate to large effect. Despite this, for most traits only a small proportion of the genetic variance believed to exist is explained by the variants found. It is possible that much of the currently unexplained variance is due to rare variants having larger effects than those of common variants. Until recently it was cost-prohibitive to investigate such variants on anything but a small and targeted scale. However, current sequencing technology allows for investigation of rare variants on a larger scale, for instance resequencing the entire exon-coding regions of the genome (exome) in hundreds or thousands of individuals. As is often the case, the development of methods for data analysis lagges behind the technology for data generation. The most commonly used analysis method computes an overall gene statistic by contrasting the aggregate number of rare, putatively functional variants in subjects with phenotypes in the extreme tails of the distribution, assuming that all these putatively functional variants with frequency below an arbitrary threshold have the same effect on the trait of interest. Here we explore a number of alternative analysis methods, based on (1) aggregating the rare variants by exon/gene part, (2) smoothing the aggregated number of rare variants by genetic position (and possibly allele frequency) and (3) weighted aggregation of rare variants based on predicted functionality, calculated using structural or conservation based metrics. We consider both binary and quantitative traits, investigating the performance of our methods via extensive simulation, varying sample size, models for etiology and assumptions about the functionality of rare variants. We provide guidance for choosing the quasi-optimal method based on these parameters. Finally, we demonstrate our methods on data from a number of recent studies involving large scale resequencing of candidate genes.

## 1932/T/Poster Board #481

**Comparison of Genotype Imputation Methods for SNP Array Data.** *C.T. Chang[1], Y.J. Lin[1], C.Y. Tang[1], W.P. Hsieh[2].* 1) Computer Science, National Tsing Hua University, HsinChu, Taiwan, Taiwan; 2) Institute of Statistics, National Tsing Hua University, HsinChu, Taiwan.

The high throughput technology for genotyping has made genome-wide association possible. The SNP data derived from the array-based technology cannot avoid missing values since they are transformed from intensity data and are subject to the probe quality. Hence, there are many algorithms developed to impute the missing genotypes by utilizing the LD structure or the haplotypes from HapMap samples. Imputation can increase the power of the association study and does not cost extra money to type the missing SNPs. More and more genotype imputation software have been developed for this purpose and they have not been evaluated in a genome-wide association study. We compare the following software: BIMBAM v0.99, BEAGLE v3.0.3, fastPHASE v1.4.0, IMPUTE v0.5.0, MACH v1.0.16, PLINK, SNPMSTAT v3.1, and test them on linux kernel version 2.6 amd64 platform. Our purpose of this study is to integrate all the methods into a unifying format and facilitate genome-wide association study. The dataset used for evaluation is the HapMap data. Randomly selected SNPs from chromosome 21 of HapMap samples are masked to evaluate the imputation methods. The assessment is made on the accuracy, concordance rate, processing speed, and memory usage. We found that the performances of each method differ from populations. Therefore, an optimal imputation method is constructed by a voting and fusion system. When the results of the included methods are inconsistent, the final result is voted by all the modules. It summarizes the results and gives a better overall imputation.

## 1933/T/Poster Board #482

**LD Mapping of Disease Gene and Haplotype Analysis on Textile Plot.** *N. Kumasaka, Y. Nakamura, N. Kamatani.* Ctr Genomic Med, RIKEN, Tokyo, Japan.

We have been introducing textile plot (Kumasaka et al., 2008) to provide a visualization of LD structure so as to maximize deep insight into genetic variation present in the multiple SNP genotype data. The plot can accentuate LD by specific geometrical shapes. The LD between adjacent SNPs is shown by line crossings between adjacent loci so that low-grade line crossing indicates high dependency of alleles between SNPs, and vertical dispersion of genotypes approximates the structure of pairwise correlation coefficients for any number of SNPs. The haplotype structure can be also directly confirmed through the diplotype configuration as the queues of multiple genotypes on the textile plot. Application of this technique to simulated and real data sets illustrates the potential usefulness of the textile plot as an aid to the LD mapping of disease gene in conjunction with haplotype analysis.

## 1934/T/Poster Board #483

**Bayesian Methods for Investigating Hardy-Weinberg Equilibrium.** *J. Wakefield.* Statistics & Biostatistics, Univ Washington, Seattle, WA.

Testing for Hardy-Weinberg equilibrium is commonplace and is usually carried out via frequentist approaches. Unfortunately, the latter suffer from a number of drawbacks. First, the discreteness of the sample space means that uniformity of p-values under the null cannot be assumed. Second, the interpretation of the subsequent p-values, and choice of significance threshold depends critically on sample size, since equilibrium will always be rejected at conventional levels with large sample sizes. Finally, when applied in genome-wide contexts multiple testing is also a significant issue. We describe a Bayesian approach to the investigation of Hardy-Weinberg equilibrium using both Bayes factors (for hypothesis testing), and the examination of posterior distributions (for estimation). The choice of prior distribution is particularly important for testing, and we describe this choice with respect to a number of case studies including an example with nine alleles, and a genome-wide association study. The parameterization adopted under the alternative will vary depending on the nature of the data, with the use of tests for Hardy-Weinberg as a quality control measure in GWAS clearly differing from the more traditional application in population genetics. For the latter we parameterize in terms of fixation indices. The use of Bayesian methods is appealing for a number of reasons: the discreteness of the sample space is irrelevant since only the observed data are considered in the calculation, the choice of significance threshold in a hypothesis testing situation can be driven by the costs of making the two potential sources of error, and the examination of posterior distributions gives insight into reasons for departure from equilibrium. Freely-available software allows the straightforward application of the methods described.

## 1935/T/Poster Board #484

**Evidence of *CACNA1C, IGF2BP2, JAZF1, TCF7L2,* and *WFS1* Variants for Risk of Type 2 Diabetes in the NHLBI Family Heart Study GWA Data.** *P. An, M. Feitosa, M.A. Province, I.B. Borecki.* Division of Statistical Genomics, Department of Genetics, Washington University School of Medicine, St Louis, MO.

Variants of known type 2 diabetes (T2D) genes and the KEGG T2D (hsa04930) pathway genes were assessed for their association with T2D status in the NHLBI Family Heart Study (FHS). A total of 897 Caucasian family members including 14% T2D cases had phenotype and genotype data with up to 2.5 million typed and imputed SNPs in the FHS. A total of 4,944 SNPs covering 15 known T2D genes and 37 KEGG T2D pathway genes were assessed using logistic regression under an allele dosage model with generalized estimating equation to account for familial dependencies. Covariates in this analysis included age, age2, sex, and field center. $P<0.0055$ from a modified FDR approach was used to flag significance considering correlations of these genes and SNPs in the presence of prior knowledge these selected genes. Significant association was found in 5 genes that included 2 SNPs in *CACNA1C* (rs2108704, rs12426831, $p$= 0.0010), 28 SNPs in *IGF2BP2* (around rs4402960, $p$=0.0034), 1 SNP in *JAZF1* (rs6462063, $p$=0.0040), 2 SNPs in *TCF7L2* (rs4506565, rs7903146, $p$=0.0046, 0.0033, respectively), and 40 SNPs in *WFS1* (around rs5018648 including 2 coding SNPs rs1801206 and rs734312, $p$=0.0011, 0.0005, 0.0033, respectively). For risk of T2D, risk allele frequencies of these variants were 0.21-0.70, effect size estimates were <1.5%, and odds ratio point estimates were <1.6. Among the 28 emerged variants in this analysis, 3 exact SNPs (*IGF2BP2* rs4402960, *TCF7L2* rs4506565, and *WFS1* rs5018648) replicated reports in multiple large GWA studies. Mechanisms of these gene variants in raising risk of T2D are yet currently unknown. Taken together, this analysis reconfirmed effects of variants in *CACNA1C, IGF2BP2, JAZF1, TCF7L2,* and *WFS1* genes for risk of T2D. Survey of SNP*SNP and BMI*SNP interacting effects of these variants for risk of T2D is underway in the FHS cohort.

## 1936/T/Poster Board #485

**Heritability of Longevity in the Amish.** *K.L. Spencer[1], A.C. Davis[1], L. Jiang[1], R. Laux[1], P.J. Gallins[2], N. Schnetz-Boutaud[1], L.L. McFarland[1], D. Fuzzell[1], C. Knebusch[1], M. Creason[2], L. Caywood[2], C.E. Jackson[3], W.K. Scott[2], M.A. Pericak-Vance[2], J.L. McCauley[2], J.L. Haines[1].* 1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Miami Institute for Human Genomics, Miller School of Medicine, University of Miami, Miami, FL; 3) Scott & White, Temple, TX.

Purpose: Successful aging is a complex trait, influenced in part by genetic factors. Longevity, or age at death, is an important component of this phenotype. We set out to determine the heritability of age at death in an Amish population whose present-day members reside in Holmes County, Ohio and Elkhart and LaGrange Counties, Indiana. Because their lifestyle has remained consistent over the last few centuries, environmental variance is minimized, making this an ideal population for studying longevity. Methods: Using information from 2,988 individuals in a single Amish pedigree dating back to the 1700s, we estimated the heritability of longevity using the software program SOLAR, with and without considering gender as a covariate. We excluded individuals who died before age 30 to eliminate deaths due to childhood illnesses and accidents. Results: The average at death was 70.1 years (standard deviation=15.1 years, range=30 to 106 years). The unadjusted estimate of narrow sense heritability ($h^2$) was 0.13 and highly significant (p<1.0x10-12). Adjusting for gender did not substantially change the results ($h^2$=0.14, p<1.0x10-12). Conclusion: A significant portion of the variance underlying longevity in the Amish is heritable. Our heritability estimate was somewhat lower than a previous study of the Old Order Amish of Lancaster, Pennsylvania (Mitchell et al. 2001, $h^2$=0.25), though still consistent with a significant genetic effect. Given these data, the Amish represent a useful research population for gene discovery in longevity.

## 1937/T/Poster Board #486

**A new method for detecting IBD regions in multiple individuals: making disease mapping based on very few individuals possible.** *I. Moltke[1], A. Albrechtsen[2], T. van Overseem Hansen[3], F.C. Nielsen[3], R. Nielsen[4,5].* 1) Dept Biology, Univ Copenhagen, Denmark; 2) Dept Biostatistics, Univ Copenhagen, Denmark; 3) Dept Clinical Biochemistry, Rigshopitalet, Denmark; 4) Dept Integrative Biology, Univ California Berkeley, USA; 5) Dept Statistics, Univ California Berkeley, USA.

All individuals in a population are related if traced back long enough, which means that they will share regions Identical By Descent (IBD). The more distantly related the individuals are, the less they are likely to share. This makes it possible to detect regions containing disease causing genetic variants using seemingly unrelated affected individuals by identifying which region they share IBD. With today's easy access to genome wide SNP data a method for identifying IBD regions based such data is therefore highly desirable.

Here we present an MCMC method for detecting IBD regions among multiple individuals from a population sample. It is based on a probabilistic model applicable to un-phased SNP data which simultaneously models IBD sharing among chromosomes from multiple individuals. The new method can take inbreeding, allele frequencies, genotyping errors and genomic distances into account and it can detect IBD regions without any pedigree information. The simultaneous modeling of multiple chromosomes makes the method more powerful and accurate than existing methods that are all based on pairwise relatedness.

To demonstrate the potential of the method we have applied it to SNP chip data from five seemingly unrelated individuals affected by Breast and/or Ovarian cancer. This allowed us to successfully map the disease causing founder mutation to a region of approximately 3 Mb containing the BRCA1 gene.

## 1938/T/Poster Board #487

**Estimation of the contribution of rare disease-predisposing variants to complex diseases.** *W. Guan, L.J. Scott, M. Boehnke.* Dept Biostatistics and Center for Statistical Genetics, Univ Michigan, Ann Arbor, MI.

In the recent years, a large number of genome-wide association (GWA) studies have been conducted on multiple complex diseases. However, most of the common risk variants identified through these studies make only modest contributions to disease risk. The rapid advance in the next-generation sequencing technologies allows a near-to-complete survey of the genomic regions of interest and better studies of rare disease-predisposing variants. A common strategy to test the association of the rare variants with disease of interest is to pool the variants within a gene or a region as a single unit. With the availability of familial samples, an alternative approach is to look for co-transmission of disease with the possible linked rare alleles. Through analytically calculations and computer simulations, we have computed the power of such a linkage-based test given different numbers of linked disease-predisposing variants, assuming all these variants have very low allele frequencies but complete or high disease penetrance. We hope our results can help to understand the reality of the common diseases, rare variants assumption and its impact on the analyses of re-sequencing data that will be inexpensively available soon.

## 1939/T/Poster Board #488

**Developing SNP content for the Affymetrix next-generation whole-genome mapping panel.** *Y. Zhan, T. Asbury, S. Cawley, J. Gollub, E. Hubbell, G. Liu, R. Lu, Y. Lu, R. Mei, M. Moorhead, A. Pirani, M. Purdy, K. Schweighofer, A. Schweitzer, M. Shapero, T. Webster, L. Weng, A. Williams, J. Zheng, K. Jones.* Affymetrix, Inc. 3420 Central Expressway Santa Clara, CA 95051.

The flood of novel variants being discovered is fueling demand for an evolving suite of new genotyping panels to type these variants in a cost-efficient and high-throughput manner. In response to this need a new array-based system has been developed by Affymetrix, leveraging a new assay that combines the sensitivity of hybridization with the specificity of ligation and resulting in a high-performance next-generation genotyping technology.

This new assay has been used on a diverse panel of 1300 samples to screen variants from dbSNP build 129, including many variants from the 1000 genomes project and with good representation of rare alleles. The resulting database of validated variants is a resource from which multiple panels can be derived - either “top-up” panels to extend the coverage of previously-conducted Genome Wide Association Studies, or stand-alone panels optimizing coverage of common and rare variants for use in new studies.

We describe the process of the SNP screen and illustrate how an initial SNP panel is designed from the validated content using an algorithm that optimizes for a combination of technical performance and genetic coverage in a variety of populations and SNP categories.

## 1940/T/Poster Board #489

**Systematic comparison of haplotype inference error across diverse populations.** *K.A. Drake[1,2], J. Brooks[2], K. McKeown[2], A. Olson[2], E. Ruark[2], E.G. Burchard[1].* 1) University of California- San Francisco, San Francisco, CA; 2) University of California- Berkeley, Berkeley, CA.

Haplotypes are most commonly inferred using statistical methods. Each method has an intrinsic error rate. A systematic comparison of the method-specific error rate across populations has not been performed to date. Admixture and differences in patterns of linkage disequilibrium (LD) may cause haplotype inference error to vary across populations. We sought to determine how the error rate, the proportion of incorrectly inferred haplotypes out of all ambiguous haplotypes, differed across four HapMap populations and to identify unique characteristics of haplotype regions that were predictive of error. Trio data for each population was used to deduce true haplotypes in 100 haplotype regions of 20 kilobase pairs each that were randomly sampled from chromosome 1. Haplotypes were inferred separately on the unrelated founders and unrelated offspring using four methods (PHASE, Beagle, Shape-IT, and fastPHASE). The true haplotypes were compared to the inferred haplotypes to calculate the error rate for each population and method. The error rate was highest in the Maasai, followed by the Yoruba, Mexicans, and Europeans for all methods. Beagle had a much higher error rate than the other methods for all populations. This was expected because Beagle is sensitive to small sample sizes like those in the HapMap populations. Regions with high error were similar across both methods and populations. The error rate was compared in the founders and offspring for each population and method to examine the effect of sample size on error. The smaller offspring group had a higher error rate than the larger founder group for most of the populations and methods. However, in the Mexican population the error rate was similar in the founders and offspring for all of the methods except Beagle. Random forest identified LD and number of heterozygous SNPs as the most predictive factors for error, although several other features were also predictive of error. These results demonstrate that there are differences in haplotype inference error across populations with varying admixture and LD patterns. This difference in error may result in differences in the results of genetic association studies using haplotypes across populations.

## 1941/T/Poster Board #490

**Investigation of maternal effects, maternal-foetal interactions and parent-of-origin effects (imprinting), using mothers and their offspring.** *H. Cordell, H. Ainsworth, J. Unwin.* Newcastle University, Newcastle upon Tyne, United Kingdom.

Many complex genetic influences, including epigenetic effects, may be expected to operate via mechanisms in the inter-uterine environment. A popular design for the investigation of such effects, including effects of maternal genotype and maternal-foetal interactions, is to collect DNA from affected offspring and their mothers. This design can also be used for the investigation of parent-of-origin (imprinting) effects, although greater efficiency may be achievable via the additional collection of DNA from fathers, where possible. Here we propose a novel multinomial modelling approach that allows the estimation of complex genetic effects of this type using data from either case/mother duos or case/parent trios. Through the incorporation of additional assumptions (such as Hardy-Weinberg equilibrium, random mating and known allele frequencies) and/or the incorporation of additional control samples (such as unrelated controls, controls and their mothers, or both parents of controls), we show that the parameters of interest are identifiable and well-estimated by our method. We investigate the required sample sizes and data structures necessary to provide accurate estimation of such effects and high power for their detection. Our method is illustrated by application to data on several candidate genes involved in congenital cardiovascular malformation.

## 1942/T/Poster Board #491

**Mining the Information Content of Natural Variation in Health Disparity Research.** *T.E. Mason[1], L. Ricks-Santi[1,2], J. Lindesay[3], P. Kurian[3], W. Hercules[3], G.M. Dunston[1,4].* 1) National Human Genome Center, Howard University, Washington, DC; 2) Howard University Cancer Center, Washington, DC; 3) Department of Physics, Howard University, Washington, DC; 4) Department of Microbiology, Howard University, Washington, DC.

Background: The most challenging problem confronting human geneticists today is deciphering how information is stored and communicated in DNA. The science of information theory developed by physicist Claude Shannon may be applicable to deciphering the "information content" (IC) encoded in the patterns of DNA sequence variation associated with disease in individuals and populations. Advances in sequencing the human genome, taken together with the construction of high density haplotype maps provide unique tools for testing a mathematical measure of IC in the human genome. Methods: We mined the IC of haplotypes associated with immunoresponsiveness in host adaptation to the environment by modifying Shannon's general equation for calculating entropy to measure the IC present in haplotype blocks of the human major histocompatibility complex (HLA-DR region). Since haplotype block composition varies in SNP count, we derived a normalization factor and the normalized information content (NIC) was calculated for the haplotype blocks constructed by Haploview v4.2. Genotype data was obtained from the Hap Map Phase 3 study population of African Americans from the southwest United States. The NIC scores were graphed to assess their distribution and outliers were identified. To determine the potential biomedical significance of IC we scanned the outliers for regulatory elements via ConSite. Results: The NIC scores for the region analyzed were uniformly distributed between zero and one, with a mean of 0.6133 (SD=0.1287; SE= 0.0094). Five blocks had NIC scores < 0.3624. Of the eleven SNPs in these blocks, two were in introns of the gene FOXC1 with the other nine in intergenic regions. Thirty-four putative transcription factor binding sites (TFBS) were identified and categorized for the five blocks, with the associated transcription factors having established correlations with known health disparities. Conclusion: The application of a mathematical method for measuring the information content of haplotype variation is intriguing and may provide a useful tool for understanding the role of biophysical information in dissecting the biology of disease.

## 1943/T/Poster Board #492

**Base calling for Resequencing Chips.** *W. Wang[1,2], P. Shen[1], M. Yu[1], S. Lin[3], T. Klopstock[4], R. Horvath[5], C. Palm[1], L. Pique[6], I. Schrijver[6], D. Cutler[7], M. Mindrinos[1], R. Davis[1], T. Speed[2], C. Scharfe[1].* 1) Stanford Genome Tech Ctr, Stanford Univ, Palo Alto, CA, USA; 2) Dept of Statistics, UC Berkeley, Berkeley, CA, USA; 3) Illumina Inc., San Diego, CA, USA; 4) Dept of Neurology, Ludwig Maximilians U., Munich, Germany; 5) Friedrich-Baur-Institute, Ludwig Maximilians U., Munich, Germany; 6) Dept of Pathology and Pediatrics, Stanford U., Stanford,CA, USA; 7) Dept of Human Genetics, Emory U., Atlanta, GA, USA.

Resequencing candidate genes for rare DNA variants with a minor allele frequency (MAF) of <0.05 across many medical cases is essential to identify causal variants for genetic disorders. Medical resequencing (MRS) arrays, preceded by multiplex target amplification, provide a rapid and cost-effective way of performing this task. Previously developed base-calling algorithms for resequencing arrays can only achieve high accuracy at a low call rate (90-95%). We developed SRMA -- Sequence Robust Multi-array Analysis, for MRS arrays, to achieve higher accuracy, while calling the remaining 5% of the sequence. This algorithm first determines the possible variant sites (observed occurrence <1 in 1kb) and the candidate variant alleles, and then performs variant calling for all samples at the variant sites that could be common or rare SNPs. We formalize the statistical framework and present a procedure to perform candidate gene resequencing. We specifically address three practical concerns for resequencing arrays: 1) quality assessment of multiplex target amplifications; 2) variations in discrimination of reference and variant signals caused by experiments (i.e. average intensity, lab effects) and chemistry (i.e. base pair composition, GC content and fragment length) that are genotype specific; 3) no training data is available to estimate variant-specific parameters at most loci. We build on robust linear mixture models to address these issues. We also provide a quality score to indicate high-confidence base-calls, and a reliability score to identify probes showing insufficient discrimination between reference and variant signals. We have used SRMA to resequence approximately 4Mb of DNA corresponding to the exons of 39 candidate nuclear genes for hereditary optic neuropathies (Mitochondrial diseases) in 40 individuals. As compared to the Sanger sequence, we obtained a false positive rate of approximately 1 in 50,000 bp and a false negative rate of approximately 10% (FDR=3%), with a 99.99% call rate. These efforts represent key steps towards our goal of performing effective candidate gene resequencing of human diseases.

## 1944/T/Poster Board #493

**An Epidemiological Study on Welders Exposed to Fumes Containing Nickel and Chromium to Evaluate Genotoxic Occupational Hazard of Welding.** *S.S. Chettiar, A.R. Patel, M.V. Rao.* Zoology Department, Human Cytogenetics Division, Gujarat University, Ahmedabad, Gujarat, India.

Purpose: Large occupational groups, such as welders are currently exposed equally to high levels of Nickel and Chromium and may therefore be at increased degree of health risk. A retrospective exposure assessment of welding fumes containing chromium and nickel was conducted at industrial development areas around Ahmedabad, India for a nested case-control study with welders. Methodology: Peripheral blood was collected from these individuals after obtaining written consent and subjected to DNA damage analysis. Chromosomal aberrations (CA), Cytoknesis blocked micronucleus assay and single cell gel electrophoresis assay (comet assay) were studied as biomarker for genotoxicity. Estimation of Cr and Ni content was done in whole blood by inductively coupled plasma atomic emission spectrometry (ICPAES), which revealed welders had higher Cr and Ni content when compared with controls. Complete blood profile was also undertaken in the welders. Chromosomal aberrations were scored by totaling the chromatid breaks and gaps as well as chromosomal break and gaps. The Comet assay was carried out to quantify basal DNA damage. The mean comet tail length was used to measure double strand breaks and tail moment was measured for single strand breaks. Results and Conclusion: The results indicated that the welders had a larger mean comet tail length than that of the controls ($p<0.001$) and increased CA. Frequency of micronucleus was significantly ($p<0.01$) increased in welders when compared to unexposed individuals. Analysis of variance revealed that occupational exposure ($P < 0.05$) had a significant effect on DNA damage, whereas smoking and age had no significant effect on DNA damage. The current study suggested that degree of DNA damage is directly dependent on duration of exposure to Cr and Ni in ambient air and drinking water at workplaces.

## 1945/T/Poster Board #494

**Genome-wide Screening for alternative Otosclerosis Gene Loci.** *R. Birkenhäger, N. Lüblinghoff, K. Pohlmann, E. Prera, M. Petridi, R. Laszig.* Department of Oto-Rhino-Laryngology, Head and Neck Surgery, University Medical Center Freiburg, Killianstrasse 5, D-79106 Freiburg, Germany.

Background: Otosclerosis is one of the most frequent reason of hearing loss in adults and is caused by abnormal bone homeostasis of the otic capsule that leads to bony fixation of the stapedial footplate in the oval window. Impaired ossicular chain mobility results in a conductive hearing loss. In about 10% of all cases, an additional cochlear component develops, which represents most likely the encroachment of otosclerotic foci on the labyrinthine capsule that leads to a mixed or sensorineural hearing loss (SHL). The etiology of otosclerosis is unclear, although several hypotheses implicate genetic, viral, immunological, hormonal or endocrine factors. Epidemiological studies have indicated autosomal dominant inheritance with variable and reduced penetrance. So far seven loci (OTSC1-5, 6 & 7) for otosclerosis have been described, located on chromosomes 15q, 7q, 6p, 16q, 3q and 6q, but none of the genes have been identified. An alternative genetic approach, candidate-gene association studies, suggest modestly evidence that the genes COL1A1,COl1A2, COL2A1 and TGFβ1 contribute to disease development. Recently a genome-wide analysis identified single nucleotide polymorphisms (SNP) in the RELN gene associated with otosclerosis. In this study we performed a whole genome haplotype analysis of a large familiy to identify novel or verify known OTSC loci. Additionally we have accomplished SNP analysis in a German population at the TGFβ1 and RELN gene loci. Methods: All patients considered for this project had a proven otosclerosis and underwent stapes microsurgery. The familiy used for the genome-wide screen is a large South-East European family with 52 members (18 affected). The genome-wide haplotype analysis was applied using the Affymetrix 500 K SNP-Array. For SNP analysis at the TGFβ1 and RELN gene loci 329 patients, mainly of a German population, and a case control group were used. For statistical analysis the Bonferonni correction was used. Results: With the genome-wide haplotype analysis of a large family with 18 affected members it was possible to identified alternative gene loci for otosclerosis. SNP analysis in a German population showed in contrast to the literature no significant association to the TGFβ1 loci. Conclusion: Genetic factors play a significant role in the etiology of otosclerosis. Identification of these genes could lead to substantial improvements in the ability to diagnose and possibly even prevent this type of hearing impairment.

## 1946/T/Poster Board #495

**Auditory and Genetic Characterization of a Large American Pedigree with Inherited, Progressive, Post-lingual, Sensorineural Hearing Loss.** *V. Street[1], E. Thilo[2], P. Strombom[3].* 1) Bloedel Hearing Res Ctr, Univ Washington, Seattle, WA; 2) Neurobiology Program, Dept of Biology University of Washington Seattle,WA; 3) School of Medicine Tufts University Boston, MA.

Large families with monogenic non-syndromic hearing loss have allowed the mapping of at least 100 auditory related deafness (DFN) chromosomal loci. These loci have greatly enhanced our understanding of how the cochlea functions when receiving information during normal and pathogenic states. Here, we characterize the auditory and genetic features of a large American pedigree (referred to as the HL4 family, HL for hearing loss) segregating the autosomal dominant trait of progressive, post-lingual, sensorineural hearing loss that first impacts the higher auditory frequencies. Members of the HL4 family begin to notice hearing loss in their late teens to early twenties. In general, similarly-aged HL4 family members have comparable audiogram contours. To appreciate more fully the rate of hearing loss in the HL4 family with each decade of life, an audioprofile was constructed. Audiogram data for 21 affected individuals was plotted in Excel as level of hearing loss versus age with each frequency representing a unique data set. Using the trend line graph feature, best-fit regression lines were fit to the data. Equations of these regression lines were used to calculate expected hearing loss for ages 10-70 in ten year steps. These predictions were then plotted as hearing loss versus frequency with each line representing a different age group. The downward sloping audiogram configuration seen in affected HL4 family members shares features with audiograms for hearing impaired families with mutations in the DFNA2 (KCNQ4), DFNA5, and DFNA20/26 (ACTG1) loci/genes. Using 31 DNA samples from the HL4 family, linkage to DFNA 2, 5, and 20/26 were tested and excluded. Linkage has also been excluded to chromosomes 1, 5, 6, 7, 8, 17, and 18 representing approximately 36% of the genome.

## 1947/T/Poster Board #496

**SNPsniffer: Mining for gene candidates in the "genetic" vicinity of SNPs associated with disease.** *K. Elliott.* Wellcome Trust Centre Human Genetics, University of Oxford, United Kingdom.

The raft of recent genome wide association studies has identified hundreds of SNPs associated with common human diseases. However, only a small fraction of these have been proven to be the functional variants giving rise to disease. Many publications detailing potential candidate genes in the vicinity of these SNPs will report the most proximal gene which is not necessarily the best candidate or likely contain the associated functional variant. Given that linkage disequilibrium (LD) may extend for 100s of kb the functional variant giving rise to the association signal may affect a gene that is some distance away and several genes removed from the signal SNP. To complicate matters further functional elements controlling gene expression may be 100ks of kb away. An example is the region of LD surrounding the type 2 diabetes associated SNP rs5015480 which contains two compelling candidate genes, HHEX adjacent to the SNP and IDE which is 2 genes away. This type of scenario lead to the development of a tool, SNPsniffer, which provides an informed assessment of the LD structure of the region surrounding SNPs and the genes harboured within. This tool defines the region +/- 0.1 cM of the associated SNP which has an 85% likelihood of containing the linked functional variant (assuming the SNP follows HapMap reported patterns of LD). 50kb flanks are added to allow for close-by genes that may have regulatory variants within this region (eQTL studies suggest >90% of functional variants fall within the gene plus 50kb flanking regions). For each of the genes in the region the program interrogates information from NCBI's Gene, OMIM, PubMed, UniGene, HomoloGene, BLAST and Jackson's MGI databases, using a list of weighted disease-specific keywords, and a disease relevance score is generated. The output generated is in easily navigable HTML pages with positions of 0.1 cM boundaries and the SNP relative to surrounding genes. Of the 207 SNPs assessed, an average of 6.4 genes were found to be within the region defined by the tool and where there was more than one gene, 67% of genes flanking or spanning the SNP were not the best functional candidate as scored by the program. SNPsniffer provides a useful visualization of functional neighbourhood of the gene in the context of LD architecture and will provide researchers with important information in selecting SNPs for further study and reporting the functional candidacy of SNPs associated with disease.

## 1948/T/Poster Board #497

**A novel locus for autosomal dominant Retinitis Pigmentosa (RP35) in a family of German origin.** *Q. Prescott[1], C. Chakarova[1], A. Shah[1], N. Waseem[1], E. Zrenner[2], S. Bhattacharya[1].* 1) Dept of Genetics, Inst Ophthalmology, London, United Kingdom; 2) Molecular Genetics Laboratory, Institute for Ophthalmic Research, Centre for Ophthalmology, University Tübingen, Tübingen, Germany.

Purpose: To map a novel locus for autosomal dominant Retinitis Pigmentosa (adRP) and to identify the disease causing gene using a large three generation family of German origin. Methods: 17 individuals (7 affected, 9 unaffected members and one spouse) from the family underwent standard ophthalmological evaluations at the Institute for Ophthalmic Research, Tubingen, Germany. All previously known loci for adRP were excluded using two microsatellite markers flanking the disease gene at each locus. In parallel, a DNA of one affected individual was loaded on ASPER Chip for direct detection for known adRP mutations. Finally we undertook further linkage analysis by hybridizing all family DNAs to 50K Affymetrix SNP arrays. The genotypes were assigned after quality control screening with Affymetrix Genotyping Consol 3.0.2. Erroneous genotypes were cleaned with Alhomora and Pedcheck. Results: The data was analyzed with Genehunter using two point analysis between the disease and marker locus. Several regions with reasonably high LOD scores (approaching 3.00) were obtained. Given the size of the family a near maximum LOD score of 2.99 ($\theta$=0) was obtained at a novel locus in the human genome. This was confirmed with corresponding ABI Microsatellite markers from that region. Additional SNP analysis narrowed down the critical interval to 5.4 Mb. Additional families with adRP tested for linkage to this locus could not further refine the region. Conclusion: We have identified a family with autosomal dominant Retinitis Pigmentosa that clearly demonstrates the presence of a new RP locus in the human genome (RP35). Further investigation will use NimbleGen Sequence capture services where 5.4 Mb of selected region will be enriched for next generation sequencing on the ABI SOLiD sequencing platform. To evaluate this new approach a known TOPORS mutation (c.2474_2475insA) in a patient DNA will be used as a positive control. Detailed confirmation and characterization of any mutation found will be checked for segregation in this RP35 family and against ECCAC panels of normal controls.

## 1949/T/Poster Board #498

**Mucolipidosis IIIA in a Chinese family associated with GNPTAB mutation.** *T. Zhan, X. Cui, Y. Liu, J. Zhang, Q. Wang, M. Liu.* Center for Human Genome Research and College of Life Science and Technology, Huazhong University of Science and Technology, Wuhan, Hubei, China.

ML III alpha/beta (ML IIIA, OMIM 252600), one of the lysosomal storage diseases, is also known as autosomal recessive inherited disease caused by absence or reduction of lysosomal enzyme N-acetylglucosamine-1-phosphotransferase (GlcNAc -phosphotransferase, GlcNAc-PT), result in the abnormal of the enzymes entry the lysosomal. GlcNac-1-phosphotransferase exists as a heterohexamer comprising three subunits, $\alpha/\beta$ encoded by GNPTAB and $\gamma$ encoded by GNPTAG, respectively. The $\alpha$ /$\beta$ subunits contain the catalytic site of the enzyme and are encoded by the GNPTAB gene. Mutations in the GNPTAB gene can cause ML IIIA. In this report, we identified and characterized a four-generation Chinese family, in which 4 patients display symptom of Mucolipidosis. Linkage and haplotype analysis mapped the disease gene of this Chinese family to chromosome 12 with a maximum LOD score of 2.64 at marker D20S112, where GNPTAB habored. DNA sequence for the whole coding region and exon-intron boundries of GNPTAB revealed compound heterozygous mutations in the family, a splicing mutation IVS13+1G>A (c.2715+1G>A), and a novel nonsense mutation p.R364X (c.1090C>T). All 4 patients in the family carry both of the GNPTAB mutations. The novel p.R364X mutation did not exist in unaffected family members and 226 normal controls. The IVS13+1G>A (c.2715+1G>A) mutation causes skipping of exon 12 directly onto exon 14 due to a deletion of 1103bp of exon 13 as previous reports, while p.R364X truncates the protein in the $\alpha$-subunit, yielding truncated $\alpha$-subunit and no $\beta$ -subunit of GNPTAB. This study is the first report that compound heterozygotes of mutations in GNPTAB may cause MLIIIA in Chinese and it expands the spectrum of mutations in GNPTAB causing MLIIIA. Further studies for the two mutations might help to understand the function of GNPTAB, and the relationship between GNPTAB mutations and the phenotypes of this disease.

## 1950/T/Poster Board #499

**Mapping a gene for Chiari I malformation in a single family: the identification of candidate haplotypes.** *D.A. Dyment[1], J. Parboosingh[1], L. Maclaren[1], J.N. Scott[2], B. Fernandez[3], A.M. Innes[1].* 1) University of Calgary, Calgary, Alberta, Canada; 2) Department of Diagnostic Imaging, University of Calgary, Calgary, Alberta; 3) Department of Medical Genetics, University of Memorial, St. Johns, Newfoundland.

Chiari I malformation (CM1) is the caudal displacement of the cerebellar tonsils >5mm past the foramen magnum. CM1 is thought to arise from a mesodermal defect during the development of the posterior fossa. There have been reports of families with multiple affected individuals as well as monozygotic twin pairs concordant for CM1 suggesting heritable forms of the condition. In addition, CM1 is seen repeatedly in association with several genetic syndromes including connective tissue disorders, disorders of the RAS pathway and craniosynostosis syndromes. Individuals with cytogenetic imbalances also have been reported with CM1. A naturally occurring animal model exists as CM1 is frequent in King Charles Cavalier spaniels. Despite this, no genes have yet been identified to cause non-syndromic CM1. We present a 3 generation family segregating isolated CM1 as an autosomal dominant disorder with incomplete penetrance. There are 10 individuals affected with CM1 (cerebellar tonsils >5mm) and another 3 cases with borderline CM1 (cerebellar tonsils 3-5mm). Twenty-three family members were genotyped for 6081 SNP's across the genome. A non-parametric analysis in a subset of the pedigree showed multiple regions with evidence for linkage LOD>2 and one region with significant linkage; LOD=3.55 at chromosome 19p12. The identification of the putative CM1 gene would further our understanding of the development of the posterior fossa and provide valuable information to CM1 patients and their families.

## 1951/T/Poster Board #500

**Genome-wide Linkage Analyses of Hereditary Prostate Cancer Families with One or More Members with Colon Cancer Provides Further Evidence for a Prostate Cancer Susceptibility Locus on 15q13-q14.** *L.M. FitzGerald[1], S.K. McDonnell[2], E.E. Carlson[2], W. Langeberg[1], L.M. McIntosh[1], K. Deutsch[3], L. Hood[3], E.A. Ostrander[4], D.J. Schaid[2], J.L. Stanford[1,5].* 1) Prostate Cancer Studies, Fred Hutchinson CRC, Seattle, WA; 2) Division of Biostatistics, Mayo Clinic, Rochester, 55905, USA; 3) Institute for Systems Biology, Seattle, 98103, USA; 4) Cancer Genetics Branch, NHGRI, National Institutes of Health, Bethesda, 20892, USA; 5) Department of Epidemiology, School of Public Health, University of Washington, Seattle, 98195, USA.

The search for susceptibility loci in hereditary prostate cancer (HPC) has proven challenging due to genetic and disease heterogeneity. One method used to increase genetic homogeneity is to stratify family collections based on the occurrence of other cancers. This method has the advantage of not only increasing the likelihood of detecting prostate cancer susceptibility loci, but may also identify loci with pleiotropic effects. We have identified and performed linkage analyses on members of 100 HPC families with one or more first-degree relatives with colon cancer. Pedigrees were stratified into families with one or more colon cancer case (n=100) and families with two or more colon cancer cases (n=28). These subsets were analyzed for 'prostate cancer' and 'prostate or colon cancer'. When analysed for 'prostate cancer', suggestive evidence for linkage (LOD≥1.86) was identified at 11q21, 18q21 and 19q13 in families with one or more colon cancer cases, and at 1p34, 15q13-q14 and 19q13 in families with two or more colon cancer cases. When analysed for 'prostate or colon cancer', suggestive evidence for linkage was identified at 11q21-q25, 15q14 and 18q21 in families with one or more colon cancer cases, and at 11q14, 13q32, 15q14 and 21q22 in families with two or more colon cancer cases. Stronger evidence for linkage was identified at 15q14 when analysing the 'prostate cancer' (recessive HLOD=3.33) and the 'prostate or colon cancer' (recessive HLOD=3.74) phenotypes in families with two or more colon cancer cases. The results presented here provide further suggestive evidence for prostate cancer susceptibility loci on chromosomes 11q14, 15q13-q14 and 19q13 and highlight loci at 11q21, 15q13-q14 and 18q21 as having possible pleiotropic effects. This study demonstrates the benefit of utilizing a comprehensive family history of other cancers to create more genetically homogenous collections of HPC pedigrees for linkage analyses.

**Unraveling the LD Association Signal in a GWA Study of Lung Cancer.** *P. Scheet, M.R. Spitz, C.I. Amos.* Epidemiology, M. D. Anderson Cancer Center, Houston, TX.

Initial findings from genome-wide association (GWA) studies conducted in European samples may produce broad association signals, covering multiple major loci. Here we attempt to tease apart the linkage disequilibrium (LD) signal from one such study of lung cancer. The initial GWA study was conducted on 1,154 cases and 1,137 controls, all of European descent, from which an association peak was discovered on 15q25. To further refine the signal, 34 SNPs from this region were measured in 870 African American samples. A strongly associated SNP (rs16969968) in the region is fixed in African populations. One haplotype group strongly differentiates the cases and controls, and rs16969968 exists on 60% of these haplotypes. Here, we investigate the following potential sources of association signal: large segments of European ancestry in chromosomes from African American sample; a haplotype common in individuals of European ancestry; and additional SNPs in the region (typed or untyped). To do so, we use a model for haplotype variation and imputation-based LD mapping to condition on these various sources and look for residual effects.

## 1953/T/Poster Board #502

**Genome-Wide Linkage Scan for Prostate Cancer Susceptibility in Finland: Evidence for Novel Loci on 4q13, 14q32 and 15q26 and confirmation of signal on 17q21-22.** *T. Wahlfors[1], A. George[2,3], H. Nati[1], C. Simpson[2], C.D. Cropp[2], T. Tammela[4], J. Bailey-Wilson[2], J. Schleutker[1].* 1) Institute of Medical Technology, University of Tampere and Tampere University Hospital, Tampere, Finland; 2) National Human Genome Research Institute, National Institutes of Health, Baltimore, Maryland; 3) Fox Chase Cancer Center, Philadelphia, Pennsylvania; 4) Department of Urology, Tampere University Hospital, University of Tampere, Tampere, Finland.

Prostate cancer (PRCA) genome-wide-linkage (GWL) studies have been used to localize rare and highly penetrant cancer susceptibility genes. Linkage studies performed in different ethnic backgrounds and populations have been somewhat disparate, resulting in multiple, often irreproducible signals because of genetic heterogeneity and high sporadic background of the disease. Our first GWL (GWL-I) study identified two novel loci with just 10 analyzed families. Here, we conducted a second genome-wide linkage (GWL-II) scan with 413 microsatellite markers in 44 new Finnish prostate cancer families. All GWL-II families had at least three affected individuals per family and had not been previously analyzed.. GENEHUNTER-PLUS was used for parametric and non-parametric GWL-II analyses. Additionally, to further dissect the linked loci, detailed clinical information was used in an Ordered Subset Analysis (OSA). The results of our GWL-II study provided evidence of linkage to sites on 15q26, 4q13, 17q21-22, and 14q32. OSA analyses provided increased evidence of linkage to 17q21-22, 15q26, and 4q24. Next we analyzed the combined GWL-I and GWL-II families. We also analysed a subset of families from GWL-I and GWL-II with at least two aggressive PRCA patients who were not a parent-offspring pair. The combined GWS-I/GWS-II analysis gave evidence of linkage to nine HPC linkage peaks; namely 17q21-22, 10q22, 14q32, 4q22-23, 4q25, 3q25-26.3, 15q26, 13q34, 6q12-16. Genome-wide multipoint analysis using GENEHUNTER-PLUS gave the highest HLOD score of 3.62 ($\alpha$=0.9191) at markers on 17q21-22 with a corresponding maximum NPL score of 2.92 (p=0.002) and homogeneity multipoint LOD = 3.61 at the same location. These results are noteworthy since linkage to this region has been previously observed and reported in studies of various populations. Subset results of “aggressive” pedigrees demonstrated lower evidence of linkage than when all families were analyzed together. Fine-mapping analysis of these linked regions is ongoing and will be performed using TaqMan® OpenArray Genotyping System. Furthermore, candidate genes in top ranked linked loci are currently under analysis.

## 1954/T/Poster Board #503

**A novel locus for autosomal dominant cone-rod dystrophy in a family of Gypsy origin.** *K. Kamenarova[1], S. Cherninkova[2], Q. Prescott[3], M. Romero Durán[1], A. Krishna[1], L. Valdés Sánchez[1], A. Oscar[2], R. Kaneva[4], I. Kremensky[4], C. Chakarova[3], I. Tournev[5], S. Bhattacharya[1].* 1) Department of Cellular Therapy, CSIC CABIMER, Seville, Seville, Spain; 2) Department of Neurology and Ophthalmology, University Alexandrovska Hospital, Sofia, Bulgaria; 3) Department of Genetics, Institute of Ophthalmology, UCL, London, UK; 4) Molecular Medicine Center, Medical University-Sofia, Sofia, Bulgaria; 5) Department of Neurology, University Alexandrovska Hospital, Sofia, Bulgaria.

**Methods:** 16 individuals (6 affected, 8 unaffected members and two spouses) from the family underwent standard ophthalmological evaluations at the Department of Neurology and Ophthalmology, University Alexandrovska Hospital, Sofia, Bulgaria. The phenotype was analyzed as an autosomal dominant trait with complete penetrance (0.9990) and a frequency of 0.0001. All previously known loci for adCRD were excluded using two microsatellite markers flanking the disease gene and at least one inner for each locus. This was followed by a genome-wide scan using microsatellite markers (ABI PRISM ® Linkage Mapping Sets V2.5). The data were used to calculate the LOD scores using the program MLINK for two point analysis. To create the haplotypes the data were converted for Genehunter and the erroneous genotypes were cleaned by Pedcheck. The software searched for the common regions shared between the affected individuals in the family and evidence for linkage to a genome interval was obtained. **Results:** The genome-wide search led to the identification of several regions with positive LOD scores approaching 1.5 and only one region gave a LOD score of 2.40 ($\theta$ = 0.0). All affected individuals shared a common haplotype when tested with a number of microsatellite markers spanning the linked region. This tentatively defines a novel locus for adCRD in the human genome. SNP analysis narrowed down the critical interval to 7.2 Mb. Several candidate genes within the tentatively linked region were screened for mutations by direct sequencing but so far no changes that segregate with the disease have been found. **Conclusion:** We have identified a family with autosomal dominant cone-rod dystrophy that is strongly suggestive for a new adCRD locus in the human genome, and is the only locus for adCRD known to map in this region. There are 45 genes in the critical interval that remain to be sequenced to identify the pathological change that cause this type of adCRD.

## 1955/T/Poster Board #504

**The Hunt for the Causative Gene in the *GLC1B* Locus.** *R. Sharafieh[1,2], A. Child[2], M. Sarfarazi[1].* 1) University of Connecticut Health Center, Farmington, CT; 2) St. George’s, University of London, London, U.K.

Purpose: The original *GLC1B* locus was mapped to the 2p11.2-q12.2 region, flanked by D2S2161 (2p11.2) and D2S176 (2q12.2) markers. Since then, other groups have confirmed and may have additionally reduced the area of interest to 2q11-q12, between markers D2S1381 and D2S176, a 6.66Mb region harboring a total of 37 genes. We utilized association studies to narrow down the number of genes to be screened in hopes of finding the putative gene(s) responsible for primary open-angle glaucoma (POAG) within the *GLC1B* region. Methods: Highly polymorphic SNP markers from the 37 candidate genes were selected using the Hapmap database. SNP genotyping was carried out with the ABI-SNaPshot Multiplex System and direct DNA sequencing was performed on an ABI-3100 machine employing 380 British subjects (190 POAG and 190 normal controls). Genotypic data was calculated for all subjects and statistically evaluated with SNP-STAT and PLINKS programs. Finally, genes with significant association were chosen for gene screening using sequence specific primers flanking the intron-exon boundaries for PCR amplification and direct DNA sequencing. Results: A two stage approach was implemented for gathering the genotypic data. The detection phase used 95 POAG subjects that included 30 probands from families with prior consistent linkage to the *GLC1B* locus. Our initial statistical analysis showed that genotypic or allelic association studies were significant for 10 of the 37 genes investigated. The authentication phase used an additional 95 POAG and a total of 190 matched normal control subjects. These 380 subjects were genotyped for SNP markers mapping to 6 of those genes (*RNF149, CREG2, IL1RL1, TBC1D8, C2orf29, PDCL3*). From this new round of case/control association study, rs13151 in the *RNF149* gene showed statistically significant (p=0.0077; OR=1.75). We sequenced this gene in 98 POAG families and observed 19 variations. The only sequence change in exon-1 (N139S) did not segregate in the two original families identified in. Selection of other SNP markers from other areas of these 37 genes and generation of their genotypic data in the same group of POAG and normal subjects are planned for the near future. Conclusions: Merging analysis of genetic linkage data with targeted gene association studies may accelerate in the identification of potential genes for a large candidate region. The application for this method in the *GLC1B* locus is being further investigated.

## 1956/T/Poster Board #505

**Replication of *MTNR1B* polymorphism with fasting glucose in Hong Kong Chinese population.** *C. Tam, J. Ho, W. So, R. Ma, J. Chan.* Department of Medicine and Therapeutics, The Chinese University of Hong Kong, Hong Kong, China.

***Background***: Recent genome-wide association studies in European populations suggest that melatonin receptor 1B (*MTNR1B*) gene located on chromosome 11q21-q22 is strongly associated with fasting glucose concentrations and glucose-stimulated insulin secretion, as well as predicts future type 2 diabetes (T2D). *MTNR1B* encodes one of the two high-affinity G-protein-coupled receptors for the pineal gland hormone melatonin which had previously been suggested to be involved in pathogenesis of T2D. In this study, we aim to replicate the association of the common *MTNR1B* rs10830963 polymorphism with extensive metabolic traits in Hong Kong Chinese population.

***Methods***: The single nucleotide polymorphism was genotyped in 583 adults [age mean ± SD = 41.4 ± 11 years, % males = 45] and 1065 adolescents [age mean ± SD = 15.4 ± 2 years, % males = 46] that participate in a health screening program. Associations of rs10830963 at additive model with metabolic traits including body mass index (BMI), systolic and diastolic blood pressure, lipids (total cholesterol, triglyceride, HDL, LDL) as well as fasting glucose were assessed by linear regression adjusted for covariates age and sex.

***Results***: Based on our findings, the reported risk allele G of rs10830963 is consistently and significantly associated with an increased concentration of fasting glucose (P = 0.004, mean ± SD = 4.80 ± 0.38 mmol/l for GG carriers, 4.79 ± 0.38 mmol/l for GC carriers, 4.74 ± 0.38 mmol/l for CC carriers). However, we did not observe any association between rs10830963 and other metabolic traits.

***Conclusions***: In summary, our study support *MTNR1B* as a susceptibility locus influencing fasting glucose in Chinese population.

## 1957/T/Poster Board #506

**Analysis of copy number changes in Aicardi syndrome.** *N. Miyake[1], M. Kato[2], H. Saitsu[1], T. Mizuguchi[1], N. Matsumoto[1].* 1) Department of Human Genetics, Yokohama City University Graduate School of Medicine; 2) Department of Pediatrics, Yamagata University School of Medicine.

Aicardi syndrome [OMIM #304050] (AIC) is a congenital disorder characterized by the triads of agenesis of the corpus callosum, chorioretinal lacunae, and infantile spasms. The exact frequency of this disease is not known, but more than 450 cases have been already reported. AIC is considered as an X-linked dominant disorder, because almost all of AIC cases are female (supposedly male-lethal). It is very difficult to perform the linkage analysis which requires the pedigrees, because majority is sporadic and severely affected since birth with poor reproductive fitness. The causative gene has not been isolated even though the AIC gene was mapped to Xp22, based on a case showing de novo balanced 3/X translocation (46,X,t(X;3)(p22;q12)). Positional cloning from chromosomal abnormalities including copy number changes (CNCs) would be a practical approach for the AIC gene. In this study, we analyzed 23 Japanese AIC cases (2 male and 21 female) using Gene Chip Human Mapping 250K NSP1 Array (Affymetrics) to detect CNCs. CNCs were confirmed using FISH and /or quantitative PCR. Parental samples were also checked if available. We could not find any causative CNCs. Higher resolution arrays would be a next choice. All the following clinicians are highly appreciated for their participation to this work; Drs. Hirano S, Yoshikawa H, Abe S, Fujimoto S, Ando N, Shigetomo R, Suenaga N, Sugita K, Sudo A, Ono H, Akaboshi S, Tanaka R, Osaka H, Hirai S, Tokunaga Y, Inui T, Koshino S, Takahashi Y.

## 1958/T/Poster Board #507

**A genome-wide linkage scan for blood lipid phenotypes in the Khatri Sikh Diabetes Study (SDS).** *D.K. Sanghera[1,2], M.F. Begum[3], A. Mukerjee[4], S. Ralhan[5], G.S. Wander[5], N.K. Mehra[6], J.R. Singh[7], R.E. Ferrell[4], M.I. Kamboh[4], D.E. Weeks[3,4].* 1) Dept Pediatrics, Section of Genetics, College of Medicine, Univ Oklahoma HSC, Oklahoma, OK; 2) College of Pharmacy, Univ Oklahoma HSC, Oklahoma, OK; 3) Dept. Biostatistics, Univ Pittsburgh, PA; 4) Dept Human Genetics, Univ Pittsburgh, PA; 5) Section of Cardiology, Hero DMC Heart Instititute, Ludhiana, India; 6) Dept Transplant Immunology and Immuno-genetics, All India Institute of Medical Sciences and Research, New Delhi, India; 7) Center for Genetic Disorders, Guru Nanak Dev University, Amritsar, India.

In this investigation, we have carried out an autosomal genome-wide linkage analysis using robust score statistics to map genes for five quantitative traits of blood lipids including total cholesterol, high-density lipoprotein (HDL), low-density lipoprotein (LDL), very low-density lipoprotein (VLDL) cholesterol, and triglycerides in a unique family-based cohort from the Sikh Diabetes Study (SDS). A total of 870 individuals (526 male/344 female) from 321 pedigrees were successfully genotyped using 398 polymorphic microsatellite markers with an average spacing of 9.26 cM on the autosomes. A genome-wide linkage scan using QTL-ALL analysis revealed promising linkage signals with p-values ≤ 0.005 for total cholesterol, LDL cholesterol, and HDL cholesterol at chromosomes 5p15, 9q21, 10q21, 10p11, and 22q13. The most significant signal (p-value=0.0011) occurred at 10q21.2 for HDL cholesterol. We also observed linkage signals for total cholesterol at 22q13.32 (p-value=0.0016) and 5p15.33 (p-value=0.0031) and for LDL cholesterol at 10p11.23 (p-value=0.0045). Most of these identified regions in this Sikh population have been linked to lipid-related traits in previous studies and also contain other plausible candidate genes. Although these regions are not part of the loci detected for quantitative lipid traits by recent genome-wide association studies (GWAS) performed in Caucasians, convincing replication of these results from the findings of prior independent linkage studies suggests that these regions might contain novel susceptibility loci for serum lipids. Further denser and more informative genotyping in each of these regions would be important to discover functional loci influencing blood lipids. Our study represents the first large scale genome-wide effort to identify chromosomal regions with putative loci affecting lipid levels in a community of Khatri Sikhs from Northern India.

## 1959/T/Poster Board #508

**Linkage of epilepsy plus cleft lip syndrome to 14p11.2.** *D. Bai, J.N. Bailey, M. Tanaka, R.M. Durón, A.V. Delgado-Escueta.* Neurology, UCLA David Geffen School of Medicine & VA GLAHS, Los Angeles, CA.

Epilepsies are the most common neurological disorders worldwide, affecting approximately 50 to 100 million persons. Children of epileptic mother suffer from cleft lip with/without cleft palate (CL/P) more frequently than children of non-epileptic mother. Mothers of children with CL/P have a higher prevalence of epilepsy. Epilepsies associated with CL/P have been attributed mostly to teratogenic affects of antiepileptic drugs. We studied a four generation Caucasian family with both epilepsy and CL/P. Thirty family members (eight affected and 22 unaffected) participated in this study. Among eight affected members, five suffered from epilepsies, one was affected with both epilepsy and CL/P and two had only CL/P. Parents of both members with only CL/P had no epilepsy and no history of taking antiepileptic drugs. A genome wide linkage scan was performed with Marshfield standard 10 cM genome scan set 16 under an autosomal dominant model with 50 percent penetrance. We observed significant linkage to 14q11.2 (D14S742) with a LOD score of 3.36. Linkage was suggestive to 10p13 (D10S1430) with LOD score of 2.62, to 7p21.3 (GATA119B03, or D7S2200) with a LOD score of 2.21 and to15q12 (D15S1513) with a LOD score of 1.74. These findings provide evidence of significant linkage between epilepsy plus CL/P and 14q11.2. Results also support the hypothesis of epilepsy plus CL/P, as a syndrome, that shares common genetic susceptibility in early neuronal development. In clinical practice, in addition to looking for teratogenic affects of antiepileptic drugs, we should also pay attention to genetic factors underlying CL/P born from epileptic mother.

## 1960/T/Poster Board #509

**A novel locus for autosomal dominant non-syndromic hearing impairment, maps to chromosome 12q24.** *j. cheng, y. zhu, b. han, y. sun, j. li, d. han, p. dai, h. yuan.* Inst. Of Otolaryngology, Chinese PLA General Hospital, beijing, China.

Hereditary non-syndromic sensorineural hearing loss is a genetically highly heterogeneous group of disorders. To date, at least 60 loci for autosomal dominant non-syndromic sensorineural hearing loss (DFNA) have been identified by linkage analysis. Here we report the mapping of a novel autosomal dominant deafness locus at 12q24 by studying a large multi-generational Chinese family with post-lingual, high-frequency hearing loss that progresses to involve all frequencies. Onset of hearing loss in all affected subjects occurred in the second through fourth decade of life. Genomewide linkage analysis was then performed using Affymetrix Genome-Wide Human SNP Array 5.0. Linkage analysis was carried out under a fully penetrant autosomal dominant mode of inheritance with no phenocopies. Heterogeneity LOD (HLOD) analysis reveals the evidence of genetic heterogeneity for DFNA and evidence of linkage in a subset of the families to 12q24 (HLOD=5.656). Microsatellites markers was using for refined mapping and get a maximum two-point LOD score of 5.35 at theta=0 obtained for marker D12S76. Haplotype analysis placed the novel locus within a 5.63 cM genetic interval defined by markers D2S86 and D2S1612 without overlapping with the other identified DFNA loci. DNA sequencing of coding regions and exon/intron boundaries of candidate genes in this interval is being conducted to reveal disease-causing mutation in this family.

## 1961/T/Poster Board #510

**Genome-wide linkage analysis of sister pairs affected with uterine leiomyomata reveals locus on chromosome 3.** *S. Eggert[1], K. Huyck[4], P. Somasundaram[3], E. Stewart[5], A. Schnell[6], K. T.Cuenco[6], C. Morton[1,2,3].* 1) Department of Pathology, Harvard Medical School, Boston, MA; 2) Department of Pathology, Brigham and Women's Hospital, Boston, MA; 3) Obstetrics, Gynecology and Reproductive Biology, Brigham and Women's Hospital, Boston, MA; 4) Department of Pathology, University of Vermont, Burlington, VT; 5) Mayo Clinic, Rochester, MN; 6) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA.

Uterine leiomyomata (UL), commonly known as fibroids, are the most prevalent pelvic tumors in women. UL pose a major public health problem given their rate of prevalence (>70%) and symptoms (~20-25%) in women of reproductive age and their indication for >200,000 hysterectomies in the U.S. annually. A genetic basis for tumor development is supported by the observation of recurrent chromosomal aberrations. Further, analyses of ethnic predisposition, twin studies, and familial aggregation indicate a genetic component to UL predisposition, but no genome-wide study for heritable variants has been reported. A genome-wide SNP linkage panel was applied to 385 UL sister pair families, and a suggestive peak on chromosome 3 was detected by nonparametric linkage analyses (NPL = 3.08, rs954282). The genomic region of interest, as defined by NPL scores >2, extends 20 Mb (rs12629588 to rs11720298) and contains ~250 genes. This same region is also associated with height and age at first menarche, traits associated with UL. These findings concur with previous reports relating early menarche with shorter stature and increased risk of UL. Additional SNP fine mapping and sequencing across this region will be performed in cases and controls to identify possible causal variants associated with UL predisposition. Further understanding of genetic variants associated with UL will provide insight into the biology of tumor development and may lead to improved management or novel therapy.

## 1962/T/Poster Board #511

**Mapping of a novel locus for hereditary gingival overgrowth to chromosome 7.** *P.S. Hart[1], D. Pallos[4], S.T. Han[2], P. Sulima[2], T. Wu[3], R. Muralidharan[2], S.I. Jang[2], T.C. Hart[2].* 1) Office of the Clinical Director, NHGRI, NIH, Bethesda, MD; 2) Human Craniofacial Genetics Section, NIDCR, NIH, Bethesda MD; 3) CIT, NIH, Bethesda MD; 4) Department of Periodontology, University of Taubaté, São Paulo, Brazil.

Hereditary Gingival fibromatosis (HGF) is a benign overgrowth of the keratinized gingiva and can occur as an isolated or syndromic trait. Genetic heterogeneity has been documented for the isolated, non-syndromic (NS) forms, with at least 4 loci (mapping to 2p22, 2p23.3, 5q13-q22, 11p15) localized by linkage studies. Mutation of the SOS1 gene on 2p22 is the only causative gene identified to date for NS- HGF. The mutant SOS1 protein constitutively activates the MAP kinase signaling pathway, and is associated with increased fibroblast proliferation. A four generation Brazilian family segregating NS autosomal dominant HGF was ascertained in accordance with institutional review board approval from the corresponding university and the NIH. Diagnosis was based on the presence of isolated gingival overgrowth. A total of 64 members were available for this study, including 30 affected individuals. Sequence analysis of SOS1 revealed no mutations. Linkage analysis identified a 14 Mb region on chromosome 7q, bounded by D7S684 and D7S798, representing a novel locus. The maximum two-point LOD score of 8.44 was obtained at D7S688, while a multipoint LOD score of >10.0 was obtained for the interval. Several genes, including *RHEB, BRAF, CDK5* and *CSGlcA-T*, map to this interval and were selected as initial candidate genes based upon involvement in Ras signaling, cell growth or cell cycle regulation or transition. Sequence analysis of the full coding region, exon/intron junctions, and 500 bp of the promoter of more than 40 genes in the candidate region failed to reveal any mutations, but did reveal several novel sequence variants. For example, sequencing of *CSGlcA-T* revealed a novel SNP in the 5' UTR. This SNP segregated with the phenotype but was also found in 14% of ethnically matched controls, supporting its classification as a polymorphism. Subsequently, gene array and transcriptome profiling have indicated altered expression of several genes in the candidate interval, primarily related to regulation of cellular processes, particularly cellular adhesion and transporter activities. Sequencing analysis of the differently regulated genes in the interval is ongoing. This study identifies a new locus for HGF, further documenting genetic heterogeneity for this condition.

## 1963/T/Poster Board #512

**Heritability and Linkage of Serum Homocysteine in Caribbean Hispanics: The Family Study of Stroke Risk and Carotid Atherosclerosis.** *S. Slifer[1], D. Della-Morte[2], A. Beecham[1], B. Boden-Albala[3], M.S. McClendon[2], T. Rundek[2], S.H. Blanton[1], R.L. Sacco[2].* 1) Miami Inst for Human Genomics, Univ Miami, Miami, FL; 2) Dept of Neurology, Univ Miami, Miami, FL; 3) Division of Stroke, Dept of Neurology, Columbia Univ, New York, NY.

Elevated plasma total homocysteine(Hcy) levels are often associated with increased risk of ischemic heart disease and stroke. Since Hcy is a quantitative trait, variance components methods allow analysis of a more complete picture of the diagnostic spectrum than disease status alone. Importantly, although extensive candidate gene studies have identified several Hcy genetic variants such as MTHFR 677C-T, genes involved in Hcy have not been well characterized in the Caribbean Hispanic population.

Hispanic probands were selected from the Northern Manhattan Family Study (NOMAS). The resulting 100 families included 1362 individuals with all families having >80% of members of Dominican descent. A 10 cM genomic screen of 405 microsatellite markers was performed, using SOLAR to analyze Hcy as a quantitative trait while controlling for significant covariates in multipoint linkage analysis. One-third of the families had a majority of members enrolled in the Dominican Republic(DR), resulting in significant differences in diet and lifestyle. Such differences among individuals were accounted for with covariates in the linkage analysis while ordered subset analysis(OSA) was used to reduce possible phenotypic heterogeneity at a family level. After covariate adjustment, Hcy had an overall polygenic heritability of 0.44($p < 0.0001$). Ch 17 presented the most significant evidence for linkage at D17S2193(MLOD=2.66, empirical p=0.0005). OSA analysis based on families ranked by the proportion of individuals living in the DR gave significantly increased evidence for linkage(MLOD=3.92, p=0.0022) for 58 families with the highest DR enrollment. Interestingly, the second highest peak on ch 2 at D2S1356(MLOD=1.77, empirical p=0.0033) also increased after OSA analysis, this time after ranking families from lowest proportion of individuals enrolled in DR to highest(MLOD = 2.82, p = 0.0097) for 81 families with lowest DR enrollment. Analysis of Hcy as a quantitative trait may allow a more complete picture of cardiovascular risk. We identified two regions that showed suggestive linkage to Hcy levels in Caribbean Hispanic families from the DR. While individual environmental variation may be controlled by using covariates in the linkage analysis, further differences may persist at the family level, indicating possible heterogeneity of phenotypic Hcy levels.

## 1964/T/Poster Board #513

**Detection of a Hotspot for Mutations in the Third β-Strand of KITLG Responsible for Familial Progressive Hyperpigmentation.** *M. Amyere[1], T. Vogt[2], J. Hoo[3], F. Brandrup[4], M. Vikkula[1].* 1) Lab Human Molec Genetics, Christian de Duve Inst, Brussels, Belgium; 2) Department of Dermatology, University of Regensburg, Germany; 3) Department of Pediatrics, SUNY Upstate Medical University, Syracuse, New York; 4) Department of Dermatology, Odense University Hospital, Odense, Denmark.

Familial Progressive Hyperpigmentation (FPH) is an autosomal dominant disorder with reduced penetrance. The clinical signs consist of progressive diffuse, partly blotchy hyperpigmentation lesions, multiple café-au-lait spots, intermingled with scattered hypopigmented appearing maculae, and lentigenes. Histological and ultrastructural sections from the hyperpigmented lesions display strong basal hyperpigmentation of the epidermis with numerous melanophages containing large amounts of melanin. In contrast, the hypopigmented appearing macula show a slight basal hyperpigmentation of epidermis, but virtually no melanophages in the upper dermis (Zanardo et al., 2004). We performed a genome-wide linkage analysis in seven families using the Affymetrix SNP GeneChip Human Mapping Arrays, and identified significant linkage on 12q14.3-q22. Wang and collaborators reported a mutation in the KITLG gene on 12q in one Chinese family with FPH. We screened our affected family members and discovered a mutation in five of the families. The reported substitution Asn36Ser was found in three families living in the same area in Germany, and two novel substitutions, Val33Ala and Thr34Pro, in two other families. All the mutations cosegregated with the hyperpigmentation phenotype. Interestingly, all three mutations are located in the highly conserved third β-strand of the KITLG protein. This finding gives the first evidence for importance of this motif in the activation of the tyrosinase activity, which leads to increased melanin synthesis and FPH. ## 1965/T/Poster Board #514

**Molecular genetics study of anterior segment dysgeneses in Arab patients.** *M.A. Aldahmesh[1], A.O Khan[1,2], F. Alzahrani[1], F.S Alkuraya[1,3,4].* 1) Department of Genetics, Developmental genetics Unit, King Faisal Specialist Hospital and Research Center, Riyadh, Saudi Arabia; 2) Department of Pediatric Ophthalmology, King Khaled Eye Specialist Hospital, Riyadh, Saudi Arabia; 3) Department of Pediatrics, King Khalid University Hospital and College of Medicine, King Saud University, Riyadh, Saudi Arabia; 4) Department of Anatomy and Cell Biology, College of Medicine, Alfaisal University, Riyadh, Saudi Arabia.

Anterior segment dysgenesis (ASD) (aniridia included) represents a heterogeneous group of ocular developmental abnormalities. The underlying genetic defect in the majority of ASD patients is still unknown. The purpose of this study is to systematically search for the underlying genetic defect in Saudi patients with ASD. We have enrolled a total of 36 individuals representing 21 families with phenotypes ranging from classical aniridia to the most complex forms of ASD. 4 approaches were used in this study: 1) Mutation analysis of genes known to cause ASD in humans 2) Mutation analysis of *CITED*-2 as a candidate gene based on the KO mouse phenotype 3) Genomewide analysis of copy number in all mutation-negative patients and 4) Homozygosity mapping, where applicable. Mutation analysis: 2 missense mutations in *PITX3* were identified in 2 sporadic patients with ASD phenotype. Although no point mutations in *PAX6* were identified, MLPA analysis revealed the presence of 2 deletion events (refined by Chip-based analysis, see below) involving the *PAX6* locus in 2 sporadic patients. No patients with *CITED*-2 mutations were identified. Copy number analysis: 250K SNP arrays revealed the presence of 1 duplication and 5 deletion events. 2 of the deletion events involved the PAX6 locus and were observed in patients with classical aniridia. Another deletion was also observed in association with classical aniridia that involves a genomic region 93Mb downstream of *PAX6*. A family of an affected mother and 3 affected children was found to cosegregate classical aniridia with a novel duplication in a dominant fashion. Finally, 2 deletion events involving chromosomes 2 and 9 were found to cosegregate with ASD in 2 families and they likely harbor novel ASD genes. Homozygosity Mapping: Using the same SNP arrays, we generated genomewide map of blocks of homozygosity in 2 consanguineous families. The first family with 9 affected individuals gave a sharp peak with high LOD score on chromosome 10 while the other family with 2 affected individuals revealed two peaks on chromosomes 2 and 12. Our analysis suggests that a more comprehensive genomic approach to patients with ASD is likely to increase the diagnostic yield. Using positional cloning (copy number analysis and linkage analysis), we have identified a number of candidate ASD intervals and work is underway to define the culprit genes/sequences within these loci.

## 1966/T/Poster Board #515

**Genome-wide Association in Model Organisms: Accounting for Relatedness.** *A. Skol[1], M. Abney[2], R. Cheng[2], A. Palmer[2].* 1) Med/Sec Gen Med, Univ Chicago, Chicago, IL; 2) Department of Human Genetics, Univ Chicago, Chicago, IL.

Advanced intercross lines (AIL) have been used to fine map quantitative trait loci (QTL) in a number of model organisms. We performed genome wide association analysis for sensitivity to methamphetamine using a combination of F2 and F34 mice. We used simulations to demonstrate that Type I (false positive) errors are dramatically inflated when the relationships among individuals are ignored; to address this concern we used statistical procedures that account for relatedness among individuals. We show that either permutation or gene dropping can be used to assess significance provided that relatedness is accounted for in the model. Our results identify multiple well localized genome-wide significant QTLs for sensitivity to methamphetamine using an analysis that combines data from the F2 and F34 populations. Our approach takes advantage of the greater power of F2 populations and the greater precision of F34 populations. We discuss how our methods might be extended to other laboratory populations (e.g. heterogenous stocks, outbred mice) where failure to account for genetic relatedness may also increase type I errors.

## 1967/T/Poster Board #516

**Fine-mapping of the FTO association signal in 3 thousand individuals of European and African descent.** *C. Dina[1,2], J.C. Chèvre[1], D. Meyre[1], D. Balding[4], P. Froguel[3], FTO group.* 1) UMR 8090, Lille Biol Inst, CNRS, Lille, France; 2) INSERM UMR915 CNRS ERL3147, Thorax Institute, Nantes, France; 3) Section of Genomic Medicine, Hammersmith Hospital, Imperial College London, Du Cane Road, London W12 0NN, United Kingdom; 4) Department of Epidemiology & Public Health Imperial College, St Mary's Campus.

Several association studies, either in extreme case-control samples or population-based have established very strong association of SNPs in intron 1 of the gene FTO with Body Mass Index and/or obesity. These SNPs are located within a 47 kb block overlapping exon 1, intron 1 and a portion of exon 2. We previously tested SNPs in the intronic highly conserved regions, and reported strongest association with SNP, rs1421085, but no putative functional polymorphism have been identified so far. While GWAS discovered numbers of genetic associations with various traits, the identification of the polymorphism(s) that cause this association is still uncommon. Furthermore, FTO locus showed only weak association in African descent populations. Using haplotype clustering methods, we first performed a fine-mapping analysis of the FTO locus to identify the underlying causal variant. Forty SNPs, spanning 100 kb which include the 47kb as well adjacent blocks were genotyped 2,446 controls and 1,935 obese adults and children. This design covers, with $r2 > 0.8$, all the HapMapSNPs displaying a MAF higher than 1% in this region. The distribution of posterior location probability, obtained using the HapCluster program, highlighted a 95% credible interval of 20 kb long. This region was sequenced in 90 individuals and 68 new unreported variants were discovered, along with 63, already described in databases. A total of 140 SNPs were selected for further genotyping in 9,000 individuals, either because of their high LD with associated SNP and to increase information on the haplotype structure. All individuals in this dataset were of European descent 220 of Senegalese origin and a selection of individuals of African descent in our different studies (196). We combined observed and imputed genotypes, inferred from the 90 individual panel, into an association study aimed at identifying variations displaying most significant association. A subset of highly significant SNPs was identified, including those already reported as well as newly identified SNPs. The results in the African descent samples were not significant and thus not conclusive to further select putatively causal SNPs. Nevertheless, the LD and allele frequency structure gives additional valuable information. In conclusion our fine mapping and deep sequencing approach identifed a subset of putatively functional SNPs located in FTO intron 1 was identified, whose evaluation of functional properties is in progress.

## 1968/T/Poster Board #517

**Admixture Mapping of Sarcoidosis in African Americans.** *A.M. Levin[1], I. Datta[1], J. Yang[1], P.M. Mckeigue[2], C. Gray-Mcguire[3], M.C. Iannuzzi[4], B.A. Rybicki[1].* 1) Biostatistics and Research Epi, Henry Ford Health System, Detroit, MI; 2) MRC Human Genetics Unit, University of Edinburgh Western General Hospital, Edinburgh, UK; 3) Arthritis and Immunology Program, Oklahoma Medical Research Foundation, Oklahoma City, OK; 4) Department of Medicine, State University of New York Upstate Medical University, Syracuse, NY.

Sarcoidosis, a multi-organ granulomatous inflammatory disease, likely results from an exaggerated T cell response to an airborne antigen. A genetic predisposition has long been posited, and genome-wide linkage analyses and a recent genome-wide association study (GWAS) have identified regions of the genome harboring variants in specific candidate genes associated with susceptibility. With an incidence rate 3.7 fold higher than Caucasians, African Americans are more commonly affected by sarcoidosis, implying that African ancestry may play an important role in the etiology and pathogenesis of this disease. Therefore, we conducted the first sarcoidosis genome-wide scan to find regions of increased African origin that may harbor disease risk variants using a map of 1,231 single nucleotide polymorphisms (SNPs) highly informative for differentiating between African and Caucasian ancestry. We conducted our analysis using the admixture mapping program ADMIXMAP on genotypes of 1,301 unrelated individuals (1,014 cases and 287 controls). Overall, the mean estimates of African and European admixture proportions in this sample were 0.82 and 0.18, respectively. The global mean estimates of African ancestry were 0.83 in the cases and 0.81 in the controls (p=0.04). Our best evidence for African genomic regions associated with increased risk of sarcoidosis were found on chromosome 5p14.3-13.2 (SNP rs35397 p=0.005), 6p22.3-23.31 (SNP rs11962335 p=0.003), and 13q31.3-33.3 (SNP rs987531 p=0.004). Our best evidence for African genomic regions associated with decreased risk of sarcoidosis were found on chromosome 2p12-11.2 (SNP rs4852696 p=0.003), 2q35-37.1 (SNP rs6761192 p=0.006), 5q23.1-31.1 (SNP CV11532818 p=0.007), 6q23.2-25.1 (SNP rs1480642 p=0.001), and 8p21.3-p11.21(SNP rs1462906 p= 0.002). The ancestry-associated 5p locus fell within a region that we previously identified though linkage analysis. The 6p locus encompasses the HLA region, which contains genes previously shown to be associated with sarcoidosis risk. Further, both the 5p and 6q loci contain SNPs that were recently identified and validated to be associated with risk in a sarcoidosis GWAS of Caucasians. In summary, while none of our results achieved genome-wide significance, this first admixture mapping study of sarcoidosis in African Americans has corroborated prior evidence of loci associated with risk and may have pointed towards new sarcoidosis susceptibility regions.

## 1969/T/Poster Board #518

**MYH9 and non-diabetic kidney disease: narrowing the region of association by fine mapping.** *C. Winkler[1], G. Nelson[1], D. Bowden[2], B. Freedman[2], J. Kopp[3].* 1) Dept Molec Gen Epidemiology, SAIC, NCI-Frederick, Frederick, MD; 2) Wake Forest University, Raleigh, NC; 3) NIDDK, NIH, Bethesda, MD.

*MYH9* was previously identified as a major effect gene for HIV-associated nephropathy (HIVAN), idiopathic focal segmental glomerulosclerosis (I-FSGS) and as a risk factor for non-diabetic end stage renal disease (ESKD) in African Americans. The most informative risk alleles were contained within a haplotype spanning introns 12 and 23, (OR≈2-7; p<10-8). *MYH9* risk alleles are very frequent in African-Americans (≈60%) and much less European-Americans (<4%), thus explaining a major USA and global health disparity. To refine the region of association and identify potential causal SNPs, we performed a fine-mapping study of *MYH9* in I-FSGS and HIVAN cases and controls using 79 tagging or otherwise informative SNPs. The strongest associations are for two closely correlated SNPs in introns 13 and 14, (OR= 5.7, p<10-26 for combined HIVAN and I-FSGS, and OR = 2.8, p<10-22 for ESKD, recessive model). These SNPs also are common in African Americans (52 to 59%) and rare in European Americans (4 to 9%). The newly identified SNPs narrow the region of interest, point to alternative splicing as a possible mechanism for the observed associations with non-diabetic kidney disease, and enhance the power of *MYH9* genotyping for genetic screening and diagnosis.

## 1970/T/Poster Board #519

**Autosomal dominant distal motor neuropathy: an italian family not linked to known loci.** *M. Muglia[1], L. Citrigno[1,2], M. Pennisi[3], A. Patitucci[1], R. Barome[3], A. Magariello[1], A.L. Gabriele[1], G. Pennisi[3], R. Mazzei[1], F.L. Conforti[1], C. Ungaro[1], M. Zappia[3], A. Gambardella[1].* 1) ISN-CNR, Mangone Cosenza, Italy; 2) Department of Neurosciences, Psychiatric and Anesthesiological Sciences, University of Messina, Messina (Italy); 3) Department of Neurosciences, University of Catania, Catania (Italy).

The distal motor neuro(no)pathy (dHMN) is a heterogeneous group of disorders characterized by an exclusive involvement of the motor part of the peripheral nervous system. The overall clinical picture consists of progressive weakness and wasting of the extensor muscles of toes and feet. Later on, weakness and wasting also involves the distal upper limb muscles. Foot deformity is a common feature. Often, unusual or additional features are present in ‘complicated’ distal HMN, including predominance in the hands, vocal cord paralysis, diaphragm paralysis and pyramidal tract signs. The classification of the dHMN is complex and based on multiple factors such as age at onset, mode of inheritance and the presence/absence of additional and complicating features like vocal cord and diaphragmatic paralyses or pyramidal dysfunctions. Currently, autosomal dominant, autosomal recessive and X-linked forms have been described, 16 chromosomal loci have been mapped, and eight different genes have been detected. We studied a four generation Italian family where the dHMN phenotype segregated as an autosomal dominant trait. Eight subjects out of a total of 12 subjects ( 6 men and 2 women, aged 13-79 years) were affected. One subject in the upper first generation was assumed to have dHMN by history. Seven patients from three generations (II to IV) were studied. At the time of the study main clinical features included symmetrical progressive weakness and atrophy of the hand muscles and distal lower limb muscles. Electrophysiological findings of motor axonal polyneuropathy were found in 3 patients (aged 13 to 45 years) with variable clinical severity. We performed genetic linkage analysis with DNA markers from current-known dHMN loci. No support for linkage to any of the known loci was found in our family, confirming a genetic heterogeneity within autosomal dominant dHMN.

## 1971/T/Poster Board #520

**Genomewide identity by descent and homozygosity mapping reveals candidate regions for genetic susceptibility to obsessive-compulsive and tic disorders.** *E. Nurmi[1], B. Merriman[2], J. McCracken[1], S. Nelson[1,2], The OCD Collaborative Genetics Study.* 1) Department of Psychiatry, University of California at Los Angeles, Los Angeles, CA; 2) Department of Human Genetics, University of California at Los Angeles, Los Angeles, CA.

Obsessive-compulsive disorder (OCD) is a common psychiatric diagnosis producing significant psychological distress and social and occupational impairment. OCD is characterized by persistent, intrusive, disruptive thoughts and related repetitive rituals aimed at neutralizing these obsessions. While twin and family studies support a strong genetic etiology, risk alleles for OCD have yet to be identified. A highly familial subset of OCD is defined by an early age of onset and is associated with tics. In the OCD Collaborative Genetics Study (OCGS) sample, we observe a 5-fold increased rate of Tourette Syndrome (TS) and other tic disorders in relatives of female probands with early age of onset and comorbid tics. This subset of 32 families may represent a discrete population with greater genetic loading and homogeneity that is more amenable to genetic studies of OCD and tic susceptibility. We performed genomewide SNP genotyping in this sample using the 1M Illumina SNP chip. These data were analyzed for copy number variants (CNVs) and larger than expected regions of homozygosity and pairwise identity. Pedigree-free identity by descent (IBD) mapping can identify large genomic intervals inherited from a common ancestor in affected individuals of unknown relationship. The presence of large chromosomal haplotypes shared by multiple distantly-related affected individuals provides strong evidence for association with the selected phenotype. IBD mapping in our dataset revealed pairwise sharing of a 20 cM region of chromosome 2 mapping within a local female-specific linkage peak in the OCGS dataset. A 3 cM block of homozygosity across this region was identified in a third proband. Large blocks of IBD (5-14 cM) between 3 individuals were observed on chromosomes 8 and X. Two probands carried overlapping stretches of homozygosity on chromosome 2 that mapped to the only prominent linkage peak detected in genomewide screens for TS. Two regions of extended homozygosity encompassed candidate genes selected *a priori* on chromosomes 11 and 18. Several other promising candidate regions were identified. Genes mapping within these intervals were cataloged and prioritized for in-depth analysis. These data will compliment parallel association analyses, and will fuel and focus ongoing efforts to identify OCD and tic disorder susceptibility genes.

## 1972/T/Poster Board #521

**Genome-wide Linkage Analysis for Genetic Causes of Macular Telangiectasia Type 2.** *N.L. Parmalee[1], K. Kiryluk[2], M. Gillies[5], R. Allikmets[3,4], The MacTel Project.* 1) Genetics and Development, Columbia University, New York, NY; 2) Department of Medicine, Nephrology, Columbia University, New York, NY; 3) Department of Ophthalmology, Columbia University, New York, NY; 4) Department of Pathology, Columbia University, New York, NY; 5) Clinical Ophthalmology and Eye Health, The University of Sydney, Sydney, Australia.

Macular Telangiectasia Type 2 is an adult onset disease that affects the macular region of the retina, resulting in reduction of central visual acuity in patients. Prevalence is approximated at 1:1000. While most cases appear to be sporadic, several families have been identified with multiple affected family members. The disease presents between the 3rd and 5th decade of life with changes in autofluorescence in the macula, decreased macular pigment, and neovascularization of the inner retina. Retinal thickening and the presence of a macular cyst in the juxtafoveolar region are frequently seen with optical coherence tomography. The disease is usually bilateral, and shows no difference in prevalence by gender. Because diagnosis depends on very subtle criteria, it is thought that macular telangiectasia may be underdiagnosed. The MacTel Project is an international consortium formed to study this disease. DNA samples have been collected by 22 centers in 8 countries. Retinal images are taken at the center of enrollment and sent to one reading center where are images are adjudicated to ensure that identical diagnostic criteria are applied across the cohort. At present we have DNA samples from 261 affected individuals, 143 relatives, and 63 unrelated controls. We identified 16 multiplex families and genotyped a total of 64 probands and family members on the Illumina 1M Duo chip for linkage and candidate gene analysis. Four families were later determined to be singleplex families and were removed from analysis; 12 families with 54 total individuals were analyzed for linkage. SNPs were selected for inclusion in linkage analysis based on: no missing calls, MAF greater than .25, cluster separation greater than .75, and GenTrain score greater than .80. This set of markers was then pruned for linkage disequilibrium in PLINK, removing markers with $R^2$ greater than .40. The remaining markers were partitioned into four independent sets of approximately 10,000 markers each, which were analyzed in MERLIN. Preliminary multipoint parametric and non-parametric analyses show peaks on chromosomes 1p and 10q, which are currently under analysis. Patients and families enrolled in the study are followed on a yearly basis to investigate the progression of the disease. We anticipate that the number of families available for linkage analysis will increase over the course of the study.

## 1973/T/Poster Board #522

**A Unified case-control association testing with unknown multilevel relationships.** *Y. Choi[1], T. Bhangale[1], S. Smith[2], L. Diatchenko[2], W. Maixner[2], J.M. Jordan[3], C.L. Hyde[4], S. John[5], B.S. Weir[1,6].* 1) Department of Biostatistics, University of Washington, Seattle, WA; 2) Algynomics Inc, Chapel Hill, NC; 3) Thurston Arthritis Research Center, University of North Carolina at Chapel Hill, Chapel Hill, NC; 4) Clinical Research Statistics, Pfizer Global Research & Development, New London, CT; 5) Molecular Medicine, Pfizer Global Research & Development, New London, CT; 6) Department of Genome Science, University of Washington, Seattle, WA.

Genome-wide association studies suffer from high rates of false-positive results when unknown population structures and cryptic relatedness exist. A number of methods have been proposed for testing association between markers and disease in structured populations and genomic control (GC) and principal component analysis (PCA) are most commonly used. We have developed a unified mixed-model approach to account for unrecognized population structures and familial-level relatedness for binary traits. We estimated unknown population structures and cryptic relatedness using maximum-likelihood methods and used logistic mixed model for testing association in multilevel structured populations. Our approach allows estimating relatedness in structured populations and adjusting the effect of potential confounders or environmental factors simultaneously. We compared a new approach with two previous methods, GC and PCA, and applied it to simulated data and to a real sample from Johnson County, North Carolina.

## 1974/T/Poster Board #523

**Genetic and Functional Analysis Suggest that FGFR1 Contributes to Human Obesity.** *H. Jiao[1,2], I. Dahlman[3], N. Mejhert[3], C. Henegar[4], A. Hinney[5], J. Hoffstedt[3], D. Brodin[1], B. Dubern[4], P. Galan[6], S. Czernichow[6], A. Silveira[7], F. Van't Hooft[7], T. Axelsson[8], M. Ryden[3], J. Hebebrand[5], J. Kere[1,2], K. Dahlman-Wright[1], A. Hamsten[7], K. Clement[4], P. Arner[3].* 1) Department of Biosciences and Nutrition, Karolinska Institutet, SE-141 57 Stockholm, Sweden; 2) Clinical Research Centre, Karolinska University Hospital, SE-141 57 Stockholm, Sweden; 3) Department of Medicine at Karolinska Institutet and Karolinska University Hospital, SE-141 86 Stockholm, Sweden; 4) INSERM, U-872, Nutriomique (team 7) 75006 Paris, France; University Pierre and Marie Curie-Paris 6, Cordeliers Research Center, 75006 Paris, France; AP-HP, Pitié-Salpétrière Hospital, 75013 Paris, France; 5) Department of Child and Adolescent Psychiatry of the University of Duisburg-Essen, Essen, Germany; 6) INSERM, U-557/INRA U-1125, CNAM, UP13, CRNH-IdF, 93017 Bobigny, France; University Paris 13, 93017, Bobigny, France; AP-HP, Avicenne Hospital, 93017 Bobigny, France; 7) Cardiovascular Genetics Group, Atherosclerosis Research Unit, Department of Medicine, Solna, Karolinska Institutet, SE-17176 Stockholm, Sweden; 8) Molecular Medicine, Department of Medical Sciences, Uppsala University, Uppsala, Sweden.

Objective: The aim of this study was to identify susceptibility genes for obesity by focusing on subjects with extreme obesity, and to investigate pathophysiological mechanisms linking these genes to adiposity. Research Design and Methods: A genome-wide association analysis was performed on subjects with early onset or morbid obesity [N=164] and elderly that had always been lean [N=164]. Results were replicated in cohort 2-5 comprising a total of 4674 severely obese subjects and 5663 lean or population-based controls. Results: rs7012413 (MAF~30%) in the fibroblast growth factor receptor 1 (FGFR1) gene associated with obesity in each of five investigated cohorts (N=10665) with an over all odds ratio of 1.20 [1.09 - 1.33] and P 1.8x10 -6 which was 7.0x10-8 in a recessive model. FGFR1 and one of its ligands, fibroblast growth factor-1 (FGF-1), regulate adipogenesis. In studies of human abdominal subcutaneous adipose tissue we observed increased FGFR1 levels in obese versus lean subjects. rs7012413 CC genotype associated with lower adipose tissue FGFR1 levels than CT or TT. FGF-1 was secreted within adipose tissue with increased rates in obesity. In conclusion a polymorphism in FGFR1 associates with obesity and may affect body fat accumulation through FGF-1/FGFR1 mediated paracrine regulation of adipogenesis. This study is the first to imply adipose tissue as a primary organ regulating common obesity.

## 1975/T/Poster Board #524

**Genome-wide association analysis of Body Mass Index in Pima Indians.** *A. Malhotra, S. Kobes, W.C. Knowler, L.J. Baier, R.L. Hanson.* NIDDK, Phoenix, AZ.

Obesity is an increasing health problem in the United States and worldwide. Numerous studies have been done to understand the genetic contributors to Body Mass Index (BMI), a measure of obesity, but only a limited number of susceptibility variants have been identified. In the current study, genome-wide association (GWA) analysis was performed for BMI in 1149 Pima Indians (526 males and 623 females; age ≥15 years) using single nucleotide polymorphisms (SNPs) from the 1 million Affymetrix SNP panel. Of the genotyped SNPs, 454,194 passed quality control procedures and had minor allele frequency >0.05; these were analyzed for association with BMI. Phenotypic data included BMI at multiple examinations (range: 1-15 examinations for a given individual) collected from 1965-2004. Average BMI from all 6,079 exams in these individuals was 33.5 kg/m2. Within-family association tests were performed for each SNP using a maximum-likelihood based mixed model procedure, as implemented in the Statistical Analysis System (SAS) software. Variance components representing family membership and repeated measures within an individual (assuming an autoregressive correlation structure) were included in the analysis and the BMI measurements were adjusted for sex, birth year, and age. The strongest associations were with 6 adjacent SNPs on chromosome 6 (located at 53,493,043bp-53,509,958bp with p-value range: 1.62x10-6 to 3.81x10-6). In addition, 3 SNPs (located at 20,863,634bp-20,881,374bp) on chromosome 4 were associated with BMI (p=1.71x10-6 to 2.68x10-6). While these specific regions do not contain known obesity genes, they should be further explored for novel causal variants. We also assessed evidence for association for SNPs near previously identified susceptibility genes. SNPs near several genes including NEGR1 (p=0.0214), RASAL2 (p=0.0006), DGKG (p= 0.0420), FTO (p=0.0122), and MCR4 (p=0.0033) were associated with BMI in the present study. In conclusion, SNPs on chromosomes 6 and 4 were associated with BMI in Pima Indians. Further analysis of these regions is particularly important since a majority of previous studies have been done in Caucasian populations, whereas genetic susceptibility factors may differ by ethnicity.

## 1976/T/Poster Board #525

**Ethnic diversity in fine mapping of the susceptibility loci *G6PC2-ABCB11* for fasting glucose and *CDKAL1* for type 2 diabetes.** *F. Takeuchi[1], T. Katsuya[2], S. Chakrewarthy[3], K. Yamamoto[4], T. Fujisawa[2], E. Nakashima[5], K. Ohnaka[6], H. Ikegami[7], T. Sugiyama[8], T. Nabika[9], A. Kasturiratne[3], S. Yamaguchi[9], S. Kono[6], R. Takayanagi[6], Y. Yamori[10], S. Kobayashi[9], T. Ogihara[11], A. de Silva[3], R. Wickremasinghe[3], N. Kato[1] for the NIBIO GWA Study.* 1) Research Institute, International Medical Center of Japan; 2) Osaka University Graduate School of Medicine; 3) University of Kelaniya; 4) Medical Institute of Bioregulation, Kyushu University; 5) Nagoya University Graduate School of Medicine; 6) Graduate School of Medical Sciences, Kyushu University; 7) Kinki University School of Medicine; 8) Institute for Adult Diseases, Asahi Life Foundation; 9) Shimane University School of Medicine; 10) Research Institute for Production Development; 11) Osaka General Medical Center.

**Objective.** Recently, genome-wide association (GWA) studies have successfully identified numerous loci influencing disease susceptibility or quantitative traits. To discern the causal variant(s), we need to enumerate potential causal variants and narrow them down in the region of interest. Along this line, we compared populations of European and Asian descent to refine association signals at two susceptibility loci *G6PC2-ABCB11* and *CDKAL1* for glycemic traits previously identified by GWA studies of Europeans.

**Methods.** In the *G6PC2-ABCB11* region, we examined fasting glucose association in 776 non-diabetic Japanese samples who are part of our ongoing GWA study, and chose index SNPs for further genotyping in the general populations of Japanese ($N$ = 4,813) and Sri Lankans ($N$ = 2,319). In the *CDKAL1* region, based on our GWA study in the Japanese, we compared haplotypes and their association with type 2 diabetes (T2D) between the Japanese and Europeans. SNPs representing the associations were tested in case-control samples of Japanese ($N$ = 2,774) and Sri Lankans ($N$ = 1,114).

**Results.** We could confirm the association of fasting glucose with variants at *G6PC2-ABCB11*. In addition to the reported SNP rs560887, we identified significant associations at a novel variant rs3755157 in both the Japanese ($\beta$ = 0.057 mmol/l, $P = 2.6 \times 10^{-8}$) and Sri Lankans ($\beta$ = 0.069 mmol/l, $P$ = 0.001), with allelic heterogeneity implicated between the two SNPs. In the *CDKAL1* region, the use of ethnic diversity in linkage disequilibrium (LD) pattern helped to refine T2D association signals to an index SNP rs9368222. Furthermore, cross-population filtering could appreciably reduce potential causal variants; i.e., from 79 to 7 in the *G6PC2-ABCB11* region and from 69 to 3 in the *CDKAL1* region.

**Conclusions.** It has been argued that populations of African descent may be advantageous for fine mapping but statistical power could be limiting due to the unavailability of sufficiently large samples and/or a smaller effect size. Instead, our data demonstrate that ethnic diversity in the pattern and strength of LD between populations of European and Asian descent can allow us to appreciably reduce potential causal variants and also to focus on most promising variants for functional follow-up.

## 1977/T/Poster Board #526

**Multi-stage genome-wide association study uncovers genetic factors influencing the P300 event-related brain potential.** *M. Zlojutro[1], N. Manz[2], M. Rangaswamy[2], X. Xuei[3], L. Bierut[4], H. Edenberg[3], T. Foroud[3], A. Goate[4], V. Hesselbrock[5], S. Kuperman[6], J. Nurnberger Jr.[3], J. Rice[4], M. Schuckit[7], B. Porjesz[2], L. Almasy[1], COGA Collaborators.* 1) Genetics, Southwest Foundation for Biomedical Research, San Antonio, TX; 2) Department of Psychiatry, SUNY Health Science Center, Brooklyn, NY; 3) Indiana University School of Medicine, Indianapolis, IN; 4) Department of Psychiatry, Washington University School of Medicine, St. Louis, MO; 5) Department of Psychiatry, University of Connecticut, Farmington, CT; 6) University of Iowa, Psychiatry Research, Iowa City, IA; 7) University of California, San Diego, CA.

Event-related brain potentials (ERPs) are measurements of neuroelectric activity that are altered in patients with various psychiatric disorders and may serve as quantitative correlates of disease liability. In particular, alcoholic subjects and their offspring exhibit a reduction in the amplitude of the P300 component, a positive oscillatory wave occurring approximately 300-500 milliseconds after a target stimulus during a cognitive task. Results of a genome-wide association study (GWAS) based on the Illumina HumanHap 1 million SNP array are presented for the P300 component at the Pz scalp position for 1,123 unrelated case-control samples ascertained from the Collaborative Study on the Genetics of Alcoholism (COGA). Although the most statistically significant SNPs did not achieve genome-wide significant association after adjustment for multiple-testing (smallest P = 2.8 x 10-6 for rs12043526), several new genomic regions not previously identified through linkage analyses were implicated, with 50 top-ranking SNPs selected for follow-up genotyping in 1,374 family-based COGA samples. The most compelling association obtained in the follow-up data was for marker rs2148682, located within the evolutionary conserved gene DNAJC6, a regulator of molecular chaperone activity on chromosome 1p31 (Bonferroni corrected P = 8.7 x 10-3; two-stage combined P = 1.3 x 10-4). Other convincing associations were discovered for markers in the forkhead box transcription factor FOXP4 on chromosome 6p21 (combined P = 3.0 x 10-6) and in FRMD4A on chromosome 10p13 (combined P = 3.7 x 10-5). This large-scale GWAS highlights previously unknown biological pathways contributing to the P300 brain potential in individuals with alcohol dependence.

**Recombination Intensity and Hot Spot Distribution across Major Histocompatibility Complex Based on Preimplantation HLA Haplotyping Data.** *T. Sharapova, S. Rechitsky, O. Verlinsky, A. Kuliev, Y. Verlinsky.* Reproductive Genetics Institute, Chicago, IL.

The fine scale distribution of meiotic recombination in humans can be inferred from the population SNP genotyping data, assessed by linkage studies or measured by high-resolution sperm typing. Each approach has its limitations, lowering the accuracy of the existing recombination maps. Major Histocompatibility Complex (MHC) is one of the most extensively studied regions of human genome. Genotyping of 20,000 single sperms has been previously performed to build the recombination map of human MHC. The method infers several biases due to reported significant individual and gender dependent variation in recombination rate. We present estimation of recombination rate and its distribution within MHC region based on the analysis of preimplantation HLA haplotyping data comprising both male and female meioses. Preimplantation haplotyping has been performed for 110 couples in a need of HLA matching stem cell donor for an affected sibling. STR genotyping of 5.4Mb region encompassing MHC has been performed in single blastomeres and polar bodies using nested multiplex PCR. A panel of 24 STR markers was applied, dividing the MHC region into 23 segments. In total 1787 male and 1930 female meioses received from 245 IVF/PGD cycles have been studied resulting in the identification and mapping of 33 and 50 recombinant chromosomes respectively. The estimated comprehensive recombination intensity within 5.4Mb segment (D6S248-D6S1618) was 0.37cM/Mb for males and 0.53cM/Mb for females with female: male ratio of 1.5. Eleven out of 23 segments showed 1.8-8 fold difference in crossover intensity between males and females supporting gender related variation in recombination activity. In females 6 segments located within HLA class II region displayed a 1.6-4.8 fold increase in recombination activity compared to the expected rate of 0.53cM/Mb. Three of them (D6S2447-G51152, TAP1-Ring3 and Ring3-D6S1560) correspond to the previously described hotspots detected by sperm typing in males (DQB1-DQB3, DMB and Ring3-DPB1). One segment D6S1629 to D6S1568 showed a significantly higher recombination intensity (P<0.05) representing a hotspot of 268kb which has not been previously described. The study represents the first extensive direct measurement of recombination rate within MHC region in females using preimplantation haplotyping data. The results support the heterogeneity in recombination intensity within MHC and indicate the presence of novel hotspot adjacent to HLA class II region.

## 1979/T/Poster Board #528

**Identification of Genes Involved in the Regulation of Hematopoiesis.** *M. Varney, V. Sollars.* Marshall University Joan C. Edwards School of Medicine, Huntington, WV.

Proper regulation of gene expression, protein expression, and protein activity is vital to the development of blood cells. When the expression of particular genes and proteins involved in the differentiation of hematopoietic stem and progenitor cells is altered from normal patterns, differentiation can be blocked and progenitor cell frequency can be increased significantly, contributing to hematopoietic malignancies. One such malignancy, acute myelogenous leukemia (AML) is characterized by the expansion of the myeloid progenitor cell compartment. To identify genes that control the regulation of hematopoiesis, we studied the size of the myeloid progenitor cell compartment in 27 strains of inbred mice. Phenotypic information was collected by performing hematopoietic progenitor cell assays called colony forming cell (CFC) assays. By comparing phenotypic similarities and differences among the strains to genotypic similarities and differences among the strains via in silico mapping, we were able to identify 2 genes, and 1 additional chromosomal region of interest in controlling hematopoiesis. More specifically, these genes were implicated in the phenotypes associated with the development of macrophages and granulocytes. In silico mapping is a bioinformatics technique that is based on single nucleotide polymorphism (SNP) markers. It generates information that can be used to identify chromosomal regions containing genes that are responsible for the phenotype studied. Both genes implicated in this study, Slit3 and Foxo1, have been shown to play roles in other cancers. Further investigation into these genes and the additional chromosomal region of interest may yield new information about them as possible oncogenes or tumor suppressors in AML.

## 1980/T/Poster Board #529

**A novel role for the non-receptor protein tyrosine phosphatase PTPN14 in lymphangiogenesis.** *A.C. Au[1], P.A. Hernandez[1], E. Lieber[3], B.D. Gelb[1, 2], G.A. Diaz[1, 2].* 1) Department of Genetics & Genomic Sciences, Mount Sinai School of Medicine, New York, NY; 2) Department of Pediatrics, Mount Sinai School of Medicine, New York, NY; 3) Department of Pediatrics, Lincoln Hospital and Mental Health Center, Bronx, NY.

The lymphatic system serves as a unidirectional recovery system that transports fluid, cells and macromolecules from interstitial spaces back into the central circulation. Perturbations in lymphatic vasculature development, maintenance or function lead to a variety of pathological disorders, including lymphedema. Through genome-wide mapping of a multi-generational consanguineous kindred with autosomal recessive inheritance of choanal atresia and lymphedema, we have mapped the trait to chromosome 1q32-41. Further analysis of the 13.2-cM critical region spanning 8.6 Mb led to the identification of a loss-of-function mutation in the non-receptor protein tyrosine phosphatase gene *PTPN14*. Despite extensive effort, other kindreds with choanal atresia and lymphedema were not identified. To prove causality between *PTPN14* mutation and lymphedema, we have generated a mouse model of *PTPN14* deficiency from an ES cell line in which the *Ptpn14* locus was disrupted by a gene trap. Mice homozygous for a *Ptpn14* trap allele recapitulated the lymphedema phenotype in the form of hindlimb and forelimb swelling. Immunofluorescence staining of ear sections from symptomatic mice revealed a hyperplastic dermal lymphatic network, whereas the blood vasculature was apparently unaffected. Although high expression of PTPN14 in human umbilical vein endothelial cells suggested an important role in endothelial cell regulation, no role in lymphatic development or function has been described. In order to elucidate the physiological role of PTPN14 in lymphangiogenesis, we tested the hypothesis that PTPN14 functioned as a regulator of the lymphangiogenic factor vascular endothelial growth factor receptor-3 (VEGFR-3). The effect of PTPN14 expression on VEGFR-3 phosphorylation status after ligand activation and the ability of the proteins to form a complex formation were tested in transiently transfected cells. We observed that tyrosine phosphorylation of VEGFR-3 receptors was diminished in cells co-expressing the wild type, but not the mutant, PTPN14. In addition, the proteins were found to form a complex as detected by co-immunoprecipitation assays. Our cumulative data are consistent with an inhibitory functional interaction between PTPN14 and VEGFR-3, potentially through a direct physical complex. Based on these findings, we propose that PTPN14 functions as a regulator of lymphatic development in mammals and is a novel candidate molecule for the modulation of lymphangiogenesis *in vivo*.

## 1981/T/Poster Board #530

**A genome-wide association scan localizes a QTL influencing Epstein-Barr virus infection to the major histocompatibility complex region.** *R. Rubicz[1], R. Yolken[2], L. Bauman[1], M. Carless[1], E.I. Drigalenko[1], J.E. Curran[1], M.P. Johnson[1], S.E. Cole[1], T.D. Dyer[1], L. Almasy[1], M.C. Mahaney[1], E. Kraig[3], E.K. Moses[1], C.T. Leach[4], J. Blangero[1], H.H.H. Göring[1].* 1) Dept. of Genetics, Southwest Foundation for Biomedical Resesearch, San Antonio, TX; 2) Dept. of Pediatrics, Johns Hopkins School of Medicine, Baltimore, MD; 3) Dept. of Cellular and Structural Biology, University of Texas Health Science Center at San Antonio, San Antonio, TX; 4) Dept. of Pediatrics, University of Texas Health Science Center at San Antonio, San Antonio, TX.

To better understand the role of infections with common pathogens in chronic inflammation, we measured IgG antibodies to the Epstein-Barr virus (EBV) nuclear antigen (EBNA) in >1,000 randomly ascertained Mexican American participants (age range 15-94 years) in the San Antonio Family Heart Study. EBV is a common herpes virus. Many infections are asymptomatic but primary infections in adolescents and young adults often lead to infectious mononucleosis. In some individuals, infection leads to more serious diseases including cancers such as Burkitt's Lymphoma and nasopharyngeal carcinoma. Reasons for the observed differential response to EBV infection are little known but likely include genetic susceptibility to infection. Anti-EBNA IgG antibody titer was measured in plasma samples using solid phase enzyme immunoassay methods. In our sample, 48% of the individuals had definitive levels of antibodies, 24% had intermediate, suggestive levels, and 8% did not have detectable levels. No significant differences were observed by sex or age. Under the assumption that the IgG antibody level to EBNA is a meaningful reflection of infection, we sought to localize genetic factors that influence the serological phenotypes. Both the quantitative antibody titer and the discrete serostatus phenotype were found to be significantly heritable (with estimates of 40% and 63%, respectively). Shared environmental factors, modeled via co-habitation, were non-significant. We performed a genome-wide association scan on 856 individuals with phenotype and genotype data (generated using Illumina's HumanHap 550 BeadChip) under an additive measured genotype association model, accounting for the non-independence of family members using a random effects kinship model. We detected genome-wide significant associations on chromosome 6 in the human leukocyte antigen (HLA) region. The most significant association was obtained with SNP rs4248166 in *BTNL2*, a gene which is associated with T-cell function ($p = 9.0*10^{-9}$ and $2.8*10^{-9}$ for the quantitative and the qualitative phenotype, respectively). Multiple SNPs in the region support this finding. Our results indicate that EBV infection is regulated by genetic determinants within the HLA complex. Further analysis of this finding might lead to an increased understanding of the role of EBV in human disease as well as better methods for predicting individual response to EBV infection.

## 1982/T/Poster Board #531

**Admixture mapping for fetal hemoglobin QTLs in Jamaica: prospects and challenges.** *C.A. McKenzie[1], J. Butler[2,10], L. Creary[3], N. Hanchard[4], S.G. Yi[5], X. Zhu[5], I. Hambleton[6], V. Taylor[7], J. Hirschhorn[2,9,10,11], S. Menzel[8], T.E. Forrester[1], S.L. Thein[8].* 1) Tropical Metabolism Research Unit, University of the West Indies, Kingston, Jamaica; 2) Division of Genetics, Boston Children's Hospital, Boston, USA; 3) NHS Blood and Transplant, London, UK; 4) Department of Pediatric and Adolescent Medicine, Mayo Clinic, Rochester, USA; 5) Department of Epidemiology and Biostatistics, School of Medicine, Case Western Reserve University, Cleveland, USA; 6) Chronic Disease Research Centre, University of the West Indies, Cave Hill, Barbados; 7) National Blood Transfusion Service, Kingston, Jamaica; 8) King's College London School of Medicine, Division of Gene and Cell Based Therapy, London, UK; 9) Division of Endocrinology, Boston Children's Hosp, Boston, USA; 10) Broad Institute, Cambridge, USA; 11) Department of Genetics, Harvard Medical School, Boston, USA.

An elevated level of fetal hemoglobin (HbF) provides significant amelioration of the severity of hemoglobinopathies such as β-thalassemia and sickle cell disease (SCD). Clinical trials demonstrate that medications such as hydroxyurea, which act in part by raising HbF levels, provide important clinical benefits; identifying determinants of HbF is thus of considerable interest. HbF levels display strong genetic determination and 3 quantitative trait loci (QTLs) have been identified so far. We and others have shown that there are significant differences in HbF levels between white European- and African-descent populations. Admixture mapping of novel QTLs in appropriate populations might be possible if ethnic differences are related to genetic ancestry. In order to assess the prospects for admixture mapping in Jamaica we have genotyped 72 SNPs in samples obtained from our previous study of healthy African-descent participants (n = 189) from the main blood donation center in the capital Kingston (A/C) and from a rural enclave (n = 641), founded in the early 1800s by German immigrants (A/G). The markers include 20 SNPs on chromosomes 2, 6, and 11 that were previously reported to be associated with HbF (HbFSNPs), 40 ancestry informative markers from across the genome (G-AIMs) and 12 AIMs from HbF-associated regions (R-AIMs). HbF was represented by F cell (FC) levels measured using flow cytometry. The average percentage of European ancestry (P_ceu) was significantly higher and more variable ($P < 0.001$) in the A/G group (23.8 ± 27.4%) than in the A/C group (7.5 ± 6.0%). P_ceu was significantly associated ($P < 0.05$) with FC after adjustment for age, sex, sickle carrier status, and C-158T HBG2 genotype. We added each of the markers in turn to this base model to test for FC-marker association. At least one HbFSNP from each of the previously-reported HbF-associated chromosomal regions was significantly associated with FC. One G-AIM (on chr. 14) was marginally associated with FC. None of the R-AIMs was associated with FC. A review of the distribution of P_ceu and pairwise disequilibrium between unlinked and linked markers indicates that there is important stratification within and between the A/C and A/G samples. These results extend previous results (to a non-anemic African-descent group) and also provide important information for the design of genome-wide admixture mapping studies for novel HbF QTLs and other traits of medical importance in Jamaica.

## 1983/T/Poster Board #532

**Linkage analysis using 370K chips in two sets of Retinitis Pigmentosa pedigree samples.** *F. Cheng[1,2], C. Li[1], L. Wang[3], X. Zhang[1,2], B. Liu[1,2], G. Li[3], C. Zeng[1].* 1) Beijing Institute of Genomics, Chinese Academy of Sciences, Beijing, China; 2) Graduate School of Chinese Academy of Sciences, Beijing, China; 3) Beijing Institute of Ophthalmology, Beijing Tongren Hospital, Capital University of Medical Science, Beijing, China.

Using whole genome chip for linkage analysis has been shown as an efficient strategy to map disease related genes in comparison with application of STR probes. Here we report the mapping of retinitis pigmentosa (RP) susceptible genes by chip analysis in two Chinese RP families. RP shows considerable symptomatic and genetic heterozygosity in different cases. Both pedigrees, each with 7 and 8 patients respectively, showed incomplete and dominant inheritance model. All infected ones showed RP symptoms before 30 years old and a few had RP even before 10.

DNA samples were hybridized to Illumina 370K CNV-quad chips and SNPs with poor call rates were removed for further analysis. Large families were divided into small nuclear trio families for relationship test. After exclusion of a few SNPs showing Mendelian errors, Merlin package was used to do the Linkage study. Chromosome regions with positive LOD scores were further subjected to haplotype analysis. According to the relationships of nuclear families, parental haplotypes of each trio were deduced from genotype data to determine the transmission. Finally, four different haplotypes showing strong RP co-segregation were identified. With about 2Mb in each, two regions in chromosome 1 and 8 were obtained from family 1, and two separate regions in chromosome 14 were resolved in family 2, respectively.

To verify above results, STR markers near these four regions were then chosen to type in related samples. Mlink package was used for two-point linkage analysis. At recombination rate $\theta=0$, LOD score were 3.160 and 2.600 for D14S258 and D14S68 in family 1, and LOD scores were 1.852 and 1.710 for D1S425 and D8S1771 in family 2, respectively. Four candidate genes in these regions have been selected for re-sequencing based on gene annotation and function related studies. A two-nucleotide insertion (CT) in the third exon of RD3 (retinal degeneration 3) was identified in RP affected members but not in healthy ones in family 1. No mutation was found in candidate gene NRG1 (neuregulin 1). Sequence analysis of RDH12 (retinol dehydrogenase 12), and ABCD4 (ATP-binding cassette, sub-family D, member 4) was in the process.

## 1984/T/Poster Board #533

**Identification of 11 novel mutations in 8 BBS genes via high-resolution homozygosity mapping.** *H.M. Harville[1], S. Held[1], A. Diaz-Font[2], E.E. Davis[3], B.H Diplas[3], J. MacDonald[1], W. Zhou[1], M. Chaki[1], P.L. Beales[2], N. Katsanis[3], E. Otto[1], F. Hildebrandt[1].* 1) Howard Hughes Medical Institute and Departments of Pediatrics and of Human Genetics, University of Michigan Health System, Ann Arbor, MI, USA; 2) Molecular Medicine Unit, UCL Institute of Child Health, London, UK; 3) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD, USA.

Bardet-Biedl syndrome (BBS) is primarily an autosomal recessive disorder characterized by rod-cone dystrophy, obesity, mental retardation, hypogonadism, post-axial polydactyly, renal cysts, and other anomalies of the kidney and urinary tract. To date, mutations in 14 genes have been identified as causing BBS. The vast genetic heterogeneity of BBS renders diagnosis difficult in terms of both the time and cost required to screen all 204 coding exons. Here, we report the use of genome-wide homozygosity mapping as a tool to identify homozygous segments in BBS patients at known BBS loci. In a worldwide cohort of 45 families, we identified, via direct exon sequencing, causative mutations in 20 families. Eleven mutations were novel, thereby increasing the number of known BBS mutations by 5% (11/218). Thus, in the presence of extreme genetic locus heterogeneity, homozygosity mapping provides a valuable approach to the molecular genetic diagnosis of BBS and the discovery of novel pathogenic mutations.

## 1985/T/Poster Board #534

**Brain arteriovenous malformation maps to 5p13-q14, 15q11-q13 and 18p11: Linkage analysis with clipped fingernail DNA on SNP array.** *H. Kuniba[1,2,6], M. Oikawa[1,3,6], T. Kondoh[4], A. Kinoshita[1,6], H. Moriuchi[2], T. Nagayasu[3], N. Niikawa[5,6], K. Yoshiura[1,6].* 1) Dept Hum Genet, Nagasaki University, Nagasaki, Japan; 2) Dept Pediatrics, Nagasaki University, Nagasaki, Japan; 3) Dept Surgical Oncology, Nagasaki University, Nagasaki, Japan; 4) Misakaenosono Mutsumi, The institute for persons with severe intellectual/motor disabilities, Konagai, Japan; 5) Research Institute of Personalized Health Sciences, Health Sciences University of Hokkaido, Tobetsu, Japan; 6) Solution Oriented Research for Science and Technology (SORST), Japan Science and Technology Agency (JST), Tokyo, Japan.

Familial arteriovenous malformations (AVM) in the brain is a very rare disease, which is defined as the occurrence of AVM in two or more relatives (up to third-degree relatives) in a family without any associated disorders such as a hereditary hemorrhagic telangiectasia. We encountered a Japanese family, including four affected members in four successive generations, with brain AVM. A genome-wide linkage analysis using Affymetrix GeneChip 10K 2.0 Xba Array was carried out on the pedigree. While blood samples for DNA extraction were provided by only the proband, clipped fingernails were obtained for DNA extraction from the other ten individuals in the family with informed consent. SNP genotyping from the fingernail samples were successful, showing the mean SNP call rate of 92.49%. Multipoint LOD scores were calculated using MERLIN software and we identified 18 regions with positive LOD scores. Haplotype and linkage analyses with microsatellite markers in these regions confirmed three possible disease-responsible loci, i.e., 5p13.2-q14.1, 15q11.2-q13.1 and 18p11.32-p11.22. Ten selected genes within 5p13.2-q14.1 were directly sequenced. The candidate genes consisted of *MAP3K1*, *DAB2*, *OCLN*, *FGF10*, *ESM1*, *ITGA1*, *ITGA2*, *EGFLAM*, *ERBB2IP*, and *PIK3R1*. Although no causative genetic alteration was found in these genes, we cannot rule out the possibility that the loci are responsible for familial brain AVM. This is the first report of adoption of fingernail DNA for SNP array analysis to detect susceptible regions to brain AVM.

## 1986/T/Poster Board #535

**Quantitative Trait Linkage Analysis of Gamma-Band Response in Over 600 Individuals in a Nepalese Population Genetic Isolate.** *S.L. Santangelo[1,2,3], T. Sitnikova[1,2], M.H. Hall[1,4], D. Yu[2], J. Subedi[5], S. Ojha[6], P. Shrestha[7], P. Shrestha[7], S. Tamang[7], J.L. VandeBerg[8], J. Blangero[8], S. Williams-Blangero[8].* 1) Harvard Medical School, Dept Psychiatry, Boston, MA, USA; 2) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA, USA; 3) Harvard School of Public Health, Boston, MA, USA; 4) Psychology Research Laboratory, McLean Hospital, Belmont, MA, USA; 5) Miami University, Dept. Sociology, Gerontology, Oxford, OH, USA; 6) Tribhuvan University Institute of Medicine, Dept. Psychiatry, Kathmandu, Nepal; 7) Nepal Biomedical Research Center, Kathmandu, Nepal; 8) Southwest Foundation for Biomedical Research, San Antonio, TX, USA.

In an effort to map genes influencing schizophrenia, we measured schizophrenia endophenotypes in over 600 members of a genetic isolate from Jiri, Nepal. The sampled individuals are from a single pedigree in the Jirel population comprising 2500 individuals who participated in a genome-wide linkage scan. One of the traits we measured is oscillatory brain activity in the gamma-band range (35-45Hz), which may arise from synchronized output of parvalbumin-expressing, fast spiking GABA neurons to the pyramidal cell assemblies. Abnormalities in this neural mechanism have been documented in schizophrenia patients and their first-degree relatives. We measured induced gamma-band activity between 250-550 msec after infrequent stimuli onset in the classic auditory oddball paradigm. The power of the event-related induced activity was calculated at the the PZ, P3 and P4 scalp locations in 614 individuals via the Instantaneous Frequency Analysis module of Neuroscan Scan 4.0 software based on the method of complex demodulation. Gamma-band response was evaluated in a quantitative trait locus (QTL) genome-wide linkage analysis after estimating heritability. Heritabilities for gamma band activity at all three scalp locations were significant, controlling for age and sex, and ranged from 0.19-0.22 (p=0.002-0.006). QTL linkage analysis for gamma response, adjusted for age and sex, yielded peak LOD scores of 1.63 on chromosome 6 (182 cM) for PZ; 1.42 on chromosome 2 (98 cM) for P3, and 1.84 on chromosome 2 (98 cM) for P4. There was also a LOD of 1.31 on chromosome 2 (98 cM) for PZ. For this Nepalese pedigree and marker set, evidence of suggestive linkage (likely to happen ≤ once by chance in a genome scan) is obtained for LOD scores ≥ 1.65. Therefore, we obtained suggestive linkage (maxLOD = 1.84) at chromosome 2p13 at the P4 electrode, with similar signals at the same chromosomal location at the PZ and P3 electrodes. Linkage to this same region was previously found for schizophrenia in another population isolate in Palau, Micronesia. Genes in this region include: transforming growth factor alpha (TGFA), implicated in circadian sleep-wake cycles, SPRED2, a member of the Sprouty family of proteins that regulate growth factor-induced activation of the MAP kinase cascade, and sepiapterin reductase (SPR) an enzyme that catalyzes the final step in the synthesis of tetrahydrobiopterin (BH4), an essential cofactor for synthesis of many neurotransmitters, including serotonin.

## 1987/T/Poster Board #536

**Chromosome 3q22 and BMPR2 mutations interact epistatically to cause familial pulmonary arterial hypertension.** *R. Subaran[1], L. Rodgriguez[1], W.C.L. Stewart[1], S. Marathe[1], S. Pramanik[2], R.J. Barst[2], W.K. Chung[2], D.A. Greenberg[1].* 1) Biostatistics, Columbia Univ, New York, NY; 2) Columbia University Medical Center, New York, NY.

A heritable trait with low penetrance, familial pulmonary arterial hypertension (FPAH) presents a tractable model for understanding complex diseases. The most extensively characterized determinant of FPAH expression is the BMPR2 gene. BMPR2 encodes the bone morphogenetic protein type II receptor and regulates proliferation of the pulmonary vasculature. Though nearly all FPAH cases carry heterozygous, loss-of-function BMPR2 mutations, over 80% of individuals as a whole with these mutations never express disease. Therefore, BMPR2 mutation status alone is an unreliable predictor of FPAH. We explore the possibility that additional genetic factors influence FPAH expression among BMPR2 carriers. By performing genome-wide linkage analysis on 15 FPAH families, all segregating BMPR2 mutations, we find 4 previously unreported loci linked (LOD > 2.0) to FPAH: 2p22, 3p12, 3q22 and 13q21. One of these loci, 3q22, shows strong evidence for linkage (LOD = 3.43). Imputation of trait model by maximizing the LOD score at 3q22 with respect to penetrance suggests 65-70% penetrance at this locus. Therefore, examining co-segregation of both 3q22 and the BMPR2 locus can be a far better predictor of FPAH than checking BMPR2-mutation status alone. While outlining a paradigm for understanding diseases of even greater complexity, our studies also uncover a novel locus interacting epistatically with BMPR2, allowing better prediction and treatment of FPAH.

## 1988/T/Poster Board #537

**A QTL on chromosome 7p influences the timing of the pubertal growth spurt in healthy children from the Fels Longitudinal Study.** *B. Towne[1], J. Blangero[2], E.W. Demerath[3], K.D. Williams[4], T.D. Dyer[2], S.A. Cole[2], W.C. Chumlea[1], R.M. Siervogel[1], S.A. Czerwinski[1].* 1) Wright State University, Dayton, OH; 2) Southwest Foundation for Biomedical Research, San Antonio, TX; 3) University of Minnesota, Minneapolis, MN; 4) Temple University, Philadelphia, PA.

Adult stature, and stature measured at any age during childhood, is highly heritable, and recent genome-wide analyses have identified QTL and SNPs linked or associated with adult or childhood stature. Very little, however, is known of genetic influences on specific features of individual growth patterns during childhood. In this study, we applied a triple logistic curve-fitting method to extensive serial height data from 475 healthy children aged 2 years to early adulthood (233 boys and 242 girls) in the Fels Longitudinal Study to identify in each of them the timing of the initiation of the pubertal growth spurt (age at pre-pubertal minimum growth velocity or "age at take-off" - ATO) and the timing of the pubertal growth spurt while at its most intense (age at peak height velocity - APHV). Mean ATO and APHV in these boys and girls was 10.68 and 8.72 years, and 13.75 and 11.53 years, respectively. The heritability of ATO was high in magnitude and significance ($h^2$ = 0.69 ± 0.10; p < 0.0001), as was the heritability of APHV ($h^2$ = 0.72 ± 0.10; p < 0.0001). Each of these children has been genotyped for ~400 STR markers spanning the autosomal genome. In genotype-by-sex (GxS) interaction models incorporating sex-specific variance components, significant linkage of ATO to 7p21.1-15.3 at 37 cM between markers D7S507 and D7S493 was found (LOD = 4.12), as was significant linkage of APHV to this exact same chromosomal region (LOD = 4.21). The effect of this 7p QTL on the timing of the pubertal growth spurt was more pronounced in females than in males. Contained within the support interval of this 7p QTL for the timing of the pubertal growth spurt is the growth hormone releasing hormone receptor gene (GHRHR). Johansson et al. (2009) recently reported significant linkage results in this same region of chromosome 7p for height in two samples of primarily adults from Sweden, and they found tagSNP haplotypes in GHRHR to be associated with height in their study samples. Other positional candidate genes in this region of 7p and known to regulate aspects of skeletal growth and development include the HOXA1-13 gene cluster at 7p15.2. Together, these findings suggest the presence of a gene or genes on chromosome 7p that influence the timing of pubertal growth, as well as other aspects of growth including height status. Supported by NIH grants R01HD12252, R01HD40377, F32HD053206, and R37MH59490.

## 1989/T/Poster Board #538

**Genome-wide Linkage Analysis Using SNP Chip on a Korean Family with Late-Onset Nonsyndromic Hearing Loss.** *H.-H. Won[1,2], H.-J. Kim[3], S.H. Hong[4], J.-W. Kim[3].* 1) Samsung Biomedical Research Institute, Seoul, Korea; 2) Department of Bio and Brain Engineering, Korea Advanced Institute of Science and Technology, Daejeon, Korea; 3) Department of Laboratory Medicine and Genetics, Sungkyunkwan University School of Medicine, Samsung Medical Center, Seoul, Korea; 4) Department of Otorhinolaryngology and Head and Neck Surgery, Sungkyunkwan University School of Medicine, Samsung Medical Center, Seoul, Korea.

Hereditary hearing loss (HL) represents the most extreme example of genetic heterogeneity, and a growing list of chromosomal loci and genes have been uncovered to underlie the condition. Linkage analysis is one of the powerful approaches for the identification of disease-causing genes, and the typical polymorphic markers used for the approach have been mutiallelic microsatellite markers (or short tandem repeats). However, single nucleotide polymorphisms (SNPs), bi-allelic markers, have advantages including its abundance in the human genome and ease of typing. In this study, we tried to localize the disease gene for nonsyndromic late-onset HL in a Korean family through a genome-wide linkage analysis using a set of SNP markers. Blood samples were collected from 21 individuals in the pedigree, of which the pattern of disease running was suggestive of autosomal dominance inheritance. The Illumina 6K SNP linkage panel was used as the markers, the MERLIN program was used for the calculation of linkage scores. Mutipoint parametric and nonparametric analyses were performed to yield LOD sores and NPL scores, respectively. We found a chromosomal locus on the band 5q31 to have a significantly high linkage scores both on multipoint parametric and non-parametric analyses. Haplotype analyses also revealed the heterozygous allele disease haplotype in affected individuals. The chromosome band 5q31 is one of the gene-rich genomic segments, and several known disease loci (genes) have been previously identified in the chromosome band 5q31 in linkage with hereditary HL including DFNA1 (*DIAPH1*), DFNA15 (*POU4F3*), DFNA42, and DFNA54. We performed direct sequencing of the two known HL genes (*DIAPH1* and *POU4F3*) within our locus and found no mutations, suggesting there would be a novel HL gene in the region. This study demonstrated that linkage analysis using biallelic, SNP markers can successfully identify the disease locus for HL. Identification of a novel HL gene by the candidate gene study within our locus on the chromosome band 5q31 will further extend the genetic heterogeneity of hereditary HL in human.

## 1990/T/Poster Board #539

**Genetic linkage evidence for distinct subtypes of schizophrenia characterized by age at onset and neurocognitive deficits.** *Y.J. Lien[1,2], P.C. Hsiao[2], C.M. Liu[3,4], S.V. Faraone[5], M.T. Tsuang[6,7], H.G. Hwu[1,3,4], W.J. Chen[1,2,3,4].* 1) Institute of Epidemiology, College of Public Health, National Taiwan University, Taipei, Taiwan; 2) Genetic Epidemiology Core Laboratory, Division of Genomic Medicine, Research Center for Medical Excellence, National Taiwan University, Taipei, Taiwan; 3) The Department of Psychiatry, College of Medicine, National Taiwan University, Taipei, Taiwan; 4) Department of Psychiatry, National Taiwan University Hospital, Taipei, Taiwan; 5) The Genetics Research Program and the Department of Psychiatry and Behavioral Sciences, SUNY Upstate Medical University, Syracuse, NY; 6) The Department of Psychiatry and the Center for Behavioral Genomics, University of California, San Diego, CA; 7) Harvard Institute of Psychiatric Epidemiology and Genetics, Harvard Departments of Epidemiology and Psychiatry, Boston, MA.

As schizophrenia is genetically and phenotypically heterogeneous, targeting subphenotypes with possible greater genetic loadings may help reveal a more homogeneous subset of families with greater linkage signals. This study aimed to evaluate the genetic linkage evidence for schizophrenia in subsets of families using earlier age at onset or greater neurocognitive deficits as subphenotypes. Participants of this study included patients with schizophrenia and their first-degree relatives recruited from six data collection research center throughout Taiwan. The sample comprised 1,207 affected individuals and 1,035 unaffected individuals of Han Chinese ethnicity from 557 sib-pair families co-affected with DSM-IV schizophrenia. Subjects completed a face-to-face semi-structured interview, the Continuous Performance Test (CPT), the Wisconsin Card Sorting Test, and were genotyped with 386 microsatellite markers across the genome. A series of nested ordered subset genome-wide linkage analyses were conducted and the statistical significance for a subset-derived increase in linkage signal was evaluated using permutations to obtain a chromosome-wide p value. Five chromosomal regions (2q, 7q, 8q, 9p, and 12q) had significant increases in maximum nonparametric linkage z (NPL-Z) scores in subsets of families of patients with schizophrenia characterized by age at onset or neurocognitive deficits compared with those obtained in initial linkage analyses using all available families. A maximum NPL-Z score of 4.12 (empirical $p = 0.007$) at 2q22.1 was found in 295 families ranked by increasing age at onset. Based on this subset, a further subsetting by false alarm rate on the undegraded and degraded CPT obtained further increase in the nested subset-based NPL-Z on 2q22.1, with a score of 5.36 (empirical $p = 0.004$) in 228 families and 5.50 (empirical $p = 0.001$) in 243 families, respectively. We found strong evidence of linkage on chromosome 2q22.1 in families of schizophrenia patients with younger age at onset and more CPT false alarm rates. We also found evidence of linkage on 7q, 8q, 9p, and 12q in families with particular neurocognitive deficits. These results highlight the importance of incorporating genetic-related subphenotypes in unraveling the complex genetics of schizophrenia.

## 1991/T/Poster Board #540

**Anthropometric traits for eyes and nose show evidence of genetic effect in Mongolian individuals.** *D.W. Suh[2,3], S.W. LiM[1,2,4], H.J. Kim[2,3], J.H. Yi[2], J.I. Kim[1,2,4], J.S. Seo[1,2,3,5].* 1) Department of Biochemistry and Molecular Biology, Seoul National University College of Medicine, Seoul 110-799, Korea; 2) ILCHUN Genomic Medicine Insititute, Medical Research Center, Seoul National University, Seoul 110-799, Korea; 3) Department of Biomedical Sciences, Seoul National University Graduate School, Seoul 110-799, Korea; 4) Psoma Therapeutics, Inc., Seoul 110-799, Korea; 5) Macrogen Inc., Seoul 153-023, Korea.

The anthropometric traits for eyes and nose are complex quantitative traits influenced by many factors including genetic and environmental input. There have been only a handful of reports regarding the genetic effect and the genes linked to phenotypes of eyes and nose. The aim of this study is to determine the amount of genetic effect and quantitative trait locus (QTL) of 7 eyes and nose anthropometric traits in an isolated Mongolian population, using the data collected from 1,014 individuals (434 male and 580 female) of Mongolian origin. Frontal and dextrolateral photograph of each subject were taken, and 7 eyes and nose anthropometric traits were recorded. 349 short tandem repeat (STR) microsatellite markers on 22 autosomes of each subject were also genotyped. Heritability estimates of 7 eyes and nose size adjusted by significant covariates among age, sex, age*sex, age^2 and age^2*sex were ranged between 0.48 to 0.84. With variance-component linkage analysis, we found evidence of linkage (multipoint LOD score ≥2.0) on chromosome 1, 2, 4, 11 and 13. The peaks on chromosome 2 and 4 were found to overlap in more than one trait. Implementing 4 additional covariates (height, weight, BMI and body fat) yielded increase in the heritability estimates (h2=0.48-0.90), and evidences of linkage (multipoint LOD score ≥2.0) could be detected on chromosome 4, 5, 9, 13, 15, 17 and 18. Highest multipoint LOD score was 3.9 in bilateral eye fissure length on chromosome 5, where the region included additional linkage peak in biocular width. Further efforts will assist in our understanding of the link between genetic factors and the human anthropometric traits.

**A novel locus for autosomal recessive non-syndromic mental rentardation (NSMR) maps to 13q12.3-q13.2.** *A. Noor[1], A. Mir[2], A. Mikhailov[1], A. Fennell[1], M. Ayub[3], J.B. Vincent[1].* 1) Neurogenetics Section, Center For Addiction and Mental Health (CAMH), Toronto, ON, Canada; 2) Department of Bio-Sciences, COMSATS Institute of Information Technology (CIIT), Islamabad, Pakistan; 3) St. Luke's Hospital, Middlesborough, UK.

BACKGROUND: Mental retardation (MR) is defined by an intelligence quotient (IQ) of less than 70 associated with functional deficits in adaptive behavior, and has a prevalence of 1-3% in the population. Although non syndromal autosomal recessive forms of MR (NS-ARMR) are believed to be relatively more common, only five genes have been reported so far. The objective of the present study was to identify a new locusgene for ARMR. METHODS: We ascertained a consanguineous family affected with non-syndromic autosomal recessive mental retardation. The phenotype was present in 4 individuals from two branches of the family. To map the chromosomal location of the causative gene we undertook Affymetrix 5.0 gene chip SNP analyses of all affected individuals and two unaffected individuals, assuming that a founder mutation was responsible. RESULTS: All affected individuals shared a 4.9 Mb haplo-identical region of homozygosity located on chromosome 13q12.3-q13.2, defined by SNP markers rs9506126 and rs9598929. The physical location of the critical region is 28,727 Mb to 33,621 Mb (UCSC, March 2006) and it contains ~30 Refseq genes. We have identified several candidate genes within this locus including UBL3, KATNAL1, FRY, PDS5B and KIAA0774. Sequencing of candidate genes to identify the causative mutation is in process. CONCLUSION: We have mapped the chromosomal location of a novel gene responsible for autosomal recessive non-syndromic mental retardation.

**A novel autosomal recessive syndrome of mental retardation, kyphoscoliosis and congenital heart disease maps to chromosome 11q14-q23.** *A. Tzschach[1], M. Garshasbi[1,2], P. Nekooee[2], R. Kariminejad[3], H. Ropers[1], A. Kuss[1], H. Najmabadi[2,3], K. Kahrizi[2].* 1) Human Molecular Genetics, Max Planck Institute for Molecular Genetics, Berlin, Germany; 2) Genetics Research Center, University of Social Welfare and Rehabilitation Sciences, Tehran, Iran; 3) Kariminejad/Najmabadi Pathology & Genetics Center, Tehran, Iran.

We report on three siblings - two brothers and a sister born to healthy consanguineous Iranian parents - with a novel mental retardation/multiple congenital anomalies (MR/MCA) syndrome. All three patients suffered from moderate to severe mental retardation, kyphoscoliosis which became apparent at the age of approximately 6 years and congenital heart disease. Body measurements were within the normal range, and metabolic tests and neurological investigations were normal in all patients. Chromosome analysis including array CGH revealed no abnormalities. The patients had three healthy siblings; their parents were first cousins. Assuming an autosomal recessive gene defect in this family, we performed genome-wide linkage analysis (homozygosity mapping) using a 10K SNP array (Affymetrix) and identified a single linkage interval on the long arm of chromosome 11. The homozygous interval was flanked by SNPs rs1391221 and rs1880206 and spans 28 Mb in 11q14.2-q23.2. The LOD score was 2.65. The similarity of the clinical features, the pedigree structure and the linkage data suggest that the patients in this family suffer from a novel autosomal recessive MR/MCA syndrome. Mutation analysis in candidate genes within the homozygous interval will eventually disclose the underlying genetic defect in this family.

## 1994/T/Poster Board #543

**Genome-wide association study of cataract in the Marshfield Personalized Medicine Research Project as part of the eMERGE network.** *E.S. Torstenson[1], C.A. McCarty[2], S.D. Turner[1], Y. Bradford[1], D. Berg[3], P. Peissig[3], J. Linneman[3], J. Starren[3], C. Waudby[2], L. Chen[4], M.D. Ritchie[1].* 1) Center Human Genetics Research, Vanderbilt Univ, Nashville, TN; 2) The Center for Human Genetics , Marshfield Clinic Research Foundation; 3) Biomedical Informatics Research Center, Marshfield Clinic Research Foundation; 4) Department of Opthalmology, Marshfield Clinic Research Foundation.

The Electronic Medical Records and Genomics (eMERGE) network is an NHGRI funded initiative with the goal of testing whether electronic medical record (EMR) systems can serve as a resource for collecting phenotypic information for genomic studies. To test this hypothesis, five groups around the United States are using natural language processing algorithms to derive phenotypes in patients who have DNA samples in the institution's biobank. The Marshfield Clinic in Central Wisconsin represents one such institution and our phenotypes are cataract and high-density lipoprotein (HDL) cholesterol (U01-HG004608). Here we will discuss our genome-wide association study for cataract. Cataract is the leading cause of vision loss in the US and blindness in the world. Summary prevalence estimates indicate that 17.2% of Americans aged 40 years and older have cataract in either eye and 5.1% have pseudophakia/aphakia (previous cataract surgery). With increased life expectancy, the number of cataract cases and cataract surgeries is expected to increase dramatically unless primary prevention strategies can be developed and successfully implemented. Known environmental risk factors for cataract include cigarette smoking, ultraviolet light and chronic steroid use. It has been suggested that as many as 40 genes may be involved in age-related cataract. Evidence for a major gene has been identified for cortical and nuclear cataract, with heritability estimates of 58% and 48%, respectively. To date, no genome-wide association studies of age-related cataract in unrelated individuals have been reported in the medical literature. Presence or absence of cataract (through surgery records, diagnosis codes, and natural language processing) in addition to cataract type (cortical and nuclear) was electronically harvested from subject EMRs in 3900 individuals (2600 cases and 1300 controls). All samples were genotyped with the Illumina 660-Quad platform. Each SNP passing rigorous quality control measures was tested for association with cataract using logistic regression, assuming an additive model. Here we report several highly significant findings, shedding some light on the genetic contribution to cataract. Finally, we demonstrate the success of using an EMR-derived phenotype to perform genetic analysis of complex disease. This study along with the other eMERGE projects provide evidence supporting the use of biobanks linked to EMRs for genomic studies.

## 1995/T/Poster Board #544

**Novel compound heterozygous mutations in CERKL cause autosomal recessive retinitis pigmentosa in a non-consanguineous Chinese family.** *L. Wang, Z.H. Tang, T. Ke, Q. Wang, M.G. Liu.* Huazhong University of Science and Technology, Wuhan, Hubei, China.

Objective: To identify the genetic basis of severe autosomal recessive retinitis pigmentosa in a non-consanguineous Chinese family. Methods: Linkage and halpotype analyses were used to identify chromosomal location of the pathogenic gene in the arRP family. Direct DNA sequence analysis was used to identify the disease-causing mutation, and to demonstrate if the mutations co-segregate with the disease in the family. Results: The disease gene in the Chinese arRP family was linked to the RP26 locus. DNA sequence analysis revealed two compound heterozygous mutations in the newly identified RP26 disease-causing gene, CERKL. One mutation is c.156_157insT in exon 2, and the other is c.758delT in exon 5. The affected individuals in the family inherited both mutations, whereas two unaffected sisters inherited normal alleles from their parents. The two mutations were not detected in 100 unrelated normal controls. Conclusions: There are only three mutations have been identified in CERKL, and all of them were detected in consanguineous families. Here we report two novel CERKL mutations, c.156_157insT in exon2, and c.758delT in exon5, in a non-consanguineous Chinese arRP family. It is the first report that compound heterozygous mutations of CERKL may cause severe RP. These studies expand the spectrum of CERKL mutations causing arRP. Clinical Relevance: Clinical and genetic characterization of retinitis pigmentosa may provide more accurate prognosis in RP patients, and help to understand the pathology of this important disease.

## 1996/T/Poster Board #545

**Predicting the functional importance of SNPs to improve the power of genome-wide association studies.** *R.J. Klein, M.A. Levenstien.* Program in Cancer Biology and Genetics, Memorial Sloan-Kettering Cancer Center, New York, NY 10065, USA.

Over the last several years, genome-wide association studies (GWAS) have successfully identified numerous alleles associated with common disease. Despite these successes, it is clear that these variants do not explain the full heritability of these diseases. One problem with GWAS is that the large number of single nucleotide polymorphisms (SNPs) tested require a severe multiple testing correction. To have the power to detect a genome-wide significance level of $10^{-7}$ requires extremely large studies, especially for alleles of modest effect. If we could predict *a priori* which SNPs are most likely to have some functional consequence, we may be able to reduce the number of tests and thereby increase the power of GWAS without increasing the study size. To begin to identify those sequence features most likely to contain functionally important variants, we cross-referenced bioinformatic annotation of genomic sequence features with minimally biased genome-wide data on SNP allele frequencies. Using the annotations available in the Ensembl database, we categorize SNPs in the human genome into classes related to regulatory features, such as epigenetic modifications and transcription factor binding sites in addition to classes related to gene structure and cross-species conservation. Based on population genetic theory, we expect the dereived allele frequencies to trend lower in functional classes of elements than in those that are neutrally evolving. We assess the strength of natural selection for each class relative to the genome as a whole using the distribution of derived allele frequencies (DAF) within each class. We apply this DAF analysis to Perlegen resequenced SNPs genome-wide. Groups of regulatory elements annotated by Ensmbl as well as some individual elements, such as PolII binding sites, DNase I hypersensitivity sites, and several histone methylation sites, show negative selection in comparison to the genome as a whole. In fact, some histone modification sites in addition to constrained elements outside of genes appear to have derived allele frequencies comparable with those of the coding regions. We estimate that if one were to restrict analysis of GWAS to SNPs that fall in the functional classes we identify, the number of SNPs to be tested would be reduced by two orders of magnitude, thereby yielding increased power.

## 1997/T/Poster Board #546

**The tumor suppressor LKB1 kinase gene associated with type 2 diabetes.** *P. Keshavarz[1], H. Inoue[2].* 1) Department of Genetics, Guilan University of Medical Science, Rasht, Iran; 2) Institute for Genome Reseach, The University of Tolkushima.

Inactivating germ line mutations in the LKB1 gene underlie Peutz-Jeghers syndrome characterized by hamartomatous polyps and an elevated risk for cancer. The tumor suppressor LKB1 is an upstream kinase in the AMP-activated protein kinase (AMPK) cascade provided a molecular link between energy metabolism and cancer. A recent study by Shaw and colleagues elucidated the role of LKB1 in type 2 diabetes. To assess whether the LKB1 variants has any impact to type 2 diabetes in Japanese, we screened all ten exons, their exon-intron boundaries, and the 5' and 3' flanking regions of LKB1 to identify single nucleotide polymorphisms (SNPs), and we genotyped 911 unrelated Japanese type 2 diabetic patients and 876 control subjects to show possible associations between genotypes or haplotypes and type 2 diabetes. We observed associations of nominal significance with an intronic SNP in the LKB1 (rs741765; OR 1.33, 95% CI 1.05-1.67, p = 0.017, under a recessive genetic model with type 2 diabetes. In the haplotype analysis, consisting of six representative SNPs, revealed one haplotype, to be associated with type 2 diabetes (P = 0.03). We speculate that the LKB1 gene influences insulin resistance and susceptibility to type 2 diabetes in the Japanese population.

## 1998/T/Poster Board #547

**A whole genome-wide association study of psoriasis within the Japanese population using 26,061 microsatellite markers.** *A. Oka[1], T. Mabuchi[2], H. Hayashi[1], K. Yamaguchi[1], E. Matsushita[1], Y. Keisuke[3], S. Mano[4], A. Ozawa[2], T. Gozyobori[5], H. Inoko[1].* 1) Division of Basic Medical Science and Molecular Medicine, Department of Molecular Life Science, Tokai University School of Medicine, Isehara, Kanagawa 259-1193, Japan; 2) Departments of Dermatology, Tokai University School of Medicine, Isehara, Kanagawa 259-1193, Japan; 3) Department of Cardiorenal and Health Medicine, Yokohama City University School of Medicine, Yokohama Kanagawa 236-0004, Japan; 4) Institute of Natural Sciences, Nagoya City University, Nagoya 467-8501, Japan; 5) Center for Information Biology and DNA Data Bank of Japan, National Institute of Genetics, Shizuoka 411-8540, Japan.

Psoriasis is a common skin disorder characterized by inflammatory cell infiltration and hyperproliferation of epidermal cells. The familial nature of this disease, which affects almost 2% of Caucasian populations, has long been recognized on the basis of twin studies and linkage analysis. However, in the Japanese population, a lower incidence (0.1%) has been observed with most psoriasis cases being sporadic. These facts define psoriasis as a multifactorial disease triggered by the involvement of some environmental factors in individuals with a particular genetic background. We have recently tested and established the use of approximately 26,000 microsatellite markers for genome-wide association studies of common diseases (http://www.jbirc.aist.go.jp/gdbs/). Our aim now was to apply the same collection of microsatellite markers to identify the susceptibility loci and the pathogenic genes responsible for psoriasis in a case-control association study of the Japanese population. An initial set of 375 psoriasis patients and an identical number of control samples, all of Japanese descent, were applied by pooled DNA genotyping in the three-step genomic screen. Microsatellites that had remained statistically different between cases and controls in all three screening steps were confirmed by individual genotyping using the same set of 375 patients and 375 controls and the additional set of 186 patients and 186 controls. Accordingly, we found significant association for one microsatellite as assessed by the Fisher's exact test, except for psoriasis-susceptibility locus (PSORS1) of the HLA region, when we applied a p-value 2.6x10^-7 for significance after Bonferroni's correction to account for multiple comparisons. This microsatellite was located at 5'-flanking region of one gene of the GPCR family. Moreover the expression level in peripheral blood mononuclear cell was the correlation with the susceptibility allele, however the function of this gene was not clear so far.

## 1999/T/Poster Board #548

**Genetic study of otosclerosis in NL founder population.** *N. Abdelfatah[1], S. Moore[3], T. Batten[4], K. Hodgkinson[1], A. Griffin[2], D. Galaturia[1], C. Negrijn[1], T. Young[1].* 1) Memorial University of NL, St John's, NL, Canada; 2) Central Regional Integrated Health Authority, Grand Falls-Windsor, NL A2A 2E1; 3) Department of Pediatrics, Memorial University of Newfoundland, St. John's, NL, Canada; 4) ENT Consultants, 1Paton St, St John'S, NL A1B 4S8.

Introduction Otosclerosis is a common form of hearing loss in the Caucasian population with a prevalence of 0.3-0.4 worldwide. Histological studies indicates that sclerotic foci in the temporal bone invade the stapedio-vestibular joint that leads to fixation of the stapes bone in to the oval window and cause the development of conductive hearing loss. The etiology of otosclerosis is unknown, but genes and environmental factors with possible interaction between them are believed to cause otosclerosis. Since 1998, seven loci (OTSC1, OTSC2, OTSC3, OTSC4, OTSC5, OTSC7, OTSC8) segregating with autosomal dominant form of otosclerosis have been mapped; none of the genes have been identified yet. Also, several association studies including several genes (COL1A1, COL1A2, NOG and RELN genes) have been carried out with sporadic forms of otosclerosis. Seven unrelated otosclerosis families were ascertained from Newfoundland, a genetically isolated population. Purpose of the study: To identify the disease-causing gene(s) for otosclerosis in families with autosomal dominant form of inheritance, and understand the mechanism underlying disease development. Methods: Two large multiplex NL families (2114, 2108) and five other probands were genotyped for microsatellite markers span the intervals of the seven known loci, the collagen genes COL1A1, COL1A2 and NOG genes. Haplotypes across the ten loci were constructed manually using the least number of recombination. Results: Haplotypes analysis demonstrate that all affected 2114 family members share a region of 10.7Mb that overlaps with the original 17.9 Mb region at OTSC3 and a region of 53.0 Mb at chr7 including OTSC2 and COL1A2 and RELN, genes were previously associated with otosclerosis. Haplotypes analysis for family 2081 exclude the linkage to OTSC1, OTSC2, OTSC3, OTSC5, OTSC8, and COL1A1, NOG gene. Further genotyping and haplotype construction for the remaining loci and genes are in progress. Summary: A five generation family (2114) appears to be linked to OTSC3 and OTSC2. Also, all affected members share a large haplotype that includes COL1A2 and RELN genes. A four generation family (2081) has been excluded from the linkage to six of the mapped otosclerosis loci and two associated genes. Comparing haplotype of potentially linked locus at OTSC3 among seven probands, three of the seven probands share a portion the linked region. Further studies are in progress to confirm the linkage.

**A Fine Mapping Theorem to Refine Results from Association Genetic Studies.** *S.J. Schrodi, V.E. Garcia, C.M. Rowland.* Dept Statistical Genetics, Celera, Alameda, CA.

Much remains to be explained about human genetic architecture and specific variants underlying important traits such as disease phenotypes - both critical to successful fine mapping following GWAS. High density mapping and inference of susceptibility variants is highly reliant upon the positional pattern of disease association peaks. In this work we describe the nature of the decay curve of association patterns due to declining LD from a causative site. Under a variety of disease models, we show that the central tendency approximation $\chi^2_M \sim r^2 \chi^2_D$ holds, where $\chi^2_M$ and $\chi^2_D$ are the chi-sq statistics at a marker and disease-causing site, respectively; and $r^2$ is the standard measure of LD between the two sites. We use the phrase "fine mapping theorem" for this approx to underscore its potential utility in discovering specific variants underlying traits studied in very high density mapping studies. Monte Carlo simulations were used to characterize the amount of error in the approximation. These results showed that the maximum mean squared error is a concave function of $r^2$ peaking at intermediate levels of r2 across all the disease models screened. Next, given a potential causative polymorphism and several closely-linked sites with disease association data, a method was developed to quantify the departure from the fine mapping theorem. Calculating this departure metric for all SNPs in an associated region will give a measure of correspondence with the fine mapping theorem for each polymorphism, and enable one to determine the most likely (i.e. those with the smallest departure metric) disease-causing variants under a theoretical model (i.e. a single disease-predisposing variant and numerous closely-linked markers associated with disease solely through LD). Lastly, we applied these approaches to previously-published fine mapping datasets for type 1 diabetes (*IL2RA* region consisting of 305 SNPs) and rheumatoid arthritis (*TRAF1* region consisting of 138 SNPs). In both datasets, single SNPs with the highest correspondence to the theoretical association decay patterns were identified. Conversely, SNPs deviating from their chi-sq values expected under the theorem may constitute additional susceptibility polymorphisms in the region studied. Similar applications of this fine mapping theorem may prove to be a pragmatic approach to delineate genes, gene regions, or functional motifs responsible for disease etiology subsequent to initial genetic results from GWAS.

## 2001/T/Poster Board #550

**Homologous Genomic Loci Can Cause Genotyping Errors and can be Overrepresented in SNP Panels Selected according to Linkage Disequilibrium Tagging Methods.** *A.L. Guiney, J.A. Fagerness, A. W. Kirby, J. W. Smoller.* Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA.

Many commonly assayed single nucleotide polymorphisms (SNPs) occur within sequences that share high homology to regions elsewhere in the genome. Assays of these SNPs, which commonly use relatively short target sequences, will not always be specific to the single desired locus. Assays that interrogate more than one genomic locus can result in false genotypes that appear to be properly assayed SNPs, and can pass standard quality control filters. Many of these incorrectly genotyped polymorphisms appear in commonly used SNP databases. Because their apparent genotypes are not the result of one locus' genetic variability these SNPs will be out of linkage disequilibrium (LD) with nearby polymorphisms and will break up otherwise contiguous blocks of (LD). As a result they will be overrepresented in SNP panels selected according to LD tagging methods. In addition, they can show false associations to studied phenotypes.

**Mutations in the Integrin responsible for a congenital muscular dystrophy with hyperlaxicity and their impact on normal cellular adhesion.** *M. Tetreault[1,2], I. Thiffault[1,2], L. Loisel[1], J. Mathieu[3], Y. Robitaille[4], M. Vanasse[5], B. Brais[1,2].* 1) Laboratoire de Neurogenetique et motricite, CRCHUM Hopital Notre-Dame, Montreal, QC, Canada; 2) Neuromics Center for Excellence of Universite de Montreal, Universite de Montreal, CRCHUM Hopital Notre-Dame, Montreal, QC, Canada; 3) Carrefour de la sante de Jonquiere, Saguenay, QC, Canada; 4) Departement de pathologie, Hopital Sainte-Justine, Montreal, QC, Canada; 5) Clinique des maladies neuromusculaires, Centre de readaptation Marie-Enfant, Hopital Sainte-Justine, Montreal, QC, Canada.

Congenital muscular dystrophies (CMD) are a heterogeneous group of disorders. A growing number of CMD have been found to be associated with joint hyperlaxicity. We recruited 16 French-Canadian cases belonging to 13 families from Southwestern Quebec affected by an autosomal recessive congenital muscular dystrophy with hyperlaxicity (CMDH). All patients present muscle weakness, proximal contractures coexisting with distal joint hyperlaxicity. They have a more benign course than most described CMD, with preservation of walking into adult age in most cases. Mutations were uncovered in an integrin. To date, deletion, complex insertions (Alu, LTR) and partial duplications of the gene were uncovered in the patients. Considering that integrins are transmembrane proteins that interact with extracellular matrix proteins we performed cell adhesion assays using cell lines from patients with different mutations. Comparing controls and patients cell lines; we found that these mutations modified the binding ability to certain extracellular partners. The identification of mutations in a second integrin gene causing a congenital muscular dystrophy confirms the importance of this family of proteins in ensuring the proper interactions between the extracellular matrix and the membrane essential to normal muscle development and function.

## 2003/T/Poster Board #552

**Replication of synergy between genetic variants in TF and HFE as risk factors for Alzheimer's Disease.** *J.S.K. Kauwe[1,2], S. Bertelsen[2], K. Mayo[2], C. Cruchaga[2], R. Abraham[3], P. Hollingworth[3], D. Harold[3], M.J. Owen[3], J. Williams[3], S. Lovestone[4], J.C. Morris[2], A.M. Goate[2].* 1) Department of Biology, Brigham Young University, Provo, UT; 2) Department of Psychiatry, Washington University School of Medicine, St. Louis, MO; 3) MRC Centre for Neuropsychiatric Genetics and Genomics, Department of Psychological Medicine, School of Medicine, Cardiff University, Cardiff, UK; 4) Department of Neuroscience, Institute of Psychiatry, Kings College, London, UK.

Alzheimer's disease (AD) is a complex disease that is likely influenced by many genetic and environmental factors. Evidence from the Alzgene meta-analyses and several recent studies suggests rs1049296 in transferrin (TF) is associated with risk for AD. However, as is the case with many reported associations, replication has been difficult and often yields inconsistent results. It has been suggested that this lack of replication may be a "signature of epistasis". Citing evidence that iron may play a role in AD pathology, Robson et al. (2004) reported that epistatic interaction between rs1049296 (P589S) and rs1800562 (C282Y) in the hemochromatosis gene (HFE) results in significant association with risk for AD. In this study we attempted to replicate their findings in a total of 1166 cases and 1404 controls from three European and European American populations. We observed significant association between bi-carriers of the minor alleles of rs1049296 and rs1800562 in the combined sample using synergy factor (p=0.0016, OR= 2.71). These results validate those of the previous report and suggest that TF and HFE modulate risk for AD.

## 2004/T/Poster Board #553

**Schizophrenia and cancer gene networks: a comparative study and their applications.** *Z. Zhao[1,2,3], J. Sun[1,2].* 1) Biomedical Informatics, Vanderbilt University, Nashville, TN; 2) Department of Psychiatry, Vanderbilt University, Nashville, TN; 3) Vanderbilt-Ingram Cancer Center (VICC), Nashville, TN.

Schizophrenia is a heritable and major psychiatric disorder whose pathogenesis likely involves multiple genes interacting themselves or with environment. Cancers have been found to be caused by many genes and their interactions in the cellular systems. In this study, we first compiled the schizophrenia candidate genes and general cancer genes. The schizophrenia candidate genes were selected based on a multi-dimensional evidence-based approach using genes from association studies, linkage scans, gene expression, and literature search. We used independent unbiased p values in the genome-wide associate studies (GWAS) to search for the optimal weight matrix, which was subsequently applied to prioritize schizophrenia candidate genes (SZGenes). In addition to schizophrenia and cancer genes, we also selected neurodevelopment related genes, essential genes and non-disease genes for comparison. Next, we extracted the subnetworks in the whole human protein-protein interaction (PPI) network. Our comparative analysis demonstrated that SZGenes tend to have intermediate connectivity and intermediate efficiency with which a perturbation can spread throughout the network relative to cancer genes, essential genes and non-essential genes. Furthermore, we found that SZGenes do not have a strong trend on interacting with each other or clustering compared to cancer genes. This difference suggests that schizophrenia and cancer might have different pathological mechanisms even though both have been considered as complex disease. Finally, we identified a few novel schizophrenia candidate genes from some schizophrenia small subnetworks that are enriched with small GWAS p values. Our follow up experiments verified them being associated with schizophrenia. This study represents the first systematic gene ranking and network analysis for schizophrenia and comparison with cancer. The extracted disease-specific networks also provided an opportunity for identifying novel candidate genes.

## 2005/T/Poster Board #554

**Does copy number variation influence personality?** *A.T. Bagshaw[1], P.R. Joyce[2], M.A. Kennedy[1].* 1) Department of Pathology, University of Otago, Christchurch, New Zealand; 2) Department of Psychological Medicine, University of Otago, Christchurch, New Zealand.

It has recently emerged that copy number variants (CNVs) consisting of insertions and deletions kilo bases or mega bases in size are a very common and potentially important source of genetic variation. Investigation of the phenotypic effects of this variation is still in its infancy, but several studies have reported associations between CNV and neuro-psychiatric phenotypes including schizophrenia and autism. To further our understanding of this link we are studying the relationship between CNV and personality traits, some of which show significant heritability and appear to act as risk factors for various mental disorders. Our initial work used publicly available data to determine whether any candidate genes for personality are located within known CNV regions. Out of 196 candidate genes considered, we found 136 that overlap with CNVs larger than 1 kb listed in the Database of Genomic Variants [1]. However, almost all particular CNVs are rare, and none of our candidate genes are in CNV with a population frequency greater than 4 percent, based on the most comprehensive dataset available [2]. We have therefore taken the approach of genotyping the ten most commonly occurring known CNVs, anticipating an effect of CNV on the expression of both participant and distal genes, for which there is reasonable evidence [3]. Our test subjects include several cohorts (over 1000 individuals), for which we have personality data assessed using Cloninger's Temperament and Character Inventory (TCI) questionnaire [4]. We will report association data from these common CNVs with novelty seeking and other specific heritable components of personality. 1. ## 2006/T/Poster Board #555

**Deletion of *CHRNA7* suggests that this gene mediates part or all of the phenotype for deletion 15q13.3.** *A. Beaudet[1], C. Schaaf[1], S.-W. Cheung[1], A. Patel[1], P. Stankiewicz[1], B. Lanpher[2], L. Immken[3], G. Simpson Patel[3], M. Shinawi[1].* 1) Dept Molec & Human Gen, Baylor Col Med, Houston, TX; 2) Div of Medical Genetics, Vanderbilt Univ, Franklin, TN; 3) Medical Genetics, Specially for Children, Austin, Tx.

Deletion of chromosome 15q13.3 has been associated with mental retardation, idiopathic epilepsy, autism, schizophrenia, and bipolar disorder. The majority of patients have one or more of these findings, but some individuals have a normal or near normal phenotype indicating that the penetrance may be 70-90%. The typical deletion interval includes six genes: *OTUD7A, KLF13, TRPM1, MTMR10, MTMR15,* and *CHRNA7*. The CHRNA7 gene encodes the $\alpha$7 subunit of the neuronal nicotinic acetylcholine receptor, which functions as a homopentameric synaptic ion channel. *CHRNA7* has been suggested as a candidate gene in schizophrenia and has been considered to be the most likely gene to be contributing to the epilepsy and neurobehavioral abnormalities associated with deletion 15q13.3. We have identified three children with deletions of CHRNA7 and a portion of *OTUD7A* which encodes a deubiquitinating enzyme, but leaving the other four genes intact. The propositii were 14 months, 20 months, and 15 years of age when studied and had combinations of failure to thrive, hypotonia, developmental delay, and mental retardation. Parents were studied in one family, and the deletion was inherited from the mother. These data strengthen the possibility that *CHRNA7* mediates part or all of the phenotypic effects seen with deletion 15q13.3, but a contribution from *OTUD7A* remains a possibility. We also have identified 30 families with the reciprocal duplication which was inherited in most cases rather than de novo. Extended families with the duplication are being evaluated to determine if there is any evidence for phenotypic effects. We are sequencing the *CHRNA7* gene searching for point mutations in patients with various developmental disabilities.

## 2007/T/Poster Board #556

**SNPs in the regulatory subunit of calcineurin are associated with CSF phospho-tau protein levels, and risk for Alzheimer's Disease.** *C. Cruchaga[1], J.S Kauwe[1], K. Mayo[1], S. Bertelsen[1], P. Nowotny[1], A.R. Shah[2], A.M. Fagan[2], D.M. Holtzman[2], J.C. Morris[2], A. Goate[1,2].* 1) Dept Psychiatry, Washington Univ, St Louis, MO; 2) Department of Neurology, Washington University, St. Louis, MO, USA.

Using cerebrospinal fluid (CSF) tau and A$\beta$42 levels as endophenotypes for Alzheimer's disease (AD) provides biological models for the effects of disease-associated genetic variation. We have previously shown that genetic variation within MAPT influences CSF ptau181 levels in AD subjects and is associated with age at onset. To identify additional genetic variation influencing CSF ptau181 levels, we selected 384 single nucleotide polymorphisms (SNPs) in 34 genes related to tau posttranslational modification and tested for association with CSF ptau181 levels in 374 individuals. Follow-up of the significant SNPs in a second independent CSF series replicated the associations for SNPs located in genes encoding the regulatory (PPP3R1; rs1868402; p=6.28x10$^{-05}$) and in the catalytic (PPP3CA; rs17030739 p= 2.05x10$^{-04}$) subunits of the phosphatase PP2B (calcineurin). To further investigate these associations and their interaction with A$\beta$ pathology we used CSF A$\beta$42 levels to stratify the sample into those with and without likely A$\beta$ deposition in brain. The association with CSF ptau181 levels is driven by cognitively normal individuals with likely A$\beta$ deposition. Rs1868402 also showed association with PPP3R1 mRNA levels and plaque pathology in the same strata and with risk for AD (p=0.01, OR=1.19, 95%CI = 1.01-1.39). Following cerebral deposition of A$\beta$, rs1868402 or another highly correlated functional SNP increases risk for AD by regulating PPP3R1 expression, leading to increased tau phosphorylation and pathology. Using CSF tau and A$\beta$42 levels as endophenotypes provides a biological model of rs18684102 and calcineurin and identifies an interaction between A$\beta$ and tau pathology wherein tau events occur after A$\beta$ deposition.

## 2008/T/Poster Board #557

**Screening of genes that have an important role in the development of motor neurons in ALS patients.** *H. Daoud, P. N. Valdmanis, F. Gros-Louis, P. A. Dion, G. A. Rouleau.* Center of excellence in neuromics, University of Montreal, Montreal, Quebec, Canada.

Background: SOD1 is a highly-expressed gene in the brain that, when mutated, yields a remarkably selective phenotype only in motor neurons. This may be due to genetic or physical interactions with genes specific to this population of neurons. A set of genes specifically expressed at different stages of development in mouse corticospinal motor neurons (CSMN) has been recently identified, including 29 statistically significant and biologically relevant genes. Several of these key genes are potentially instructive for CSMN development while others are exclusively expressed within the CSMN. We hypothesized that these genes represent good candidates which might be mutated in ALS patients. Interactions of these genes with SOD1 could help explain the specificity of neuron-targeting in ALS. Objectives: To screen ALS patients in order to identify novel mutations in a subset of genes specifically expressed in CSMN. This may help to implicate genes crucial to motor neuron development as causative in ALS. Methods: Following a complete annotation of 29 CSMN-specific genes, the entire exonic sequence of these genes were sequenced in a cohort of 190 (80 SOD1-negative familial ALS and 110 sporadic ALS) individuals. Non-disease causative polymorphisms were eliminated following a search for them in SNP databases and by sequencing 190 ethnically matched controls. Results: A total of 322 variants were identified, including 175 intronics, 8 UTRs, 69 silents, and 69 missenses and 1 nonsense mutation. Of the missense changes, 20 are known SNPs, 36 are frequent changes, and 33 are rare variants. Of the rare variants, 16 are predicted to potentially harm the function of the protein. Follow-up examination of these genes in additional ALS and control samples will help to determine which one(s) are significant to ALS. Conclusions: We identified several potential causative variants in a set of 29 genes that had never been studied before. Genes with excess of mutations will be screened in additional familial and sporadic cases. In the future, we plan to functionally characterize these mutations in in vitro and in vivo models.

## 2009/T/Poster Board #558

**Association of the polymorphism -308 G/A of the gene TNF-$\alpha$ in Mexican Parkinson`s patients.** *M. Garza[1], M.C.E. Vargas[2], E. Martinez[3], F.J. Jimenez[4], A.M. Puebla[5], M.P. Gallegos[2].* 1) Neuroscience, Universidad Autonoma de Guadalajara, Zapopan, Zapopan, Mexico; 2) Laboratorio de Genetica Molecular, CIBO, IMSS; 3) Centro Universitario de los Lagos, Universidad de Guadalajara; 4) Hospital de Especialidades, CMNO, IMSS; 5) Laboratorio de Inmunofarmacologia, CIBO, IMSS.

Parkinson disease (PD) is the second most common neurodegenerative disease that affects elderly people over 65 years old, some present genetic factors could be responsible for the development of this disease. The gene TNF-$\alpha$ (tumor necrosis factor - alpha) codes for a proinflammatory cytokine segregated by activated macrophages. This cytokine is involved in the regulation of different biological processes that includes neuroprotective or neurodeleterious effects depending on the stage of the disease. In our case-control association study we analyzed 71 patients with PD, and 197 controls in the general population of the Occident of Mexico, we amplify a fragment of 107 bp of the gene TNF-$\alpha$ by polymerase chain reaction (PCR), this fragment contents a recognition site for the restriction enzyme NcoI for the wild type allele (G) that generates two fragments of 78 bp and 20 bp. The polymorphic allele (A) is free of this recognition site for NcoI. The allele A for the polymorphism -308 G/A of the gene TNF-$\alpha$ is present in 15% (21/139) of the patients with PD and in 9% (34/393) of the controls, when we compare this data our findings are stadistically significant OR 1.88 (CI 0.99-3.48), p<0.05. In conclusion, the allele A shown a significant association with PD in the Occident of Mexico.

## 2010/T/Poster Board #559

**Association Analysis of Adenosine A1 receptor (ADORA1) and Dopamine D1 receptor (DRD1) genes with schizophrenia in the Japanese population.** *L. Gotoh[1], H. Mitsuyasu[1], A. Takata[1], Y. Kobayashi[1], K. Yamada[2], T. Yoshikawa[2], H. Kawasaki[1], S. Kanba[1].* 1) Dept Neuropsychiatry, Kyushu Univ, Fukuoka, Japan; 2) Laboratory for Molecular Psychiatry, RIKEN Brain Science Institute, Saitama, Japan.

Antipsychotic agents used for the treatment of schizophrenia affect dopamine D2 receptor (DRD2) mediated neurotransmissions, suggesting that dopaminergic dysfunction plays an important role in the pathophysiology of schizophrenia. On the other hands, it is shown that SCH23390, a selective DRD1 antagonist, inhibited PCP-induced schizophrenia-like behaviors. It is also reported that adenosine neurotransmitter system has functional interaction with dopaminergic neurotransmission. It is also known that N6-cyclopentyladenosine, ADORA1 agonist functionally involved in inhibition of PCP-induced behavior of schizophrenia model rats, as well as DRD1 antagonist. Therefore, it is possible to hypothesize that the functions of ADORA1 and DRD1 could be some part of the pathophysiology of schizophrenia. We reported that ADORA1 gene polymorphisms are involved in pathophysiology of schizophrenia using the Japanese population in Kyushu region in our previous association study. In this study, we carried out the replication study using the schizophrenia samples in Kanto region in Japan. In addition, we also investigated the association between DRD1 gene polymorphisms and schizophrenia phenotype in the same population. The case-control samples consisted of 570 unrelated schizophrenia patients (285 men, 285 women; mean age 47.0 ± 11.4 years) and 570 age- and sex-matched controls (285 men, 285 women; mean age 46.7 ± 11.1 years). Eight SNPs (5 SNPs of ADORA1 gene which indicated statistical significant tendency in previous study and 3 SNPs of DRD1 gene which are polymorphic in Japanese based on the database of HapMap project) were genotyped by Taqman real-time PCR method. Association analysis of each polymorphism was performed between schizophrenia patients and controls. The result showed that one SNP of DRD1 gene indicated statistically significant difference between the two populations (P<0.05), but no SNPs of ADORA1 gene indicated significant difference. However, after Bonferroni correction, this statistical difference of DRD1 gene polymorphism was disappeared. Further analysis such as haplotype prediction, linkage disequilibrium calculation, sliding window analysis and multi-variate statistical analysis are in progress. All subjects were given informed consent before blood collection strictly based on the Ethics Committees of the Nagoya University Graduate School of Medicine, Fujita Health University, and the RIKEN Brain Science Institute.

## 2011/T/Poster Board #560

**RGS4 gene in Schizophrenia: case-control and family-based studies, drug response and Tardive Dyskinesia.** *Y. Hirata[1], RP. Souza[1], N. King[1], JA. Lieberman[2], HY. Meltzer[3], G. Remington[1], JL. Kennedy[1].* 1) Neurogenetics Section, CAMH, Univ Toronto, Toronto, ON, Canada; 2) Department of Psychiatry, Columbia University, NY, USA; 3) Departments of Psychiatry and Pharmacology, Vanderbilt University, Nashville, TN, USA.

Purpose: The regulator of G-protein signalling 4 (RGS4) is a key player in dopamine action in the brain, and thus represents a candidate gene for schizophrenia (SCZ). The RGS4 gene and SCZ has shown mixed association results. Recently, a few studies have investigated the association of RGS4 polymorphisms with sub-phenotypes of SCZ. To further clarify the role of RGS4 in this disease, we examined the association of RGS4 with the diagnosis of SCZ in both case-control and family-based samples, and with clozapine response as well as tardive dyskinesia (TD), a potentially irreversible movement disorder associated with chronic antipsychotic exposure. Methods: We examined 4 tagged SNPs across the RGS4 gene (7 kb) in a sample of 182 case-control pairs and 104 small nuclear familes. Genotyping was done using an Illumina platform. SPSS 13.0 and Haploview 4.0 were used for genotype and allelic analyses. Haplotype analyses were performed using UNPHASED 3.0.13 and Haploview 4.0. For the family sample FBAT1.0 was used. Multiple test correction was performed using permutation testing. Results: No marker was out of HW equilibrium in either the case or control sample. We did not observe any association with single marker or haplotype analyses in the case-controls. In the families, nominal significance was observed for SNPs rs2661319 (p=0.034) and rs2842030 (p=0.049), but these did not remain significant after permutation tests. Haplotype analyses showed nominal associations with SCZ, but after permutation, the T-G haplotype (rs2842030-rs10799897) remained significant (p=0.049). When the two sample sets were combined, the G allele of rs2661319 had overall risk significance for SCZ (p=0.009). For analysis of clozapine response (N=139) we found significant association for rs10799897 (genotype: p=0.035, allele: p=0.041). The haplotype A-C (rs10799897-rs10759) was also significant after permutation (p=0.027). For analysis of TD (N= 106) we found no single marker association. The A-G haplotype (rs2661319-rs2842030) remained significant after permutation (p=0.038). Conclusion: We found moderate association between RGS4 and SCZ in our SCZ samples and the sub-phenotypes of clozapine response and TD. Given the important role of RGS4 in dopamine and other neurotransmitter signalling in the brain, further work on larger samples is warranted.

## 2012/T/Poster Board #561

**Genome-Wide Association points to the *NLGN4X*, *CTNND2*, and *DAB1* genes as candidates genes for Autism Spectrum Disorders.** *J. Holden[1,2,3], X. Liu[1,2], M.L. Hudson[1,2], Y. Qiao[5], N. Riendeau[5], I.L. Cohen[6], A.E. Chudley[7], C. Forster-Gibson[4], E. Rajcan-Separovic[5], M.E.S. Lewis[5], ASD-CARC.* 1) Autism Research Program, Ongwanada Resource Ctr, Kingston, ON, Canada; 2) Dept. Psychiatry, Queen's University, Kingston, ON, Canada; 3) Dept. Physiology, Queen's University, Kingston, ON, Canada; 4) Dept. Family Medicine, Queen's University, Kingston, ON, Canada; 5) Dept. Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 6) Dept. Psychology, Institute for Basic Research in Developmental Disabilities, Staten Island, NY, USA; 7) Dept. Human Genetics, University of Manitoba, Winnipeg, MB, Canada.

Autism Spectrum Disorders (ASDs) are the most common childhood developmental disorder. They are defined by significant deficits in communication, social reciprocity and behaviour and include Autistic Disorder, Asperger syndrome and Pervasive Developmental Disorder-Not Otherwise Specified (PDD-NOS). Several chromosomal regions have been implicated as harbouring autism-risk genes, based on candidate gene, linkage and copy number variant studies. More recently, genome-wide association and genome-wide linkage studies are being applied to this etiologically heterogeneous group. We performed a family based GWA study on 255 affected individuals and their parents from 150 simplex and 48 multiplex families using the Affymetrix 250k *Nsp* SNP array. Our strongest findings were for three SNPs within or flanking the *NLGN4X* gene on the X-chromosome at Xp22.31-32 (rs7881412: $p = 6.66 \times 10^{-16}$; rs4593704: $p = 2.03 \times 10^{-7}$; rs5916143: $p = 1.68 \times 10^{-13}$). NLGN4X plays a role in the maturation and function of neuronal synapses and previous studies have found mutations in this gene in several persons with autism, Asperger syndrome and intellectual disability. SNPs in two other genes showed marginally significant association: two SNPs within the *CTNND2* gene at 5p15.2 (rs258841: $p = 9.03 \times 10^{-8}$ and rs10065669: $p = 8.94 \times 10^{-7}$) and one SNP in the *DAB1* gene at 1p32.2 (rs17115767: $p = 5.61 \times 10^{-8}$). The *CTNND2* gene encodes catenin delta-2, and is within a CNV we reported in a patient with ASD without the classical Cri-du-Chat cry. This gene was recently found to be disrupted in a subject with schizophrenia (Vrijenhoek et al, 2008). The DAB1 (disabled 1 homolog of Drosophila) protein is required for neuronal layering in the cerebral cortex and cerebellum and is part of the Reelin-Dab1 signaling pathway. Given the association of the *RELN* gene with ASDs in previous studies, *DAB1* is also an excellent candidate gene for autism.

## 2013/T/Poster Board #562

**Association Analysis of Adenosine A1 receptor (ADORA1) and Dopamine D1 receptor (DRD1) genes with bipolar disorder in the Japanese population.** *H. Kawasaki[1], L. Gotoh[1], H. Mitsuyasu[1], A. Takata[1], Y. Kobayashi[1], K. Yamada[2], T. Yoshikawa[2], S. Kanba[1].* 1) Dept Neuropsychiatry, Kyushu Univ, Fukuoka, Japan; 2) Laboratory for Molecular Psychiatry, RIKEN Brain Science Institute, Saitama, Japan.

Bipolar disorder (BD), known as manic-depressive illness, is a frequent and severe psychiatric disorder. There have been various studies regarding the pathophysiological mechanisms of BD, although the etiology is still unknown. One of the several candidate genes involved in the pathogenesis of BD is dopamine D1 receptor (DRD1), especially its function in the prefrontal cortex. In our previous studies, we reported that the adenosine A1 receptor (ADORA1) may be genetically associated with schizophrenia, which may share the same molecular basis with BD. It is reported that the adenosine neurotransmission systems affect the functions of dopaminergic neurotransmission systems. Therefore, it is possible to hypothesize that the functions of ADORA1 and DRD1 are involved in the pathophysiology of the BD. To clarify the genetic relationship between these receptors and BD, we carried out the association study using the Japanese population. The subjects for the case-control analysis consisted of 366 patients with BD (181 males and 185 females; 50.1±13.4 years old), and 370 control subjects (185 males and 185 females; 50.6±12.6 years old). Eight SNPs (5 SNPs of ADORA1 gene which indicated statistical significant tendency in our previous study of schizophrenia and 3 SNPs of DRD1 gene which are polymorphic in Japanese based on the database of HapMap project) were genotyped by Taqman real-time PCR method. Association analysis of each polymorphism was performed between BD patients and controls. The result showed that one SNP of ADORA1 gene and two SNPs of DRD1 gene indicated statistically significant difference between the two populations (P<0.05). However, after Bonferroni correction, these statistical differences of ADORA1 and DRD1 gene polymorphisms were disappeared. Further analysis such as haplotype prediction, linkage disequilibrium calculation, sliding window analysis and multi-variate statistical analysis are in progress. All subjects were given informed consent before blood collection strictly based on the Ethics Committees of the Nagoya University Graduate School of Medicine, Fujita Health University, and the RIKEN Brain Science Institute.

**LINGO1 polymorphisms are associated with essential tremor in Europeans.** *S. Klebe[1], S. Thier[1], D. Lorenz[1], M. Nothnagel[2], G. Stevanin[3,4,5], A. Durr[3,4,5], A. Nebel[6], S. Schreiber[6], G. Kuhlenbäumer[7], G. Deuschl[1].* 1) Department of Neurology, University Hospital Schleswig-Holstein, Kiel, Germany; 2) Institute of Medical Informatics and Statistics, Kiel, Germany; 3) AP-HP, Pitié-Salpêtrière Hospital Department of Genetics and Cytogenetics, Paris, France; 4) INSERM, U975, Paris, France; 5) Université Pierre et Marie Curie-Paris 6, UMR_S975, CNRS7225, Centre de Recherche Insitut du Cerveau et de la Moelle, Pitié-Salpêtrière Hospital, Paris, France; 6) Institute of Clinical Molecular Biology, Christian-Albrechts-University Kiel, Germany; 7) Institute of Experimental Medicine, Christian-Albrechts-University, Kiel, Germany.

Essential Tremor (ET) is one of the most common movement disorders. Former association studies focussing on candidate genes in ET found a number of risk variants but most of them were not replicated. Very recently, a genome wide association study revealed two intronic sequence variants in the LINGO1 gene associated with ET. Here, we have confirmed for the first time association between sequence variants in the LINGO1 gene and the ET phenotype in independent German and French ET samples. The ORs for the identified intronic markers rs8030859 (P = 1.0x10-4), rs9652490 (P = 9.1x10-4) and rs11856808 (P = 3.6x10-2) were 1.72 (C.I.: 1.31-2.26), 1.61 (C.I.: 1.21-2.14) and 1.30 (C.I.: 1.02-1.66), respectively, in our German sample. LINGO1 is an interesting candidate gene because it plays a key role in the CNS biology, is selectively expressed in the nervous system and is an inhibitor of oligodendrocyte differentiation and neuronal myelination. Our study gives further evidence that LINGO1 acts as a susceptibility gene for ET.

## 2015/T/Poster Board #564

**Genetic Analysis of Monozygotic Twins Discordant for Cognitive Abilities.** *K. Kobayashi[1], M. Furukawa[1], C. Yu[1], C. Shikishima[2], J. Ando[2], T. Toda[1,3].* 1) Division of Molecular Brain Science, Department of Physiology and Cell Biology, Kobe University Graduate School of Medicine, Kobe, Japan; 2) Department of Education, Faculty of Letters, Keio University, Tokyo, Japan; 3) Division of Neurology, Kobe University Graduate School of Medicine, Kobe, Japan.

Recent study showed that copy-number variations (CNVs) exist within even monozygotic twins and that CNV analysis in phenotypically discordant monozygotic twins may provide a powerful tool for identifying disease-predisposition loci. In order to try to identify the genes which are associated with intelligence, we studied DNAs from lymphocytes of eight pairs of monozygotic twins with discordant intelligence quotient (IQ) by using the Affymetrix 500K SNP array for genome-wide CNV analysis. Almost no CNV differences were seen in the twin pairs, but several CNVs were found on chromosomes 4q22.1, 7q22.1, 19q13.3, and others, in which some interesting genes reside. Further studies will be conducted to identify genes associated with intelligence.

## 2016/T/Poster Board #565

**PPopulation- and Family-Based Studies Confirm A Role for Functional Polymorphisms of the *MTHFR* Gene in the Etiology of Autism.** *X. Liu[1,4], F. Solehdin[2], I. Cohen[3,4], S. Lewis[2,4], J. Holden[1,4].* 1) Dept Psychiatry, Queen's Univ, Kingston, ON, Canada; 2) Dept Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 3) Dept Psychology, NYS Institute for Basic Research in Developmental Disabilities, Staten Island, NY USA; 4) The Autism Spectrum Disorders - Canadian American Research Consortium (ASD-CARC; www.autismresearch.ca).

Autism spectrum disorders (ASDs) are a group of debilitating neurodevelopmental conditions characterized by impairments in verbal and non-verbal communication, social interaction and the presence of repetitive behaviours and restricted interests. Despite a general lack of success in identifying genes that are responsible for a majority of ASD cases, there are some striking observations that suggest that changes in both a wide variety of genes and epigenetic modifications of the genome by methylation of CpG islands that are important for normal brain development and growth, cognitive function and behaviour are involved in their etiology. For example, the risk for ASD is very high for persons with the fragile X, Prader Willi, and Rett syndromes, all of which are associated with abnormal methylation. Two variants in the methylenetetrahydrofolate reductase (MTHFR) gene have been shown to affect DNA methylation levels, and one of these has been shown to be associated with autism susceptibility. We examined these two functional SNPs in the MTHFR gene, C677T and A1298C, in a cohort of Caucasian families with a single child diagnosed with an ASD in both case-control and family-based studies. (We cannot rule out that some of these families would not be multiplex families.) The SNPs were in moderately strong linkage disequilibrium. Population-based case-control comparisons revealed a higher frequency of the low-activity 677T allele (*P=0.0004*), higher prevalence of 677TT genotypes (*P=0.0016*), marginally higher frequency of the 1298A allele (*P=0.056*) and a trend towards increased prevalence of the 1298AA genotype (*P=0.124*) in autistic probands versus controls. Analysis of combined genotypes revealed a significantly higher frequency of the double homozygous 677TT/1298AA genotype (*P=0.007*) and the 677T-1298A haplotype in affected individuals relative to controls (*P=0.0004*). Family-Based Association Testing (FBAT) demonstrated significant transmission disequilibrium for both C677T and A1298C, with an excess transmission of the 677T (*P=0.000065*) and 1298A (*P=0.015*) alleles and the 677T-1298A haplotype (*P=0.000091*) from parents to affected offspring. These results suggest that reduced MTHFR activity may serve as an epigenetic risk factor for autism in some families.

## 2017/T/Poster Board #566

**A familial duplication affecting the RORA gene co-segregates with visuo-neuropsychological impairment and focal glucose metabolism decrease.** *S. Markx[1], T. Vrijenhoek[2], J.I. Friedman[3], I.M. Janssen[2], W.A. van der Vliet[2], L. Edelmann[3], K.L. Davis[3], J.M. Silverman[3], H.G. Brunner[2], A. Geurts van Kessel[2], J.A. Veltman[2].* 1) Department of Psychiatry, Columbia University, New York; 2) Department of Human Genetics, Nijmegen Centre for Molecular Life Sciences, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands; 3) Departments of Psychiatry and Human Genetics, Mount Sinai School of Medicine, New York, USA.

Recent genomic research has revealed many genomic rearrangements - predominantly copy number variation (CNV) - underlying mental disorders. Sometimes the phenotypic consequences of such a rearrangement are immediately evident, but much more often this is not the case, especially in more complex phenotypes. One solution would be to improve phenotypic analysis by applying high-resolution imaging techniques such as magnetic resonance imaging (MRI) and positron emission topography (PET) to detect clinical subtleties that are usually not detected in routine diagnosis. We exemplify the importance of this approach in our study on the role of a rare CNV in a family of which members had variable psychiatric phenotypes. We identified a partial duplication of a brain-specific isoform of the RORA gene in three family members with psychosis-related clinical phenotype. Routine diagnosis and assessment of intellectual abilities based on the Wechsler Adult Intelligence Scale-Third Edition (WAIS-III) initially gave inconsistent results for the three members: the mother suffered from major depression episodes, but had normal IQ; her two daughters were diagnosed for schizophrenia and severe mental retardation. Detailed MRI and PET-based brain analysis demonstrated the co-segregation of the duplication with neuropsychological impairment - specifically visuo-constructive and visuo-analytic aspects - and decreased glucose metabolism in the thalamus and peri-ventricular white matter. While homozygous loss-of-function deletion of RORA in mice results in a *staggerer* phenotype, characterized by severe ataxia and cerebellar atrophy, the current study is the first to show implications of variation in RORA with neuropsychiatric phenotype in humans. Interestingly, the RORA gene is located on 15q22, a genomic region previously linked to the quantitative trait visual attention in schizophrenia patients. Our study highlights the importance of performing both detailed genotypic and phenotypic studies in complex traits, and indicated that RORA plays an important role in visual attention defects.

## 2018/T/Poster Board #567

**Association analysis between HTR2A and prepulse inhibition with normal controls and schizophrenia in the Japanese population.** *M. Moriwaki[1,2], T. Kishi[1], T. Kitajima[1], M. Ikeda[1,3], Y. Yamanouchi[1], Y. Kinoshita[1], K. Kawashima[1], T. Okochi[1], T. Okumura[1], T. Tsunoka[1], O. Furukawa[2], K. Fujita[2], N. Iwata[1].* 1) Department of Psychiatry, Fujita Health University School of Medicine, Toyoake, Aichi 470-1192, Japanpsychiatry, Fujita Health University, Toyoake, Aichi, Japan; 2) Okehazama Hospital, Toyoake, Aichi, 470-1168, Japan; 3) Department of Psychological Medicine, School of Medicine, Cardiff University, Heath Park, Cardiff, CF14 4XN, United Kingdom.

Impairment of the prepulse inhibition (PPI) deficit and the acoustic startle reflex (ASR) habituation is considered to be one of the endophenotypes for schizophrenia. A recent our study has showed that a PPI deficit was detected in Japanese schizophrenic patients. Also, other study reported that PPI and habituation of the ASR are modulated by polymorphisms in serotonin 2A receptor gene (HTR2A) in schizophrenia. Therefore, we investigated the association between the two functional SNPs in HTR2A prepulse inhibition with normal controls and schizophrenia in the Japanese population. We evaluated the startle measures of mean magnitude of ASR, habituation (HAB), and PPI at prepulse sound pressure intensities of 82 dB (PPI82), 86 dB (PPI86), and 90 dB (PPI90). ASR was significantly different between schizophrenic patients and controls. HAB and all PPI session data from schizophrenic patients were significantly lower than in controls. In addition, we detected significant differences for ASR, habituation and each PPI (82, 86 and 90dB) between schizophrenic patients and controls with the use of multiple regression analysis. HTR2A genotypes, the gender and smoking state were not correlated with ASR, habituation or any PPI in multiple regression analysis. In conclusion, we suggested that functional SNPs in HTR2A did not play a major role of pathophysiology for PPI with schizophrenia and controls in the Japanese population.

## 2019/T/Poster Board #568

**Homozygosity mapping in 4 unrelated Iranian families with autosomal recessive mental retardation identifies overlapping linkage intervals on chromosome 1p34: a frequent cause of ARMR?** *H. Najmabadi[1,3], M. Garshasbi[2], I. Bahman[1], S. Ghadami[1], M.M. Motazacker[2], L. Abbasi Moheb[2], S. Esmaeeli Nieh[2], L. Puettmann[2], M. Mohseni[1], M.J. Soltani Banavandi[1], H. Darvish[1], P. Jamali[4], P. Nikoui[5], F. Soleimani[1], H. Hu[2], W. Chen[2], K. Kahrizi[1], A. Tzschach[2], A.W. Kuss[2], H.H. Ropers[2].* 1) University of Social Welfare and Rehabilitation Sc, Tehran, Iran; 2) Max-Planck-Institute for Molecular Genetics, Berlin, Germany; 3) Kariminejad-Najmabadi Pathology and Genetics Center, Tehran, Iran; 4) Shahroud Welfare Institution, Shahroud, Iran; 5) Bandar Abbas Welfare Institution, Bandar Abbas, Iran.

Other than X-linked mental retardation, autosomal recessive mental retardation (ARMR) has so far received very little attention. This holds particularly for non-syndromic forms (NS-ARMR). To date, only 13 loci for NS-ARMR and no more than 5 genes for this condition have been published. Recently, autozygosity mapping in 78 families with NS-ARMR has revealed that the molecular basis of NS-ARMR (Najmabadi et al., 2007, Hum. Genet. 121(1):43-8) is extremely heterozygous. Indeed, two recurrent mutations have only been observed in a single gene (Garshasbi et al., 2008, Am. J. Hum. Genet. 82(5):1158-64; Molinari et al., 2008, Am J Hum Genet. 82(5):1158-64), suggesting that there are no frequent genetic causes of NS-ARMR. Still, in the course of an ongoing large-scale investigation into the molecular causes of ARMR, we have now identified four consanguineous families, three with non-syndromic and one with syndromic ARMR. In each of the families the analysis yielded a single, almost identical homozygous interval on chromosome 1p34. This is the most conspicuous clustering of linkage intervals observed in our entire cohort of more than 250 consanguineous Iranian families that have undergone autozygosity mapping so far. Therefore, it is tempting to speculate that the underlying defect in three or even all four of these families involves the same gene locus, MRT4 (Najmabadi et al., 2007, Hum. Genet. 121(1):43-8), which may well account for several percent of the ARMR causing mutations in the Iranian population. The genomic region that is common between these intervals comprises 7.7 Mb and encompasses 128 genes. Mutations in the coding regions of several genes, including STIL and POMGNT1, two candidate genes for syndromic forms of MR, were excluded by Sanger sequencing. Chromosome sorting and next generation sequencing, a novel strategy recently pioneered in our laboratories, is now in progress to speed up the search for the underlying gene defect or defects. Results of these studies will be reported.

## 2020/T/Poster Board #569

**Impact of *DRD2* on ADHD-Type Behavior in a Population-Based Birth Cohort: Effect on Women's Temperament.** *E. Nyman[1,2], A. Loukola[1], T. Varilo[1,2,3], A. Taanila[4,5], T. Hurtig[4,6], I. Moilanen[6], J. McGough[7], M.-R. Järvelin[4,8,9], S. Smalley[7], S.F. Nelson[7,10], L. Peltonen[1,2,3,11].* 1) Public Health Genomics Unit, Institute for Molecular Medicine Finland FIMM, Helsinki, Finland; 2) Department of Medical Genetics, University of Helsinki, Finland; 3) Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, MA, USA; 4) Institute of Health Sciences, University of Oulu, Finland; 5) Unit of General Practice, University Hospital of Oulu, Finland; 6) Clinic of Child Psychiatry, University and University Hospital of Oulu, Finland; 7) Semel Institute for Neuroscience and Human Behavior, University of California, Los Angeles, USA; 8) Department of Epidemiology and Public Health, Imperial College London, UK; 9) Department of Child and Adolescent Health, National Institute for Health and Welfare, Helsinki, Finland; 10) Department of Human Genetics, University of California, Los Angeles, USA; 11) 11 Wellcome Trust Sanger Institute, Cambridge, UK.

Attention-deficit/hyperactivity disorder (ADHD) is a common childhood-onset disorder with a significant impact on public health and strong evidence for genetic contribution to disease risk. Previously we have reported results of a candidate gene study in a population-based birth cohort, The Northern Finland 1986 Birth Cohort (NFBC 1986), showing association of a variant of *Dopamine receptor D2 (DRD2)* with ADHD in males but not in females. The current study tests the potential impact of dopamine receptor gene variants on Cloninger temperament traits in the ADHD study sample from NFBC 1986. The NFBC 1986 cohort population of over 9000 individuals is characterized by founder effect, isolation and minimized genetic heterogeneity. We utilized a unique population sample ascertained from this cohort. The systematically ascertained subjects had stringent inclusion criteria for lifetime diagnosis of ADHD using a best estimate procedure and DSM-IV criteria, resulting in 178 definitive or probable (falling 1 symptom short) ADHD cases and 157 symptom free controls. In this sample we genotyped markers in all the known genes of the dopamine receptor gene family and tested them against temperament traits. We found evidence for association of *DRD2* with low Persistence among ADHD females, but not in males. The *DRD2* variant associating with low Persistence in females is the same variant we previously found associating with ADHD in males of this same cohort. Furthermore, we have previously reported an association of the same *DRD2* variant with low Persistence in a similar, older birth cohort, The Northern Finland Birth Cohort 1966. The current study adds further support to our previous results on the involvement of *DRD2* in the etiology of ADHD-type temperament. Together the results of these two investigations suggest that *DRD2* may have an impact on ADHD-type temperament in both males and females, but the particular outcome of its effect appears to be gender-specific, manifesting as a disorder in males and as ADHD-type temperament in females. Furthermore, these findings propose that the putative role of low Persistence as a possible endophenotype for ADHD deserves more attention in further studies.

## 2021/T/Poster Board #570

**Association study of serotonin transporter polymorphism with bipolar disorder, schizophrenia and TCI scale in the Japanese.** *N. Oribe, H. Mitsuyasu, L. Gotoh, H. Kawasaki, S. Kanba.* Dept Neuropsychiatry, Kyushu Univ, Fukuoka, Japan.

Since serotonin transporter (SERT) is one of the sites of action of antidepressants, this gene has been indicated to be related to the pathophysiological mechanisms of mood and anxiety disorders. Differences in SERT expression and function produced by gene polymorphisms are associated with several psychiatric diseases. Two polymorphic regions of SERT gene, a 44-base-pair (bp) insertion / deletion polymorphism in the promoter region (SERTPR) and variable number of tandem repeats (VNTR) in second intron (SERT-in2), have been characterized. SERT-in2 is reported to be associated with unipolar depression, bipolar depression, schizophrenia, and anxiety disorders. SERTPR is also shown to be associated with unipolar and bipolar depression. However, the results from various sources are inconsistent. In this study, we investigated the frequency distribution of polymorphic variants of short (S, s) and long (L, l) alleles, genotypes and haplotypes of SERTPR, and SERTin2, in patients with bipolar disorder (BD) and schizophrenia (SZ) and compared them with those obtained from the Japanese normal controls (NC). Twenty four BD patients and 191 SZ patients diagnosed using the Structured Clinical Interview for DSM-IV (SCID) and 77 NCs were included in this study. The SERTin2 and SERTPR were genotyped by electrophoresis and association analyses were performed. As a result, SERTPR indicated statistically significant differences between BD and NC, and SZ and NC, whereas SERTin2 showed no difference. Additionally, several studies suggested that the function of the serotonin neurotransmission systems associate with some psychological tendencies in human although it is still controversial. Thus, we investigated the associations of SERTPR and SERTin2 polymorphisms with Temperament and Character Inventory (TCI) scales. We genotyped 56 Japanese (16 BD patients and 40 NCs) with SERT polymorphisms and also carried out the TCI tests. However the results showed no significant association. Further analysis with more samples is now in progress. All subjects were given informed consent before blood collection strictly based on the ethical regulations of Kyushu University.

## 2022/T/Poster Board #571

**Evidence for epistasis between AKT and FOXO3A as risk factors in bipolar disorder.** *M.A. Romano-Silva[1,4], L.A. Magno[4], D.M. Miranda[3,4], A.A. Ferreira[1], F.S. Neves[1], L.A. De Marco[2,4], H. Correa[1,4].* 1) Saude Mental, Faculdade de Medicina, Universidade Federal Minas Gerais, Belo Horizonte, MG, Brazil; 2) Cirurgia, Faculdade de Medicina, Universidade Federal de Minas Gerais; 3) Hospital Julia Kubitschek, FHEMIG, MG, Brazil; 4) INCT de Medicina Molecular, Faculdade de Medicina, Universidade Federal de Minas Gerais, MG, Brazil.

Bipolar Disorder (BD) is one of the leading causes of disability amongst all medical and psychiatric conditions, affecting approximately 1-3% of the worldwide population. In this study, using a case-control approach in a Brazilian population, we aimed to investigate whether AKTIP, AKT and FOXO3A polymorphisms, candidate genes that encode key proteins in the signaling of dopaminergic and serotonergic systems, were associated with BD. In addition, we analyzed the role of selected SNPs conferring vulnerability to suicidal behavior and explored the epistasis among FOXO3A, AKT and AKTIP genes. Subjects were diagnosed with Bipolar Disorder I or II (age = 41.4±12.9). TaqMan SNP genotyping assays were used. We found that demographic and clinical data were associated with lifetime history of suicide attempt. Bipolar Disorder was associated with two FOXO3A SNPs in both allele and genotype distribution (SNP1, genotype: p=0.0109, allele: p=0.0280; SNP2, genotype: p=0.0072, allele: p=0.0068) which remained significant after $1X10^5$ permutations. AKT1 polymorphisms showed association with general suicide attempt (rs1130214, p=0.0471) and especially violent attempt (rs2494746, p= 0.039). Strong LD was observed in FOXO3A (block 1: D'= 1; block 2: D' 0.98) and AKT1 gene (block 1: D'= 1). Significant differences in both FOXO3A and AKT1 haplotypes frequencies between bipolar patients and control was detected. The combined effects of the polymorphisms of AKT1, AKTIP and FOXO3A, in gene-gene interaction analysis, were associated with BD and this data indicated that a synergistic interaction increases the susceptibility to BD. (cross-validation consistency: 10/10; testing balanced accuracy: 0.7530; OR= 12.449 and p= 0.0063). Our data suggest that demographic and clinical characteristics and genetic variations in the AKT1, AKTIP and FOXO3A pathway are associated with increased risk for BD in a Brazilian sample.

## 2023/T/Poster Board #572

**The role of common and rare variants in NOTCH3 Gene in age associated cerebral small vessel disease.** *H. Schmidt[1,2], M. Tscherner[1], R. Schmidt[2].* 1) Molecular Biology, Medical University Graz, Graz, Austria; 2) Department of Neurology, Medical University Graz, Graz, Austria.

Background: Cerebral small vessel disease detected by brain MRI as white matter lesions (WML) and/ or lacunes is present in >0.20; of the population aged over 65. WML progress rapidly and lead to cognitive decline, gait disturbances as well as stroke. Risk factors for WML are age and hypertension, its heritability is 0.55-0.70. CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukencephalopathy) represents a monogenetic form of cerebral small vessel disease. It is caused by mutations in NOTCH3 gene. The aim of the study was to describe the distribution of genetic variants in the NOTCH3 gene in the elderly and evaluate their roles in age-associated WML. Methods: The study was conducted in the cohort of the Austrian Stroke Prevention Study (ASPS) a single centre, prospective population based study in the normal elderly in Graz, Austria. WML was defined by brain T2-weighted MRI images and wml volume was measured by a semi-automated algorithm. The NOTCH3 gene including the 5`and 3`-regions was screened for sequence variants by dHPLC and by direct sequencing in 88 ASPS participants with and in 82 without WML. Common SNPs which showed different frequency between the 2 screening subsets, were genotyped using the TaqMan technology in the whole ASPS cohort (N=923). We used the additive genetic model to test association between these SNPs and WML volume. Adjustment was done for age and hypertension. Results: We detected 35 SNPs in the NOTCH3 gene, 23 SNPs were located in exons, 4 in introns, 3 in the promoter and 2 in the 3' UTR. In total 10 SNPs were novel. Among the 35 SNPs 10 SNPs had a minor allele frequency of >0.05;. Three of these SNPs, rs7257550 (beta= -0,114, p= 0,0496796) rs10423702 (beta= -0,116, p= 0,044) and rs1044009 (beta= -0,116, p= 0,048) were significantly associated with WML volume before correction for multiple testing. We detected 25 rare SNPs (MAF<0.05), 12 were missense, 5 silent mutations, 2 were in introns, 2 in the promoter and 2 in the 3'-UTR. Discussion: This is the first study investigating genetic variations in NOTCH3 gene in the normal population and their relation to age associated cerebral small vessel disease. We found that both common and rare variants are frequent in NOTCH3. Common SNPs might enhance the risk for WML in the elderly, but larger studies are needed to test if this association is real. The role of rare SNPs in the development of WML have to be further evaluated.

## 2024/T/Poster Board #573

**Integrated next-generation sequencing and array based analysis of genetic modifiers in Velocardiofacial Syndrome (VCFS).** *A. Urban[1,2], Y. Zhang[1], D. Palejev[1], R. Haraksingh[2], J.O. Korbel[3], M. Snyder[2], S. Weissman[1].* 1) Genetics Department, Yale Univ, New Haven, CT; 2) MCDB Department, Yale University, New Haven, CT; 3) European Molecular Biology Laboratory, EMBL, Heidelberg, Germany.

Schizophrenia is a major public health concern (affecting 1% of the population) and a complex disease with a strong genetic component. Velocardiofacial Syndrome (VCFS) is typically caused by a 3 Mbp heterozygous deletion on chromosome 22q11 and up to 30% of patients develop schizophrenia or similar symptoms. This makes VCFS a prime point of entry to understand the complex genetic etiology of schizophrenia. However, the search for the modifying genetic variants needed to differentiate the 30% of the patients with mental disease from the remaining 70%, with both groups carrying the 3 Mbp main deletion, has so far stayed incomplete. Earlier we used High-Resolution CGH (HR-CGH) on NimbleGen 385K custom arrays to show that the main deletion can substantially vary in size between patients [Urban, Korbel et al., PNAS 06] and that there are additional, smaller, CNVs to be found within the 3 Mbp deletion interval on the non-deleted chromosome [Korbel, Urban et al., PNAS 07]. Then we developed HR-PEM (paired-end mapping) [Korbel, Urban, Affourtit et al., Science 07] (also [Korbel et al., Genome Biol., 09]) for sequencing based high-resolution CNV analysis, and identified 22q11 as a hotspot for small CNV/SV. Here we report on the integrated genome-wide search for modifiers in VCFS using HR-CGH and HR-PEM in conjunction with array capture resequencing (ACRes). We are using a custom designed 385K NimbleGen longmer array to capture a 5 Mbp locus containing the VCFS region on chromosome 22q11 and a NimbleGen 2.1M longmer array to capture all exons in the human genome. We sequence the captured fractions on the Illumina Genome Analyzer 2, but using the paired-end protocol to enhance the power of detection and to reach out from the exons into their regulatory regions. Through this we can detect any type of genetic variant in the target regions, from single nucleotide changes to large CNV/SV, and we correlate and validate the results with HR-CGH data for the same samples. We have applied this approach to a panel of VCFS patients, unaffected relatives and controls and have detected several hundred genetic variants. We also analyze genome-wide transcriptional activity in cell lines from the same VCFS patients, using Illumina GA2 based RNA-Seq to be able to detect intensity of expression as well as variable splicing, allele specific transcription and novel and non-exonic transcripts, and can now correlate the RNA-Seq data with the ACRes data on genetic variation.

## 2025/T/Poster Board #574

**Common Variant (CV) and Rare Deletion in the Tyrosine Hydroxylase Gene Contribute to Parkinson Disease Risk.** *L. Wang, T. Edwards, G. Daffu, A. Burt, I. Konidari, W. Scott, S. Zuchner, E. Martin, J. Vance.* Miami Institute for Human Genomics and Dr. John T. Macdonald Foundation Department of Human Genetics, Miller School of Medicine, University of Miami, Miami FL.

Parkinson disease (PD) is characterized by a progressive loss of dopaminergic neurons in the substantia nigra. The tyrosine hydroxylase (TH) gene encodes a key enzyme for the biosynthesis of dopamine. Mutations in TH have been previously described as an etiology for an autosomal recessive, dopamine responsive dystonia (Segawa syndrome) and infantile Parkinsonism. Previous association studies of TH did not find evidence for association with PD, which could be attributed to the small sample sizes (N≤430) and limited number of variants (N≤2) examined. To thoroughly examine TH, we evaluated 12 tagSNPs surrounding TH in 697 PD cases and 213 unrelated controls. Initial analysis showed no association (p>0.05). However, tagSNP rs2070782 was also genotyped in two previous large scale studies of PD: a genome wide association study (GWAS) on the NINDS Neurogenetics repository samples (N=537), and a candidate gene study of 268 SNPs from 121 candidate genes in a Japanese cohort (N=380). This SNP was not significant in either study. To increase statistical power, we performed a joint analysis of the three studies (N=1827 total) using publicly available data. Indeed, this analysis found evidence for association at rs2070282 with PD risk (p=0.008, OR=1.2). In all studies, the C allele is more frequent in cases (0.48 to 0.56) than in controls (0.44 to 0.48). Recently, we completed a GWAS of PD using the Illumina Human610-Quad chip. Copy number variation (CNV) analysis using the SNP array found a novel deletion over entire TH gene in one PD patient, which was confirmed by quantitative PCR (qPCR). Patient's age-of-onset was 54 years. Her clinical presentation was mild and typical for dopamine responsive PD, with no evidence of dystonia. We are the first to provide evidence for both association at a CV and existence of a rare CNV in TH for PD risk. The pattern described here for TH mirrors that found in $\alpha$-synuclein gene, where point mutations, CNVs, and CVs all are associated with risk of PD. Our study highlights challenges in genetic studies of complex diseases: the effect size of CVs is usually small and the low prevalence of rare variants (RVs, including deletions) makes them hard to identify. Sharing data and performing joint analysis is instrumental to detect CVs with small effect sizes. Both CVs and RVs need to be considered for a more complete and comprehensive understanding of the genetic architecture of complex phenotypes.

## 2026/T/Poster Board #575

**Genome-wide homozygous haplotype mapping to identify Autism Spectrum Disorder candidate genes.** 
*J. Casey[1], T. Magelhaes[2], J. Conroy[1], R. Regan[1], N. Shah[1], R. Anney[3], E. Heron[3], A. Green[1,4], L. Gallagher[3], M. Gill[3], D. Shields[1], A. Vicente[2], S. Ennis[1], Autism Genome Project (www.autismgenome.org).* 1) Health Sciences Center, University College Dublin, Dublin 4, Ireland; 2) Instituto Gulbenkian de Ciencia, Oeiras, Portugal; 3) Department of Psychiatry, Trinity College Dublin, Ireland; 4) National Centre for Medical Genetics, Ireland.

Autism spectrum disorder (ASD) is a severe neurodevelopmental disorder of complex and heterogeneous aetiology. ASD is characterised by altered cognitive ability including impaired language and communication skills, deficits in social reciprocity and repetitive and restricted patterns of behaviour and interests. Evidence to support a strong genetic component in the aetiology of ASD stems largely from twin studies which demonstrate a much higher heritability in monozygotic (92%) compared to dizygotic (2-10%) twins. Recent studies offer support for the hypothesis that rare genetic variants contribute to the disorder. However the systematic detection of susceptibility genes containing low-frequency mutations in the genome is technically challenging. Large tracts of extended homozygosity represent a newly explored form of genetic variation and may be highly relevant in disease gene discovery. The mapping of homozygous regions of matching haplotype on a genome-wide scale could help to identify low-frequency potentially disease-liable candidate genes associated with complex disorders. A cohort of ~1500 ASD trios was genotyped for 1 million SNPs allowing adequate coverage for detection of extended runs of homozygosity. The 4000 sample cohort was clustered and separated into analysis groups based on common population ancestry. For each group we applied a whole-genome homozygous haplotype (HH) mapping approach to identify HH that are statistically more prevalent in ASD probands compared to parental controls. Such regions may facilitate the identification of novel risk genes contributing to this complex disorder. The genes within the significant HH were assessed in terms of their biological relevance to the ASD phenotype. Our research identified a number of novel candidate ASD genes of functional and positional relevance. We also replicated significant findings across multiple population analysis groups and the main findings will be presented at the ASHG 2009. Furthermore an unexpectedly high proportion of published ASD genes are located within HH that are significantly more common in ASD patients. Pathway analysis of the significant candidates showed an excess of genes involved in axon guidance, an interesting observation given the recent implication of this gene family in ASD. Our study highlights the utility of HH mapping as a candidate-gene identification strategy and may improve our understanding of the molecular network underlying this complex disorder.

## 2027/T/Poster Board #576

**Contactin 4 as an Autism Susceptibility Locus.** 
*C.E. Cottrell[1], N. Bir[2], E. Varga[2], D. Cunningham[2,4], R. Zernzach[3], J.M. Gastier-Foster[1,5], K. McBride[2,4], G.E. Herman[2,4].* 1) Department of Pathology and Laboratory Medicine, Nationwide Children's Hospital, Columbus, OH; 2) Center for Molecular and Human Genetics, The Research Institute at Nationwide Children's Hospital, Columbus, OH; 3) Department of Pediatrics, Wright-Patterson Air Force Base, OH; 4) Department of Pediatrics, The Ohio State University, Columbus, OH; 5) Department of Pathology, The Ohio State University, Columbus, OH.

Autism spectrum disorders (ASDs) are a heterogenous and common group of developmental disorders. Affected children demonstrate severe impairments in language and social interaction skills, in addition to stereotypic behaviors. Identifiable genetic causes account for ≤20% of cases. Among these causes, *de novo* and inherited copy number variations (CNVs) have been described in a subset of ASD patients using comparative genomic hybridization (CGH). In recent reports, both structural and sequence variation have been described in the contactin and contactin associated protein (CNTNAP) gene family in association with neurodevelopmental disorders, including ASDs. Contactin proteins are members of the immunoglobulin family of axon-associated cell adhesion molecules that function in the formation and maintenance of neuronal networks. Contactins interact with CNTNAPs to form complexes that promote neuronal migration and axon guidance. Using array CGH, we identified a maternally inherited 1.09 Mb deletion at 3p26.3 encompassing the 5' end of the contactin 4 gene (*CNTN4*) in a patient with severe autism. Based on this finding and previous reports of CNV associated with autism in this region, we sought to further define the role of *CNTN4* as a candidate gene for ASDs. Sequencing of the 22 coding exons of *CNTN4* was performed on 88 patients enrolled in an autism registry at Nationwide Children's Hospital. Inclusion in the registry was based on the clinical diagnosis of an ASD using DSM IV criteria and/or ADOS testing. Four patients were found to have a unique variant within the coding region of *CNTN4*. Each of these variants was inherited from an unaffected parent and altered a highly conserved amino acid residue. Three of the 4 variants were calculated to be damaging on the basis of protein prediction software. To our knowledge, none of these variants has been previously reported. Sequence analysis of *CNTN4* was performed on 107 control samples. One coding variant was detected in our control population and was found to alter a highly conserved amino acid. This variant was not detected in our autism population. In summary, we have found an increased frequency of rare variants in *CNTN4* within an ASD cohort in comparison to normal controls, and we provide additional evidence of CNV in the 3p26 region contributing to an autism phenotype. On the basis of these findings, we believe that *CNTN4* may prove to be an important locus for ASD disease susceptibility.

## 2028/T/Poster Board #577

**Testing Epilepsy Candidate Genes for Association to Autism in a Genome Wide Association Study Dataset.** *M. Cuccaro[1], D. Ma[1], D. Salyakina[1], R. Tuchman[3], I. Konidari[1], P. Whitehead[1], A. Griswold[1], H.H. Wright[2], R.K. Abramson[2], E.R. Martin[1], J. Jaworski[1], J. Hussman[5], J.R. Gilbert[1], J. Haines[4], M.A. Pericak-Vance[1].* 1) Dept Med, Univ Miami Sch Med, Miami, FL; 2) Neuropsychiatry, USC-SOM, Columia, SC; 3) Dept Neurology, Univ Miami Sch Med, Miami, FL; 4) Cent Hum Gen Res, Vanderbilit Univ, Nashville, TN; 5) Hussman Foundation, Ellicott City, MD.

Autism and epilepsy are common complex disorders which each result in significant behavioral and developmental problems. Conditional prevalence estimates or the rate at which epilepsy is present in autism is conservatively estimated at 25% to 30%. This co-occurrence far exceeds than what would be expected by chance and often results in a more severe phenotype and extremely poor prognosis. The biologic mechanisms that account for this co-occurrence have eluded discovery. Several conceptual models have proposed a common brain pathology in which autism and epilepsy are independent consequences of the same underlying disorder. Given the overlap in these two disorders we propose that epilepsy risk genes are etiologically relevant to autism. In this study we tested the hypothesis that epilepsy related candidate genes may confer risk to autism. Using existing genome wide association study (GWAS) data, we examined 27 candidate genes, selected on the basis of previous reports of association or biological relevance to epilepsy or epilepsy and co-occurring autism. In the initial GWAS, our discovery dataset consisted of 438 Caucasian autism trio families genotyped on the Illumina 1m Beadchip while our validation dataset consisted of 487 autism trio families from the Autism Genetics Resource Exchange (AGRE). In the initial GWAS, all SNPs were tested for association to autism using the Pedigree Disequilibrium Test, a family based test for association. We examined markers in our autism GWAS dataset for each of the 27 candidate genes correcting for the number of available markers in each gene. In addition, only those markers that showed significant association to autism in the MIHG, AGRE, and combined analyses were deemed relevant. Examination of our GWAS results across the 27 genes revealed a significant association to three SNPs (rs11079919, rs2107441, rs9898731) in CACNA1G a calcium channel gene which impacts a variety of functions including neuronal firing patterns. This gene is of greater interest as well given recent evidence from a high density SNP association study which implicated CACNA1G as a candidate gene for autism. We will discuss the implications of examining epilepsy risk genes such as ion channel genes for autism as well as co-occurring autism and epilepsy.

## 2029/T/Poster Board #578

**Neuropeptide S receptor 1, and its ligand neuropeptide S, associate with panic disorder in the Finnish population.** *J. Donner[1,2], S. Pirkola[3,4], J. Suvisaari[3], K. Silander[5], J. Terwilliger[6,7,8], J. Lönnqvist[3,4], L. Peltonen[2,5,9,10], J. Kere[2,11,12], I. Hovatta[1,2,3].* 1) Research Program of Molecular Neurology, University of Helsinki, Helsinki, Finland; 2) Department of Medical Genetics, University of Helsinki, Helsinki, Finland; 3) Department of Mental Health and Substance Abuse Services, National Institute for Health and Welfare, Helsinki, Finland; 4) Department of Psychiatry, Helsinki University Central Hospital, Helsinki, Finland; 5) Public Health Genomics Unit, National Institute for Health and Welfare, and FIMM, Institute of Molecular Medicine Finland, Helsinki, Finland; 6) Department of Genetics and Development, Department of Psychiatry, Columbia Genome Center, Columbia University, New York, USA; 7) Division of Medical Genetics, New York State Psychiatric Institute, New York, USA; 8) Faculty of Medicine, University of Helsinki, Helsinki, Finland; 9) Wellcome Trust Sanger Institute, Hinxton, UK; 10) The Broad Institute of MIT and Harvard, Cambridge, USA; 11) Folkhälsan Institute of Genetics, Helsinki, Finland; 12) Department of Biosciences and Nutrition, Karolinska Institutet, and Clinical Research Centre, Karolinska University Hospital, Huddinge, Sweden.

The G protein-coupled receptor NPSR1 (neuropeptide S receptor 1) and its ligand NPS (neuropeptide S) form a signaling system with multidimensional functions. These genes have mainly been implicated in susceptibility to asthma in humans, and regulation of anxiety and arousal in rodents. This is interesting as anxiety disorders and asthma show comorbidity in several epidemiological studies. We investigated a sample collected as part of the Finnish epidemiological Health 2000 Survey, and consisting of a representative sample (n = 6005) of the general adult Finnish population. We first evaluated the epidemiological association between asthma and anxiety disorders. Analysis of specific anxiety disorders (panic disorder, generalized anxiety disorder, social phobia, and agoraphobia) revealed that subjects with agoraphobia had asthma significantly more often than subjects without agoraphobia (14.1% vs. 4.0%, $\chi^2 = 20.1$, $P = 3.0 \times 10^{-4}$). We then addressed the possible role of NPSR1 and NPS as susceptibility genes for human anxiety disorders with a genetic association study in the same anxiety disorder patients (n = 321) and matched controls (n = 653). We genotyped 66 single nucleotide polymorphisms (SNPs) located across NPSR1 and NPS genes Several SNP alleles and haplotypes within both examined genes associated with panic disorder diagnosis specifically. Overall, the strongest support for association in NPSR1 was observed for rs17199659 (panic disorder without agoraphobia; p = 0.001), and in NPS for rs1999635 (panic disorder with and without agoraphobia combined; p =0.007). The discovered findings are particularly intriguing, as panic disorder is the anxiety disorder most frequently co-occurring with asthma, and these diseases share some symptoms, such as a sensation of being smothered, choking, and hyperventilation-induced dyspnea. Our results suggest that NPS-NPSR1 signaling may modulate susceptibility to human anxiety disorders. Therefore, further studies of this recently characterized neuropeptide system in the context of human anxiety are warranted.

## 2030/T/Poster Board #579

**No association between Magel2 and schizophrenia in the Japanese population.** *Y. Fukuo[1], T. Kishi[1], T. Kitajima[1], M. Ikeda[1,4], Y. Yamanouchi[1], Y. Kinoshita[1], K. Kawashima[1], T. Okochi[1], T. Okumura[1], T. Tsunoka[1], T. Inada[3], N. Ozaki[2], N. Iwata[1].* 1) Department of Psychiatry, Fujita health University; 2) Department of Psychiatry, Nagoya University; 3) Neuropsychiatric Research Institute, Seiwa Hospital; 4) Department of Psychological Medicine, School of Medicine, Cardiff University.

Recently the clock genes have been reported to play some roles in neural transmitter systems, including the dopamine system, as well as to regulate circadian rhythms. Abnormalities in both of these mechanisms are thought to be involved in the pathophysiology of such as schizophrenia. Magel2 was reported circadian output gene and association with Prader-Willi syndrome. Recently, Magel2 null mice showed relatively normal motor and cognitive dysfunctions. Therefore, we investigated the association between the three tagging SNPs in Magel2 and the risk of these psychiatric disorders in Japanese patients diagnosed with schizophrenia (733 patients) and 795 Japanese controls. However, no significant association was found with schizophrenia in the allele/genotype-wise and haplotype-wise analysis. In conclusion, we suggest that Magel2 may not play a major role in the pathophysiology of Japanese schizophrenic patients. However, it will be important to replicate and confirm these findings in other independent studies using large samples.

## 2031/T/Poster Board #580

**Replication of highly associated polymorphisms and candidate genes in an independent dataset for late-onset Alzheimer Disease.** *P.J. Gallins[1], G.W. Beecham[1], A.C. Naj[1], M.A. Slifer[1], P.L. Whitehead[1], G. Cai[2], Y. Kajiwara[2], V. Haroutunian[2], J.R. Gilbert[1], E.R. Martin[1], J.D. Buxbaum[2], J.L. Haines[3], M.A. Pericak-Vance[1].* 1) University of Miami, Miami, FL; 2) Mount Sinai School of Medicine, New York, NY; 3) Vanderbilt University, Nashville, TN.

Alzheimer Disease is the leading cause of dementia in the elderly and has a complex etiology, with strong genetic and environmental determinants. Only *Apolipoprotein E* (*APOE*) polymorphisms have been consistently associated with the risk of late-onset Alzheimer Disease (LOAD), but they contribute only a small portion of the underlying genetic effect. In a previously published genome-wide association study (GWAS) using the Illumina HumanHap 550 beadchip, 32 single-nucleotide polymorphisms (SNPs) in 19 regions outside the vicinity of APOE were highly associated with LOAD (P<5E-5). An additional 29 SNPs in 9 candidate genes (*ADAM12*, *CSF1*, *GBP2*, *KCNMA1*, *NOS2A*, *SORCS2*, *SORCS3*, *SORL1*, *WWC1*) from Alzgene (http://www.alzforum.org/res/com/gen/alzgene/) and four novel regions (1q42, 4q28, 6q14, 19q13) demonstrated nominal association with LOAD in joint analyses of two GWAS datasets incorporating imputation (Beecham et al., AJHG 2009; 84:35-43). To replicate these association signals, genotypes were drawn from the Illumina Human1M beadchip on a novel set of 399 cases and 356 controls, and additional genotyping of 133 SNPs in these candidate genes and novel regions in the combined case-control set was performed using a BioTrove OpenArray assay. In the novel case-control set, SNP associations were replicated in 3 out of 19 highly associated regions (1p33, 6q25, 9p21) from the previous GWAS at P<0.05, with the strongest association of P=0.02 for SNP rs11754661 on 6q25. SNPs within 4 candidate genes (*ADAM12*, *KCNMA1*, *SORCS2*, *WWC1*) demonstrated nominally significant associations with LOAD, with the peak association among these in *KCNMA1* at rs1659789 with P=0.0006. Jointly analyzing the original and novel case-control datasets, SNPs within candidate genes *CSF1* (rs1058885, P=0.04) and *SORL1* (rs624310, P=0.02) and novel region 1q42 (rs17773715, P=0.003) also demonstrated modest associations with LOAD. This study replicates associations of variation in candidate genes with LOAD observed in previous candidate gene association studies and confirmed in meta-analysis (Bertram et al., Nat Genet 2007; 39(1): 17-23), lending additional support to their role in LOAD. Further investigation into the biological roles of these candidate genes in Alzheimer Disease pathology is merited.

## 2032/T/Poster Board #581

**Identification of TRAPPC9 as a Cause of Non-Syndromic Autosomal Recessive Mental Retardation.** *L. Kaufman[1,2], A. Mir[3], A. Noor[1,2], J. Vincent[1].* 1) Neuropsychiatry and Development Lab, Neurogenetics Section, University of Toronto, Toronto, Ontario, Canada; 2) Institute of Medical Science, University of Toronto, Toronto, Ontario, Canada; 3) Dept. of Bioscience, COMSATS Institute of Information Technology, Islamabad, Pakistan.

In this study, we have identified the sixth causal gene for non-syndromic autosomal recessive mental retardation (NS-ARMR). Low IQ and deficits in adaptive behaviours such as social, language and self-help skills characterize MR. It affects 1-3% the population worldwide. Non-syndromic autosomal recessive mental retardation (NS-ARMR) may make up as many as 25% of MR cases. Patients with non-syndromic MR present with mental retardation only, whereas patients with syndromic MR present with additional clinical features affecting multiple systems. Despite the high prevalence of NS-ARMR, little is known about its genetic basis. To date, only five genes have been implicated in this disease: TUSC3, CRBN, GRIK2, PRSS12 and CC2D1A. Understanding the genetic causes for mental retardation is a vital component of elucidating pathological mechanisms, and other potentially pathological genes. In addition, because of the frequent co-occurrence of MR in autism, this may help us identify etiological mechanisms of autism. We have identified a mutation in a large consanguineous NS-ARMR family from Pakistan. Consanguinity, marriage between related individuals, is a powerful tool for identifying rare variants that cause disease. Parents who share DNA through sharing a recent common ancestor will produce offspring with more homozygous regions, which can unmask potentially pathological mutations. Using 5.0 Affymetrix genome-wide SNP chips we analyzed the DNA of affected family members. We used dChip software to perform autozygosity mapping, and identified a 3Mb disease locus. This region, located on chromosome 8q24, contains 12 genes. We used sequencing to elucidate the disease causing gene and mutation. We identified a C>T mutation in exon 7 of the gene TRAPPC9 (trafficking protein particle complex 9), resulting in the nonsense mutation R377X which would prematurely truncate the protein. The mutation was not identified in 290 Pakistani controls. The protein product of TRAPPC9, NIBP, is involved in the activation of the NF-$\kappa$-$\beta$ signaling pathway. It is ubiquitously expressed at low levels, but shows particularly high expression in the muscle, kidney, brain, heart and placenta. It may be involved in neuronal differentiation and neuronal survival. It also likely plays a role in protein trafficking in the golgi apparatus. Future studies on TRAPPC9 will determine its role in MR and may help elucidate a common pathway in NS-ARMR.

## 2033/T/Poster Board #582

**Association analysis of the VWF candidate gene and major depression in the GAIN sample.** *I.P. Kovac[1], J.M. McCaffery[2], N. Frasure-Smith[1,5,8], A. Barhdadi[1,6], Q. Ling Duan[3,4], F. Lespérance[7], P. Théroux[1], G.A. Rouleau[6,8], M.P. Dubé[1,6].* 1) Res Ctr, Montreal Heart Inst, Montreal, PQ, Canada; 2) Weight Control and Diabetes Research Center, Brown Medical School and The Miriam Hospital, Providence, RI; 3) Department of Human Genetics, McGill University, Montreal, QC; 4) Centre for Excellence in Neuromics, University of Montreal and the Centre Hospitalier de l'Université de Montreal, Montreal, QC; 5) Department of Psychiatry and School of Nursing, McGill University; Department of Psychiatry, University of Montreal, Montreal, QC; 6) Department of Medicine, Université de Montréal, Montreal, QC; 7) Department of Psychiatry, Centre Hospitalier de l'Université de Montréal, Montreal, QC; 8) Centre Hospitalier de l'Université de Montréal, Montreal, QC.

In our previous study on depression in coronary artery disease (CAD) patients (McCaffery et al. 2009), we have reported an association between the VWF gene and the Beck Depression Scale measure in 977 cardiac patients. We did not observe this association in subjects without CAD from the same population. In order to further evaluate whether this association is limited to cardiac patients, we aim to test whether VWF is associated with depression in a reference population that is unselected for CAD. Here, we performed an association analysis of the SNPs in the VWF gene region with major depressive disorder using the publicly available data from the GAIN Major Depressive Disorder project. The GAIN data set contained 1754 cases and 1800 controls described previously. As part of quality control, 55 individuals were removed as population outliers. The data contained 42 SNPs in the VWF region on chromosome 12, including our previously associated rs216873 SNP. The 42 SNPs had over 95% genotype call rate, MAF ≥1%, HWE p>10-6. In order to increase coverage for association analyses, we have imputed un-typed SNPs in this region using the MACH software, based on the phased haplotypes of the 60 HapMap CEU individuals at 270 SNPs covering the VWF gene (Hapmap rel21a) as input. After imputation, we excluded SNPs with Rsq<=0.3 (squared correlation between imputed and true genotypes) and monomorphic SNPs (MAF=0), retaining 199/273 SNPs. Further 2 SNPs were excluded due to failing HWE test in controls (SAS 9.1.3), retaining 197 SNPs. We performed association analysis with the case status using an additive genetic model with logistic regression using Proc Logistic (SAS 9.1.3). Analyses were conducted either with sex as a covariate as per our original study (1711 cases and 1787 controls), or with age, sex, smoking and alcohol as covariates (1697 cases and 1653 controls). We used posterior probabilities for the most likely genotype obtained from MACH imputation as weights in these analyses. We corrected for multiple testing by the method of Li and Ji. We did not find significant association between any of the SNPs in the VWF gene region and the case status for major depressive disorder. The p-values for association of rs216873 were 0.69 and 0.59. While the absence of association could be due to various factors, this result is consistent with the hypothesis that the effect of the VWF gene is limited to cardiac patients. Further independent testing will be required.

## 2034/T/Poster Board #583

**Convergent functional genomics: from a BDNF memory model in rat to the identification of genetic variants for cognitive abilities in human.** *S. Le Hellard[1,2], B. Håvik[1,2], T. Espeseth[3], A.J. Lundervold[4], S. Djurovic[5], D.J. Porteous[6], C.R. Bramham[7], I.J. Deary[8], I. Reinvang[3], V.M. Steen[1,2].* 1) Clinical Medicine, University of Bergen, Bergen, Norway; 2) Dr Einar Martens' Research Group for Biological Psychiatry, Center for Medical Genetics and Molecular Medicine, Haukeland University Hospital, Bergen, Norway; 3) Center for the Study of Human Cognition, Department of Psychology, University of Oslo, Norway; 4) Department of Biological and Medical Psychology, University of Bergen, Norway; 5) Department of medical genetics, Oslo University Hospital - Ullevål, 0407 Oslo, Norway; 6) Centre for Cognitive Ageing and Cognitive Epidemiology, Medical Genetics Section, University of Edinburgh Centre for Molecular Medicine, UK; 7) Dept of Biomedicine and Bergen Mental Health Research Center, University of Bergen, Norway; 8) Centre for Cognitive Ageing and Cognitive Epidemiology, Department of Psychology, University of Edinburgh, UK.

Human memory and general cognitive abilities are complex functions with wide variability between individuals. Although empirical evidence for genetic factors underlying cognitive variation is strong, evidence for specific genetic variants has proved challenging. In an effort to identify novel genes involved in cognition we used a convergent functional genomics approach. In a rat model we identified a panel of genes that are strongly up-regulated following BDNF-induced long-term potentiation of synaptic efficacy in the hippocampus. We examined genetic markers tagging these genes for their association with inter-individual differences in performance on cognitive psychometric tests, using three independent samples (N=271, 550 and 1077) of adults individuals. We found significant association, which survives permutation testing, between several variants in *DCLK1* and IQ scores, and verbal memory, consistent in the three samples. Our results show a potential effect of a BDNF-induced gene on cognitive performance in humans.

## 2035/T/Poster Board #584

**Molecular and clinical characterization of de novo DPYD deletions in unrelated individuals with autism spectrum disorder.** *C.R. Marshall[1], A. Noor[2], S.M. Nikkel[3], A. Lionel[1], C. Noakes[4], C. Fairbrother-Davis[4], W. Roberts[4], J. Vincent[2], S.W. Scherer[1].* 1) The Centre for Applied Genomics and Program in Genetics and Genome Biology, The Hospital for Sick Children and University of Toronto, Toronto, ON, Canada; 2) Centre for Addiction and Mental Health, Clarke Institute and Department of Psychiatry, University of Toronto, Toronto, ON, Canada; 3) Department of Medical Genetics, Children's Hospital of Eastern Ontario, Ottawa, ON, Canada; 4) Autism Research Unit, The Hospital for Sick Children, Toronto, ON, Canada.

The dihydropyrimidine dehydrogenese gene (DPYD) spans approximately 850kb of genomic sequence at 1p21.3 and encodes an enzyme that is the initial and rate limiting step in the catabolism of pyrimidine bases. Recessive mutations in this gene cause thymine-uraciluria, which is typically associated with neurological symptoms such as motor and mental delay as well as seizures. A consistent phenotype for dihydropyrimidine dehydrogenese deficiency has yet to emerge and our recent studies have suggested that cases with large hemizygous deletions involving the DPYD locus present with varying complex phenotypes including developmental delay and autistic-like features. As part of a genome scan of 427 unrelated individuals with an autism spectrum disorder (ASD) diagnoses we detected a male proband from a simplex family with a de novo ~1Mb deletion fully encompassing DPYD. In a second unrelated clinical case, a 1.5 Mb de novo deletion encompassing DPYD and Polypyrimidine tract binding protein 2 (PTBP2) was detected in a female patient with an initial diagnosis of Pervasive Developmental Disorder (PDD). A male sibling with a milder phenotype also had the deletion with parent of origin analysis suggesting maternal germline mosaicism. This sibling pair was reassessed and both received a formal ASD diagnosis. Comparison of proband phenotypes did not reveal markedly similar phenotypes suggesting that haploinsufficiency of DPYD presents with a variable phenotype. Exon sequencing of 300 unrelated autistic probands revealed several inherited missense mutations but no nonsense changes. The combined data suggests that, although rare, large deletions involving DPYD may contribute genetic risk to an ASD phenotype in some individuals, perhaps under a multiple-hit model, which we will discuss.

## 2036/T/Poster Board #585

**A rare polymorphism in GABRB3 segregating with childhood absence epilepsy and generalized spike and waves in a French-Canadian family.** *C. Martin[1], P. Lachance-Touchette[1], C. Poulin[1], M. Gravel[1], L. Carmant[2], P. Cossette[1].* 1) Research Center of the CHUM Notre-Dame, Centre d'excellence en neuromique de l'Université de Montréal, Montréal, Qc., Canada; 2) CHU Sainte-Justine, Pediatric Department, Service of Neurology, University of Montreal, Montréal, Qc., Canada.

Mutations in the GABRB3 have been recently associated with Childhood absence epilepsy (CAE) families from Honduras and Mexico. In this study, we aimed to determine the frequency of mutation in this gene in our cohort of families with CAE and other related idiopathic generalized epilepsy (IGE) syndromes. We screened the open reading frame of GABRB3 in 183 French Canadian individuals with IGE including 88 with CAE. A total of 9 SNPs have been identified, 5 of which are novel. The previously described P11S missense mutation was found in three affected and one unaffected individuals from a French-Canadian family. Phenotypes in affected individuals include CAE, asymptomatic generalized spike and wave's discharges and late onset idiopathic generalized tonic clonic seizures. However, the P11S variant was also found in one of our 190 control individuals from French-Canadian origin, suggesting that this variant is rather a rare polymorphism in this population. Our study nonetheless suggests that the P11S mutation in GABRB3 is associated with CAE and related phenotypes. Further screening of other IGE cohorts from various ethnic origins would help confirming the association between this rare functional variant and epilepsy.

## 2037/T/Poster Board #586

**Systematic association analysis and follow-up between genetic variation at the positional and functional candidate gene *SV2A* and schizophrenia in a large combined sample of German descent.** *M. Mattheisen[1,2,3,8], T.W. Mühleisen[1,3,8], S. Herms[1,3], R. Breuer[4], V. Nieratschker[4], I. Nenadic[5], H. Sauer[5], B. Basmanav[1,3], R. Abou Jamra[1,3], J. Schumacher[6], J. Strohmaier[4], S.H. Witt[4], P. Propping[1], M.P. Baur[2], D. Rujescu[7], T.G. Schulze[6], M. Rietschel[4], M.M. Nöthen[1,3], S. Cichon[1,3].* 1) Institute of Human Genetics, University of Bonn, Bonn, Germany; 2) Institute for Medical Biometry, Informatics, and Epidemiology, University of Bonn, Bonn, Germany; 3) Institute of Human Genetics, Department of Genomics, Life & Brain Center, University of Bonn, Bonn, Germany; 4) Department of Genetic Epidemiology in Psychiatry, Central Institute of Mental Health, Mannheim, Germany; 5) Department of Psychiatry, University of Jena, Jena, Germany; 6) Genetic Basis of Mood and Anxiety Disorders, NIMH/NIH, Bethesda, MD, USA; 7) Division of Molecular and Clinical Neurobiology, Department of Psychiatry, Ludwig-Maximilians University Munich, Munich, Germany; 8) These authors contributed equally.

In the present study, we report the results of the first systematic association study between *SV2A* genetic variation and schizophrenia. There is combined evidence from linkage, functional, animal, and clinical studies, which makes the gene for the synaptic vesicle glycoprotein 2A (SV2A) a promising candidate gene for schizophrenia susceptibility. For Stage I analysis, we genotyped 5 haplotype tagging SNPs selected from HapMap, covering the entire *SV2A* gene and flanking sequences that capture all haplotypes at a frequency > 1% in the CEU population for a large patient-control sample originating from the German population (800 cases and 854 controls). All SNPs with a callrate below 96% (n=1) were excluded. Subsequent additional QC filters did not necessitate to exclude further SNPs. Single marker analysis showed nominal Armitage's Trend Test P values of 0.0061 for SNP rs15931. After inclusion of a follow-up sample of German origin, totalling to 4,218 individuals (40.5% cases), the P value for rs15931 further improved (p = 0.0042). The LD estimates for SNPs in candidate genes for schizophrenia, flanking *SV2A* yielded no r-squared value >0.2 and hence indicate that our findings are independent with respect to previous association findings for the linkage region. In conclusion, our results suggest that *SV2A* may be involved in the development of schizophrenia. However, independent replication studies are warranted to confirm our finding.

## 2038/T/Poster Board #587

**Polymorphism located between *CPT1B* and *CHKB*, and *HLA-DRB1*1501-DQB1*0602* haplotype confer susceptibility to CNS hypersomnias (essential hypersomnia).** *T. Miyagawa[1], M. Honda[2,3], M. Kawashima[1,4], M. Shimada[1], S. Tanaka[2], Y. Honda[3], K. Tokunaga[1].* 1) Department of Human Genetics, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan; 2) The Sleep Disorders Research Project, Tokyo Institute of Psychiatry, Tokyo, Japan; 3) Japan Somnology Center, Neuropsychiatric Research Institute, Tokyo, Japan; 4) Center for Narcolepsy, Stanford University School of Medicine, Palo Alto, California, United States of America.

We previously reported that SNP rs5770917 located between the carnitine palmitoyltransferase 1B (*CPT1B*) and choline kinase beta (*CHKB*) genes was associated with susceptibility to narcolepsy with cataplexy after performing a genome-wide association study in Japanese and Korean populations ($P = 1.4 \times 10^{-7}$; OR = 1.68). Moreover, it is noteworthy that all narcoleptic patients with cataplexy in Japan carry a human leukocyte antigen (*HLA*)-*DRB1*1501-DQB1*0602* haplotype. This study was conducted in order to investigate whether these genetic markers are associated with Japanese CNS hypersomnias (essential hypersomnia: EHS) other than narcolepsy with cataplexy. Diagnostic criteria for EHS comprised three clinical items: 1) recurrent daytime sleep episodes that occur basically every day over a period of at least 6 months; 2) absence of cataplexy; 3) the condition does not meet the diagnostic criteria of any other disorder causing excessive daytime sleepiness, such as sleep-apnea syndrome. Genotyping for SNP rs5770917 in cases (n = 137) was performed using Taqman genotyping assays. For controls, we used the genotype data (n = 569) from the previous genome-wide association study for narcolepsy with cataplexy. Genotyping for *HLA-DRB1* and *HLA-DQB1* in cases (n = 137) was performed by Luminex Multi-Analyte Profiling system (xMAP) with a WAKFlow HLA typing kit (Wakunaga, Hiroshima, Japan). We did not perform HLA-typing in controls, instead we utilized *HLA-DRB1* and *HLA-DQB1* frequency data obtained from Japanese Society for Histocompatibility and Immunogenetics databank (a total of 516 Japanese general population were genotyped). EHS was significantly associated with SNP rs5770917 ($P = 3.6 \times 10^{-3}$; OR = 1.56) and *HLA-DRB1*1501-DQB1*0602* haplotype ($P = 9.2 \times 10^{-11}$; OR = 3.97). No interaction between the two markers was observed in EHS, thus suggesting that these markers independently affect susceptibility to EHS. CPT1B, CHKB and HLA are candidates for susceptibility to CNS hypersomnias (EHS), as well as narcolepsy with cataplexy.

## 2039/T/Poster Board #588

**Survey of known candidate genes in a large GWAS study finds support for association of variation in *ACSL6* in schizophrenia.** *T.M. Mühleisen[1,2,8], M. Mattheisen[1,2,3,8], B. Basmanav[1,2], F. Degenhardt[1,2], A. Forstner[1,2], A. Breuer[4], V. Nieratschker[4], S. Witt[1,2], . GROUP Consortium[5], E. Strengman[6], R. Cantor[7], D. Rujescu[8], M.P. Baur[3], M.M. Nöthen[1,2], M. Rietschel[4], R. Ophoff[6,7,9], S. Cichon[1,2,9].* 1) Insitute of Human Genetics, Bonn, Germany; 2) Institute of Human Genetics, Department of Genomics, Life & Brain Center, University of Bonn, Bonn, Germany; 3) Institute for Medical Biometry, Informatics, and Epidemiology, University of Bonn, Bonn, Germany; 4) Department of Genetic Epidemiology in Psychiatry, Central Institute of Mental Health, Mannheim, Germany; 5) GROUP Consortium: Maastricht University Medical Centre, Academic Medical Centre University of Amsterdam, University Medical Center Groningen, University Medical Center Utrecht, The Netherlands; 6) The Netherlands Department of Medical Genetics and Rudolf Magnus Institute of Neuroscience, University Medical Center Utrecht, Utrecht, The Netherlands; 7) UCLA Center for Neurobehavioral Genetics, Los Angeles, California, USA; 8) Division of Molecular and Clinical Neurobiology, Department of Psychiatry, Ludwig-Maximilians-University Munich, Munich, Germany; 9) These authors contributed equally to this work.

Schizophrenia is a devastating neuropsychiatric disorder with a life-time prevalence of about 1% in all populations world-wide. Candidate gene and genome-wide association studies (GWAS) have come up with a few very promising genes that are likely to be involved in disease development, but more replication results are still warranted. In the current study, we present the association results of a large GWAS of SCZ for candidate genes. Our GWAS comprised 4883 individuals (1169 cases and 3714 controls) from Germany and the Netherlands. The results are given for a list of SNPs derived from studies that have referred positive and/ or negative association findings and hence cover a collection of candidate genes that have shown evidence for association in at least one study (http://www.schizophreniaforum.org/res/sczgene (accessed 30th of May 2009)). Out of an original list of 7045 SNPs from 786 genes, 1711 SNPs were present in the quality controlled dataset of our GWAS. We identified 95 SNPs with a $P$ value < 0.05 in the Cochran-Mantel-Haenszel test. Five SNPs yielded a $P$ value < 0.001 implicated in 4 genes (*ACSL6*, *RAPGEF6*, *PDE4B* and *DISC1*) and of these 2 SNPs also yielded a $P$ value < 0.0001 (both *ACSL2*, $r^2 = 0.29$). The best result was obtained for rs2240525 in *ACSL6* with a $P$ value of $5.27 * 10^{-6}$. Our results provide additional support for an involvement of these genes in the development of schizophrenia.

## 2040/T/Poster Board #589

**No association between NOS3 and schizophrenia in a Japanese population.** *T. Okochi[1], T. Kishi[1], M. Ikeda[1,3], T. Kitajima[1], Y. Yamnouchi[1], Y. Kinoshita[1], K. Kawashima[1], T. Tsunoka[1], T. Okumura[1], Y. Fukuo[1], T. Inada[4], N. Ozaki[2], N. Iwata[1].* 1) Department of Psychiatry, Fujita Health University; 2) Department of Psychiatry, Nagoya University Graduate School of Medicine; 3) Department of Psychological Medicine, School of Medicine, Cardiff University; 4) Neuropsychiatric Research Institute, Seiwa Hospital.

Nitric oxide (NO) is gaseous neurotransmitter that involved in a variety of mechanisms in the central nervous system. The evidences from pharmacological studies in animal and postmortem studies support an association between NO and psychotic disorders such as schizophrenia and mood disorder. One of the enzymes influencing NO function in the human brain is the endothelial nitric oxide synthase (NOS3). Recent study reported association between haplotype of NOS3 and bipolar disorder. In this study, we conducted a gene-based case-control study between tagging single nucleotide polymorphisms (SNPs) in NOS3 [6 SNPs including 2 functional SNPs (rs2070744, rs1799983)] and schizophrenia in a Japanese population (725 schizophrenia and 699 controls). No significant association was found between tagging SNPs in NOS3 and schizophrenia in the allele/genotype-wise or haplotype-wise analyses. In conclusion, we suggest that NOS3 is unlikely to contribute to susceptibility to schizophrenia in the Japanese population. However, it will be necessary to validate or replicate our association in other, larger population samples.

## 2041/T/Poster Board #590

**Genetic association analysis of functional polymorphisms in neuronal nitric oxide synthase 1 gene (NOS1) and mood disorders and fluvoxamine response in major depressive disorder in the Japanese population.** *T. Okumura[1], T. Kishi[1], T. Okochi[1], M. Ikeda[3], T. Kitajima[1], Y. Yamanouchi[1], Y. Kinoshita[1], K. Kawashima[1], T. Tsunoka[1], T. Inada[4], N. Ozaki[2], N. Iwata[1].* 1) Department of Psychiatry, Fujita Health University, Toyoake, Japan; 2) Department of Psychiatry, Nagoya University Graduate School of Medicine; 3) Department of Psychological Medicine, School of Medicine, Cardiff University, Heath Park, Cardiff; 4) Neuropsychiatric Research Institute, Seiwa Hospital.

[Background]Nitric oxide (NO) has been reported to play roles in neural transmitter release and N-methyl-D-aspartate (NMDA) receptor activation, as well as to be related to oxidative stress. Abnormalities in both of these mechanisms are thought to be involved in the pathophysiology of mood disorders including major depressive disorder (MDD) and bipolar disorder (BP). In addition, several lines of evidence support an association between abnormalities in neuronal nitric oxide synthases (nNOS) and mood disorders. Therefore, we studied the association of nNOS gene (NOS1) with mood disorders and the efficacy of fluvoxamine treatment in Japanese MDD patients. [Materials and methods] Using a SNP (exlc: rs41279104) reported biological functional SNPs, we conducted a genetic association analysis of case-control samples (325 MDD patients, 154 BP patients and 807 controls) in the Japanese population. In addition, we performed association analysis between NOS1 and the efficacy of fluvoxamine treatment in 117 MDD patients. We defined a clinical response as a decrease of more than a 50% in baseline SIGH-D within 8 weeks, and clinical remission as a SIGH-D score of less than 7 at 8 weeks. [Results]We did not detect a significant association of NOS1 with MDD, BP or the fluvoxamine therapeutic response in MDD in allele/genotype-wise analysis. [Discussion] We did not detect an association between only one marker (rs41279104) in NOS1 and Japanese mood disorders patients and fluvoxamine response, but sample sizes were probably too small to allow a meaningful test. Moreover, because we did not perform an association analysis based on Linkage disequilibrium (LD) and a mutation scan of NOS1, a replication in study using a larger sample and based on LD may be required for conclusive results.

## 2042/T/Poster Board #591

**Variants in SLITRK1 are associated with the Obsessive-Compulsive Disorder Spectrum.** *U. Ozomaro[1], R. Moessner[2], M. Cuccaro[1], M. Pericak-Vance[1], M. Wagner[2], G. Feng[3], S. Züchner[1].* 1) Miami Institute for Human Genomics, University of Miami, Miami, USA; 2) Psychiatrische Klinik der Universitaet Bonn, Bonn, Germany; 3) Department of Neurobiology, Duke University Medical Center, Durham, USA.

Obsessive-Compulsive Disorder (OCD) and the spectrum of closely related disorders are characterized by persistent intrusive thoughts (obsessions), repetitive actions (compulsions), and excessive anxiety. Although heritability studies in OCD have shown an increased risk for first degree relatives, and twin studies revealed higher concordance amongst monozygotic twins (compared to dizygotic twins), the identification of the underlying risk-conferring genetic variation by means of classic genetic association studies has proven to be difficult. Recently, the possibility of a larger contribution of rare genetic variants to the risk of psychiatric disorder has been suggested by several successful studies. In accordance with this hypothesis, we applied a rare variant association study design to explore SLITRK1, a gene previously linked to disorders of the OCD spectrum. We directly resequenced SLITRK1 in 279 OCD spectrum cases and in 185 psychiatric controls. We identified two novel nonsynonymous variants in five cases, N400I and T418S. The N400I variant was found in one case, while the T418S change was identified in four cases. Neither variant, nor any other nonsynonymous changes were detected in the controls. In a previous study, we identified two rare variants in SLITRK1, R584K and S593G, whose sequence changes were significantly associated with trichotillomania, an OCD spectrum disorder. Taking into consideration the combined mutation load of our two studies, OCD spectrum cases are significantly associated with variants in SLITRK1 (complete gene sequencing; p=0.043, Fisher's exact test). SLITRK1 codes for a neurite modulating protein and is found in the striatum. Additional support for a role of SLITRK1 in OCD spectrum disorders comes from a recent SLITRK1 knockout mouse characterized by anxiety and by mirroring aspects of the human disorder. We are currently performing functional in-vitro studies to further clarify the molecular consequences of these variants.

## 2043/T/Poster Board #592

**Association study of the CNV overlapping GSK3β (glycogen synthase kinase-3β) gene with mood disorders.** *E. Saus[1], V. Soria[2], G. Escaramís[3,1], J.M. Crespo[2,4], J. Valero[5], A. Gutiérrez-Zotes[5], L. Martorell[5], E. Vilella[5], J.M. Menchón[2,4], X. Estivill[1,3], M. Urretavizcaya[2,4], M. Gratacòs[3,1].* 1) Genetic Causes of Disease Group, Genes and Disease Program, Center for Genomic Regulation (CRG-UPF), Barcelona, Catalonia, Spain; 2) CIBERSAM (CIBER en Salud Mental), Mood Disorders Clinical and Research Unit, Psychiatry Department, Bellvitge University Hospital, Barcelona, Spain; 3) CIBER en Epidemiología y Salud Pública (CIBERESP), Instituto de Salud Carlos III, Madrid, Spain; 4) Department of Clinical Sciences, Bellvitge Campus, Barcelona University, Barcelona, Spain; 5) Grup d'Investigació en Psiquiatria. Hospital Universitari Institut Pere Mata, Rovira i Virgili University, Reus, Spain.

Glycogen synthase kinase-3β (GSK3β), particularly abundant in the CNS (central nervous system), is known to regulate such critical cellular functions as structure, gene expression, mobility and apoptosis. Recent findings support that GSK3β may play a role in the pathophysiology and treatment of mood disorders (MD), in part through its modulatory function in the circadian clock mechanism. Lachman et al. (2006) found a statistically significant increased number of gains in a CNV (copy number variant) partially overlapping with GSK3β in bipolar patients compared with control individuals. Here, we replicated this experiment in a Spanish sample of MD under the hypothesis that this CNV overlapping with GSK3β gene could partially underlie the susceptibility to MD and also could be associated with specific clinical subphenotypes. The clinical sample consisted of 444 patients with MD (256 Unipolar Major Depressive Disorder, 188 Bipolar Disorder) and 428 psychiatrically screened control subjects. All samples were genotyped in triplicate by qPCR (SYBR Green I). All triplicates undergone a quality control measure, and a linear mixed model was generated to normalize all the data allowing a posterior relative quantification of gains and losses. We found a total of 42 samples with gains and 13 samples with losses, accounting for 18 gains and 4 losses in MD patients, and 24 gains and 9 losses in controls. An association study considering the diagnostic (MD vs. controls) adjusting by age and sex was first performed, but no significant result was obtained. Then, we tested 5 different subphenotypes previously related with GSK3β within the MD patients group: polarity, seasonality, chronotype, antidepressant treatment response and age at onset. We only obtained a positive nominal result for seasonality, although statistical significance was lost after Bonferroni correction. In this sense, MD patients carrying changes in GSK3β CNV (especially losses) have a tendency to present a seasonal pattern. While we have not been able to confirm a direct involvement of GSK3β copy number variant in the susceptibility to MD, changes in copy number in GSK3β could partially contribute to the presentation of seasonal pattern in some of these patients.

## 2044/T/Poster Board #593

**Association of language and reading phenotypes with SNPs of KIAA0319 in a population selected for language impairment.** *S. Smith[1], M. Rice[2].* 1) Dept Pediatrics and Munroe Meyer Institute, Univ Nebraska Med Center, Omaha, NE; 2) Dept. Speech-Language and Hearing, Dole Human Devel Center, Univ Kansas, Lawrence, KS.

Language impairment, reading disability, and speech sound disorder are developmental disorders with separate clinical definitions but which often occur together in children, and this comorbidity may be due in part to common genetic influences. Our previous linkage analyses in a population of children selected for language impairment replicated the linkage of reading and language phenotypes to microsatellite markers on chromosome 6p22 in the DYX2 region. The linked markers flanked the two candidate genes for reading disability, DCDC2 and KIAA0319. To confirm this finding and determine if one or both of the candidate genes were involved in language impairment, we followed up with 36 SNPs spanning the genes VMP, DCDC2, KIAA0319, and TTRAP. The subjects were the nuclear families of probands from 86 families totaling 220 children who have been involved in longitudinal language studies by Dr. Rice. The probands were ascertained from speech/language pathologists and were screened for intelligence in the normal range, normal hearing, intelligible speech, and language disability using standardized criteria. Eight phenotypes were evaluated in the children, including measures of language, grammatical morphology, reading, and articulation. Using FBAT analysis (additive hypothesis), only 5 SNPs showed significant association, and all of these were in or near KIAA0319. Three of these SNPs have previously been reported to show association with reading phenotypes in other studies (e.g., Francks et al., 2004; Cope et al., 2005; Luciano et al., 2007), and the same alleles were found to be associated with reading and language problems in our study. These SNPs are in the 5' region and first intron of KIAA0319, suggesting that their association is with elements that regulate the level of expression of the gene. Research supported by NIDCD R01 DC01803 to Dr. Rice.

## 2045/T/Poster Board #594

**Delineation of an overlapping 10q deletion involving PCDH15 with neuropsychiatric disease.** *N. Sobreira[1], N. Feng[1], G. Thomas[3], J. Mulle[4], J. MacGrath[2], S. Warren[4], D. Avramopoulos[1], A. Pulver[2], D. Valle[1].* 1) Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Department of Psychiatry, Johns Hopkins University School of Medicine, Baltimore, MD; 3) Kennedy Krieger Institute, Baltimore, MD; 4) Department of Human Genetics, Emory University, Atlanta, GA.

Schizophrenia (SZ) is a chronic, disabling illness with extensive phenotypic and genetic heterogeneity and an incidence of 1%. The causes are still poorly understood but there is a strong genetic component (80% heritability). Associations between SZ and several candidate genes have been replicated in various samples but other than *DISC1*, causative variants have not been identified. Bipolar disorder (BPD) is a mood disorder characterized by intermittent episodes of mania or hypomania and depression often complicated by frank psychosis. Lifetime risk for BPD has been reported to be as high as 4%. Heritability estimates are similar to those for SZ but even fewer genes have been found with only *CACNA1C* and *ANK3* being identified in well-replicated studies. SZ and BPD have overlapping symptoms and pedigrees with both diagnoses are common. We identified two families segregating SZ and BPD-like phenotypes with overlapping deletions on 10q. The first, JHU2000, includes an affected mother and 2 affected sibs with del(10)(q21.1q21.2) or (q21.2q22.1) identified by standard cytogenetics. The mother has seizures and has been variously diagnosed as BPD or SZ since age 17 yrs. The daughter has attention deficit disorder, and cognitive deficits. The son has ADHD, depression, episodes of mania and the diagnoses of BPD. We utilized quantitative PCR, long-range PCR, and sequencing to define the boundaries of an 8.1 Mb deletion that extends from 55,376,528 bp to 63,475,465 bp at 10q21.1-q21.2. This deletion removes 19 genes including *PCDH15* and *ANK3*. Recessive truncating mutations in *PCDH15* cause Usher syndrome type 1, a deafness-blindness disorder which has been suggested to have an increased incidence of neuropsychiatric disease. The second family, JHU88293, was identified in a genome-wide SNP genotyping screen for CNVs in SZ and has ~4.2 Mb deletion estimated to extend from 53.2 to 57.5 Mb. The female proband has SZ while the father, who also has the deletion, is said to be normal. The minimal overlap in these two families is from 55.4 to 57.5 Mb. *PCDH15* is the only annotated gene in this interval,which also includes a large segment of the gene desert upstream of *ZWINT1*. The observations in these 2 families strongly suggest that a gene or genes in 10q21.1-q21.2, possibly *PCDH15*, contribute risk for a neuropsychiatric disorder with features of SZ and/or BPD.

## 2046/T/Poster Board #595

**Leucine rich repeat gene polymorphisms are associated with autism spectrum disorder susceptibility in populations of European ancestry.** *I. Sousa[1], T.G. Clark[1,2], R. Holt[1], A.T. Pagnamenta[1], N. Sykes[1], E. Mulder[3], A.J. Bailey[4], A. Battaglia[5], S.M. Klauck[6], F. Poustka[7], A.P. Monaco[1], International Molecular Genetic Study of Autism Consortium.* 1) Wellcome Trust Ctr, Univ Oxford, Oxford, United Kingdom; 2) Wellcome Trust Sanger Institute, Hinxton, Cambridge CB10 1SA, UK; 3) Department of Psychiatry, Child and Adolescent Psychiatry, University Medical Center Groningen, PO Box 660, 9700 AR Groningen, the Netherlands; 4) University Department of Psychiatry, Warneford Hospital,Oxford, UK; 5) Stella Maris Clinical Research Institute for Child and Adolescent Neuropsychiatry, Calambrone (Pisa), Italy; 6) Division of Molecular Genome Analysis, German Cancer Research Center, Heidelberg, Germany; 7) Department of Child and Adolescent Psychiatry, Johann Wolfgang Goethe-University, Frankfurt/Main, Germany.

Autism is a severe and highly heritable neurodevelopmental disorder characterised by impairments in social interaction, communication, and restricted interests/behaviours. Several cell adhesion transmembrane leucine-rich repeat (LRR) proteins are highly expressed in the nervous system and thought to be key regulators of its development. Here we present an association study analysing the roles of four promising candidate nested genes - *LRRTM1* (2p), *LRRTM3* (10q), *LRRN1* (3p) and *LRRN3* (7q) - in order to identify common genetic risk factors underlying autism spectrum disorders (ASDs). To gain a better understanding of the genetic variation that may underlie these four gene regions and how they may influence susceptibility to ASDs, a family-based association study was undertaken in 735 families of European ancestry selected from four different population cohorts. Significant results were found for *LRRN3* and *LRRTM3* ($P < 0.005$), using both single locus and haplotype approaches. In addition, a case-control analysis was performed supporting the evidence found for *LRRN3* and *LRRTM3* and pointing to new significant results in the latter ($P < 0.005$). Overall, our findings implicate the neuronal leucine rich genes *LRRN3* and *LRRTM3* to have a role in ASD susceptibility.

## 2047/T/Poster Board #596

**Further investigation of *IMMP2L*, *LRRN3* and *DOCK4* as potential candidate genes for autism susceptibility.** *N.H. Sykes[1], A.T. Pagnamenta[1], G. Lunter[1], H. Kugoh[2], M. Oshimura[2], E. Bacchelli[3], E. Maestrini[3], A.J. Bailey[4], A.P. Monaco[1], IMGSAC (http://www.well.ox.ac.uk/~maestrin/iat.html).* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Department of Molecular and Cell Genetics, Tottori University, Tottori, Japan; 3) Department of Biology, University of Bologna, Bologna, Italy; 4) University Department of Psychiatry, Park Hospital for Children, Oxford.

Autism is a severe neurodevelopmental disorder that usually occurs due to a complex genetic predisposition. The International Molecular Genetic Study of Autism Consortium (IMGSAC) previously identified a susceptibility locus for autism on chromosome 7 (*AUTS1*). A subsequent high-density association analysis of the region tested more than 3000 single nucleotide polymorphisms (SNPs) in all known genes and non-genic highly conserved sequences. SNP genotype data were also used to investigate copy number variation (CNV) within this region. Association and CNV analyses highlighted several genes that warrant further investigation, including *IMMP2L* (which contains a nested gene *LRRN3* in intron 3) and *DOCK4*. An independent replication of association at rs2217262 and the finding of a deletion segregating in a sib-pair family provided support for the involvement of *DOCK4* in autism susceptibility.

To further investigate the genes *IMMP2L*, *LRRN3* and *DOCK4* a number of approaches have since been taken. Firstly, the *DOCK*4 deletion has been characterised at base pair resolution and is being assessed more extensively within the extended family pedigree. Secondly, given the evidence of parent-of-origin effects at the *IMMP2L* locus, the expression of the genes *IMMP2L*, *LRRN3* and *DOCK4* were observed in human/mouse A9 monochromosomal hybrids. The cell lines contained a human maternal or paternal chromosome 7, derived from primary fibroblasts. All three genes were found to have both maternal and paternal expression, which excludes imprinting within these cell lines.

Currently a high-throughput sequencing experiment is being conducted using next generation sequencing technology, to identify rare variants within the genes *IMMP2L*, *LRRN3* and *DOCK4*. Sequencing will be conducted with the Illumina® Genome Analyzer using one affected individual per IMGSAC multiplex family, chosen from a subset that displays linkage to chromosome 7. Initially a pilot study will be performed in which 50 CEU DNAs will be pooled together and sequenced for approximately 75kb of our region of interest. In this way we will be able to verify the ability of the platform to identify rare variants.

## 2048/T/Poster Board #597

**Association between dopamine D4 receptor (*DRD4*) -521 C/T polymorphism and sensation seeking behaviour in female alpine skiers and snowboarders.** *C.T. Thomson[1], C.W. Hanna[2], K.L. Morton[1], P. Wang[1], M.R. Beauchamp[1], J.L. Rupert[1].* 1) Sch Human Kinetics, Univ British Columbia, Vancouver, BC, Canada; 2) Department of Medical Genetics, Univ British Columbia, Vancouver, BC, Canada.

Previous research has shown a large genetic influence over personality traits, especially sensation seeking (SS). Sensation seeking is the desire to seek out new and thrilling experiences. One gene thought to influence this behavioral trait is *DRD4*, in which variants have been associated with SS or novelty in some, but not all studies. The inconsistencies between studies may be due to heterogeneity in both the behaviours and the populations being assessed. Some studies included only males and few studies have *a priori* analyzed males and females separately. SS has been associated with high-risk sports, including skiing; however this is the first study to address the possibility that genetics may play a role in individuals' inclination towards SS in sport. Using the Contextual Sensation Seeking Questionnaire (CSSQ) for Skiing, developed and validated for this study, and the Zuckerman-Kuhlman Personality Questionnaire (ZKPQ), levels of SS in males and females were analyzed in association with *DRD4* -521 C/T. Behavioural analysis of skiers (N = 206) revealed a significant correlation ($r^2$= 0.497, p < 0.001) between skier behaviour (CSSQ) and skier personality scores (ZKPQ). Genotype analysis (N = 109) revealed allele frequencies of 0.54 C and 0.46 T. A significant association was found between the -521 T allele (CT and TT genotypes) and low contextual skiing SS behaviour in the females (N = 54, p = 0.004), however no association was found between ZKPQ SS scores and -521 C/T in females (p = 0.164) nor males (N=55, p = 0.178). This study provides support that the alleles of the DRD4 -521 C/T polymorphism are associated with context-specific SS behaviours in females, but not in males. Whether the lack of association in males is due to variations in the biochemical properties of the dopamine receptor or whether social pressures differentially influence male and female sensation-seeking behaviour are areas that require further investigation.

## 2049/T/Poster Board #598

**A 1q42 Deletion Involving DISC1, DISC2 and TSNAX in an Autism Spectrum Disorder.** *T.F. Beck[1], J.M. Williams[1], D.M. Pearson[1], M.B. Proud[2], S.W. Cheung[1], D.A. Scott[1].* 1) Deparment of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, USA; 2) Department of Pediatrics-Neurology, Baylor College of Medicine, Houston, TX, USA.

Autism spectrum disorders (ASDs) affect approximately 1 in 500 children 3 to 10 years of age, with a significantly higher risk for male children (6.8 times higher) than for females. Individuals with ASDs have impairments in social, communicative, and behavior development that are often accompanied by abnormalities in cognitive functioning, learning, attention, and sensory processing. In this report we describe a three year old male child with an autism spectrum disorder who carries a 2Mb deletion of chromosome 1q42. Array comparative genome hybridization revealed that this deletion involves at least three genesDISC1, DISC2 and TSNAXwhich have been found to be associated with autism and neuropsychiatric disorders in multiple studies and are likely to play key roles in normal central nervous system development. Analysis of this region in the patient's unaffected mother demonstrated the same deletion. To investigate the possibility that our patient's phenotype involved unmasking of paternally inherited deleterious changes, we sequenced the coding regions of DISC1 and TSNAX in our patient. Two nonsynonymous changes were identified in DISC1 but both were judged to be benign using the on-line tool PolyPhen which predicts the impact of an amino acid substitution on protein structure and function using physical and comparative considerations. DISC2 was not screened for changes since it is thought to be a noncoding antisense transcript. These results suggest other genetic and/or environmental factors, some of which may be sex specific, may modify the phenotypic effects of this deletion. While this case provides evidence for the potential role of DISC1, DISC2 and TSNAX in the development of autism spectrum disorders, it is equally clear that caution must be used when providing families with prognostic information and genetic counseling regarding such deletions.

## 2050/T/Poster Board #599

**Mutation analysis of functional candidate genes for Aicardi syndrome.** *X. Wang[1], V.R Sutton[2], T. Eble[2], C. O'neill[1], R. Lewis[2,3], I.B Van den Veyver[1,2].* 1) Dept of Obstetrics and gynecology; 2) Dept of Molecular and human genetics,; 3) Dept of Ophthalmology, Baylor College of Medicine, Houston, TX 77030,USA.

Aicardi syndrome is characterized by developmental abnormalities that primarily affect the eyes and the brain and is associated with early-onset and often intractable seizures.

This severe neurodevelopmental disorder affects almost exclusively females and rarely 47,XXY males, which strongly suggests that Aicardi syndrome is caused by de novo dominant mutations in an X-linked gene. Evidence of excess skewing of X-inactivation in females with Aicardi syndrome further supports this hypothesis. Because genetic linkage approaches to map the gene for Aicardi syndrome cannot be used due to the lack of familial cases, we previously used genome-wide high-resolution array-CGH analysis to screen the DNA of 38 girls with Aicardi syndrome for copy number changes, but no disease-causing changes were detected in these patients. In parallel with these efforts, we are using informed approaches to select X-linked candidate genes for mutation analysis by direct sequencing of PCR-amplified coding exons.

To date, we have analyzed 17 genes, including 5 previously selected genes *ARHGAP6*, *HCCS*, *MID1*, *MSL3L1* and *FLNA*.Twelve additional genes were selected and sequenced based on 1) known or putative function related to Aicardi (*CDKL5, MSN, ARX* conserved sequence blocks in 3'UTR, *IGBP1*); 2) proximally to interesting chromosomal breakpoint in patients with Aicardi syndrome or overlapping phenotypes (*CXORF15, GPM6B, EGFL6*); 3) Interaction with disease-causing genes for similar phenotypes found by network analysis(*CASK, NGFRAP1, NAP1L2, MAGEH1, PCTK1*). So far, no disease-causing mutations or copy number changes by array CGH were detected in these functional candidate genes. Southern analysis with cDNA probes from genes of interest to detect smaller (intragenic) genomic rearrangements, is still ongoing.

## 2051/T/Poster Board #600

**The effect of chr16p11.2 microdeletions and microduplications on gene expression in Autism Spectrum Disorders and Schizophrenia.** *M. Kusenda[1,2], V. Vacic[1], S. Yoon[1], M. Wigler[1], J. Sebat[1].* 1) Cold Spring Harbor Lab, Cold Spring Harbor, NY 11724; 2) Graduate Program in Genetics, Stony Brook University, NY 11794, USA.

The number of rare variants found to be associated with multiple psychiatric disorders is growing. One such locus is a recurrent ~600kb copy number variant (CNV) at 16p11.2, occurring in approximately 1% of autism and 0.3% of schizophrenia cases, as compared to 0.01% of the general population. We hypothesize that one or more of the 25 genes at this locus contribute to the neurodevelopmental phenotype observed in patients with psychiatric disorders. To determine how gene function is altered by this CNV, we analyzed genome wide expression data from Epstein Barr Virus (EBV) transformed Lymphoblast cell lines (LCL), of patients with autism or schizophrenia who have a de novo or inherited 16p11.2 rearrangement. Using RNA expression profiling by Affymetrix Human Genome U133 Plus 2.0 chip, we examined differential cis and trans gene expression in individuals with 1, 2, or 3 copies of the genomic region. (6, 19, 16 respectively) To avoid skewing of data due to limited sample size we customized the Significance Analysis of Microarrays (SAM) method to utilize all samples while accounting for sources of bias. Our data highlighted 140 genes located both within and outside of the mutation which expression correlates with genotype. Some of these genes play a role in development while others have been associated with psychiatric disorders. We are currently analyzing our list of 140 dysregulated genes to identify pathways and functions relevant to neurodevelopment, and psychiatric disorders. Data generated by this study will give insight into dosage sensitive genes within the risk variant, and may help pinpoint genes which are relevant to pathology of the psychiatric disorders associated with this region.

## 2052/T/Poster Board #601

**Increased Amylase 1 Gene Copy Number in Autism.** *C. Aguado[1], I. Cuscó[1], L.A. Pérez-Jurado[1,2].* 1) Unitat de Genètica, Universitat Pompeu Fabra and Centro de Investigación Biomédica en Red de Enfermedades Raras (CIBERER), Barcelona, Spain; 2) Programa de Medicina Molecular i Genètica, Hospital Vall d'Hebrón, Barcelona, Spain.

Autism Spectrum Disorders (ASDs) are a group of conditions with common neurodevelopmental defects affecting socialization, communication skills and behavior, considered to have a multifactorial etiology. Prevalence of ASDs is substantially greater than previously recognised, approaching 1% of the child population, and appears to be on the rise. Whether the increase is due to better ascertainment, increased incidence or both is unclear, and the putative genetic or environmental factors responsible for such an increase remain unknown. One pathogenic hypothesis is that some environmental factors might act on genetically susceptible individuals during early postnatal stages triggering an abnormal neuronal growth or inflammation to alter the normal development of neuronal circuits in ASD. In a search for structural genomic variants using comparative genomic hybridization with BAC microarrays we detected significantly different hybridization signals in the region of the amylase genes at 1p21.1 in ASD patients with respect to controls. We then determined the AMY1 diploid gene copy number using the reported AMY1-specific real-time qPCR assay. We observed that the mean+/-SD number of AMY1 copies in Spaniards is 6.1+/-4.0 (n=89, similar to other Europeans), while it is significantly higher, 9.2+/-5.0, p<0.0001, in the group of idiopathic ASD from the same region (n=85). The analysis of maternal and paternal samples from ASD patients revealed similarly high results in both cases (~8.5+/-4.7 AMY1 copies), suggesting that the increased AMY1 copy number gene in ASD is inherited in most cases without skewed parent of origin. Replication of the results in other ASD cohorts is underway. The AMY1 gene, coding for the salivary alpha-amylase mostly involved in the digestion of starch and other carbohydrates, has been shown to undergo natural selection with increased copy number in farming populations. Much higher AMY1 copy numbers could increase ASD susceptibility by modifying digestion and/or immune response to starch and other foods. Our findings link genetic structural variation to putative dietary factors that could contribute to the pathogenesis of ASD acting either during pregnancy or early in life.

## 2053/T/Poster Board #602

**Inheritance of 15q11-13 Duplications in Autism Pedigrees.** *R.J. Robison[1], N. Matsunami[3], K. Allen-Brady[2], D. Cannon[1], M. Hobbs[4], J. Stevens[3], L. Baird[3], T. Varvil[3], C. Pingree[1], M.F. Leppert[3], W. McMahon[1], H. Coon[1].* 1) Department of Psychiatry, University of Utah, Salt Lake City, UT; 2) Department of Biomedical Informatics, University of Utah, Salt Lake City, UT; 3) Eccles Institute of Human Genetics, University of Utah, Salt Lake City, UT; 4) Division of Infectious Diseases, University of Utah, Salt Lake City, UT.

**Introduction:** Autism Spectrum Disorders (ASDs) are a set of complex, early-onset neurodevelopmental disorders. 15q11-13 contains a cluster of imprinted genes essential for normal neurodevelopment, and is also known as the PWS/AS region. Duplications of 15q11-13 have been associated with ASDs, particularly when maternally inherited, and are thought to occur in up to 5% of autism. These abnormalities often occur as an inverted duplication known as idic(15). **Methods:** 113 subjects with ASDs, along with both parents, were genotyped using the Affymetrix 250K NSP platform. Analysis of copy number state at each SNP probe was performed using the Affymetrix Genotyping Console (GTC), with HapMap CEU samples as controls. 55 of these subjects with ASDs (but not parents) were also genotyped independently on the Affymetrix 6.0 platform. An additional 55 psychiatrically-screened normal control subjects obtained via dbGaP that had been genotyped on the 6.0 platform were also analyzed using GTC software. **Results:** Comparison of Affymetrix 250K and 6.0 platforms for individuals genotyped on both revealed a high degree of qualitative consistency, but a large difference in size of the CNVs detected on each platform. **Discussion:** A high number of maternally-inherited chromosome 15q11-13 duplications was seen in this sample. Common breakpoints predispose 15q to genomic rearrangements and this region is known to be highly polymorphic. While previous studies have found a lower percentage of maternal 15q11-13 duplications, these studies used different methods and diagnostic criteria. Follow-up will include attempting to validate key findings using quantitative PCR, performing additional genotyping using the higher density 6.0 arrays, CNV analysis using multiple software algorithms, and tracing CNVs through extended pedigrees beyond parental transmission. We will also explore the relationship between validated CNVs and particular autism phenotypes. Additional studies are needed to better characterize the role of this important cytogenetic region in ASDs.

## 2054/T/Poster Board #603

**Novel copy number variation in autism.** *S.A. Thomson[1], S.C. Lund[1], B.L. Yaspan[1], D. Pinto[2], E.L. Crawford[1], C.R. Marshall[2], S.W. Scherer[2], E. Kistner[3], N.J. Cox[3], E.H. Cook[4], J.S. Sutcliffe[1].* 1) Centers for Human Genetics Research and Molecular Neuroscience, Vanderbilt Univ, Nashville, TN; 2) Centre for Applied Genomics, Hospital for Sick Children, Toronto, Ontario; 3) Department of Medicine, University of Chicago, Chicago, IL; 4) Institute for Juvenile Research, Department of Psychiatry, University of Illinois-Chicago, Chicago, IL.

Autism is a neurodevelopmental disorder that affects ~1 in 150 individuals and is characterized by deficits in reciprocal social interaction, communication and patterns of repetitive behaviors and restricted interests. Twin and family studies indicate high heritability, but evidence supports a highly complex architecture for the underlying genetic etiology. Recent discoveries point to copy number variation (CNV) as an important class of rare variation that may cause or increase risk for autism. A series of 89 autism probands were screened using either the Affymetrix 6.0 or Illumina 1M SNP platforms. Data were analyzed using multiple algorithms to maximize sensitivity and specificity of CNV detection (Partek, dChip, and AffyConsole for Affy 6.0 and QuantiSNP, PennCNV and Gnosis for Illumina 1M). Variants predicted by 2+ algorithms were prioritized for validation by qPCR and/or genotyping on an independent array platform. Analyses of Affymetrix data from 49 probands identified 3,265 CNV predictions, of which 668 (20%) were called by 2 and 353 (11%) by 3 algorithms. Mean and median sizes were 171kb and 73kb, respectively. Among the 2+ predictions, 482 (47%) were in genic regions and 306 (63%) contained exons. 540 (53%) were predicted to be losses, and 481 (47%) gains. Illumina predictions from 40 probands found 11255 CNV predictions; 1185 (11%) were called by 2 and 399 (4%) by 3 algorithms. Mean and median sizes were 70kb and 21kb, respectively. Among 2+ algorithm predictions, 849 (54%) contained genes; 629 (74%) exons and 220 (26%) intronic regions. The majority were losses (1117; 71%). Prioritized CNVs were confirmed by qPCR and the majority found to be inherited. Most CNVs in autism are inherited, and their interpretation is more difficult. Possible explanations include reduced penetrance in parents or greater overall mutation burden in probands who have multiple variants. CNVs that affect genes implicated previously by de novo variants, or involved in dominantly-inherited MR, are very likely to confer risk. DOCK8 is a gene fitting both scenarios. In conclusion, several of the confirmed CNVs in this study identified loci previously implicated in mental retardation and/or autism, as well as neuronal cell surface molecules with a range of specific functions including cell adhesion, migration, synaptic vesicle release and cellular signaling. These findings further underscore the important role played by CNVs in the genetic etiology of autism.

## 2055/T/Poster Board #604

**Elucidating the genetic architecture of familial schizophrenia using rare copy number variant and linkage scans.** *B. Xu[1,2], A. Woodroffe[3], L. Rodriguez-Murillo[1], J. Roos[4], E. van Rensburg[5], G. Abecasis[6], J. Gogos[2,7], M. Karayiorgou[1].* 1) Department of Psychiatry, Columbia University, New York, NY; 2) Department of Physiology & Cellular Biophysics, Columbia University, New York, NY; 3) Department of Epidemiology, University of Michigan, Ann Arbor, MI; 4) Weskoppies Hospital, Department of Psychiatry, Pretoria, RSA; 5) University of Pretoria, Department of Genetics, Pretoria, RSA; 6) Department of Biostatistics, University of Michigan, Ann Arbor, MI; 7) Department of Neuroscience, Columbia University, New York, NY.

To elucidate the genetic architecture of familial schizophrenia we combine linkage analysis with studies of fine-level chromosomal variation in families recruited from the Afrikaner population in South Africa. We demonstrate that individually rare inherited copy number variants (CNVs) are more frequent in cases with familial schizophrenia as compared to unaffected controls and affect almost exclusively genic regions. Interestingly, while the prevalence of rare structural variants is similar in familial and sporadic cases, the type of variants is markedly different. In addition, using a high-density linkage scan with a panel of nearly 2000 markers, we identify a region on chromosome 13q34 that shows genome-wide significant linkage to schizophrenia and show that in the families not linked to this locus, there is evidence for linkage to chromosome 1p36. No causative CNVs were identified in either locus. Overall, our results from approaches designed to detect risk variants with relatively low-frequency and high penetrance in a well-defined and relatively homogenous population, provide strong empirical evidence supporting the notion that multiple genetic variants, including individually rare ones, that affect many different genes contribute to the genetic risk of familial schizophrenia. They also highlight differences in the genetic architecture of the familial and sporadic forms of the disease.

## 2056/T/Poster Board #605

**Novel mutations found by resequencing multiple subunits of $GABA_A$ receptor in families with Idiopathic Generalized Epilepsy.** *P. Lachance Touchette[1], C. Meloche[1], P. Brown[3], P. Kinirons[1], J. Poirier[1], L. Lapointe[1], A. Lortie[2], L. Carmant[2], D. Bowie[3], P. Cossette[1].* 1) Center for Excellence in Neuromics of Université de Montréal, CHUM Research Center, Montreal, Canada; 2) CHU Sainte-Justine, Pediatric Department, Service of Neurology, University of Montreal, Montreal, Canada; 3) Department of Pharmacology & Therapeutics of McGill University, Montreal, Canada.

Idiopathic generalized epilepsies (IGE) account for approximately 30 % of all epilepsy syndromes. An increasing number of genes predisposing to the disease have been identified, including mutations in four subunits of the $GABA_A$ receptor genes (GABAR). To investigate the impact of rare variants of GABAR in IGE, we screened the coding regions of 19 genes encoding for all the known subunits of the GABAR in 96 unrelated French-Canadian individuals with the disease, including 46 familial cases. Overall, approximately 15 % of our IGE individuals have novel GABAR mutations, including 13 missense and 1 splice mutations. These mutations were not detected in more than 400 control chromosomes. The impact of each missense mutation was investigated by using several *in silico* methods each of which predict the possible impact of genetic variants on the structure and function of the mature protein. In *GABRA1*, we found an insertion of 25bp close to the splice acceptor site of exon 10 associated with intron retention (P351fsintX), as well as a D219N mutation. In *GABRG2*, we found a P83S mutation. Transfection of these three mutants GABAR in mammalian cells revealed that mutant receptors exhibit reduced expression at the cell surface. In turn, electrophysiological analysis of mutant $GABA_A$ receptors revealed that both P83S and D219N mutations are functional, although the gating properties of these recombinant receptors are significantly altered. Whether the mutations in the other GABAR subunits are associated with similar functional defects remain to be determined.

## 2057/T/Poster Board #606

**Linkage analysis of plasma dopamine β-hydroxylase activity in families segregating schizophrenia.** *J.F. Cubells[1,2], X. Sun[3], R.C. Elston[3], R.W. Bonsall[2], K. Mercer[1], W. Li[1], Y-L. Tang[1], D. Avramopoulos[4], V.K. Lasseter[4], P.S. Wolyniec[4], J.A. McGrath[4], A.E. Pulver[4].* 1) Dept. of Human Genetics, Emory Univ Sch. Med., Atlanta, GA; 2) Dept. of Psychiatry and Behavioral Sciences, Emory Univ Sch. Med., Atlanta, GA; 3) Dept. of Epidemiology and Biostatistics, Case Western Reserve Univ. Sch. Med., Cleveland, OH; 4) Dept. of Psychiatry, Johns Hopkins Sch. Med., Baltimore, MD.

Background: Dopamine β-hydroxylase (DβH) converts dopamine to norepinephrine, and occurs in human plasma, where its activity is under strong genetic control. Prior studies showed linkage between plasma DβH activity and ABO blood type, and subsequent molecular mapping showed that ABO and the structural gene encoding DβH, *DBH*, map closely together, but molecular linkage analysis of plasma DβH activity has not been reported. Methods: A total of 921 individuals from 123 pedigrees were recruited as part of the Maryland Epidemiological Study of Schizophrenia. Enzyme activity, measured using tyramine as a substrate, with product octopamine separated from reactants by HPLC and detected by electrochemical detection, was available for 284 individuals. 208 chromosome-9 SNPs from the Illumina version 4 linkage marker set were determined in 723 individuals. Two additional markers at DBH, previously shown to associate significantly with plasma DβH activity (rs 1611115 and rs 6271, both typed on the Taqman platform), were added to those from the Illumina panel. Segregation analysis was conducted using the SEGREG program, and multipoint model-based linkage analysis with MLOD, in S.A.G.E. Results: Highly significant linkage was observed between markers surrounding *DBH* and square-root transformed plasma DβH activity, with the strongest signal found under low-value dominant inheritance (multipoint LOD score = 6.34). SNPs within the *DBH* genic region were within the 1-unit support interval (LOD = 6.18). Accounting for diagnosis, age, sex, or duration of sample storage did not substantially change the results. Finally, the heritability of plasma DβH was ~0.57, a figure that is about 25% lower than previous estimates. Conclusions: The current results confirm strong linkage between the *DBH* locus and plasma DβH activity, but suggest a different mode of inheritance and somewhat lower total heritability of plasma DβH than prior association studies (which support a co-dominant model). This work sets the stage for examining potential interactions between inherited differences in DβH activity and segregation of symptomatic phenotypes in schizophrenia. Supported by NIH grant R01 MH 077233.

## 2058/T/Poster Board #607

**Genetics of multiple sclerosis.** *A. Bonetti[1,2], K. Koivisto[3], T. Pirttilä[4,5], I. Elovaara[6,15], M. Reunanen[7,8], M. Laaksonen[9,10], J. Ruutiainen[11], L. Peltonen[12,13,14], T. Rantamäki[1,2], P. Tienari[1,2].* 1) Molecular Neuroscience Programme, Biomedicum-Helsinki , University of Helsinki, Finland; 2) Helsinki University Central Hospital, Helsinki, Finland; 3) Central Hospital of Seinajöki, Seinajöki, Finland; 4) Department of Neurology and Neuroscience, University of Kuopio, Finland; 5) Kuopio University Hospital, Kuopio, Finland; 6) Department of Neurology, University of Tampere, Finland; 7) Department of Neurology, University of Oulu, Oulu, Finland; 8) Oulu University Hospital, Oulu, Finland; 9) Turku Immunology Centre, Finland; 10) Departments of Virology and Neurology, University of Turku, Turku, Finland; 11) Masku Neurological Rehabilitation Centre, Finland; 12) National Public Health Institute, University of Helsinki, Finland; 13) FIMM, Institute for Molecular Medicine Finland, Finland; 14) Wellcome Trust Sanger Institute, Hinxton, United Kingdom; 15) Tampere University Hospital, Tampere, Finland.

Multiple sclerosis (MS) is an immune-mediated demyelinating disease of the central nervous system. Multiple genes mediate predisposition to MS, the strongest so far identified is HLA-DR15. Previously, we and others have provided evidence for a role of allelic variation on chromosomes 2q33 and 19q13 in MS susceptiblity. Neither of these loci were, however, detected in a recent genome-wide association study performed in US and UK patients. We have carried out a follow-up study of these regions in a family-based association study in 700 MS families from Finland. In 19q13 we analysed 14 markers, both microsatellites and single nucleotide polymorphisms (SNPs). None of the markers showed statistically significant association with MS, including the previously suggested markers D19S876, APOE, ILT6 and D19S585. In 2q33 a nominally significant trend for association was found distal of CTLA4, with a SNP located in the inducible T-cell co-stimulator (ICOS) gene. This association was, however, non-significant upon correction for multiple comparisons. ICOS is a co-stimulatory molecule that, upon binding to its ligand, functions in parallel with HLA/T-cell receptor in the immunological synapse. The weakly (non-significantly) associated SNP is located in close proximity with an exon that we found in RT-PCR experiments to be alternatively spliced. The stability of the newly-identified transcript variant was analysed in lymphocyte cell lines and transfected cells and its subcellular localisation was analysed in transfected cells. The relative expression of ICOS transcripts was analysed in MS patients' and controls' lymphocytes using real-time PCR. These results demonstrate a novel, possibly regulatory, transcriptional variant of ICOS.

## 2059/T/Poster Board #608

**Possible association of prokineticin 2 receptor gene (PROKR2) with mood disorders in the Japanese population.** *T. Kishi[1], T. Kitajima[1,2], T. Tsunoka[1], T. Okumura[1], M. Ikeda[1], T. Okochi[1], Y. Kinoshita[1], K. Kawashima[1], Y. Yamanouchi[1], N. Ozaki[3], N. Iwata[1].* 1) Psychiatry, Fujita Health University, Toyoake, Aichi, Japan; 2) Department of Psychological Medicine, School of Medicine, Cardiff University, Heath Park, Cardiff, CF14 4XN, United Kingdom; 3) Department of Psychiatry, Nagoya University Graduate School of Medicine, Nagoya 466-8850, Japan.

Several investigations have suggested that disruption of circadian rhythms may provide the foundation for the development of mood disorders such as bipolar disorder (BP) and major depressive disorder (MDD). Recent animal studies reported that prokineticin 2 or prokineticin 2 receptor gene deficient mice showed disruptions in circadian and homeostatic regulation of sleep. This evidence indicates that prokineticin 2 gene (PROK2) and prokineticin 2 receptor gene (PROKR2) are good candidate genes for the pathogenesis of mood disorders. To evaluate the association between PROK2, PROKR2, and mood disorders, we conducted a case-control study of Japanese samples (151 bipolar patients, 319 major depressive disorder patients and 340 controls) with four and five tagging SNPs in PROK2 or PROKR2, respectively, selected by HapMap database. We detected a significant association between PROKR2 and major depressive disorder and bipolar disorder in the Japanese population. In conclusion, our findings suggest that PROKR2 may play a role in the pathophysiology of mood disorders in the Japanese population. However, because our samples were small, it will be important to replicate and confirm these findings in other independent studies using larger samples.

## 2060/T/Poster Board #609

**Genomic Characterization of Schizophrenia Candidate Gene Regions.** *A.Q. Nato[1], X. Kong[1,2], F. Chen[1,3], C. He[1,4], D. Chimento[1], B. Byrne[5], J. Naus[6], C. Chiu[1], S. Buyske[1,6], L.M. Brzustowicz[1], T.C. Matise[1].* 1) Dept Gen, Rutgers Univ, Piscataway, NJ; 2) GlaxoSmithKline, King of Prussia, PA; 3) Inst Gen Sci & Policy, Duke Univ, Durham, NC; 4) Lab Stat Gen, Rockefeller Univ, New York, NY; 5) Informatics Inst, UMDNJ, Piscataway, NJ; 6) Dept Stat, Rutgers Univ, Piscataway, NJ.

Schizophrenia (SZ) has been established to have a complex genetic aetiology with a lifetime prevalence commonly given at ~1% but systematic reviews suggested lower values of 0.44% to 0.55%. In this study, we extracted and analyzed data from the 47 published independent genomewide linkage scans for SZ from 1994 to 2009. A smoothing method and a disjoint approach were utilized to determine 19 schizophrenia candidate gene regions (SCRs). We have developed the SCR Browser for identifying the genetic markers implicated in these genome scans. We annotate each SCR by identifying the genes within these regions. We categorize these genes based on whether they are linked to diseases, functions, phenotypes, pathways, or GO terms, and on whether they are linked or associated with SZ in published linkage scans, association studies, meta-analyses, and microarray studies. We also identify copy-number variants, segmental duplications, defined regulatory regions, putative miRNA binding sites, and rearrangement hotspots within each SCR. The total SCR coverage is 427 cM with SCR sizes ranging from 16 cM to 50 cM. We identify subregions within these SCRs using the results from fine-mapping studies coupled with the diverse information used to characterize each of the SCRs. Our approach provides a novel method to determine and prioritize candidate gene regions and genomic elements that may be applied to other complex diseases.

## 2061/T/Poster Board #610

**Resequencing and association study of vesicular glutamate transporter 1 gene (VGLUT1) with schizophrenia.** *Y. Shen[1,2], C. Chen[3,4].* 1) Department of Psychiatry, Tzu-Chi General Hospital and University, Hualien, Taiwan; 2) Institute of Medical Sciences, Tzu-Chi University, Hualien, Taiwan; 3) Division of Mental Health and Addiction Medicine, Institute of Population Health Sciences, National Health Research Institutes, Zhunan, Taiwan; 4) Institute of Clinical Medicine, Tzu-Chi University, Hualien, Taiwan.

Dysregulation of glutamate neurotransmission is implicated in the pathphysiology of schizophrenia. Vesicular glutamate transporters (VGLUTs) package glutamate into vesicles in the presynaptic terminal and regulate the release of glutamate. Among these VGLUTs, abnormal VGLUT1 expression has been mostly linked to schizophrenia in postmortem brain studies. The purpose of this study was to investigate the involvement of the gene encoding the human VGLUT1 in the susceptibility to schizophrenia. In this study, we searched for genetic variants in the putative core promoter region, 5`UTR, all the exons, and 3`UTR of the VGLUT1 gene using a direct sequencing strategy in a sample of Han Chinese schizophrenic patients (n = 376) and non-psychotic controls (n = 368) from Taiwan, and conducted a case-control association study. In all regions examined, we identified two common SNPs (g.-248G>C and g.11875C>A) in the VGLUT1 gene. No differences in the allele, genotype, and haplotype frequencies were detected between the patients and control subjects. Besides, we identified eight patient-specific rare mutations in 16 out of 376 patients, including two mutations (g.-296A>G and g.-32C>T) at the core promoter region and 5'UTR, two missense (L516M and P551S) and three synonymous mutations (E24E, L118L, P133P) at exonic regions, and one mutation (g.11252G>A) at the 3'UTR. These rare mutations were not found in 368 control subjects (4.3% versus 0, P = 0.000015). Although the functional significance of these rare mutations remains to be characterized, our study lends support to the multiple rare mutations hypothesis of schizophrenia. Also, our findings provide genetic clues to indicate the involvement of the glutamate transmission pathway in the pathogenesis of schizophrenia.

## 2062/T/Poster Board #611

**Replication of a novel Autism peak region in two ethnically diverse populations.** *J. Jaworski[1], D. Ma[1], D. Salyakina[1], I. Konidari[1], P. Whitehead[1], H. Wright[2], R. Abramsom[2], E. Martin[1], J.P. Hussman[3], J.R. Gilbert[1], M. Cuccaro[1], J.L. Haines[4], M.A. Pericak-Vance[1].* 1) Miami Institute for Human Genomics MIHG, Univ Miami, Miami, FL; 2) School of Medicine, University of South Carolina, Columbia, SC; 3) Hussman Foundation, Ellicott City, Maryland; 4) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN.

Autism is one of the most heritable neuropsychiatric disorders but since no single major gene has been identified, it is now clear that it has a complex genetic etiology. We recently identified common variants in 5p14.1 that carry autism risk in Caucasian families and this was replicated in two other Caucasian datasets derived from the Autism Genetic Resource Exchange (AGRE) and the Children's Hospital of Philadelphia (CHOP). In this study, we tested the generalizability of this result by examining two diverse populations of Hispanics (Hisp) and African Americans (AA). We genotyped the families using the Illumina Human 1M beadchip. The AA dataset included 292 individuals from 85 families with 99 affecteds. The Hisp dataset included 247 individuals from 79 families with 94 affecteds. Both datasets had a mixture of parent-child trios and dyads. To account for missing parents in the dataset, the software program CAPL was used for analysis, which can make efficient use of any mix of case-control and nuclear family data. We examined SNPs within 5p14.1 from 2.58 to 2.60 Mb, the peak region of association in the Caucasian datasets. Within the AA dataset, 11 SNPS had p-values <0.05 with the peak SNP being RS12521157 (p-value= 0.006). Two of the previously reported significant 8 SNPs across this region (p<0.05) were among these 11. The Hispanic dataset had 3 SNPS with p-values <0.05 within the region with the peak being RS6878844 (p=0.03), although none of these 3 was significant in the Caucasian dataset. Despite the significantly smaller sample size in these diverse datasets, our findings indicate that 5p14.1 may indeed harbor an autism susceptibility variation that contributes to the etiology of autism across populations.

**Combining Co-expression Analysis with Genome-Wide Genetic Data to Identify Novel Candidate Genes in Autism.** *S. Strom, M. Yourshaw, L. Song, B. Merriman, H. Lee, S.F. Nelson.* UCLA, Los Angeles, CA.

Genome-wide association (GWAS) and copy number variant (CNV) analysis have identified several new genes likely contributing to Autism Spectrum Disorder (ASD) risk. However, these few genes explain only a small fraction of the estimated heritability of ASD. As yet unknown genes conferring ASD risk may generate non-significant association signals due to heterogeneity or low effect size. Analysis of the co-expression of a given gene with published ASD-related genes provides a path to highlighting the most interesting genes from amongst a multitude of false positive signals present due to chance. Co-expression correlation scores between a seed list of probe-sets from 13 genes likely to contribute to autism taken from a recent review and the over 18,000 unique genes assayed by the Affymetrix U133_2.0 microarray were obtained via the UCLA Gene Expression Tool (UGET). As a proof-of-principle, we demonstrate that mean gene-correlation scores were substantially higher for genes known to be mutated in ASD relative to a brain expression control group. We further use this tool to explore known positional candidate regions, and identify that there is significantly increased gene-gene correlation of known autism gene seed list with all genes adjacent to nominal association signals (p<0.001) in GWAS datasets. Additionally, several genes with mutations/variants linked to ASD are detected in a joint analysis incorporating co-expression with known ASD genes, SNP association, and CNV data. A small list of novel candidates are proposed, having a high likelihood of contributing to autism based on these combined analyses. Sequencing data on several novel candidates in autistic patients is presented.

## 2064/T/Poster Board #613

**In Down syndrome, synaptojanin1 over-expression is responsible for the enlargement of early endosomes, the first hallmark of Alzheimer disease pathology.** *JC. Cossec[1], S. Stora[2], C. Ripoll[3], A. Hoischen[4], S. Antonarakis[5], M. Lecourtois[6], Y. Grattau[2], J. Veltman[4], C. Duyckaerts[1], J. Delabar[3], MC. Potier[1].* 1) CRICM CNRS UMR7225, INSERM UMR975, UPMC, Pitié-Salpêtrière Hospital, 47, Bd de l'Hôpital 75013 Paris, France; 2) Institut Jérôme Lejeune, France; 3) BFA, CNRS EAC7059, Paris, France; 4) Dept. of Human Genet., Nijmegen, Netherlands; 5) Univ. of Geneva Med. Sch., Geneva, Switzerland; 6) INSERM U614, Rouen, France.

Enlarged endosomes are believed to be the first morphological change observed in Alzheimer's disease brains (AD). They are found in sporadic cases with no pathological evidence of AD yet, in Down syndrome (DS) as early as 28 weeks of gestation. It is believed that high levels of amyloid peptides (Aβ) could be the cause of these morphological changes. However in familial AD with mutations in the presenilin genes that over produce Aβ, the endosomal compartment appeared to be unchanged. We thus searched for other factors that could modify the endosome morphology in DS. In order to identify the genes from human chromosome 21 (Hsa21) responsible for this cellular phenotype, we searched for the presence of enlarged endosomes in blood cells and in transformed lymphocytes from DS patients. Blood mononuclear cells were isolated on a ficoll gradient, cultured for a few hours at 37°C to let them recover. Immunofluorescence labelling of the early endosomes was performed using an antibody against the early endosome antigen protein EEA1. Using confocal microscopy, we showed that the mean size of the endosomes was significantly increased (35%;p<0.001; n=10 for DS and controls) in cells from DS patients as compared to age matched controls. We then measured the size of early endosomes in lymphoblastoid cell lines (LCL) generated by transformation of lymphocytes with the Epstein Bar virus. As in mononuclear blood cells, LCLs from DS patients contained large endosomes. The mean size as measured by immunofluorescence was 30% higher (p<0.001;n=11 for DS and n=8 for controls). Enlarged endosomes were absent in the 3 LCLs carrying APP microduplications. This result suggested that APP is not involved in the enlargement of early endosomes in this cell type. In four out of seven LCLs from DS patients carrying partial trisomy 21 we could very clearly identify enlarged endosomes. By correlating the presence of enlarged endosomes to the triplicated genomic segment from Hsa21 we identified SYNJ1 as a candidate gene. SYNJ1 gene codes for the phosphoinositide phosphatase synaptojanin 1 protein, a key regulator of the signalling phospholipids phosphatidylinositol-4,5-biphosphate [PtdIns(4,5)P2]. We observed abnormally large endosomes in SHSY5Y cells transfected with SYNJ1 plasmid. In conclusion we have shown that synapyojanin 1 over-expression pertubing the PtdIns(4,5)P2 homeostasy of the cell, leads to defects in endocytosis associated with morphological changes of the endosomes.

## 2065/T/Poster Board #614

**SNP rs16969968 in CHRNA5 Associated with Heroin Dependence.** *E.O. Johnson[1], L.J. Bierut[2], J.C. Wang[2], A.M. Goate[2], A.H. Kral[1].* 1) Behavioral Hlth Epidemiology, RTI International, Res. Triangle Pk, NC; 2) Washington University School of Medicine, St. Louis, MO.

Neuronal nicotinic acetylcholine receptors modulate the dopamine reward pathway. In prior studies we identified an association between nicotine dependence and the non-synonymous single nucleotide polymorphism (SNP) rs16969968 in the nicotinic acetylcholine receptor α5 subunit (CHRNA5) gene (Bierut et al., 2007; Saccone et al. 2007), which has been replicated in independent samples (Bierut et al., 2008; Berrettini et al., 2008; Thorgeirsson et al. 2008; Stevens et al., 2008; Weiss et al., 2008). The minor (A) allele increases the risk of nicotine dependence (approximately 2-fold in a recessive model) and results in a aspartic acid to asparagine change at position 398 (D398N) which appears to alter receptor response to nicotine in vitro (Bierut et al., 2008). Recently, our group found the major (G) allele, relative to the minor (A) allele, increased the risk for cocaine dependence, suggesting that the genetic associations are reversed for cocaine versus nicotine dependence (Grucza et al., 2008). Here we test the hypothesis that the G allele in rs16969968 is associated with increased risk of heroin dependence. METHODS: Cases of heroin dependence came from the Urban Health Study of injection drug users (n = 267) and the non-drug abusing controls from the Family Study of Cocaine Dependence (n = 244), all were of European decent. RESULTS: The primary multiplicative model showed a significant association with heroin dependence (p = 0.05; G allele frequency 69% vs. 63% among case and controls). However, a recessive model of inheritance was found to be the best model indicating a 45% increased risk of heroin dependence associated with a G/G genotype relative to A/G or A/A genotypes (OR = 1.45, 95% CI 1.01-2.08, p = 0.04). CONCLUSION: The association between rs16969968 and heroin dependence is in the same direction as that found for cocaine dependence and the reverse of its association with nicotine dependence further supporting the potential importance of this SNP in the development of multiple substance use disorders.

## 2066/T/Poster Board #615

**Saitohin and APOE variants influence clinical features in institutionalized persons with Alzheimer Disease.** *D.L. Schutte[1], D.A. Reed[2].* 1) Col Nursing, Michigan State Univ, East Lansing, MI; 2) Aging, Disability, and Long-Term Care Program, Cecil G. Sheps Center for Health Services Research, University of North Carolina-Chapel Hill.

Alzheimer disease (AD) is a prevalent neurodegenerative disorder, characterized by dementia. AD exhibits variability in age at onset and specific cognitive, functional, and behavioral features even into the advanced stages of disease. Little is known about factors, including genetic variation, that influence clinical variability in this population. The purpose of this study was to examine the extent to which genetic variability influences phenotypic variability in institutionalized persons with advanced AD. Thirty-seven subjects diagnosed with probable AD were recruited from five long-term care facilities. Whole blood or cheek cells were collected for DNA extraction and genotyping. Subjects were genotyped for sequence variants in several candidate genes, including Apolipoprotein E (APOE) and Saitohin (STH). Measures of cognitive status (Global Deterioration Scale, Severe Impairment Battery), functional ability (Functional Abilities Checklist), and agitation (Cohen-Mansfield Agitation Inventory) were collected at four-month intervals over one year. Subjects exhibited a mean age at onset of 76.8 years. All subjects exhibited moderate to severe levels of cognitive impairment. A multilevel model approach to repeated measures revealed a genotype effect on cognition and functional ability. Thirty-five percent of the variation in cognitive status between subjects was accounted for by the presence of the APOE-ε4 allele and STH-7R allele (p < .001). APOE-ε4 (p=.088) and STH-7R (p=.043) alleles explained 22% of the inter-individual variation in functional ability. Statistical modeling of behavior was also completed using GEE. Modeling of physical aggression did not yield a significant genotype effect at the STH locus. However, for the APOE locus, a time X APOE-ε4 allele interaction was identified (p=.030), resulting from a convergence of physical aggression scores over time. The modeling of verbal agitation yielded no significant effects of time, gender, or genotype at either locus. Genotyping of additional tagging SNPS across the STH and surrounding MAPT gene are underway to enable a haplotype approach to this analysis. These results from this pilot study will guide the design of a larger study to examine both resident and facility characteristics as potential predictors of clinical subgroups in institutionalized persons with Alzheimer disease towards the goal of developing and testing more targeted interventions.

**Association of *ALDH5A1* (*SSADH*) with human capital formation and cognitive function.** *A.V. Smith[1], D.J. Benjamin[2], C.F. Chabris[3], S.M. Purcell[4], E.L. Glaeser[5], L.J. Launer[6], T.B. Harris[6], V. Gudnason[1,7], D.I. Laibson[4].* 1) Icelandic Heart Association, Kopavogur, Iceland; 2) Cornell University, Ithaca, NY, USA; 3) Union College, Schenectady, NY, USA; 4) Massachusetts General Hospital, Boston, MA, USA; 5) Harvard University, Boston, MA, USA; 6) National Institute on Aging, National Institutes of Health, Bethesda, MD, USA; 7) University of Iceland, Reykjavik, Iceland.

In recent years, there has been increasing interest in identifying genetic influences on economic behavior. Twin studies have documented heritability for income, education, and other economic phenotypes. In order to identify particular genetic variants that influence economic outcomes, we searched for associations between 8 phenotypes of economic interest--occupation, housing wealth, labor supply, human capital, time discounting, social capital, happiness, and overall health--and a set of candidate genes that may be involved in cognition and decision making. In an ethnically homogeneous sample of 2,289 participants in the Reykjavik Study-Age Gene/Environment Susceptibility Study (RS-AGES), we genotyped 415 single nucleotide polymorphisms (SNPs) across 68 genes that have published associations with cognition-related phenotypes and/or are part of the dopamine or serotonin systems. After correcting for multiple testing, we find statistically significant associations between a composite measure of discounting-related behaviors (smoking, drinking, and BMI) and the cognition-related gene *BDNF*; between a composite of social capital accumulation and the dopamine-system gene *DRD2*; and between human capital (years of schooling and number of languages spoken) and the cognition-related gene *ALDH5A1* (*SSADH*). We tested for replication in a non-overlapping sample of approximately 1700 RS-AGES participants. While the discounting and social capital results did not replicate, we found additional evidence supporting an association between human capital and *ALDH5A1* (*SSADH*). This result is consistent with a possible influence of this gene, which encodes an enzyme that metabolizes GABA, on general cognitive ability.

## 2068/T/Poster Board #617

**Association of a Functional Haplotype of the Discs, Large Homolog 4 (Drosophila) Gene with Schizophrenia in Han Chinese.** *M. Cheng[1], D.L. Liao[2], H.M. Tsai[2], J.Y. Chen[3], Y.C. Wang[3], I.C. Lai[3], C.H. Chen[1,2].* 1) Institute of Medical Sciences, Tzu-Chi University, Hualien, Taiwan; 2) Division of Mental Health and Addition Medicine, Institute of Population Health Sciences, National Health Research Institutes, Zhunan, Taiwan; 3) Department of Psychiatry, Yuli Veterans Hospital, Hualien, Taiwan.

Compelling evidence support that hypofunction of N-methyl-D-aspartate (NMDA) receptor is associated with the pathophysiology of schizophrenia. Postsynaptic density protein 95 (PSD95) interacts with NMDA receptors and plays an important role in modulating of NMDA receptor activity. Altered expression of the PSD95 in the brain has been linked to schizophrenia in several postmortem studies. The purpose of this study was to investigate whether variants of the human discs, large homolog 4 (Drosophila) (DLG4) gene that encodes PSD95 conferring susceptibility to schizophrenia. We re-sequenced the 5'UTR, all the exons, and the 3'UTR of the DLG4 gene in a sample of Han Chinese schizophrenic patients (n=434) and control subjects (n=438) from Taiwan and conducted a genetic association study. We also assessed the function of the SNPs and haplotyes of the DLG4 gene identified in this study using a reporter gene assay. We did not detect any mutations at the exonic regions of the DLG4 gene associated with schizophrenia in this sample. Nevertheless, we identified a haplotype at the 5'UTR of the DLG4 gene that was nominally associated with schizophrenia (odd ratio: 1.24, 95% confidence interval: 1.005-1.522). Reporter gene assay showed that this haplotype has significantly increased activity as compared to other haplotypes. Thus, our study indicates that DLG4 gene is associated with schizophrenia.

## 2069/T/Poster Board #618

**Positional Cloning of a Gene for Distal Motor Neuron Disease on 7q34-q36.** *A.P. Drew[1,2], I.P. Blair[1,2], K.L. Williams[1], G.A. Nicholson[1,2,3].* 1) Northcott Neurosciences, ANZAC Research Institute, Concord, New South Wales, Australia; 2) Faculty of Medicine, University of Sydney, Sydney, New South Wales, Australia; 3) Molecular Medicine Laboratory, Concord Hospital, Concord, New South Wales, Australia.

The motor neuron disorders are a group of neurodegenerative diseases that cause the selective progressive death of motor neurons, with an absence of sensory involvement. Motor neuron disease (MND) is genetically and clinically heterogeneous with the biological basis of the disease is poorly understood. MND ranges from the rapidly progressive fatal form amyotrophic lateral sclerosis (ALS), to slowly progressive forms including hereditary motor neuropathy (HMN). Approximately 10-15% of MND is familial, with the remainder being sporadic or complex genetic traits. The significant genetic and clinical overlap between types of MND imply shared pathogenic pathways. Distal HMN is a MND which affects only the lower motor neurons, causing muscle weakness and wasting, resulting in a lifelong disability. Through genetic linkage studies of a large dHMN family, a novel motor neuron disease locus was mapped to chr. 7q34-q36 (1). Haplotype analysis has defined a 12.9Mb interval flanked by the markers D7S2513 and D7S637. Meiotic recombination events in unaffected individuals suggest the candidate interval is a 6.9Mb region flanked by markers D7S615 and D7S2546. The disease interval encompasses over 100 annotated genes. To identify a pathogenic mutation we selected candidate genes prioritised by association with neurological disorders, interaction with known MND genes and expression in neuronal tissues. Exons and flanking intronic regions were sequenced in 34 genes. Following this, we sequenced one affected individual for the 7q34-q36 disease interval using NimbleGen sequence capture arrays. we achieved 80% coverage, with 18 novel nonsynonymous changes. 7 have been excluded as part of chromosomal translocations with 11 remaining to be screened. Twenty-four HMN families have been genotyped for the 7q34-q36 locus. Ten of these families carry haplotypes that segregate with the disease locus on 7q34-q36 and cannot be excluded. These families were too small to achieve significant linkage scores. The largest family with 5 affected individuals achieved a LOD score of 1.72, suggestive of linkage. Comparison of these haplotypes identified 3 smaller haplotypes associated with the disease group compared to a control group (n=55). The overlap between the families suggests common ancestry and therefore a smaller disease interval. Identification of this novel MND gene will give insights into the biological basis of both familial and sporadic motor neuron degeneration.

## 2070/T/Poster Board #619

**Variants within a 150 kb region on chromosome 15q25.1 that includes CHRNB4 and ADAMTS7 are associated with age at onset of habitual smoking.** *J. Wang[1], S. Bertelsen[1], L. Fox[1], J. Budde[1], A. Hinrichs[1], J. Rice[1], J. Nurnberger Jr.[2], V. Hesselbrock[3], H. Edenberg[4], L. Bierut[1], A. Goate[1], COGA Collaborators.* 1) Psychiatry, Washington Univ Sch Med, St Louis, MO; 2) Institute of Psychiatric Research, Indiana Univ Sch Med, Indianapolis, IN; 3) Department of Psychiatry, Univ Connecticut Sch Med, Farmington, CT; 4) Department of Biochemistry and Molecular Biology, Indiana University, Indianapolis, IN.

Several genome-wide association and candidate gene studies have linked chromosome 15q24-q25.1 (a region including the CHRNA5-CHRNA3-CHRNB4 gene cluster) with alcohol dependence, nicotine dependence and smoking-related illnesses such as lung cancer and chronic obstructive pulmonary disease. To further examine the impact of this gene cluster region on the development of substance use disorders, we tested whether variants within and flanking the CHRNA5/A3/B4 gene cluster affect age at onset of habitual smoking (20 cigarettes/day for at least six months) and nicotine dependence in a cross sectional sample of adolescents and young adults from the COGA (Collaborative Study of the Genetics of Alcoholism) families. Subjects were recruited from families affected with alcoholism (either as a first or second degree relative) and the comparison families. Participants are those who have had at least one assessment between the years 1989-2008 when they were between the ages of 12 and 25 years. The assessment used the SSAGA-IV interview, a comprehensive assessment of alcohol and other substance use and related behaviors. Using Cox proportional hazards regression analysis, we observed that variants located upstream of CHRNB4 and within an adjacent gene, ADAMTS7 significantly predict age at onset of habitual smoking. These variants are not highly correlated ($0.28<r2<0.56$) with variants that we have previously reported to affect risk for nicotine dependence and smoking related diseases. This suggests that a novel mechanism underlies the association with age at onset of habitual smoking. This work may provide genetic information that will lead to better prevention and intervention for substance use disorders among adolescents and young adults.

## 2071/T/Poster Board #620

**New generation sequencing for the identification of novel variant late-infantile neuronal ceroid lipofuscinosis (vLINCL) genes.** *M. Kousi[1], A.J. Coffey[2], E. Jakkula[3], M. Topcu[4], S. Gokben[5], D. Yuksel[6], A. Palotie[2,7,8], A.E. Lehesjoki[1].* 1) Folkhälsan Institute of Genetics, Department of Medical Genetics and Neuroscience Center, University of Helsinki, Helsinki, Finland; 2) The Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK; 3) Institute of Molecular Medicine Finland and The National Institute for Health and Welfare, Helsinki, Finland; 4) Department of Pediatrics, Hacettepe University Faculty of Medicine, Section of Child Neurology, Ankara, Turkey; 5) Department of Pediatrics, Ege University Medical Faculty, Izmir, Turkey; 6) Dr. Sami Ulus Children's Hospital, Ankara, Turkey; 7) The Broad Institute of MIT and Harvard, Cambridge, MA, USA; 8) Department of Clinical Chemistry, University of Helsinki.

The neuronal ceroid lipofuscinoses (NCLs) comprise the most common neurodegenerative disorders encountered in childhood. The clinical symptoms involve epileptic seizures, myoclonus, progressive mental and motor deterioration, visual failure and premature death. Ten subtypes of human NCLs are recognized today. Despite the progress made in identifying human NCL genes, eight of which are known to date, the knowledge of the genetic spectrum underlying this group of disorders remains still elusive. We aim to identify the underlying defected genes in 28 Turkish patients with a putative variant late-infantile NCL (vLINCL) diagnosis, in whom we excluded all known human NCL loci by sequence analysis. Towards this goal, we performed a genome-wide SNP scan in the 28 patients and four unaffected family members from 23 mostly consanguineous families using the Illumina's human610-Quad SNP chip. Homozygosity analysis was done with the PLINK program and the Illumina's Beadstudio-suite. Several regions with overlapping homozygosity in a subset of the patients were identified. Twelve candidate loci were determined by overlapping homozygosity between the siblings of three nuclear families. Two distinct loci map on each of chromosomes 16, 11, 3, and 1 and one locus on each of chromosomes 22, 17, 8 and 2. The loci harbor a total of 1,007 genes. In order to identify the genes involved with NCL we are resequencing the coding regions of all of the genes in the candidate intervals using an array-based sequence capture protocol and Illumina sequencing. When successful, our approach will lead to the identification of three novel vLINCL genes given that the three families share no common homozygous regions across the genome. Our findings suggest that the molecular genetic basis of vLINCL is more heterogeneous than previously anticipated. Completion of the genetic spectrum underlying NCLs will provide tools for their improved diagnosis and classification, as well as for understanding the underlying disease mechanisms.

## 2072/T/Poster Board #621

**Variants of the Matrix Metalloproteinase-2 (*MMP-2*) but not the Matrix Metalloproteinase-9 (*MMP-9*) genes significantly influence functional outcome after stroke.** *H. Manso[1,2], T. Krug[2,3], J. Sobral[1,2], I. Albergaria[1], G. Gaspar[1], J.M. Ferro[4], S.A. Oliveira[2,3], A.M. Vicente[1,2].* 1) Instituto Nacional de Saude Dr.Ricardo Jorge, Lisboa, Portugal; 2) Instituto Gulbenkian de Ciência, Oeiras, Portugal; 3) Instituto de Medicina Molecular, Lisboa, Portugal; 4) Serviço de Neurologia, Hospital de Santa Maria, Lisboa, Portugal.

Background and Purpose - Multiple lines of evidence suggest that genetic factors contribute to stroke recovery. The matrix metalloproteinases -2 (MMP-2) and -9 (MMP-9) are modulators of extracellular matrix components, with important regulatory functions in the Central Nervous System (CNS). Shortly after stroke, MMP-2 and MMP-9 have mainly damaging effects for brain tissue. However, MMPs also have a beneficial activity in angiogenesis and neurovascular remodelling during the delayed neuroinflammatory response phase, thus possibly contributing to stroke functional recovery. Methods - In the present study, the role of *MMP-2* and *MMP-9* genetic variants in stroke recovery was investigated in 546 stroke patients. Functional outcome was assessed three months after a stroke episode using the modified Rankin Scale (mRS), and patients were classified in two groups: good recovery (mRS≤1) or poor recovery (mRS>1). Haplotype tagging single nucleotide polymorphisms (SNPs) in the *MMP-2* (N=21) and *MMP-9* (N=4) genes were genotyped and tested for association with stroke outcome, adjusting for significant non-genetic clinical variables. Results - Six SNPs in the *MMP-2* gene were significantly associated with stroke outcome ($0.0018<P<0.0415$), two of which survived the Bonferroni correction for multiple testing. In the subset of ischemic stroke patients, association of five of these SNPs remained positive ($0.0042<P<0.0306$). No significant associations were found for the *MMP-9* gene. Conclusions - The results presented strongly indicate that *MMP-2* genetic variants are an important mediator of functional outcome after stroke.

## 2073/T/Poster Board #622

**Sequencing of *NGN2* in autism cohort identifies rare *de novo* coding mutations.** *D.S. Rudd[1], L.K. Davis[1], G.H. Kim[2], A. Jones[3], T.H. Wassink[3].* 1) Interdisciplinary Genetics Program, University of Iowa, Iowa City, IA; 2) Department of Pediatrics, University of Iowa, Iowa City, IA; 3) Department of Psychiatry, University of Iowa, Iowa City, IA.

*NGN2* (Neurogenin2) is a basic helix-loop-helix transcription factor that is known to be involved in early brain development where it enhances synaptic specificity. *NGN2* is comprised of a single exon (~800 bp) with only one known SNP and there are various mouse models available for multiple alleles of *NGN2*. Mutant mice display defects in their central nervous systems, a decrease in Cajal-Retizus cells and mis-localization of synapses in the dorsal telencephalon and the forebrain. *PAX6* and *PAX3* are transcription factors that regulate expression of *NGN2* in the dorsal and ventral sides of the neural tube, respectively. Combined with previous results that have implicated *PAX6* mutations with autism susceptibility and the required functionality of *NGN2* in early brain development, it is proposed that *NGN2* is a candidate gene for autism. 210 children with autism spectrum diagnoses from simplex and multiplex families have been sequenced to date. 200 controls are currently being sequenced with no novel base-pair changes identified to date. Preliminary sequencing results from the proband panel have identified rare mutations in *NGN2*. Among the previously unannotated sequence changes that have been identified there exists two missense mutations and one synonymous mutation. All three mutations appear to be *de novo*. [This still needs to be confirmed with micro-satellite markers.] Additional variants are being characterized.

## 2074/T/Poster Board #623

**A susceptibility locus for bipolar affective disorder identified on chromosome 3p22.3.** *R. Secolin[1], C. Banzato[2], M.C.M. Oliveira[2], M.F.R. Bittar[1], P. Dalgalarrondo[2], I. Lopes-Cendes[1].* 1) Dept of Medical Genetics, University of Campinas - UNICAMP, Campinas, SP, Brazil; 2) Dept of Medical Psychology and Psychiatry, University of Campinas - UNICAMP, Campinas, SP, Brazil.

**Rationale:** Bipolar affective disorder (BPAD) is a common psychiatric illness, with a prevalence of 0.8-2.6 % in the general population. Clinical features include episodes of mania or hypomania, interspersed with periods of depression. Genetic factors are known to contribute to the etiology of BPAD. A large genome-wide association study performed in the British population identified 21 candidate loci across the genome. However, in order to confirm and strength these findings, further replication studies in different populations are needed. In this study we aimed to evaluate these 21 candidate loci previously reported using a family-based association approach. **Methods:** We evaluated 74 pedigrees with BPAD, with a total of 411 individuals, including 96 patients who fulfilled clinical criteria for BPAD according to DSM-IV classification. We genotyped SNPs using real-time PCR (TaqMan® system, Applied Biosystems). We used the TDT POWER CALCULATOR program to verify statistical power of our sample and genotyped data was processed by the LINKGEN program, which also estimates minor allele frequency (MAF). Mendelian inconsistencies and Hardy-Weinberg Equilibrium (HWE) were evaluated by PEDCHECK and HAPLOVIEW softwares, respectively. Family-based association analysis was performed by the UNPHASED software. **Results:** We found that our sample has statistical power higher than 80% to detect association. We found significant association signals for four SNPs: rs2989476 ($p = 0.0031$), rs7570682 ($p = 0.0407$), rs9834970 ($p = 0.00013$) and rs11622475 ($p = 0.0153$). However, only SNP rs9834970 maintained statistically significance for association after Bonferroni correction ($p_{corrected} = 0.0025$), with an OR = 2.64 (95% CI= 1.30 - 5.35). **Conclusion:** We demonstrated that SNP rs9834970, located on chromosome 3p22.3, is associated with the disease phenotype in our BPAD pedigrees. This SNP maps to an intergenic region and is not known to be associated to regulatory genomic sequences. Additional SNPs are being genotyped in the candidate region in order to estimate haplotype association and to identify the putative causal variant associated with BPAD in the group of patients included in our study. Supported by FAPESP.

## 2075/T/Poster Board #624

**Study of regional candidate genes for endophenotypes and clinical features of schizophrenia in a population isolate.** *J. Wedenoja[1,2], A. Tuulio-Henriksson[3,4], J. Suvisaari[3], A. Loukola[1], I. Surakka[1], T. Varilo[1,2,5], S. Mottaqui-Tabar[1], P. Lahermo[6], E. Serkkola[7], S. Ripatti[1,8], M. Ranki-Pesonen[7], J. Lönnqvist[3,9], L. Peltonen[1,2,5,10], T. Paunio[1,3,9].* 1) Institute for Molecular Medicine Finland FIMM, University of Helsinki and National Institute for Health and Welfare, Helsinki, Finland; 2) Department of Medical Genetics, University of Helsinki, Helsinki, Finland; 3) Department of Mental Health and Substance Abuse Services, National Institute for Health and Welfare, Helsinki, Finland; 4) Department of Psychology, University of Helsinki, Helsinki, Finland; 5) Program in Medical and Population Genetics, Broad Institute of Harvard and Massachusetts Institute of Technology, Cambridge, MA, USA; 6) Genome and Technology Center, Institute for Molecular Medicine Finland FIMM, University of Helsinki, Helsinki, Finland; 7) Research and Development, Orion Pharma, Espoo, Finland; 8) Department of Medical Epidemiology and Biostatistics, Karolinska Institute, Stockholm, Sweden; 9) Department of Psychiatry, Helsinki University Central Hospital, Helsinki, Finland; 10) Human Genetics, Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, Cambridge, UK.

Challenges in identification of predisposing genes for schizophrenia favor the use of detailed disorder features and endophenotypes which potentially are more closely related to the underlying biology. In our Finnish sample of familial schizophrenia, we have identified schizophrenia loci on chromosomes 2q, 4q, and 5q. Of these, a recent meta-analysis of 32 genome-wide linkage studies also highlighted the 2q and 5q regions. Additionally, we have identified loci for schizophrenia endophenotypes on chromosomes 2q for visual working memory, and on 4q for verbal learning and memory, both overlapping the schizophrenia loci. Here, we selected 104 regional, functionally relevant candidate genes from the linked 2q33.1-2q37.3, 4q13.1-4q26, and 5q31.1-5q33.3 regions, and genotyped altogether 1511 tagging SNPs in a nationwide Finnish sample of 293 neuropsychologically tested schizophrenia families (1111 individuals), as well as 375 independent population controls. We performed association analysis of clinical diagnostic categories, clinical disorder features, and several endophenotypic traits representing the central cognitive functions impaired in schizophrenia. Our approach allowed identification of several promising associations, of which especially interesting is *ERBB4*, showing association with the severity of positive symptoms (P=0.0003) and impairments in traits related to verbal abilities (P= 0.0001). Interestingly, *ERBB4* has been previously associated with schizophrenia and verbal working memory. Similarly, *GRIA1* showed association with the severity of positive symptoms (P=0.00008), and has been previously associated with schizophrenia. Of the others, *EPHA4* showed association with schizophrenia spectrum disorders (P=0.0003) and several clinical disorder features (P=0.00006), and *EPHA5* with several verbal learning and memory traits (P=0.0001). Our findings support the view that the genetic risk of schizophrenia is at least partially mediated via the effects of the candidate genes on intermediate endophenotypes and support the use of these factors in search of specific risk variants.

## 2076/T/Poster Board #625

**A family-based association study of DNA sequence variants in GRM7 and CHL1 with schizophrenia in an Indonesian population.** *D.B. Wildenauer[1,2], C. Ganda[1,4], N. Amir[3], R. Heriani[3], I. Irmansyah[3], A. Kusumawardhani[3], M. Nasrun[3], I. Widyawati[3], S.G. Schwab[1,4].* 1) School of Psychiatry and clinical , University of Western Australia, Perth, Australia; 2) Centre of Clinical Research in Neuropsychiatry (CCRN), Mt Claremont, Western Australia; 3) Department of Psychiatry, Faculty of Medicine, University of Indonesia, Jakarta, Indonesia; 4) Western Australian Institute for Medical Research, Perth, Western Australia.

Differences in clinical presentation and outcome of schizophrenia in patients from developing countries as opposed to developed countries may suggest the presence of specific environmental and/or genetic factors. In order to address this question, we collected in Indonesia a sample of 124 families with two or more affected siblings together with their parents or unaffected siblings in cases where one parent was missing. Using this sample for linkage analysis, we reported genome-wide significant linkage to chromosome 3p in a sib-pair sample from 124 families from Indonesia. Two promising candidate genes within the linked region are the metabotropic glutamate receptor subtype 7 (GRM7), involved in glutamatergic neurotransmission, and the close homolog of L1 (CHL1), which plays a critical role in neurodevelopment. We genotyped 18 SNPs in GRM7 and one SNP in CHL1 in the sample of 124 sib-pair families, in which linkage with schizophrenia had been detected. Transmission disequilibrium analysis revealed nominally significant transmission distortion of rs17031835 in intron 1 of GRM7 (P = 0.004, not corrected for multiple testing), along with a number of haplotypes containing rs17031835. No other single marker was found to be significantly associated with schizophrenia in our sample. The results from our study provide support for the idea that glutamatergic neurotransmission and specifically the GRM7 gene might be relevant to the development of schizophrenia in the Indonesian population.

## 2077/T/Poster Board #626

**Rare variant discovery using pooled DNA for next generation sequencing; Multiple rare alleles of the ATP-binding cassette transporter A1 (ABCA1) gene as risk factors for Alzheimer's disease.** *M.K. Lupton[1], M. Daniilidou[2], M. Tsolaki[2], R. Wroe[1], S. Lovestone[1], J.F. Powell[1].* 1) Neuroscience, Institute of Psychiatry, Kings college London, London, United Kingdom; 2) Third Neurological Clinic of Aristotle University, Papanikolaou Hospital, Thessaloniki, Macedonia, Greece.

Hypercholesterolemia and the ε4 allele of the cholesterol-carrying apolipoprotein E gene are major risk factors for Alzheimer's disease (AD). Intracellular cholesterol has been shown to influence the generation of amyloid-beta peptides and the cholesterol efflux pump, ABCA1 regulates cellular cholesterol levels. Rare alleles in this gene have been shown to contribute significantly to low plasma HDL cholesterol levels. While, there has been a failure to find consistent evidence of a genetic contribution by common variants (SNPs with MAF>0.05) of this gene to AD, we hypothesized that rare variants may increase risk of AD.

We pooled DNA from 311 AD cases and 355 controls. All coding regions and splice sites were amplified by PCR which was sequenced using the next generation Illumina Genome Analyzer. Data was analysed using the alignment program MAQ. SNP identification methods were designed using Perl scripts and STATA. The impact of novel amino acid allelic variants was predicted using multiple sequence alignments and protein 3D structures. The method has been validated by individually genotyping a common SNP, and one exon has been Sanger sequenced in individuals to compare allele frequencies and assess error rate.

From the common SNPs identified one was found to have a highly significantly different frequency in case compared to controls which was confirmed in a larger sample set. There was found to be significantly more potentially pathogenic variants in cases compared to controls for rare variants (MAF<0.01). This is one of the first studies to utilise the next generation technology to carry out deep re-sequencing of pooled DNA samples rather than individuals. We have shown that it is possible to use pooled DNA samples to obtain reliable allele frequency data even for rare SNPs.

Our study confirms the hypothesis that individually rare sequence variants are sufficiently pathogenic and common in aggregate to contribute to variation in AD risk. This promising technique will make screening for all sequence variants in candidate regions more affordable.

## 2078/T/Poster Board #627

**Two independent mutations in the ZNF526 gene are associated with non-syndromic autosomal recessive mental retardation.** *L. Abbasi Moheb[1], L. Riff jensen[2], M. Garshasbi[1], K. Kahrizi[2], S. Ghadami[1], K. Wrogemann[1], H. Hu[1], R. Kariminejad[3], F. Behjati[2], M. Mohseni[2], M. Falah[4], H. Khodai[5], M. Kasiri[6], H. Darvish[2], A. Tzschach[1], H.H. Ropers[1], H. Najmabadi[2,3], A.W. Kuss[1].* 1) Human Molecular Genetics, Max Planck Institute for Molecular Genetics, Berlin, Germany; 2) University of Social Welfare and Rehabilitation Sciences, Tehran, Iran; 3) Kariminejad-Najmabadi Pathology and Genetics Center, Tehran, Iran; 4) Tehran Welfare Institution, Tehran, Iran; 5) Yazd Welfare Institution, Yazd, Iran; 6) Shahre Kord Welfare Institution, Shahre Kord, Iran.

Mental retardation (MR) is with a prevalence of about two percent one of the most common forms of genetic handicaps. So far, however, very little is known about the genetic basis of this disorder. Especially the contribution of autosomal recessive hereditary defects is largely unresolved and to date, only five genes have been found to be directly associated with non-syndromic autosomal recessive MR (NS-ARMR). We have previously identified numerous novel loci for NS-ARMR, including MRT4-11 (Najmabadi et al., 2007, Hum. Genet. 121(1):43-8). Here we report on two different single nucleotide changes in the *ZNF526* gene, which maps to MRT11, localized in a 10 Mbp linkage interval on chromosome 19 (19q13.2-13.32). These nucleotide changes were found to co-segregate with moderate to severe NS-ARMR in three large, apparently unrelated Iranian families and were absent in 572 control chromosomes. *ZNF526* encodes a C2H2 zinc finger protein with multiple functional domains. It is expressed in brain, has DNA binding properties and is thought to be involved in gene regulation. Both mutations affect functional domains of the gene product and impair its function, as suggested by in silico protein modelling and confirmed by the presence of specific changes in the gene expression patterns of lymphoblastoid cells. Several zinc finger proteins have been shown to be involved in the pathogenesis of X-linked MR, but *ZNF526* is the first to be implicated in ARMR. Moreover, *ZNF526* is only the second gene known to carry MR-associated mutations in independent families. This may suggest that *ZNF526* defects are among the more common causes of NS-ARMR, at least in the Iranian population. CHIP-seq experiments are in progress to identify regulatory targets of the ZNF526 protein.

## 2079/T/Poster Board #628

**Partial duplication of CSMD1 (CUB and sushi multiple domains 1) (arr cgh 8p23.2((2,756,521->3,188,217))x3)associated with myoclonic seizures in a one year old female.** *J. Bartley[1], E. Friedrich[2].* 1) Miller Children's Hospital, Long Beach, CA; 2) UC Irvine Medical Center, Orange, CA.

A one-year old female with myoclonic seizures was found to have a partial duplication of CSMD1 (Signature Genomic Laboratories, LLC). Her brain MRI was normal and her seizures were poorly controlled with medications and a ketogenic diet. Her mother also had a duplication of the same intronic oligomers; but she does not seizures. The extent of the duplication is approximately 431.7 Kb in size with a single copy gain of 46 oligonucleotide probes in the short arm of chromosome 8 at 8p23.2. CUB and sushi exon number have not determined to be the same in the patient and her mother. The numbers and positions of CUB and sushi domains and transmembrane domain are completely conserved among the human CSMD (CSMD1, CSMD2, CSMD3) gene family. CSMD3 at 8q23.3-q24.1 is a candidate gene for mutations causing benign adult familial myoclonic epilepsy (BBRC 309 (2003) 143-154). The rat analog of CSMD1 mRNA is expressed in developing CNS and epithelial tissues with enrichment of CSMD1 in the nerve growth cone, the amoeboid-leading edge of the growing neuron (J Immunology, (2006) 4419-4430). A duplication of 8p23.1-8p23.2 (maternal origin) with the distal breakpoint interrupting the CSMD1 gene between introns 7 and 11 was associated with speech delay, autism and learning disorders (Eur J Hum Gen 17(2009)37-43). CSMD1 mutations appear to be a candidate for causing myoclonic seizures or developmental delay and autism in children.

## 2080/T/Poster Board #629

**The influence of sleep deprivation on gene expression in humans.** *R. Pellegrino[1], C.S Guindalini[1], D.Y Sunaga[2], M.L Andersen[1], R. Martins[1], S. Tufik[1].* 1) Laboratório de Biologia Molecular do Sono - Departamento de Psicobiologia - Universidade Federal de São Paulo - Unifesp; 2) Instituto de Biociências da USP - Centro de Estudos do Genoma Humano - Universidade de São Paulo.

Chronic sleep loss is increasingly common in industrialized societies. Sleep deprivation (SD) induces several behavioral, neurochemical, cellular and metabolic alterations. We performed genome-wide mRNA expression profiles in total blood RNA using a high-density oligonucleotide array (U133 Plus 2.0 Affymetrix, Santa Clara, California) in sleep deprived men. Healthy volunteers (18-25 years old) were subjected to 48 hours of SD, followed by 24 hours of sleep recovery (SR). All participants were carefully screened with a detailed medical history, physical, and neurological examination, routine blood tests, and urine toxicology for psychotropic drugs. All assays were performed by the MolecularCore Microarray Core (Affymetrix) following the manufacturer's standard protocol. We identified 34 DEGs (differentiated expressed genes) after 48 hours of SD and 76 DEGs after 24 hours of SR, when compared to basal levels. Moreover, 92 DEGs were detected between SD versus SR groups. The DEGs included genes related to circadian rhythms, inflammatory response and cell division control. We carried out pathway analysis on the identified DEGS using the Ingenuity Pathway Analysis (IPA) tool. Pathways involving cellular growth and proliferation, hematological system development, cancer and immunological disease, as well as cell death were significantly altered after 48 hours of SD and the subsequent recovery. Our results show that long periods of sleep loss activates genes related to a number of biological processes that might have great impact on health. These data should also motivate further investigations to define the molecular effects of sleep deprivation and its implications for diverse diseases.

## 2081/T/Poster Board #630

**Genetics of non-coding RNA in alcoholism.** *A. Pietrzykowski.* Rutgers University, Cook Campus, School of Environmental and Biological Sciences, Department of Animal Sciences, 67 Poultry Farm Lane, New Brunswick, 08901.

Alcoholism is a chronic, debilitating disease and a major cause of morbidity and mortality worldwide. There is substantial evidence for genetic linkage of specific locations on some chromosomes including chromosome 1 and 15 to alcohol-related phenotypes. As our understanding of the role of protein coding genes in the development of alcoholism is well advanced, contribution of non protein coding genes, including microRNA, just started to be investigated. microRNAs encode regulatory, small RNA molecules, which typically control expression of hundreds of targets. This powerful ability places microRNAs in a unique position of master regulators of gene expression. Recently, others and we have defined a subset of microRNA species particularly important for alcohol actions in the developing and mature neurons. Specifically, miR-9 stands out as a key target of alcohol, contributing e.g. to the development of alcohol tolerance. Moreover, miR-9 expression is acutely and chronically modulated by alcohol. Here we show that at least two out of three miR-9 genes are located in high alcohol susceptibility loci located on chromosomes 1 and 15. Moreover, promoters of miR-9 genes have very little homology and SNPs profile varies among miR-9 genes and their regulatory regions, suggesting differential expression of each miR-9 gene. Further studies will test the genetic association and functional implications of SNPs related to miR-9 genes in non-alcoholic and alcoholic populations. Our studies provide new concepts of the development and therapy of alcoholism.

## 2082/T/Poster Board #631

**The Role of the Mitochondria in Autism.** *J. Conroy[1], AT. Pagnamenta[2], N. Shah[1], R. Segurado[3], J. Casey[1], R. Regan[1], T. Magelhaes[4], K. Tansey[3], D. Pinto[5], JB. Cazier[2], A. Vicente[4], A. Green[1,6], M. Gill[3], L. Gallagher[3], AP. Monaco[2], S. Ennis[1,6], Autism Genome Project (www.autismgenome.org).* 1) School of Medicine, Univeristy College Dublin, Dublin, Ireland; 2) The Wellcome Trust Centre for Human Genetics, University of Oxford, UK; 3) Department of Psychiatry, Trinity College Dublin, Ireland; 4) Instituto Gulbenkian de Ciencia, Oeiras, Portugal; 5) The Centre for Applied Genomics, The Hospital for Sick Children, Toronto, Canada; 6) The National Centre for Medical Genetics, Ireland.

Autism Spectrum Disorders (ASD) are neurodevelopmental disorders characterised by impairments in communication, social interaction, and repetitive/restrictive behaviour. Deletions in the mitochondrial genome, biochemical markers of mitochondrial dysfunction and mitochondrial disorders have been reported in individual patients with autism, for example Leigh syndrome and various oxidative phosphorylation (OXPHOS) complex deficiencies. Furthermore, two studies showed evidence that 20% and 28% of autism cases respectively, exhibited hyperlactacidemia, a known marker of mitochondrial dysfunction (Oliveira et al. 2005 and Correia et al. 2006). In larger studies, associations have also been reported with markers in the *SLC25A12* gene. The international AGP consortium has carried out whole-genome SNP and CNV analysis on a cohort of ~1500 ASD families using the Illumina 1M SNP array. To complement these studies we set out to investigate the potential role of the mitochondria in the development of autism. Nuclear genes that contribute to the structure, function and maintenance of the organelle have been identified from various online mitochondrial databases. Only those genes that showed expression in the central nervous system were tested for association using TDT set based test in "plink". Following 10,000 permutations, a number of genes that contain significantly associated SNPs have been identified. Forty-nine gene sets have an mperm p value less than 0.05, eleven of which had p values less than 0.01. These genes (n = 49) range in function including active transmembrane transport, NAD binding, protein transport and ligase activity. The Illumina 1M SNP array also contains probes for 163 polymorphisms in the mitochondrial genome. Association analysis was undertaken using the paternal genotypes as a control dataset. The most significant result was a rare Ile-Val change in the *MT-ND6* that was 6 times more frequent in probands compared to controls ($p = 0.001$). However this did not withstand correction for multiple testing. The analysis should be extended to include additional autism spectrum disorder cohorts for sufficient power to detect effects of these rare mtDNA variants. A number of other lines of investigation are taking place. These include the analysis of deletions and duplications within the mitochondrial and nuclear genome in probands and their parents. Gene-gene interactions in the OXPHOS complexes are also being tested in this larger autism cohort.

## 2083/T/Poster Board #632

**Exploring Mitochondrial Variation in Autism.** *J.R. Gilbert[1], J.L. McCauley[1], D.J. Hedges[1], M.A. Schmidt[1], H.H. Wright[2], R.K. Abramson[2], M.L. Cuccaro[1], E.R. Martin[1], J.L. Haines[3], M.A. Pericak-Vance[1].* 1) Miami Institute for Human Genomics, Miller School of Medicine, University of Miami, Miami, FL; 2) University of South Carolina, School of Medicine, Columbia, SC; 3) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN.

There has been increasing speculation that oxidative stress and abnormal energy metabolism may play a role in Autism Spectrum Disorders (ASD). There has been a profound lack of investigation into the role of mitochondrial variation in autism, despite numerous clinical reports describing patients with mitochondrial disorders or mutations who have symptoms consistent with ASD. Our laboratory sought to comprehensively examine the role of mitochondrial variation and nuclear-encoded mitochondrial gene variation with regard to ASD risk. We sequenced the mtDNA from a dataset of ~400 Caucasian proband-father pairs (379 probands/372 fathers) using the Affymetrix Human Mito2.0 chip. We examined haplogroups, characterizing both common and rare mitochondrial variations, and tested for association of both haplogroups and mitochondrial variation with ASDs. Additionally, we utilized genome-wide single nucleotide polymorphism data generated from the Illumina 1-M beadchip on all individuals to test for gene x gene interactions between mitochondrial variations and nuclear-encoded mitochondrial gene variations. Our initial examination of European-Caucasian haplogroups and haplogroup defining single-nucleotide polymorphisms (SNPs) to assess the odds of carrying each mitochondrial haplogroup/ or haplogroup defining SNP in autism probands compared to unaffected fathers indicated that there is no significant difference in haplogroup frequencies between these two groups. The examination of variation across the mtDNA genome via single marker tests of association also failed to show convincing evidence for association to autism, although it should be noted there is limited power in this current dataset to detect smaller effect sizes. Furthermore, we examined our dataset for evidence of greater total mtDNA variation in autism probands compared to their fathers including the counts of both synonymous and non-synonymous changes between cases and controls with no significant difference. As there appears to be no main effects in our current dataset, we have begun to examine the interplay between nuclear-encoded and mitochondrial variation. These data provide insight into mitochondrial variation on a level never before performed in autism. Our data as a whole indicate an absence of main effects, suggesting that the role of mitochondrial variation in ASD risk may be subtle or interactive in nature.

## 2084/T/Poster Board #633

**A novel missense mutation associated with GEFS+ in a Chinese family.** *X. Cui[1], Y. Liu[1], F. Zeng[2], T. Zhan[1], Z. Tang[1], Q. Wang[1], M. Liu[1].* 1) Huazhong University of Science and Technology, Wuhan, Hubei, China; 2) Centre Hospital of Xuan Cheng, An Hui Province, China.

Generalized epilepsy with febrile seizures plus (GEFS+) is a common familial epilepsy syndrome, which generally develops in patients' childhood. Several genes have been reported to be associated with GEFS+, including sodium-channel $\beta$1-subunit(SCN1B) , sodium-channel $\alpha$1-subunit(SCN1A), sodium-channel $\alpha$2-subunit(SCN2A), gamma-aminobutyric acid receptor-delta(GABRD) , ,and gamma-2 subunit of the gamma-aminobutyric acid receptor(GABRG2) as well. In this report, we investigated a Chinese family with GEFS+, which was autosomal dominantly inherited. Linkage analysis localized the disease-causing gene to Chromosome 2q24, with a maximum lod score of 3.01($\theta$=0.00) at D2S2330, where SCN1A harbored nearby. DNA sequence for whole coding region of SCN1A revealed a nucleotide substitution of C577 with T, causing a missense mutation L193F of SCN1A. The mutation was found to segregate with GEFS+ in this Chinese family and not present in 200 normal controls. Interestingly, the GEFS+ symptoms in the family displayed significant intra-family heterogeneity. The mutation located at the s3 segment of domain I, which might alter the $\alpha$-helix motif of this transmembrane peptide. Further studies for the L193F mutation might offer a better understanding to the function of SCN1A, and the correlation between the genotype of SCN1A and clinical expression of GEFS+.

## 2085/T/Poster Board #634

**A mutation in lysosomal integral membrane protein type 2 (*LIMP2*) associated with myoclonic epilepsy in a patient with type 3 Gaucher disease.** *J. DePaolo, O. Goker-Alpan, N. Tayebi, B. Stubblefield, N. Gupta, E. Goldin, E. Sidransky.* nhgri/nih, bethesda, md.

Lysosomal integral membrane protein type 2 (LIMP-2) is responsible for the proper sorting of glucocerebrosidase to the lysosome. Mutations in the *LIMP2/SCARB2* gene have been implicated in inherited forms of myoclonic epilepsy. Vast clinical heterogeneity is observed among patients with Gaucher disease (GD) even among individuals with the same genotype. We investigated whether a mutation in the *LIMP2* gene could impact phenotype, possibly interfering with the trafficking of glucocerebrosidase to the lysosome. Specifically, we examined the case of two siblings with congruent mutations in glucocerebrosidase (GBA), but with extremely different phenotypes. One developed progressive myoclonic epilepsy in adolescence, and subsequently dementia, while the second was relatively asymptomatic. We sequenced *LIMP2* in both sibs, and found that only the one with more severe GD and myoclonic epilepsy carried a heterozygous point mutation in *LIMP2* on amino acid residue 471, changing it from Glu to Gly. The acidic residue E471, located in the carboxyl domain is reported to be important in movement of protein within the endocytic pathway. Western blots performed on fibroblast cell lysates from both patients demonstrated that the sib with the *LIMP2* mutation had markedly decreased levels of LIMP-2. This was confirmed by immunofluorescence studies demonstrating a dramatic decrease in cellular LIMP-2 in the sib with the mutation. These results appear to shed light on the drastically different phenotypes encountered in these siblings and may have implications regarding the role of *LIMP2* in myoclonic epilepsy.

## 2086/T/Poster Board #635

**Confirmation of the association between Calpastatin and Parkinson's disease.** *A.S. Allen[1], G.A. Satten[2].* 1) Biostatistics & Bioinformatics, DukeUniversity, Durham, NC; 2) Centers for Disease Control and Prevention, Atlanta, GA.

**Background:** We recently used haplotype sharing to analyze the NINDS Parkinson's disease (PD) genome-wide association study (GWAS). Our analysis identified a genomic region containing the calpastatin (CAST) gene as associated with risk of PD (Allen and Satten, Genetic Epi. published online April 13, 2009). Calpastatin inhibits calpains which have been implicated in several neurodegenerative disorders including PD.

**Methods:** We investigated the CAST region in an independent dataset comprised of 926 Parkinson's patients and 832 neurologically normal controls taken from the Center for Inherited Disease research GWAS in Familial PD study. Fifty SNPs where chosen from the region containing CAST and were tested for PD association using two haplotype sharing tests as well as the single-SNP Mantel-Haenszel (MH) test. Adjustment for population stratification was carried out using the stratification score approach of Epstein, Allen, and Satten (AJHG 2007 ;80(5):921-30). Permutation was used to adjust for the 150 tests performed (3 tests at each of 50 loci).

**Results:** After adjusting for multiple comparisons, we found the single SNP Mantel-Haenszel test to be significant (adjusted p=0.0199) with maximum signal at rs1559085. The haplotype sharing tests did not identify any significant loci after adjustment for multiple testing. SNP rs1559085 is also part of the signal identified in the NINDS dataset and effect measures for this SNP are comparable in the two studies (allelic odds ratios: 1.45 - CIDR; 1.56 - NINDS ).

**Conclusions:** Loci in the calpastatin gene are associated with risk for PD. This, along with a plausible role for calpastatin in PD etiology, suggest Calpastatin as a priority for further study.

## 2087/T/Poster Board #636

***GBA* mutations and clinical features of patients evaluated at a referral clinic for Parkinson disease.** *J. Choi[1], G. Lopez[2], N. Gupta[1], B. Stubblefield[1], O. Goker-Alpan[1], N. Tayebi[1], E. Sidransky[1].* 1) Section on Molecular Neurogenetics, Medical Genetics Branch, NHGRI, National Institutes of Health, Bethesda, Maryland; 2) Office of Clinical Director, Medical Neurology Branch, NINDS, National Institutes of Health, Bethesda, Maryland.

Recent findings demonstrate an increased frequency of mutations in glucocerebrosidase (*GBA*), the enzyme deficient in the autosomal recessive lysosomal glycolipid storage disorder Gaucher disease (GD), among patients with Parkinson disease (PD). Parkinson disease is a common, complex motor disorder, resulting from the loss of dopamine-producing neurons. In this study, all patients referred to a new Parkinson disease clinic at the National Institutes of Health Clinical Center were prospectively evaluated in a uniform fashion by a single neurologist, using a standardized Parkinson examination. DNA from 214 PD patients and healthy controls were screened for mutations in *GBA* by sequencing all 11 exons of the gene. Seven mutant *GBA* alleles were identified among 135 patients with PD including mutations D409H, L444P, N370S, R463C, and R496H. Each was a heterozygote. No *GBA* mutations were found among 79 healthy controls. The frequency of *GBA* mutations among the PD cohort was statistically significant (p-value of 0.0484 from Fisher's exact test). Despite the limited sample size, we explored the association of *GBA* mutations with specific clinical features. On average, PD subjects carrying *GBA* mutations presented with symptoms on 3 years earlier, and showed a trend towards an increase in tremor, bradykinesia, balancing problems, shuffling gait, cognitive involvement, and dystonia. This overall increase in motor and cognitive features among patients with *GBA* mutations was reflected in their standardized scores. In patients with PD without *GBA* mutation the mean Hoehn and Yahr score was 2.2, mean UPDRS (III) score 25.4, mean MMSE score 28.8, and mean MoCA score 25.2; whereas for patients with *GBA* mutations the mean Hoehn and Yahr score was 2.6, mean UPDRS (III) score 33.4, mean MMSE score 29.1, and mean MoCA score 27.0. The lower age of onset trend supports other studies in the literature suggesting that carriers of *GBA* mutations have earlier disease onset. Further studies of the association between GD and PD will enhance our understanding of pathophysiology of the two disorders, will impact genetic counseling of patients and families and may lead to new diagnostic and therapeutic strategies for Parkinson disease.

## 2088/T/Poster Board #637

**FUS mutations are a rare cause of sporadic amyotrophic lateral sclerosis.** *S. Lai[1,2,3], Y. Abramzony[1], J.C. Schymick[1,4], R. Guerreiro[5], D.A. Stephan[6], G. Mora[7], G. Restagno[8], A. Chiò[9], B.J. Traynor[1] on behalf of The ITALSGEN Consortium.* 1) Neuromuscular Diseases Research Group, Laboratory of Neurogenetics, NIA, Bethesda, MD, USA; 2) Department of Neurology, Chang Gung Memorial Hospital and College of Medicine, Taiwan, Republic of China; 3) Department of Molecular Neuroscience and Reta Lila Weston Laboratories, Institute of Neurology, University College London, London, UK; 4) Department of Physiology, Anatomy and Genetics, University of Oxford, Oxford, UK; 5) Molecular Genetics Unit, Laboratory of Neurogenetics, NIA, Bethesda, MD, USA; 6) Navigenics, Inc, Foster City, CA, USA; 7) Salvatore Maugeri Foundation, Lissone, Italy; 8) Molecular Genetics Unit, Department of Clinical Pathology, A.S.O. O.I.R.M.-S.Anna, Turin, Italy; 9) Department of Neuroscience, University of Turin, Turin, Italy.

**Background** Recently, the *fused in sarcoma/translated in liposarcoma (FUS)* gene, located on chromosome 16p11.2, has been identified as a disease gene in familial amyotrophic lateral sclerosis. However the importance of this gene in the commoner sporadic form of the disease is not known. **Aim** The aim of this study was to further define the spectrum of *FUS* gene mutations in a large series of sporadic ALS (SALS) patients. **Methods** DNA samples were collected from 1,749 SALS of American and Italian origin. The entire coding region was sequenced in 276 SALS. As previous publications have implicated exon 15 as a hotspot for mutations within this gene, this exon was sequenced in an additional 1,473 SALS. Detected variants were evaluated in a control cohort consisting of 280 neurologically normal Italian subjects and 460 neurologically normal US subjects. **Results** Among the 1,749 SALS patients we found a total of 8 cases with missense mutations (0.4%). Of these, c.1561C>T (leading to a p.R521C change in the amino acid sequence, n = 1 case), c.1562G>A (p.R521H, n = 1) and c.1566G>A (p.R521R, n = 4) have been previously been described, whereas c.1552A>G (p.R518G, n = 1) and c.1575G>T (p.P525P, n = 1) were novel. None of these variants were present in controls. **Discussion** *FUS* gene mutations have been found in less than 0.5% of apparently SALS patients. Two novel mutations of FUS that appear to underlie motor neuron degeneration were identified.

## 2089/T/Poster Board #638

**Testing the genes and pathways behind fetal motoneuron disease as candidate genes for ALS.** *H.O. Nousiainen[1], H. Laaksovirta[2], K. Silander[1], K. Rehnström[1], H. Kääriäinen[1], M. Kestilä[1], L. Peltonen[1,3,4,5].* 1) National Institute for Health and Welfare, Public Health Genomics Unit and FIMM, Institute for Molecular Medicine Finland, Helsinki, Finland; 2) Department of Clinical Neurosciences, Helsinki University Central Hospital, Helsinki, Finland; 3) Department of Medical Genetics, University of Helsinki, Helsinki, Finland; 4) The Broad Institute, MIT, Boston, MA, USA; 5) The Wellcome Trust Sanger Institute, Hinxton CB10 1SA, UK.

Amyotrophic Lateral Sclerosis (ALS) is a late-onset, rapidly progressing neurodegenerative disease affecting motor neurons. The etiology of most ALS cases remains unknown, but mutations in Cu/Zn superoxide dismutase *SOD1*, and also *TARDBP* and *FUS*, encoding the RNA binding proteins TDP-43 and fused in liposarcoma have been implicated in a small fraction of cases of both familial and sporadic ALS. Deleterious variants in the phosphoinositide phosphatase *FIG4*, which is mutated in the juvenile form of the hereditary motor and sensory neuropathy Charcot-Marie-Tooth disease CMT4J (MIM 611228), have also been found in ALS patients. Here we have taken a pathway based approach in searching for ALS genes triggered by our recent findings in two fetal motoneuron diseases: Lethal Congenital Contracture Syndrome (LCCS1, MIM 253310) and Lethal Arthrogryposis with Anterior Horn cell Disease (LAAHD, MIM 611890). Both diseases are caused by mutations in the *GLE1* gene, which encodes for a protein that is involved in mRNA export and protein synthesis. GLE1 function is dependent of a small organic molecule, inositol hexakisphosphate ($IP_6$). Interestingly, the causative mutations of two additional lethal motoneuron diseases (LCCS2 and LCCS3) have been recently attributed to defects in enzymes that modulate the phosphatidylinositol-3-kinase/Akt signaling cascade, a pathway intimately connected with the production of $IP_6$. This suggests a role for mRNA processing in these disorders and a relationship between inositol signaling, mRNA processing, and neuronal survival. We analyzed a nationwide cohort of 250 Finnish ALS patients, both familial and sporadic, and 450 Finnish controls, excluding patients with mutations in *SOD1* (n= 18). We genotyped the remaining patient samples for 93 SNPs in six genes involved in mRNA transport and phosphoinositide signaling. We performed association and haplotype analysis using PLINK. Preliminary results revealed suggestive association between haplotypes in *ITPR2* and ALS. We observed enrichment of a rare haplotype in cases, with frequencies 0.090 and 0.060 in cases and controls, respectively. *ITPR2* has also been previously associated with ALS in European populations. Further characterization of the associated region will potentially provide additional information on the molecular mechanisms behind ALS and increase our understanding of the pathogenesis of this devastating disease.

## 2090/T/Poster Board #639

**Allelic spectrum of rare mutations within CNTNAP family members in autism spectrum disorders and related phenotypes.** *S. Szelinger[1], J.D. Gerber[1], C. Smith[2], A. Sekar[1], S. Brautigam[2], J.O. Long[1], T. Pawlowski[1], J. Pruzin[1], M. Redman[1], A.A. Kurdoglu[1], M.J. Huentelman[1], D.W. Craig[1].* 1) Neurogenomics, Translational Genomics Research Institute, Phoenix, AZ; 2) Southwest Autism Research & Resource Center, Phoenix, AZ.

The genetic basis of common complex neurobehavioral diseases such as autism, schizophrenia, and bipolar disorder are largely unknown. Multiple genome-wide association studies suggest that 'common-variants' alone do not explain a substantial portion of the variance for this highly heritable disorder. As an initial investigation into how multiple 'rare-variants' may lead to a spectrum of sub-phenotypes within and across neurobehavioral disorders, we have investigated the spectrum of rare variants within the gene *contactin associated protein 2* (CNTNAP2), along with several neurexin family members for individuals with and without autism. CNTNAP2 has been previously associated with epilepsy, Tourette's syndrome, and schizophrenia. The genes CNTNAP1, CNTNAP2, and CNTNAP4 were sequenced using both capillary Sanger-based sequencing and multiplexed sequencing on the Illumina Genome Analyzer II. Genetic variants identified from analysis of sequence traces were validated by TaqMan assays and/or further sequencing and bioinformatically evaluated for pathogenicity. Within CNTNAP2 mutations predicted to be deleterious we further examined sub-phenotypic comorbidities, such as seizures, the appearance of repetitive behaviors, and related phenotypes. A total of 300 different autistic individuals were sequenced for one or more of these genes using individuals collected from the Autism Genetic Research Exchange (AGRE) and the Southwest Autism Research and Resource Center (SARRC). Controls were obtained from lymphoblastic cell-lines provided by the National Institute of Mental Health (NIMH) and the Coriell Cell Repository. Additional controls for the same region were examined using sequence traces aligned from the International 1,000 Genomes Project. For genetic variants not found in controls, ABI TaqMan assays were designed and these variants were screened across additional controls cleared of neurological defects. Cumulative analysis indicates that the allelic spectrum of deleterious CNTNAP2 mutations can lead to substantially different comorbidities, even across a single multiplex family, suggesting that rare disease-causing mutations within CNTNAP2 require a 'second hit' that remains unknown. Overall, the diversity of sub-phenotypes observed within CNTNAP2 mutations associated with autism underscores the forthcoming challenges for elucidating how rare-variants lead to common complex neurological disorders.

## 2091/T/Poster Board #640

**A new locus for pure Spinocerebellar Ataxia associated with Erythrokeratodermia maps to chromosome 6p12.3-q16.1.** *M. Turcotte Gauthier[1], D.K. Nguyen[1], C. Meloche[1], J. Poirier[1], S.L. Girard[1], S. Forlani[2], E. Di Gregorio[4], B. Borroni[4], G. De Michele[5], A. Filla[5], D. Verbeek[6], B.P.C. Van de Warrenburg[6], C.A. Drouin[3], A. Durr[2], A. Brice[2], G. Stevanin[2], A. Brusco[4], P. Cossette[1].* 1) Centre of Excellence in Neuromics of Université de Montréal, CHUM Research Center, Montreal, Quebec, Canada; 2) INSERM/UPMC U975, Centre de Recherche Institut du Cerveau et de la Moelle Epinière, GHU Pitie-Salpetriere, Paris, France; 3) Department of Dermatology, Centre Hospitalier Régional Grand-Portage, Rivière-du-Loup, Québec, Canada; 4) Department of Neurology, University of Brescia, Italy; 5) Federico II University, Naples, Italy; 6) University Nijmegen Medical Centre, the Netherlands.

Giroux and Barbeau previously described a unique French-Canadian family segregating a combination of ataxia and hyperkeratotic erythematous plaques in an autosomal dominant mode. These skin lesions were compatible with erythrokeratodermia (EK). The family has been partially collected and the disease was potentially linked to chromosome 1p35. However, the identification of the mutated gene is pending. The objective of this study is to revisit the clinical phenotype and genetic mapping of this peculiar family. We recently reassessed the family with detailed examinations, brain MRI and EMG studies.We recollected the family and performed a whole genome scan analysis by using microsatellites markers. We also analyzed four additional families from European ancestry with autosomal dominant SCA (from the EuroSCA consortium), for which a genome scan have shown positive LOD score to the same chromosomal region. The neurological phenotype in the French-Canadian family is compatible with a pure autosomal dominant cerebellar ataxia (ADCA type III in Harding's classification) associated with cerebellar atrophy starting in late 40s. We mapped the locus for the disease on chromosome 6p12.3-q16.1 with a maximum LOD score of 5.33 for marker *D6S452*. Haplotype analysis of this family allowed us to refine the candidate gene region between markers *D6S459* and *D6S417* (46.8Mb). Linkage to this locus was confirmed in the four additional families with a maximum compiled LOD score of 9.9. So far, the sequencing of 17 candidate genes, search for CAG/CTG expansion and copy number analysis did not allow the identification of the causative gene. We have mapped a new locus for a pure autosomal dominant cerebellar ataxia (SCA31) in a total of five families from European ancestry, including a large French-Canadian family associated with EK.

## 2092/T/Poster Board #641

**Lingos in ET and PD.** *C. Vilarino-Guell.* Dept Neuroscience, Mayo Clinic, Jacksonville, FL.

A variant in LINGO1 (rs9652490) has recently been found associated with increased risk of essential tremor (ET). We set out to replicate this association in an independent case-control series of 356 essential tremor patients from North America. In addition, given the clinical and pathological overlap between essential tremor and Parkinson disease (PD), we also evaluate the effect of LINGO1 rs9652490 in two case-control series of Parkinson disease from the US and Norway. The analysis of our ET patient-control series indicated a significant association between the LINGO1 rs9652490 A allele and risk of disease (P=0.014; OR=2.2). Similarly, LINGO1 was also found significantly associated with an increased risk of PD in the US (P= 0.012; OR=2.1) and Norway series (P=0.008; OR=1.7). Combining both PD series this analysis resulted in a highly significant association (P=3.4x10-4) and a 1.8-fold increased disease risk. Combining PD and ET cases we obtained a highly significant 1.9-fold increased risk of disease (P=1.3x10-4). The genetic association of the LINGO1 locus with both ET and PD susceptibility is supported by the functional role of its encoded protein. LINGO1 is a central nervous system-specific protein component of the Nogo-66 receptor (NgR1)/p75/LINGO1 signaling complex implicated in inhibition of oligodendrocyte differentiation, axonal myelination and regeneration, and neuronal survival. The expression of LINGO1 is elevated in the substantia nigra of patients with PD compared to age-matched controls, and in ventral midbrain neurons in animal models of PD after neurotoxic lesions. Furthermore, reduction of LINGO1 activity has been shown to improve survival, growth and function of dopaminergic neurons both in primary cell cultures and in vivo experimental models of parkinsonism in rodents. Genetic association of both ET and PD with LINGO1 provides the first compelling evidence that the pathophysiology of these common movement disorders is connected.

## 2093/T/Poster Board #642

**Functioal studies of MLC1 gene novel variants in four Chinese Patients with Megalencephalic Leukoencephalopathy with Subcortical Cysts(MLC).** *J. Wang[1], A. Dhauchak[2], H. Wei[1,3], H. Xiong[1], Y. Wu[1], D. Colman[2], X. Wu[1], Y. Jiang[1].* 1) Peking University First Hospital, Beijing, China; 2) Montreal Neurological Institute, Montreal,Quebec,Canada; 3) Shanxi Medical University, Taiyuan, Shanxi, P. R. China.

Megalencephalic leukoencephalopathy with subcortical cysts (MLC, MIM# 604004) is an autosomal recessively inherited disease resulting from a deficiency of MLC1 protein. No previous data about this gene mutation in China have been reported.The objective was to identify and analyze MLC1 mutations in four Chinese patients with (MLC). Methods Direct DNA sequencing, Immunoblots, and Immunocytochemistry. Results We detected four mutations (p. G73E, p.Y198X, p. A275T, c.772-1G change to C splicing mutation in IVS9-1, and c.*48A change to T) of which four were novel. We immunostained transfected arstrocyte cells for HA-MLC1 and calnexin, an ER marker.WT MLC1 was at arstrocyte borders, whereas MLC1 mutants G73E and Y198X are mainly intracellularly localized , except for A275T, which mainly at cell borders. Western blot analyses in arstrocyte cells transfected with WT MLC1 and with the amino acid changes G73E, Y198X and A275T, in comparison with the WT MLC1 in MLC1 expression, G73E mutation showed a reduced protein expression in transfected arstrocytes, Y198X reduced at 36kDa and showed a band at about 25kDa in artrocyte cells, and no changes were observed for the A275T. The c.772-1G change to C splicing site mutation resulted in the splice acceptor AG sequence of intron nine mutate to AC. This mutation may disrupt the open reading frame (ORF) of the MLC1 gene and cause the aberrant splicing of the following exons. Conclusion MLC1 mutants associated with MLC likely disrupt MLC1 protein expression and locolization. This would be the first report about MLC1 mutations in patients in China (Supported by National Key Research Project "11-5" (No: 2006BAI05A07), Beijing Municipal Natural Science Key Project (No: 08G1469), "973" Project of the Science and Technology Ministry of China (No. 2007CB5119004) and the International Collaborative Genetic Research Training Grant (NIH/FIC, No. D43 TW06176)).

## 2094/T/Poster Board #643

**Genetic analysis and cellular localization of glucocerebrosidase in Parkinson's disease.** *M. Westerlund[1], A. Anvret[1], C. Ran[1], A. Carmine Belin[1], A. Zettergren[2], H. Nissbrandt[2], P. Söderkvist[3], T. Willows[4], C. Lind[5], O. Sydow[5], D. Galter[1], L. Olson[1].* 1) Department of Neuroscience, Karolinska Institutet, 171 77 Stockholm; 2) Department of Pharmacology, Sahlgrenska Academy at Göteborg University, 405 30 Göteborg; 3) Department of Biomedicine and Surgery, Faculty of Health Sciences, Linköping University, 581 85 Linköping; 4) Department of Neurology, Karolinska University Hospital, Huddinge, 141 86 Stockholm; 5) Department of Neurology, Karolinska University Hospital Stockholm, Solna, 171 76 Stockholm Sweden.

Recent studies have demonstrated an association between mutations in glucocerebrosidase (*GBA*), originally implicated in Gaucher's disease, and an increased risk of both familial and sporadic Parkinson's disease. The glucocerebrosidase gene is located on chromosome 1q21 and encodes a lysosomic protein which cleaves the beta-glucosidic linkage of glycosylceramide, an intermediate formed during glycolipid metabolism. To investigate the possible involvement of *GBA* in Parkinson's disease, we used pyrosequencing and real time PCR to study the non-synonymous variants T369M, N370S and L444P in a material consisting of 456 confirmed Swedish Parkinson cases and 732 unrelated control individuals. Differences in allele and genotype frequencies were compared using a Chi square test with two-sided p-values. Characterization of gene expression patterns is a prerequisite for understanding the involvement of the gene in disease. We therefore characterized the cellular localization of *GBA* mRNA in human and mouse tissues using in situ hybridization. We hypothesize that pathogenic variants in the *GBA* gene may confer risk for Parkinson's disease, and that the risk may vary between populations. Further genetic and biochemical studies on *GBA* will possibly bring new insights into the pathophysiology of Parkinson disease, which in turn can result in earlier diagnosis and design of relevant therapeutic strategies.

## 2095/T/Poster Board #644

**Investigating the genetic basis of amyotrophic lateral sclerosis: analysis of known genes and search for new loci.** *K.L. Williams[1], J. Durnall[1], A. Thoeng[1,2], J.A. Solski[1], V. Thomas[1,2], J. Crawford[1,3], S. Gopinath[1], S. Warraich[1,4], G.A. Nicholson[1,5], I.P. Blair[1,4].* 1) Northcott Neuroscience, ANZAC Res Inst, Sydney, NSW, Australia; 2) Department of Physiology, University of Sydney, NSW, Australia; 3) School of Biological Sciences, Macquarie University, NSW, Australia; 4) Faculty of Medicine, University of Sydney, NSW, Australia; 5) Molecular Medicine Laboratory, Concord Hospital, NSW, Australia.

Amyotrophic lateral sclerosis (ALS) is a fatal neurodegenerative disorder that causes the progressive degeneration of motor neurons. Familial ALS (FALS) accounts for approximately 10% of ALS cases with the remainder being sporadic (SALS). ALS is a genetically heterogenous disorder. To date, known genes only account for a small proportion of cases. We sought to investigate known ALS genes in a large cohort of ALS families, to firstly establish whether there is wider support for the proposed pathological role of these genes, and secondly, to determine the proportion of disease that can be attributed to mutations in these genes. The phenotypic expressivity of each mutation was also investigated. A genome scan is also underway among this ALS cohort to identify new disease loci. We analysed 147 Australian ALS families by direct DNA sequencing for mutations in *SOD1*, *DCTN1*, *ANG*, *CHMP2B*, *VEGF*, *TARDBP*, *FUS*, and *FIG4*. Haplotype analysis was also performed to identify any potential founder mutations. We determined that mutations in known ALS genes account for 20% of Australian ALS families, and comprise *SOD1* (15%), *FUS* (2.7%), *ANG* (2.0%), and *TARDBP* (1.4%) mutations. No mutations were identified in *DCTN1*, *CHMP2B*, *VEGF* and *FIG4*. None of the identified mutations in *SOD1* and *ANG* were present in a screen of 492 control chromosomes. We identified a novel missense mutation in *TARDBP* that was absent in 708 control chromosomes. This mutation (p.G294V) substitutes a highly conserved residue and is predicted to disrupt the glycine-rich domain in the C-terminus of TDP-43. We also identified a large *FUS* family in which the mutation segregated with the disease and provided a maximum LOD score of 4.54. Haplotype analysis suggested that no founder effect was present among *FUS* families with the same mutation thereby implicating the presence of a mutation hotspot. Among families with identified mutations, variable phenotypic expressivity was observed with gene and mutation specific effects for disease onset and duration. The genetic defects among the remaining 117 ALS families (80%) within our cohort are yet to be identified. A whole genome scan for linkage is currently underway in a subset of these families in order to identify new candidate loci for familial ALS.

## 2096/T/Poster Board #645

**Mitochondrial Rho GTPase, MIRO1, and Parkinson's disease.** *A. Anvret[1], M. Westerlund[1], C. Ran[1], D. Galter[1], C. Lind[2], T. Willows[3], O. Sydow[2], L. Olson[1], A. Carmine Belin[1].* 1) Department of Neuroscience, Karolinska Institutet, Retzius väg 8, 171 77 Stockholm, Sweden; 2) Department of Neurology, Karolinska University Hospital Solna, 171 76 Stockholm, Sweden; 3) Department of Neurology, Karolinska University Hospital Huddinge, 141 86 Stockholm, Sweden.

Mitochondria are essential in all eukaryotic cells to generate ATP and they also play a critical role in cell death mechanisms and calcium buffering. In neurons the mitochondrial network is highly dynamic, undergoing changes in morphology and motility. Mitochondria are actively recruited to specific neuronal compartments, e.g. synaptic terminals, soma, hillock and nodes of Ranvier, reflecting needs for localized energy production and calcium storage. Mitochondrial dysfunction has been implicated in Parkinson's disease. MIRO1/RHOT1 (Ras homolog gene family member T1) belongs to the mitochondrial Rho GTPase family and is involved in neuronal transport of mitochondria. The protein contains two GTPase domains, two calcium binding EF-hands and a transmembrane domain in the C-terminal, locating MIRO1 to the mitochondrial outer membrane. As a mitochondrial Rho GTPase, MIRO1 is suggested to be involved in both anterograde and retrograde transport of mitochondria and their subcellular distribution. We hypothesize that mutations in MIRO1 may lead to disturbed mitochondrial trafficking in neurons and increased risk of neurodegenerative events, such as those observed in Parkinson's disease. This is the first genetic study of MIRO1 in relation to Parkinson's disease. We investigated three different single nucleotide polymorphisms (SNP) in MIRO1; a missense, a frameshift and a synonymous SNP, in an aged-matched Swedish Parkinson case-control material using real time PCR (TaqMan). Two of the SNPs are located in each of the EF-hands and one is located in the GTPase domain. However our data does not suggest any significant association of the investigated SNPs in MIRO1 with Parkinson's disease. A related mitochondrial Rho GTPase protein, MIRO2, is also of interest due to its similar function to MIRO1 and should be equally investigated. In a further step we will study the localization and expression level of these genes at the mRNA level in rodent and human tissue using in situ hybridization and quantitative real time PCR.

## 2097/T/Poster Board #646

**Association studies of 12 candidate SNPs with late-onset Alzheimer's disease.** *L.C. Burns, R.L. Minster, F.Y.K. Demirci, S.T. DeKosky, M.I. Kamboh.* Human Genetics, University of Pittsburgh, Pittsburgh, PA.

Late-onset Alzheimer's disease (LOAD) is a multifactorial disease with the potential involvement of multiple genes. There is a known association between *APOE* gene variants and LOAD. No additional genes have been consistently demonstrated to be associated with risk of LOAD. Multiple recent genome-wide association studies (GWAS) (*Neuron* 2007, 54:713; *Am J Hum Genet* 2008, 83:623; *Am J Hum Genet* 2009, 84:35; *Nat Genet* 2009, 41:192) have found variants showing significant association with LOAD on chromosomes 11, 12 and 14 and on the X chromosome. We examined seven single nucleotide polymorphisms (SNPs) that surpassed genome-wide levels of significance and also selected five additional significant SNPs that lie within reported linkage regions. We genotyped these twelve new significant SNPs based on GWAS as well the E2/E3/E4 *APOE* polymorphism using fluorogenic 5' nuclease assays in up to 1,009 Caucasian Americans with LOAD and up to 1,010 age-matched healthy Caucasian Americans. Our data show no statistically significant associations between the twelve new SNPs examined and the risk of AD. Stratification by *APOE*4* carrier status also failed to reveal statistically significant associations. We have been unable to replicate the published associations from GWAS with our large case-control sample. Further study may be necessary to definitively rule out associations between these variants and LOAD.

## 2098/T/Poster Board #647

**IQ discrepancy as a quantitative autism endophenotype: strong evidence for loci on chromosomes 10 and 16.** *N.H. Chapman[1], A. Estes[2], J. Munson[2], R. Bernier[2], S.J. Webb[2], J. Rothstein[1], G.D. Schellenberg[6], G. Dawson[5,7], E.M. Wijsman[1,3,4].* 1) Department of Medicine, University of Washington, Seattle, WA; 2) Department of Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA; 3) Department of Genome Sciences, University of Washington, Seattle, WA; 4) Department of Biostatistics, University of Washington, Seattle, WA; 5) Department of Psychology, University of Washington, Seattle, WA; 6) Department of Pathology and Laboratory Medicine, University of Pennsylvania School of Medicine, Philadelphia PA; 7) Autism Speaks.

In studies of cognitive abilities of autistic individuals, there is a tendency for performance IQ (PIQ) to exceed verbal IQ (VIQ). This may reflect deficits in language skills that are a key part of the autism diagnosis. The difference between PIQ and VIQ (IQ discrepancy) thus has potential as a quantitative endophenotype in genetic studies of autism. One advantage of IQ discrepancy is that it can be measured on adults, thus providing more reliable parental data than other endophenotypes such as age at first word or phrase. We present the first genetic analyses of IQ discrepancy as an autism endophenotype, in 310 multiplex and mostly Caucasian families, collected as part of the NIH CPEA. IQ discrepancy scores, as measured by short forms of WPPSI-R , WISC-III or WAIS-III, are available on 76% of individuals in these families. Genetic data available includes a genome scan of 387 STRs (85% of individuals), and 10k SNP data (provided by the AGP) in a subset of 187 families. We performed clustering analyses of a discrete IQ discrepancy phenotype "high IQD" (PIQ - VIQ ≥ 15) and demonstrated significant evidence (p=0.0067) that individuals with high-IQD cluster in families. MCMC oligogenic segregation analysis demonstrates that an average of 3.9 QTLs contribute to IQ discrepancy, and identifies three clear models, with heritabilities of 33%, 18% and 20%. Genome-scan analyses utilizing MCMC joint segregation and linkage analysis of the STRs identified 5 chromosomal regions with substantial evidence of linkage. Empirical p-values were calculated for each of the 5 regions, requiring >5 months of CPU time. The regions and empirical p-values are 10p12 (p=0.001), 16q23 (p=0.015), 2p21(0.03), 6q25(p=0.047) and 15q23-25 (p=0.053). The genetic models for the QTLs on chr 10 and 16 clearly correspond to two of the models observed in the segregation analysis. QTDT analysis using 10k SNP data was performed in the regions of the strongest signals on chr 10 and 16. On each chromosome, one SNP achieved significance: on chr 10, 5 cM away from the marker (p=0.009); and on chr 16 immediately under the peak linkage signal (p=0.014). The location of the chr 10 signal coincides with a region noted in the first analysis of the IMGSAC data. The chromosome 16 signal coincides exactly with a linkage signal for non-word repetition in specific language impairment, and involves a region that is home to several cadherin genes.

## 2099/T/Poster Board #648

**Gene expression provides evidence that cell adhesion is involved in the etiology of schizophrenia.** *O. Evgrafov[1], B. Wrobel[2], X. Kang[1], G. Simpson[1], D. Malaspina[3], J. Knowles[1].* 1) Dept Psychiatry, Univ Southern California, Los Angeles, CA; 2) Otolaryngology, Univ Southern California, Los Angeles, CA; 3) Psychiatry, New York University, New York, NY.

We investigated the expression of poly-A RNA isolated from cultured neuronal cells derived from olfactory neuroepithelium (CNON) of 8 patients with schizophrenia (SZ) and 8 control individuals. Human neuroepithelium constantly produces olfactory neurons from neural stem cells and this process is simulated in CNON cultures, which are primarily composed of neuronal progenitors. The tight environmental control provided by cell culture, in comparison to using post-mortem brain samples, provided a greater signal-to-noise ratio and yielded a clear separation of SZ and control samples, in a principle component analysis. In contrast to neurons from adult brain, CNON cells express genes that are specific for development of neural system. Thus, this cellular model may be useful for the identification of genes for neurodevelopmental disorders, including most of the psychiatric disorders. We measured gene expression using Human Exon 1.0 ST Arrays (Affymetrix), preprocessed the data with RMA or GC-RMA followed by Tukey gene summarization. The data were then analyzed by ANOVA (with correction for two batches) using Partek Genomics Suite (Partek). We have also performed RNA-Seq using an Illumina Genome Analyzer II, on a portion of these samples. The ten of the top fifteen most differentially expressed genes with an uncorrected p<0.05 were validated by qPCR, as was the gene with the overall best p-value (CDH11). Genes showed low expression level (<0.001 of ACTB) detected by qPCR or RNA-Seq have been excluded from the further analysis. Most of the differentially expressed genes were expressed at a lower level in the SZ samples, than the controls. The three most differentially expressed genes were CDH6, VCAM1 and S1PR1 (EDG1). Another cadherin, CDH11, was differentially expressed (p<0.05, one-tail t-test), when validated by qPCR. Three of these are cell adhesion molecules, and the fourth, S1PR1, directly regulates cadherin expression and is involved in regulation of VCAM1. Cell adhesion molecules are known to play an important role in brain development and the observation of lower levels of these molecules in the SZ group may point to a possible mechanism for the altered neurodevelopment observed in individuals with schizophrenia. This maybe a general phenomenon of some of the psychiatric disorders as two recent GWASs of autism, another disorder with impaired social functioning, have found association with SNPs located between CDH9 and CDH10.

## 2100/T/Poster Board #649

**Hereditary spastic paraplegia with thin corpus callosum (HSP-TCC) is a frequent phenotype in Brazilian patients with hereditary spastic paraplegia.** *M.C. França Jr, C.M. Lopes, C.V. MAURER-MORELLI, M. Rosa, A. D'Abreu, I. Lopes-Cendes.* Medical Genetics, University of Campinas, Campinas, São Paulo, Brazil.

Objectives: To estimate the frequency of HSP-TCC among Brazilian patients with autosomal recessive HSP (ARHSP) and to investigate causative mutations in SPG11. Background: HSP-TCC has been mapped to chromosome (ch) 15q13-15 in Japanese families and considered to be rare in the west. Design/Methods: 52 ARHSP patients from 23 different families were clinically and radiologically evaluated in order to estimate the prevalence of HSP-TCC. MRI scans were performed in a 2T scanner and sagittal T1 weighted images used to evaluate CC volumes. In addition, we sequenced all exons of the SPACTASIN gene in patients with the HSP-TCC phenotype. Results: Fifteen individuals from 9 unrelated families had HSP-TCC as determined by MRI scans. Their mean age at first examination was 34 years and duration of disease 17.2 years. Gait abnormalities were the initial symptom, followed by slow cognitive decline. Six patients had sensory-motor axonal neuropathy and 6 individuals presented cerebellar atrophy on MRI. We found at least one mutation in exon 4 of the SPACTASIN gene. Conclusion: HSP-TCC was not rare among HSP patients seen at our neurogenetics clinic, representing 39% of all HSP families included in the present study (7/20), to date only one mutation in the SPACTASIN gene was found confirming the presence of genetic heterogeneity associated with HSP-TCC phenotype. Support: FAPESP.

## 2101/T/Poster Board #650

**Clinical value of *SCN1A* mutation screening in patients with generalized epilepsy with febrile seizures.** *M.C. Gonsales[1], P.M. Preto[2], M.M. Guerreiro[2], I. Lopes-Cendes[1].* 1) Department of Medical Genetics, University of Campinas, Campinas, Brazil; 2) Department of Neurology, University of Campinas, Campinas, Brazil.

Rationale: Mutations in the gene that codes for the $\alpha$-subunit of a neuronal voltage-gated sodium channel (*SCN1A*) have been identified in families with generalized epilepsy with febrile seizures plus (GEFS+). The phenotypic expression of GEFS+ comprises a spectrum of clinical phenotypes including severe syndromes such as myoclonic astatic epilepsy (MAE) and severe myoclonic epilepsy of infancy (SMEI). Molecular studies suggest a common genetic basis for these epilepsies and mutations in the *SCN1A* gene have also been found in SMEI patients. However, the prognostic value of these mutations and a possible correlation with the different clinical subtypes remain controversial. In addition, studies of mutations in candidate genes are important as they provide a better understanding of the physiopathologic mechanisms responsible for epileptic activity. The aim of this study was to search for mutations in the *SCN1A* gene in a group of patients with the GEFS+ spectrum and establish a genotype-phenotype correlation. Methods: Mutation screening was performed in 24 probands, eight of them with SMEI, fifteen with MAE and one with GEFS+. DNA for molecular analysis was obtained from peripheral blood, through the phenol-chloroform extraction method. All 26 exons of the *SCN1A* gene were amplified by polymerase chain reaction (PCR) and analyzed by denaturing high-performance liquid chromatography (DHPLC). Exons for which abnormal chromatographic patterns were observed have been sequenced. Results: To date, 20 *SCN1A* variants were identified, from which five are novel mutations. Three missense mutations (c.829T→C, c.971A→C and c.5434T→C) that lead to amino acid residue substitutions (C277R, H324P and W1812R) were found in patients with the most malignant phenotype of the spectrum, SMEI. According to computational analyses, these substitutions affect the function of the protein. We also found two variants that possibly alter splice donor sites (IVS4+1G→A and IVS8+3G→T) in two patients with SMEI. Both variants may change the structure of the protein and therefore be related with the severity of the phenotype. Conclusions: Potentially deleterious *SCN1A* variants were found only in patients with SMEI. Therefore, our results indicate that in patients with no familial aggregation of epilepsy (sporadic cases) molecular testing for clinical purposes seems to yield best results in patients with the most severe phenotype of the spectrum.

## 2102/T/Poster Board #651

**Association analysis of estrogen receptor (ER) binding polymorphisms in women with major depression.** *L. Graae[1], R. Karlsson[1], C. Zhao[2], S. Paddock[1].* 1) Karolinska Institutet, Neuroscience, Stockholm, Sweden; 2) Karolinska Institutet, Bioscience and Nutrition, Stockholm, Sweden.

Major depression is nearly twice as common in women compared to men with a lifetime prevalence of 21% in women (12.7% in men; Payne, Int Rev Psychiatry, 2003). Several observations suggest a possible involvement of estrogen in the pathobiology of mood disorders in women. For example, periods of hormonal fluctuations or estrogen instability have been associated with increased vulnerability to depression among susceptible women. Intracellular estrogen receptors (ERs) function as transcription factors by binding to specific DNA sequences and regulating gene transcription. Changes in the DNA sequence where the ER-complex binds could possibly affect the binding and lead to abnormal function. This might alter transcription levels of nearby genes and could be part of the disease mechanism. The aim of this study was to investigate if differences exist in ER DNA-binding sequences in depressed vs. non-depressed women. Genome-wide genotype data for 2 276 women (1200 cases and 1076 controls) were obtained from the Genetic Association Information Network (GAIN). Out of 438129 SNPs that survived the quality control analyses, 217 SNPs, found to be placed in ER DNA-binding regions, were selected for the association analysis. ER DNA-binding regions were obtained from the literature (Carroll et al. 2006, Lin et al. 2007 and unpublished data from Zhao et al. at the Department of Bioscience and Nutrition, KI, Sweden). If a SNP placed in these regions was not directly genotyped by GAIN, a SNP in high LD (r2>0.89) with the SNP of interest was chosen instead, where available. No single SNP was significant after Bonferroni correction. The p-value for the top SNP was 0.00318. This SNP is located in PITPNC1, a gene involved in regulation of the the phosphatidyl inositol pathway, which has earlier been implicated in the pathogenesis of affective disorders. Lithium and other mood stabilizing drugs, for example, are suggested to work regulatory on this pathway. One explanation for not finding a significant association in this study is that variation in ER binding sequences lacks relevance for the disease mechanism. Another reason could be that the sample size was too small. Finally, since for some interesting SNPs, neither the SNP itself nor any SNP in high LD was genotyped in the GAIN study, we may have missed true associations. We are now carrying out imputation of those missing SNPs in order to obtain more information from the available sample.

## 2103/T/Poster Board #652

**Association Studies of Autism Spectrum Disorders in Populations of European Ancestry.** *R. Holt[1], I. Sousa[1], E. Bacchelli[2], D. Brocklebank[1], E. Maestrini[2], G. Barnby[1], A.J. Bailey[3], A.P. Monaco[1], EU Autism MOLGEN Consortium.* 1) WTCHG, Univ Oxford, Oxford, United Kingdom; 2) Dipartimento di Biologia, Università di Bologna, Bologna, Italy; 3) University Department of Psychiatry, Park Hospital for Children, Oxford, United Kingdom.

Over the past decade, research on the genetic variants underlying autism and autism spectrum disorder (ASD) susceptibility has focused on two main lines of research; linkage and candidate gene studies. The vast amount of effort expended has resulted in a variety of chromosomal loci and genes being implicated in susceptibility to these disorders. Candidate gene studies have proved particularly intractable, with many studies failing to replicate previously reported associations. In a previous study of the genetics of ASD, we used four sets of samples of European ancestry; the International Molecular Genetics Study of Autism Consortium (IMGSAC) and Paris Autism Research International Study (PARIS) cohorts, and populations from Finland and the north of the Netherlands. Genotyping was performed using two 384 SNP Illumina GoldenGate® arrays to examine linkage regions and candidate genes implicated in ASD. Our results showed suggestive evidence of linkage on chromosome 2 in a subset of populations, and evidence of association to *RELN* and *GRIK2* across the entire sample. Here, we use the SNPs from the linkage array to perform association analysis in two relatively isolated European cohorts from Finland and the north of the Netherlands. Association analysis of these SNPs revealed significant associations in *MKL2* to autism and ASD (rs756472, autism $P = 2.46 \times 10^{-5}$, ASD $P = 4.31 \times 10^{-5}$) and *SND1* to autism (rs1881084, $P = 7.76 \times 10^{-5}$) in the Finnish and North Dutch cohorts, respectively. In addition, we have taken the five most strongly associated SNPs from our previous candidate gene study and genotyped them in an additional 470 trios from the IMGSAC and Northern Dutch cohorts. No significant association was identified in this replication cohort. However, when the replication data was combined with our original results to produce a total cohort of 848 trios an increased association to *RELN* (rs362780, $P = 0.001$) and marginally reduced association to *GRIK2* (rs2518261, $P = 0.008$) was identified. Therefore, our results both continue to highlight the difficulties in studying the genetics of autism, strengthen the case for further study of the role of *RELN* and *GRIK2* in ASDs, and identify two new potential candidate genes, *MKL2* and *SND1*.

**Variants of the transcription factor gene *GATA2* and the GATA-2 target region in α-synuclein (*SNCA*) are associated with Parkinson's disease (PD).** *D.M. Kay[1], J. Montimurro[1], M.G. Schlossmacher[2], E.H. Bresnick[3], C. Stevens[1], C.P. Zabetian[4,5], S.A. Factor[6], D.S. Higgins[7], C.R. Scherzer[8,9], H. Payami[1,9].* 1) Division of Genetics, Wadsworth Center, New York State Department of Health, 150 New Scotland Ave, Albany, NY, US; 2) Division of Neurosciences - OHRI, University of Ottawa, 451 Smyth Road #1462, Ottawa, Ontario, Canada; 3) University of Wisconsin School of Medicine, 383 Medical Sciences Center, 1300 University Avenue, Madison, WI, US; 4) Department of Neurology, School of Medicine, University of Washington, Seattle, WA, US; 5) Geriatric Research Education and Clinical Center, VA Puget Sound Health Care System, Seattle, WA, US; 6) Department of Neurology, Emory University School of Medicine, Atlanta, GA, US; 7) Parkinson's Disease and Movement Disorder Center, Albany Medical Center, Albany, NY, US; 8) Laboratory for Neurogenomics, Center for Neurologic Diseases, Harvard Medical School and Brigham & Women's Hospital, 65 Landsdowne Street, Suite 307A, Cambridge, MA, US; 9) equal contributors.

**Background** Increased *SNCA* dosage due to locus multiplication causes autosomal dominant PD and variation in *SNCA* expression may be critical in common, genetically complex PD. By combining gene expression analysis in humans with genetic complementation and gene silencing in cells, we discovered that GATA transcription factors regulate *SNCA* expression. Endogenous GATA-2 is highly expressed in PD-vulnerable substantia nigra, occupies a conserved region within *SNCA* intron 1, and modulates *SNCA* expression in dopaminergic cells. Here we identify variants in *GATA2* and the GATA-2 binding site region in *SNCA* that are associated with PD. **Methods** Subjects included 1971 cases and 2111 controls from NeuroGenetics Research Consortium. Six *GATA2* tagSNPs were genotyped in 602 cases and 631 controls, tested for association, and two promising SNPs were genotyped in the remaining subjects. *SNCA* intron 1 had not been studied in Caucasians; we therefore sequenced 602 cases and 583 controls, tested the identified SNPs and haplotypes for association with PD, and genotyped the remainder of samples for the promising SNPs. **Results** Two *GATA2* SNPs were associated with early onset and familial PD (all $p<0.01$). The two SNPs were not in strong linkage disequilibrium (LD); their effects on PD seemed independent. In *SNCA*, we identified 18 variants. The 11 rare variants were found in cases and controls. Among the 7 polymorphisms, 3 were significantly associated with PD. Haplotype analysis revealed that one SNP was the primary PD-associated variant, and the other two were hitchhiking via LD. The association of this SNP with PD was robust and highly significant in all PD ($p<10^{-5}$), and categories by age at onset (early $p=0.05$, late $p<10^{-4}$) and family history (positive $p=0.002$, negative $p=10^{-5}$). Risk conferred by intron 1 is not the same as risk associated with REP1. There was no evidence for statistical interaction (synergy) between *SNCA* and *GATA2*; their effects on PD risk were additive. In early-onset PD, where *GATA2* has notable effect, the largest odds ratio (OR) for either locus was ~1.4. Considered jointly, OR was 2.0 to 2.5 (p=0.001-0.005). **Conclusion** In a case-control study of 4082 subjects we find a substantial and novel association between polymorphisms in *GATA2* as well as the GATA-2 binding site region in *SNCA* and PD. Consistent with these results, variation in *SNCA* expression regulated by transcription factor GATA-2 may confer susceptibility to common, genetically complex PD.

## 2105/T/Poster Board #654

**Pleiotropic effects of the 11p13 locus on speech dyspraxia and susceptibility to Rolandic epilepsy.** *D.K. Pal[1], L.J. Strug[2], T. Clarke[1], P. Lieberman[3].* 1) Columbia University Medical Center, New York, NY, USA; 2) University of Toronto and Hospital for Sick Children, Toronto, Canada; 3) Department of Cognitive and Linguistic Sciences, Brown University, Providence, RI, USA.

Introduction. Speech sound disorder (SSD) is a common developmental comorbidity in children with Rolandic epilepsy, which is a developmental epilepsy syndrome with speech arrest and electroencephalographic (EEG) discharges emanating predominantly from the perisylvian cortex. The EEG discharges were recently mapped to variants in Elongator Complex Protein 4 (ELP4). We aimed to determine what mechanism of SSD operates in RE patients, and whether this SSD mapped to the same 11p13 locus as the EEG. Methods. We used computerized digital analysis of recorded speech to evaluate vowel duration, voice-onset time and other speech motor parameters. We performed parametric linkage analysis on 38 families, genotyped at 48 STR markers spaced at 4cM across chromosome 11 using the combined affectedness status of EEG/SSD. Results. Acoustic analysis revealed clear evidence of speech dyspraxia in all SSD affected individuals. In two-point linkage analysis, the maximum LOD score for EEG/SSD was 4.61 at D11S4102, the same marker at which we had found the maximum LOD score for EEG alone (EEG alone, LOD=3.4; SSD alone, LOD=0.83); in multipoint analysis, the highest multipoint LOD score was 7.54 at D11S914, again at the same marker where we found the maximum multipoint LOD score for the EEG (EEG alone, LOD=4.3), and with no heterogeneity. Discussion. We present evidence for speech dyspraxia underlying SSD in RE families, implicating impairment of cortico-striato-cortical tracts. Moreover, the linkage results suggest the hypothesis that ELP4 variants may have pleiotropic effects on speech development and susceptibility to epilepsy in children.

## 2106/T/Poster Board #655

**Clinical characterization and mapping of a late-onset painful recessive sensory neuropathy.** *M.L. Putorti[1,2], M. Srour[1,2], J. Mathieu[3], B. Bernard[1,2,3].* 1) Laboratoire de neurogénétique et motricité, CRCHUM Hôpital Notre-Dame, Montréal, QC, Canada; 2) Neuromics Center for Excellence of Université de Montréal, Université de Montréal, CRCHUM Hôpital Notre-Dame, Montréal, QC, Canada; 3) Carrefour de la Santé de Jonquière, Saguenay, QC, Canada.

Late-onset sensory neuropathies are usually believed to be acquired or sporadic. We have identified 16 cases belonging to 9 French-Canadian families that present on average at age 48 (27-64) with a painful sensory polyneuropathy that evolves into a sensory ataxia. Initial electrophysiological studies are not always significantly abnormal but progress to a severe axonal sensory, and to a lesser extend motor, peripheral neuropathy. The extent of the sensory loss can be quite profound in elderly patients with complete loss of position and vibration senses in extremities. The presence of one case with consanguineous parents, the equal male to female ratio (7 females/ 9 males), the absence of history of affected parents, and the 16/45 ratio of affected to unaffected cases supported a recessive mode of transmission. Considering that many of our families originated form the Saguenay-Lac Saint-Jean region of Quebec well known for its recessive founder effects, we completed a SNP genome wide scan using the Illumina Human610-Quad BeadChip. We uncovered one region of 1,1Mb shared by many of our families. Linkage using STS markers established that our largest families were mapped to this region with a maximum LOD score of 5,2. This study is the first to uncover a recessive locus responsible for a late-onset recessive painful neuropathy that evolves into a sensory ataxia.

## 2107/T/Poster Board #656

**LRRK2 variation and risk of Parkinson's disease.** *O. Ross, Genetic Epidemiology of Parkinson's Disease Consortium.* Dept Neuroscience, Mayo Clinic, Jacksonville, FL.

Leucine-rich repeat kinase 2 (LRRK2) mutations were first identified to cause familial late-onset parkinsonism, and showed idiopathic Parkinson disease (PD) may have a major genetic component. The identification of the Lrrk2 G2019S subsequently ignited the field due to its relatively high frequency in familial and seemingly sporadic PD. Overall Lrrk2 p.G2019S is found in 10 to 30% of PD patients of Ashkenazi Jewish or North African Berber ethnicity and increases risk by approximately 22 fold, the age-associated incidence of PD in carriers being over 80% at 70 years. Recently we and others identified the first two common ancestral variants acting as a 'risk-factors' for PD; LRRK2 pG2385R and pR1628P, that appear specific to Asian populations and combined may contribute to risk in over 10% of patients. To date over 75 non-synonymous LRRK2 variants have been identified through out the coding sequence of the gene. In addition there are over 30 synonymous LRRK2 coding SNPs that may influence LRRK2 transcription regulation or affect the rate of Lrrk2 protein translation, subsequent folding and protein-protein interactions. However pathogenicity, prevalence and penetrance of many remain to be determined and their given frequencies combined also indicate the potential for compound inheritance. We are genotyping over 100 exonic LRRK2 variants through the combined GEO-PD consortium patient-controls series (8,000 subjects). We have observed a number of variants that are common between patients and controls, and variants that appear to only be present in patients suggestive of pathogenicity. We will present our results which will help elucidate the role of rare LRRK2 variants in PD risk, inform diagnostic testing and future therapeutic strategies.

## 2108/T/Poster Board #657

**Association of SNPs in the CHRNA5/CHRNA3/CHRNB4 Gene Cluster with Conduct Disorder-Related Phenotypes.** *S.H. Stephens, M.B. McQueen, S.E. Young, J.K. Hewitt, M.A. Ehringer.* Institute for Behavioral Genetics, Integrative Physiology Dept, Univ Colorado, Boulder, CO.

Work from several groups provides convincing evidence for an association between several of the nAChR genes and alcohol and nicotine behaviors in humans, including lung cancer (Bierut et al, 2007; Schlaepfer et al, 2008; Wang et al, 2008; Amos et al, 2008). This work has been based on evidence that common genetic factors contribute to alcohol, nicotine, and substance use disorders, particularly in adolescence. Some of this drug use co-morbidity may be a manifestation of a more general underlying trait, characterized by a range of disinhibitory behaviors such as conduct disorder (CD). Recently, we have shown evidence for association between CD-related phenotypes and SNPs in the CHRNA5/A3/B4 gene cluster in two separate samples, as well as evidence that two SNPs in the region may lead to differences in gene expression (Schlaepfer et al, under revision). In the current study, we have examined the same SNPs in the CHRNA5/A3/B4 genes with CD-related phenotypes in a third sample, the National Longitudinal Study of Adolescent Health (Add Health). The genetic pairs subsample of the Add Health project includes approximately 2500 subjects which have been assessed at three waves during adolescence and young adulthood. The software package PBAT (Laird and Lange, 2006) was used to carry out family-based association tests on six CD-related measures across Waves I, II and III. Results of genetic association analyses in the Caucasian sample revealed evidence for association between CD-related phenotypes and SNPs rs16969968 ($P=0.038$) and rs8040868 ($P=0.009$). SNP rs16969968, located in exon 5 of CHRNA5, has been associated with nicotine dependence, lung cancer, and cocaine dependence. SNP rs8040868, located in exon 2 of CHRNA3 has shown suggestive evidence for association with CD-related phenotypes in a separate sample population (Schlaepfer et al, under review). Ongoing work using gene expression assays to further characterize the functional importance of additional SNPs in this region are in progress, including examination in lung cancer cell lines. Our results support the hypothesis that allelic variants in the CHRNA5/CHRNA3/CHRNB4 contribute to an underlying genetic predisposition to disinhibitory behaviors such as conduct disorder. These phenotypes are important precursors to substance use disorders, thereby providing additional insight into the possible role of these genes in the developmental trajectory of these disorders.

## 2109/T/Poster Board #658

**Polymorphism detection in gene GRIN 1 of ionotropic glutamate receptor activated by NMDA of a population from Bogota.** *I. Zarante[1], L. Lareo[2], P. Ayala[1], D. Ojeda[1].* 1) Instituto de Genetica Humana, Facultad de Medicina,Pontificia Universidad Javeriana, Bogota, Colombia; 2) Departamento de Nutricion y Bioquimica, Facultad de Ciencias, Pontificia Universidad Javeriana, Bogota, Colombia.

The ionotropic glutamate receptor activated by N-methyl-D-aspartate is composed by three different kinds of subunits NR1, NR2A to D and NR3A and B, which are codified by GRIN1, GRIN2 and GRIN3 genes. Since the GRIN`s genomic variability is closely related to the genetic history of the studied population, it was necessary to develop a detailed study of the frequency of the polymorphisms of the gene GRIN-1 in Colombian population. The main goal of this research was identifying polymorphisms present in 5'-UTR region and Exon 6 of gene GRIN-1, among 101 samples of umbilical cord taken on filter paper of healthy newborns at the University Hospital San Ignacio in Bogota. It was found that polymorphism A1970G with minor allele frequencies of 28.21%, doesn't differ significantly from the frequencies in Caucasian and Native American populations. Polymorphism G1140A with minor allele frequencies of 1.49% did not show any significant statistic difference with the Taiwan population. Polymorphism A1160G just showed one allelic form, the A allele.

## 2110/T/Poster Board #659

**Single nucleotide polymorphisms within D1 and D2 dopamine receptor genes are associated with heroin abuse and striatal gene expression.** *M.M. Jacobs[1], E. Keller[2], Y.L. Hurd[1].* 1) Departments of Psychiatry and Pharmacology & Systems Therapeutics, Mount Sinai School of Medicine, New York, NY, USA; 2) Department of Forensic Medicine, Semmelweis University, HU 1091, Budapest, Hungary.

Drug addiction is a complex disorder with genetic factors accounting for approximately 40-60% of overall vulnerability. Vulnerability to heroin abuse appears to have one of the strongest genetic loads compared to abuse of other addictive substances. Converging lines of evidence obtained from rodent and human brain studies have identified discrete components of cortico-striato-thalamo-cortical circuits as linked to discrete behavioral traits implicated in addiction. The corticostriatonigral circuit constitutes the "Go" pathway that facilities behavioral responses and reward sensitivity, whereas the corticostriatopallidal circuit constitutes the "No-Go" pathway involved in suppressing inappropriate responses in normal adults. The striatonigrial and striatopallidal pathways are distinct in their gene expression pattern with preferential expression of dopamine D1 (DRD1) receptors in the striatonigral pathway and dopamine D2 (DRD2) receptors in the striatopallidal pathway. Using a homogenous European Caucasian population consisting of 81 heroin abusers and 46 age-matched controls, we examined 4 single nucleotide polymorphisms (SNPs) of DRD1 and DRD2. Alleles of 1 SNP within DRD1 and 3 SNPs within DRD2 are significantly associated with heroin abuse ($P<0.05$). Additionally, expanding these analyses to haplotypes containing associated alleles improves association; a 3-marker haplotype of DRD1 and a 4-marker haplotype of DRD2 are significantly associated with heroin abuse ($P<0.01$ and 0.04, respectively). To examine DRD1 and DRD2 gene expression, we purified RNA from the putamen in a subset of these individuals and performed quantitative PCR analysis. We observed that these associated polymorphisms of DRD1 and DRD2 are significantly associated with altered gene expression in heroin abusers. Future studies will examine gene expression and genetic polymorphisms of additional genes specific to striatonigral and striatopallidal circuitry to determine their contribution to addiction vulnerability.

## 2111/T/Poster Board #660

**De novo mutations in autism affected subjects from a large cohort screening of polymorphisms in genes IL1RAPL1 and IL1RAPL2 by pooling and next generation sequencing.** *J.J. Pruzin, J.J. Corneveux, H.L. Benson, J.L. Dinh, J.S. Beckstrom, S.M. Beckstrom-Sternberg, S.D. Mastrian, J.V. Pearson, M.J. Huentelman.* Neurogenomics, Translational Genomics Research Institute, Phoenix, AZ.

Though a strong genetic component is proven to predispose a person to Autism Spectrum Disorders (ASD), the search for specific risk factors has been largely unsuccessful. This possibly results from the heterogeneity of the disorder both phenotypically and genetically. Perhaps an accumulation of a menu of rare and common variants can result in ASD. We devised a method to sequence large numbers of people with the capability of detecting both rare and common polymorphisms and chose the previously ASD linked gene Interleukin-1 Receptor Accessory Protein-Like 1 (IL1RAPL1), involved in calcium-regulated vesicle release and dendrite differentiation, on which to try the method. In this study 250 individuals were screened for exonic changes in both IL1RAPL1, and related gene IL1RAPL2, by pooled sequencing on the Illumina Genome Analyzer II. Five equimolar pools of 50 people each were created and enriched for the two genes of interest by PCR. The PCR products were recombined in equimolar ratios and sequenced. Coverage averaged from 856X to 1538X depending on pool. A minimum of 500X coverage with a deviation from the reference at a prevalence of 5% or greater was used to determine possible polymorphisms. A total of 12 polymorphisms in IL1RAPL1, found at a prevalence of 6% to 25%, were identified for verification. The two most functionally relevant changes are at positions chrX:29,882,707 and chrX:29,882,709 (UCSC version hg18) causing changes of Asp to Val and Arg to Gly respectively. Both polymorphisms are located in the Toll-interleukin 1 Receptor (TIR) domain, implicated in protein-protein interactions and thought to be important to the signal transduction pathway. IL1RAPL2 yielded twenty polymorphisms at prevalences of 6% to 43%, nine of which are located in the untranslated region. One mutation present in 2 or 3 people, located at chrX:104,848,086 (UCSC version hg18), results in a premature stop codon on exon 7 and the loss of half of the Ig-like C2-type 3 portion of the topological domain and entire TIR, and transmembrane regions of the protein.

## 2112/T/Poster Board #661

**Exploratory sequence analysis of candidate genes for repetitive and restricted behaviors in autism.** *E.L. Crawford[1], E. Kistner[2], N.J. Cox[2], E.H. Cook[3], J.S. Sutcliffe[1].* 1) Centers for Molecular Neuroscience and Human Genetics Research, Dept of Mol Phys & Biophys, Vanderbilt University, Nashville, TN; 2) Department of Medicine, University of Chicago, Chicago, IL; 3) Institute for Juvenile Research, Department of Psychiatry, University of Illinois-Chicago, Chicago, IL.

Autism is a neurodevelopmental disorder that affects approximately 1 in 150 individuals and is characterized by deficits in reciprocal social interaction, communication and patterns of repetitive behaviors and restricted interests. Twin and family studies indicate high heritability, but evidence supports a highly complex architecture for the underlying genetic etiology. Serotonin dysregulation has long been implicated in autism, and rare autism-associated variants in the serotonin transporter (SERT; gene symbol: SLC6A4) lead to gains of function involving increased activity and abnormal regulation. In autism families, these SERT variants result in more severe rigid-compulsive behaviors, but one has also been observed in multiple pedigrees with obsessive compulsive disorder (OCD). Selective serotonin reuptake inhibitors (SSRIs) that selectively target SERT are a key front-line therapy for OCD. Thus, SERT variants and SSRI treatment efficacy highlight a shared etiology between autism and OCD involving serotonin regulation via SERT. We are pursuing related hypotheses that genes and/or pathways related to SERT regulation and SSRI-responsive OCD behaviors harbor autism susceptibility alleles. In this study, we begin testing these hypotheses through a sequencing-based variant discovery paradigm in unrelated autism probands and controls for two loci, DLGAP3 and ADAMTS6. DLGAP3 is also known as SAPAP3 (SAP90/PSD95-associated protein 3), and mutations have been described in cases of OCD and trichotillomania, and a mouse knock-out shows analogous behaviors that are responsive to treatment with SSRIs. ADAMTS6 encodes a disintegrin and metalloproteinase with thrombospondin motifs 6, and this locus was identified based on its containing SNPs that significantly predict variation in gene expression of SLC6A4. Exonic sequences for these two genes have been sequenced in a pilot sample of 200 cases and controls. Multiple synonymous and nonsynonymous variants have been detected in both loci. While data at this time do not permit a conclusion that either of these genes shows a greater mutation burden in autism vs. controls, the current study is under-powered to detect particularly rare variants and modest differences in numbers of apparently damaging sequence variants in cases vs. controls. We conclude that further study may be warranted for both of these genes.

## 2113/T/Poster Board #662

**Genetic and cellular localization studies of the Protein Kinase AKT1 in Parkinson's disease.** *C. Ran[1], M. Westerlund[1], A. Anvret[1], C. Lind[2], T. Willows[3], O. Sydow[2], D. Galter[1], A. Carmine Belin[1].* 1) Department of Neuroscience, Karolinska Institutet, Retzius väg 8, 171 77 Stockholm, Sweden; 2) Department of Neurology, Karolinska University Hospital Solna, 171 76 Stockholm, Sweden; 3) Department of Neurology, Karolinska University Hospital Huddinge, 141 86 Stockholm, Sweden.

AKT1 (V-akt murine thymoma viral oncogene homolog 1) is one of three genes in the Akt/PKB protein kinase family. This family has a broad spectrum of substrates implicated in multiple signaling pathways. They are known to regulate cellular growth, proliferation, metabolism, transcriptional activity, and in particular, cell survival. AKT1 promotes survival by regulating several important mediators of apoptosis and cell survival, as well as expression of pro-survival and pro-apoptotic genes. AKT1 is fully activated when phosphorylated and once activated, it dissociates from the membrane and is translocated to the cytoplasm or nucleus to phosphorylate its substrates. As a potent mediator of cell survival, AKT1 has been associated with several forms of human cancers, but can also be linked to other pathologies. Notably, AKT1 seems to be associated with neurological disorders of the dopamine system. AKT1 is localized to chromosome 14q32.32 and this locus has been linked to bipolar disorder. Furthermore, several single nucleotide polymorphisms (SNP), low expression levels as well as reduced enzyme activity of AKT1 has further been found to associate with schizophrenia. Recently, the AKT1 pathway was suggested to play a protective role in Parkinson's disease (PD). In 2008, Xiromerisou et al. discovered a haplotype more frequently occurring in healthy controls than in PD patients in a Greek case-control material. AKT1 has also been found to show lower levels of phosphorylation in dopamine neurons of PD patients. We are investigating the protective haplotype reported by Xiromerisou et al. in a Swedish PD case-control material using pyrosequencing. 315 controls and 243 PD patients were genotyped for four SNPs: rs1130214 in the 5'UTR and rs2494743, rs2498788, rs2494746 in intron 3. We did not find a significant association for any of the investigated SNPs with PD. A haplotype analysis did not reveal any haplotypes associated with an altered risk of developing PD. To study the cellular expression pattern of AKT1 in rodent and postmortem human tissue, we used radioactive in situ hybridization and oligonucleotide probes designed to hybridize with AKT1 mRNA. Moreover, we compared the expression levels of AKT1 mRNA in postmortem tissue from PD patients and controls in order to study the possibility of Akt1/PKB$\alpha$ exerting a protective effect on neurodegenerative diseases.

## 2114/T/Poster Board #663

**Copy number variation at the spinal muscular atrophy locus and susceptibility to autism.** *I. Cusco[1], C. Aguado[1], LA. Pérez-Jurado[1,2].* 1) Unitat de Genètica, Univ Pompeu Fabra & Centro de Investigación Biomédica en Red de Enfermedades Raras (CIBERER), Barcelona, Spain; 2) Programa de Medicina Molecular i Genètica, Hospital Vall d'Hebron, Barcelona.

Autism spectrum disorders (ASD) are a group of neurodevelopmental disorders characterized by impairments in reciprocal social interaction and communication skills, restricted interests and stereotyped behaviors, with a recently established prevalence as high as 1 in 150 newborns. There is strong evidence for a genetic etiology of ASD given the 90% concordance rates in monozygotic twins and the ~50 fold increased risk for siblings. ASD is found in association with comorbid genetic conditions in 10% of cases and can be caused by several rare monogenic mutations and submicroscopic rearrangements, but it is mainly considered a complex multifactorial disorder involving multiple genes. However, the etiology of ASD in the majority of patients remains unknown and common susceptibility factors have not been identified yet. Here we report a novel genetic susceptibility factor at the highly variable 5q13.2 Spinal Muscular Atrophy locus showing strong association with the disorder. We detected a significantly different pattern of deletions and duplications at two genes (GTF2H2 and SMN2) in Spanish ASD patients (n=215) compared with controls (n=453). Data were replicated using a small subset of the AGRE consortium cohort (85 cases). Overall, individuals with gain of GTF2H2 copies and deletion of the SMN2 gene showed an increased risk for ASD with odds ratio of 14.77 (range 5.89 - 44.75, p= 8.93e-13). The analysis of 24 trios revealed that most SMN2 losses were inherited from either parent, while the GTF2H2 gains could be de novo in ~2/3 ASD probands. Copy number changes showed a strong correlation with gene expression levels by quantitative RTPCR and western blotting in lymphocytes. GTF2H2 coding for the TFIIH2 subunit of the RNA polymerase transcription initiation factor IIH involved in basal transcription and nucleotide excision repair, and SMN2 coding for the survival of motor neuron protein (SMN) involved in splicing regulation and SMN$\Delta$7 with unknown function, are therefore novel ASD candidates. Our findings open new directions to investigate the pathogenesis of the ASD phenotype and suggest that other genetic susceptibility factors for complex disorders may locate in highly instable genomic regions poorly tagged by current genotyping methods.

## 2115/T/Poster Board #664

**Variants in and around *DPYSL2* confer sex-specific risks for schizophrenia.** *Y. Liu[1], P. Chen[1], V. Lasseter[2], D. Fallin[3], J. McGrath[2], P. Wolyniec[2], G. Nestadt[2], K. Liang[4], A. Pulver[2], D. Avramopoulos[1], D. Valle[1].* 1) Institute of Genetic Medicine,Johns Hopkins University School of Medicine Baltimore, MD; 2) Department of Psychiatry, Johns Hopkins University School of Medicine Baltimore, MD; 3) 3Department of Epidemiology,Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 4) 4Department of Biostatistics, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD.

Schizophrenia (SZ) is a common disabling disorder typically with onset in young adults and multiple sex-specific phenotypic differences: females make up only ~30% of the cases; have later age of onset; higher familiarity; and, a somewhat different presentation (more affective symptoms). Association studies from multiple groups including our own have implicated *DPYSL2* (8p21, 26.5Mb), which encodes a cytosolic protein that regulates axonal growth, as a candidate gene for SZ. Recently, in a SNP fine-mapping study covering 4Mb on 8p21, we identified significant association with SNPs in intron 3 (rs5029306, p<0.0005) and 5Kb 3' (rs12155555, p<0.0001) of *DPYSL2* in an Ashkenazi Jewish (AJ) population. To find additional potential causative variants on the risk haplotype specified by these variants, we sequenced all 14 exons and 21 conserved non-coding sequences (cNCSs) in and around *DPYSL2* in 41 AJ SZ probands and 6 controls. We identified 86 SNPs in total and based on frequency, location and conservation, selected 5 non-coding SNPs and one 11-bp indel for follow-up genotyping in 729 AJ SZ (465 males, 264 females) and 1542 AJ controls. We also included one SNP (rs17088251) ~7kb 3' of *DPYSL2*, on the basis of its association in a genome wide study, ranking in the top of 0.06% for AJ women published by Shifman, et.al, 2008. Of the 7 variants, 4 showed no difference between cases and controls. In agreement with Shifman et.al., rs17088251 showed a case-control difference in females only, (p<0.05). Another SNP in the region, rs5029306, showed a stronger female specific association alone (p= 0.0017) and in a haplotype with rs17088251 (p=0.0013). More strikingly, 3 variants in the gene-free region 3' of *DPYSL2* showed a significant association specific to males both individually ($p<10^{-4}$-$10^{-5}$) and as a three SNP haplotype ($p<10^{-5}$). These variants and their distance beyond the 3' end of *DPYSL2* are: rs57045236, ~1kb; rs12155555, ~5kb and an unannotated SNP (un26633562), ~62Kb. In summary, our results: 1) replicate a female-specific risk of rs17088251 in AJ; 2) identify a SZ association with two haplotypes, one in the body of *DPYSL2*, which is female-specific and the other in 3' of *DPYSL2*, which is male-specific. These results suggest that variants in a single SZ candidate gene confer risk for SZ in multiple sex-specific ways, perhaps by cis-acting estrogen/androgen response elements in and around *DPYSL2*.

## 2116/T/Poster Board #665

**Fine mapping of AHI1 on 6q23 as a susceptibility gene to schizophrenia.** *F. Torri[1], A. Akelai[2], S. Lupoli[3], M. Sironi[4], D. Amann-Zalcenstein[5], M. Fumagalli[4], R. Cagliani[4], C. Dal Fiume[1], E. Ben-Asher[5], K. Kanyas[2], D. Lancet[5], P. Cozzi[6], E. Osimo[1], L. Strik Lievers[1], E. Salvi[1], A. Orro[6,7], J. Beckmann[8], B. Lerer[9], F. Macciardi[1,10].* 1) University of Milan, Genomics and Bionformatics Platform, Fondazione Filarete, Milan, Italy; 2) Hadassah-Hebrew University Medical Center, Jerusalem, Israel; 3) INSPE, Scientific Institute San Raffaele, Milan, Italy; 4) Scientific Institute IRCCS E. Medea, Bosisio Parini (LC), Italy; 5) Weizmann Institute of Science, Rehovot, Israel; 6) ITB, CNR, Milan, Italy; 7) CILEA Consortium, Segrate, Milan, Italy; 8) University of Lausanne, Lausanne, Switzerland; 9) Miller School of Medicine, University of Miami, Miami, FL, United States; 10) Dept of Psychiatry and Human Behavior, UCI, Irvine, CA, USA.

Schizophrenia (SCZ) is a multifactorial disorder where probably multiple genes of small to moderate effect act in combination also with environmental factors to increase the risk of illness. In previous studies, using a set of Arab-Israeli families, we identified by linkage and association mapping a susceptibility region to SCZ on the long arm of chromosome 6 (6q23.3)(1,2,3); this association was also replicated in an independent sample. The peak region includes the Abelson Helper Integration Site 1 (AHI1) and a putative gene for a human-specific hypothalamic mRNA BC040979. Here we densely map the most probable candidates in this area, performing a finer mapping of the originally identified linkage peak. The strongest single SNP and haplotype association lies within a 500 kb genomic region (135.6-136.1 Mb) encompassing the AHI1 gene and the BC040979 locus, supporting the role of AHI1 as a susceptibility gene to SCZ. Interestingly the second highest significant subregion is immediately downstream and includes PDE7B and MAP7 genes. Resequencing of a 10kb region within AHI1 in ethnically defined populations suggested that the gene has undergone a selective sweep in Europeans, in agreement with previous studies (4,5). Network analysis indicated the presence of two haplotype clades, with SCZ-susceptibility haplotypes clustering within the major clade. ## 2117/T/Poster Board #666

**Overexpressed Cyclophilin B Protectes beta Amyloid(25-35)-Induced Oxidative Stress in PC12 cell death via Reative Oxygen Species.** *J. Kwon, E. Kim, W. Choe.* Department of Biochemistry and Molecular Biology, Medical Science and Engineering Research Center for Bioreaction to Reactive Oxygen Species, Biomedical Science Institute, School of Medicine, Kyunghee University, Seoul 130-701, Korea.

Alzheimer's disease (AD) is characterized by neuronal loss and extracellular senile plaque, whose major constituent is β-amyloid protein (Aβ), a 3943 amino acid peptide derived from amyloid precursor protein. Aβ-induced neurotoxicity has been attributed in various studies to Ca2+ influx and generation of ROS. The previous studies confirmed that Aβ (2535) caused elevation of [Ca2+]c, glutamate release, ROS generation and then apoptotic neuronal cell death.

Neuronal apoptosis is one of the pathologies of Alzheimer's disease, and it has been hypothesized to be induced, at least in some degree, by beta amyloid (Aβ) protein. The mechanism by which Aβ induces cell death is not clear yet. However, it has been suggested one of the mechanisms is oxidative stress. Beta-amyloid (Aβ)-induced neurotoxicity is mediated through the generation of reactive oxygen species (ROS) and elevation of intracellular calcium. Cyclophilin B belongs to protein groups that have peptidyl-prolyl cis-trans isomerase activity (PPIase). Recent studies have shown diverse functions of cyclophilin family, and we suggest that cyclophilin B might play an antioxidant. The purpose of this study is whether overexpressed

cyclophilin B reduces Aβ -induced oxidative stress or not. To determine the effect, we used rat pheochromovytoma (pc12) cells and performed MTT assay to check the cell viability. Exposure of PC12 cells to the Aβ25-35 fragment resulted in apoptotic cell, while PC12 cells which are overexpressed cyclophilin B reduced Aβ -induced cell death. Our results suggest that overexpressed cyclophilin B has a protective effect against the Aβ-induced oxidative damage and eventually inhibited apoptotic cell death.

## 2118/T/Poster Board #667

**Late-Life Depression Is Heritable Among Old Order Amish.** *M. Slifer[1], W. Scott[1], P. Gallins[1], M. Pericak-Vance[1], J. Haines[2].* 1) MIHG, Univ Miami, Miami, FL; 2) CHGR, Vanderbilt University, Nashville, TN.

Little is known about the heritability of late-life depression. The environment plays a significant role in the development of depressive symptoms at all ages. However, the magnitude of effects of specific environmental stressors varies widely among published reports. Environmental exposures may be less heterogeneous among Amish populations. As a result, the Amish may be informative for discovery of genetic effects on traits like depression that exhibit important but difficult to capture and characterize environmental interactions. In this study, we use complete pedigree information from a set of old-order Amish participants to determine the heritability of late-life depressive symptoms. Since cognitive impairment is confounded with depressive symptoms in elderly populations, we restricted our sample to cognitively intact Amish elders. We examined 380 cognitively intact participants (mean age 80y) using the Geriatric Depression Scale (GDS). Heritability was calculated with the SOLAR© statistical software package. Overall heritability of GDS score is 0.44 (p-value=8.8X10-6). Heritability of GDS score among the 159 elderly Amish men is 0.23 and among 221 elderly Amish women is 0.76. The heritability of depressive symptoms among the elderly Amish women is about twice that reported in other Caucasian populations and is statistically significant (p-value= 3.1X10-4). These data suggest that depressive symptoms among Amish elders is heritable, particularly among women. Historically, discovery and replication of specific genetic variants associated with depression has been frustrating. The Amish may represent an informative population in which to discover genomic variation associated with late-life depression.

**A latent variable approach to optimizing genetic phenotypes for substance use disorders: Behavioral disinhibition.** *S.E. Young[1], M.C. Stallings[1,2], J.K. Hewitt[1,2]*. 1) Institute for Behavioral Genetics, University of Colorado, Boulder, CO; 2) Department of Psychology, University of Colorado, Boulder, CO.

The NIDA Genetics Consortium has recently begun an active investigation of drug-related behavioral traits that will afford more statistical power in molecular genetic studies than categorical, diagnostic methods traditionally used. In order to contribute to this effort, our Colorado NIDA Center studies are building on previous work demonstrating that substance use behavior is part of a spectrum of externalizing problems (e.g., conduct disorder, impulsivity) that reflect, in part, behavioral disinhibition (BD). We characterize BD as a lifelong disposition toward the excessive pursuit of exciting appetitive stimuli, impulsivity, risk-taking, and the unusual disregard of aversive consequences of deviant behavior. Previous research has shown that these behavioral problems tend to cluster because of a shared array of genetic risk factors. As we follow our Center participants from adolescence into early adulthood, we focus on more developmentally salient indices of BD including adult antisocial behavior, symptoms of substance abuse and dependence, and precocious/promiscuous sexual behavior. We present a latent variable approach to developing a maximally heritable and highly reliable phenotype for application to genetic linkage and association studies of substance use disorders. This method captures the common variance among highly intercorrelated, quantitative behavioral measures, while avoiding the noise associated with the impurity and measurement error in individual assessments. We examined the genetic and environmental architecture of BD as defined by the common variance among adolescent conduct disorder symptoms, adult antisocial personality symptoms, substance abuse and dependence symptoms, precocious sexual behavior, and novelty seeking. A significant portion of the variance in each of the five observed phenotypes contributed to BD. Results showed that 69% of the variance in BD was due to additive genetic influences ($p < .01$), while shared environmental influences accounted for only 13% of the variance ($p > .05$). Only precocious sexual behavior showed significant residual genetic effects (33%). These results provide compelling evidence that BD is a genetically driven propensity for a spectrum of deviant externalizing behaviors, which are known to be central to the development of substance use disorders. BD is a highly heritable, reliable phenotype that may be useful for future linkage and association studies.

## 2120/T/Poster Board #669

**Focal Neuropathological and Laminar Gene Expression Abnormalities in Dorsalateral Prefrontal Cortex in Autism.** *M. Chow[1], M. Boyle[2], S. Roy[1], T. Wynshaw-Boris[4], E. Lein[2], S. Colomarino[3], E. Courchesne[1]*. 1) UC San Diego, La Jolla, CA; 2) Allen Institute for Brain Science, Seattle, WA; 3) Autism Speaks Inc, Los Angeles, CA; 4) UC San Francisco, San Francisco, CA.

Although it is accepted that autism is a heritable neurobiological disorder, many questions remain including etiology as well as onset of underlying neurobiological defects. We hypothesize that autism begins prenatally due to abnormal cell proliferation, migration and/or laminar organization. Such possibilities have never been systematically examined in the young developing autistic cerebral cortex, but their elucidation would shed light on controversies (putative postnatal neuroinflammation, speculations about vaccines). To qualitatively and quantitatively examine the latter two possibilities, we performed in situ hybridization(ISH) as well as Nissl staining of 20 micron thick frozen sections of dorsolateral prefrontal cortex in 8 autistic male cases aged 2-14 years and 8 age-matched control males. ISH data was systematically generated using high throughput semiautomated procedures for a panel of 25 robust lamina, neuronal, and/or glial cell type-specific markers in order to search for detailed cellular cytoarchitectural abnormalities in autistic samples, as well as for a set of genes implicated in autism through gene association studies. Ten uniformly spaced sections were hybridized to digoxigenin-labeled riboprobes for each gene, with interleaved Nissl-stained sections (260 sections/case*16 cases=4160 total sections). Sections were carefully examined for features of neuropathology by two authors and findings were compared to those by a blinded clinical neuropathologist. Some autistic cases displayed focal regions of disturbance of multiple lamina-specific and neuronal-cell type-specific gene expression markers, sometimes embedded within local areas of normal marker expression. Quantitative analyses compared marker expression between pathological and neighboring regions within autistic cases as well as between autistic and control cases. Results suggest abnormal migration and disorganization across lamina and cell types in autism. This is the largest study of the young autistic postmortem cortex and the first to detail laminar- and cell-type specific gene expression abnormality and cortical disorganization. These neurodevelopmental defects cannot be caused by some speculated postnatal causes of autism, but pinpoint prenatal life as the time of autism onset. The important implications for identifying underlying causes of autism, establishing the age of neurobiological onset and creating animal, cellular and molecular models of autism are discussed.

## 2121/T/Poster Board #670

**Dominant isolated Dandy Walker malformation continuum in a four generation kindred.** *G. McGillivray[1,2,3], M. Fink[2,3,4]*. 1) Murdoch Children's Research Institute, Melbourne, Australia; 2) Royal Children's Hospital, Melbourne, Australia; 3) Royal Women's Hospital, Melbourne, Australia; 4) The University of Melbourne, Melbourne, Australia.

Dandy-Walker malformation (DWM) is heterogeneous. A significant proportion of cases have a chromosomal aetiology. DWM is also a feature of over 80 distinct inherited and sporadic syndromes. Dominant DWM with occipital cephalocele in one family links chromosome 2q36. Most cases of isolated DWM are sporadic and some patients have deletions including ZIC1 and ZIC4 on 3q24. Convincing autosomal dominant pedigrees with isolated DWM have not been described previously. The purpose of this presentation is to document the clinical, imaging and molecular cytogenetic findings in a four generation kindred with familial hydrocephalus. All affected members have variable expression of posterior fossa anomalies falling within the Dandy Walker continuum/spectrum, ranging from isolated elevation of the vermis to a full Dandy Walker malformation. Arrested or shunted hydrocephalus is a feature and affected family members have intellectual abilities ranging from normal to mild disability. Some have behavioural difficulties. The most severely affected individual is male, but another male has mild expression with cerebellar vermis elevation. X-linked inheritance cannot be excluded, but the presence of mildly affected male individuals and affected female individuals is more consistent with autosomal dominant inheritance. Recent re-evaluation of the imaging of the fetal posterior fossa and the embryology of the roof of the rhombencephalon suggests that Dandy-Walker continuum, persistent Blake's pouch cyst (BPC) and mega cisterna magna (MCM) all have the same underlying developmental aetiology. Prognosis is determined by the presence or absence of cerebellar vermian hypoplasia and the presence or absence of associated hydrocephalus related to obstruction of CSF flow into the subarachnoid spaces. Fetal MRI is an important tool in the prognostic assessment of affected pregnancies.

## 2122/T/Poster Board #671

**Association between Autism and Recurrent 17q12 Deletions.** *D. Moreno-De-Luca[1], M. Adam[1], S.M. Myers[2], A. Pakula[3], L. Weik[4], L. Guy[3], K. Uhas[1], N.J. Eisenhauer[2], M.R. Rossi[1], S. Aradhya[5], C.L. Martin[1], D.H. Ledbetter[1]*. 1) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA; 2) Geisinger Medical Center, Danville, PA; 3) Marcus Autism Center, Atlanta, GA; 4) Children's Hospital of Wisconsin, Milwaukee, WI; 5) GeneDx,Gaithersburg, MD.

A new, recurrent microdeletion of 17q12 (del 17q12) was recently reported in association with renal disease (in pediatric patients and a stillbirth) or diabetes in patients with maturity-onset diabetes of the young type 5 (MODY5). The deletion is 1.5 Mb in size, is mediated by flanking segmental duplications, and contains the HNF1B (TCF2) gene responsible for the autosomal dominant MODY5 form of diabetes. Initial reports indicated that this microdeletion was not associated with mental retardation and no features of autism disorders were noted. As part of the ISCA Consortium (International Standard Cytogenomic Array), which is a group of clinical laboratories performing whole genome copy number array analysis using a standardized array design, we studied a subset of 7752 patients, from which approximately 20% have a diagnosis of autism or autism spectrum disorders. We identified four males and one female, ranging in age from 1 to 12 years old, with the same 1.5 Mb deletion of 17q12 as recently reported in renal disease or diabetes. All four males were referred for array testing with a primary indication of autism or autistic features, and the female was referred for developmental delay. Additionally, all patients share phenotypic features such as speech delay, macrocephaly, onychodystrophy, and different degrees of renal anomalies. None of them show signs of diabetes yet, which is not surprising given their young age. Parental testing has been completed for four individuals and demonstrated that the deletion was de novo in all of them. Microsatellite testing is being performed to identify the parental chromosome from which the deletion arose, and tri-color FISH studies are underway to evaluate the presence of an inversion polymorphism that corresponds to the deleted interval. This region of proximal 17q overlaps with an autism linkage peak identified in multiple studies, predominantly associated with "male-only" families (i.e., families in whom all affected individuals are males), strongly suggesting a sex specific risk allele for autism. Interestingly, all four male patients described here had autism or autistic features. These data raise the possibility that the 17q12 microdeletion may be associated with an increased risk of autism, especially in males.

## 2123/T/Poster Board #672

**Identification of proteins that interact with the large intracellular loop of the nAChR α5 subunit: impact of the Chrna5 D398N polymorphism (rs16969968).** *T.A. Precht[2], J.A. Laughlin[2], J.A. Stitzel[1].* 1) Department of Integrative Physiology, Univ. of CO, Institute for Behavioral Genetics, Boulder, CO; 2) University of Colorado, Institute for Behavioral Genetics, Boulder, CO.

The interaction of nicotine with neuronal nicotinic acetylcholine receptors (nAChRs) is mostly responsible for the physiological and addictive aspects of smoking. Recent evidence has demonstrated that commonly occurring SNPs in CHRNA5, the gene that encodes the α5 nicotinic receptor subunit, in the human population can confer increased risk for nicotine addiction and other smoking-related phenotypes. One of the variants in CHRNA5 that repeatedly has been found to be associated with smoking-related phenotypes is the non-synonymous SNP rs16969968. This SNP converts an aspartic acid (D) residue at position 398 in the α5 nAChR subunit, which is highly conserved across vertebrate species, to an asparagine (N). In the brain, the α5 subunit predominantly assembles with α4 and β2 subunits to form an α42β22α5 nAChR. Functional studies have shown that α4β2α5N398 nAChRs are significantly less responsive to agonist stimulation than are α4β2α5D398 nAChRs, indicating this SNP dramatically decreases the function of this brain-expressed nAChR. This decrease in function was not due to a change in sensitivity to agonist, nor was it due to alteration in or differential expression of the receptor. What remains unclear is how this single amino acid change in the α5 subunit within the large intracellular loop between transmembrane domains 3 and 4 (M3M4) yields a less functional receptor upon agonist stimulation. Previous studies with both the α4 and β2 subunits have identified a wide variety of intracellular protein interactions with the M3M4 loops of these subunits that alter receptor function. Because this SNP eliminates the negative charge of the aspartic acid residue it is possible that protein-protein interactions will be altered, and this might lead to a less functional intact receptor. We intend to identify protein-protein interactions between the M3M4 intracellular loop of α5 and cytosolic proteins and determine whether the Chrna5 D398N SNP alters any identified interaction. For these experiments we have fused the α5 M3M4 loop containing either the D398 residue or the N398 residue to Glutathione-S-Transferase (GST) and will perform a pulldown experiment. Mass spectrometry will be used to identify proteins whose interactions with the α5 M3M4 loop are dependent upon the Chrna5 D398N polymorphism. Supported by NIDA grant DA017637 and WashU grant CA089392.

## 2124/T/Poster Board #673

**Defining the autism-epilepsy phenotype.** *K. Hamilton[1], R. Tuchman[2], R.K. Abramson[3], H.H. Wright[3], J.R. Gilbert[1], M. Pericak-Vance[1], M. Cuccaro[1].* 1) Miami Inst Human Genomics, Univ Miami Miller Sch Med, Miami, FL; 2) Department of Neuorology, Univ Miami Miller Sch Med, Miami, FL; 3) Department of Neuropsychiatry, Univ SC Sch Med, Columbia, SC.

Autism and epilepsy are common complex disorders. Conservative estimates suggest that ~25%-30% of individuals with autism have a comorbid seizure disorder or epilepsy. Despite ample description of the co-occurrence of autism and epilepsy, a clear understanding of why some children with autism develop epilepsy or why children with autism and epilepsy have a worse outcome has eluded the field. Comorbid features such as epilepsy offer clues as to possible genetic underpinnings for both autism and epilepsy. Given that both autism and epilepsy are clinically heterogeneous, a useful starting point for dissecting the complex genetic etiology of these co-occurring disorders requires definition of the autism-epilepsy phenotype (AE). To define the AE phenotype we identified all cases of autism with co-occurring epilepsy and complete data (n=67) and a comparison group of autism only (AUT) patients (n=412). Logistic regression (LR) modeling was used to determine which variables best differentiated AE and AUT cases. LR model selection procedure used multiple clinical variables including domain scores from the Autism Diagnostic Interview-Revised (ADI-R; Social, Verbal, Nonverbal, Repetitive, and Evidence of Abnormal Behavior), age at single words, age at first phrases, age first walked, age at symptom recognition and gender. Significance threshold for entry into the model was set at 0.10. Inspection of the Vineland Adaptive Behavior Scale composite score (VABS), an indicator of developmental level, revealed that AE cases were significantly lower than AUT controls ($p<0.001$). All subsequent analyses were adjusted for developmental level. Also, the prevalence of females was higher in the AE group vs. the AUT control group ($p<0.005$). In our LR model, four variables distinguished AE cases from AUT: VABS composite, age at symptom recognition, ADI-R Repetitive Behavior Domain score, and Evidence of Abnormal Behavior score. This study defines features unique to the AE phenotype, three of which are developmental in nature. Further, these features suggest a more severe pattern of developmental problems which is consistent with observations that individuals with co-occurring autism and epilepsy have a worse outcome. Our results, while preliminary, set the stage for additional analytic approaches (e.g., structural equation modeling and cluster analysis) as well as biologic and genetic studies to more precisely define the AE phenotype.

## 2125/T/Poster Board #674

**Deafening fever!** *S. Marlin[1, 4], Y. Nguyen[2], L. Jonard[3,4], N. Loundon[2,4], I. Rouillon[2], E. Garabedian[2,4], F. Denoyelle[2,4], D. Feldmann[3,4].* 1) Genetique, INSERM U587, Hosp Armand Trousseau, Paris, France; 2) ENT Unit, Hosp Armand Trousseau, Paris, France; 3) Biochemistry and Molecular Biology Unit, Hosp Armand Trousseau, Paris, France; 4) Reference Center for “Genetic Deafness”, Hosp Armand Trousseau, Paris, France.

Transient deafness associated with an increase in core body temperature is a rare and enigmatic phenomenon. Here, we report a novel mutation in the gene OTOF causing a temperature dependent deafness. Mutations in OTOF, which encodes otoferlin, have been previously reported to cause DFNB9, a nonsyndromic form of deafness caracterized by severe to profound, prelingual hearing impairment and auditory neuropathy. In DFNB9 patients, auditory brainstem responses (ABRs) are absent or severely distorted but otoacoustic emissions (OAE) are preserved. Otoferlin is a calcium sensitive protein that is involved in presynaptic vesicles exocytosis at the auditory inner hair cell ribbon synapse. Three siblings (ages 10, 9 and 7 years old) of a consanguinous family were found to be affected by a profound and transient deafness only present when they become febrile. Audiometric tests revealed an auditory neuropathy. As the family genotype was consistent with linkage to the DFNB9/OTOF region, we underwent a molecular analysis of the 48 exons and of the intron-exon boundaries of OTOF. This study revealed a novel mutation p.Glu1803del (E1803del) in exon 44 of OTOF. It was found to be homozygous in the patients and segregates with the hearing impairment in the family. The new mutation described here is located in the C2F domain of the protein and is associated with an unusual phenotype compared to previous reported cases of patient affected by OTOF mutations. This result open the way for new researches on the physiopathology of auditory neuropathy.

## 2126/T/Poster Board #675

**Chromosome 15 linkage analysis of two repetitive behavior phenotypes in Utah pedigrees with Autism Spectrum Disorders.** *D. Cannon, W. McMahon, K. Allen-Brady, J. Miller, R. Robison, H. Coon.* Department of Psychiatry, University of Utah School of Medicine, Salt Lake City, UT.

Because Autism Spectrum Disorder (ASD) is a heterogeneous phenotype, it has been argued that more specific ASD traits should be included in genetic research. Repetitive and stereotyped behavior, a broad ASD trait, comprises at least two more specific traits measured by different Autism Diagnostic Interview-Revised (ADI-R) items, viz. Repetitive Sensory-Motor Actions (RSMA) and Insistence on Sameness (IS). IS and RSMA differ in their phenotypic correlates and familiality. We investigated in large multiplex pedigrees linkage of both IS and RSMA on chromosome 15 and compared those linkage peaks with peaks we previously reported with ASD in the same pedigrees. Subjects were members of 70 pedigrees having at least two family members with ASD. A total of 653 subjects were genotyped, 192 of whom had a study diagnosis of ASD. RSMA included hand and finger mannerisms, unusual sensory interests, repetitive use of objects, complex mannerisms, and rocking. IS included difficulties with minor changes in personal routine or environment, resistance to trivial changes in environment, and compulsions/rituals. Genotyping services were provided by the Center for Inherited Disease Research (CIDR) using the 6K single nucleotide polymorphism (SNP) linkage panel. We performed parametric and non-parametric linkage analyses and repeated the analyses for each scale based on residual scale scores derived by using the other scale as a covariate. These residual analyses tested the extent to which linkage signals were due to variance unique to IS and RSMA phenotypes. There were two peaks. At 15q13.1-q15.1, RSMA had a max HLOD of 3.93 (NPL=4.54, marker=rs904951), and IS had a max HLOD of 2.00 (NPL n.s., marker=rs965471). At 15q21.1-q22.2, only IS was linked with a max HLOD of 1.88 (NPL=2.60, marker=rs11856). Not only was there no RSMA signal at 15q21.1-q22.2, but the IS residual signal was much stronger (HLOD=3.03, NPL=3.10) than the IS raw score signal, indicating the shared variance between IS and RSMA actually dampened the IS signal at 15q21.1-q22.2. Our findings illustrate the benefit of linkage analysis using homogeneous phenotypes. Two peaks in our previous linkage analysis of ASD affected status appear to be supported by different aspects of repetitive behavior.

## 2127/T/Poster Board #676

**Interstitial 6q deletions may include a novel locus for idiopathic generalized epilepsies.** *E. Andermann[1,2,3], D. Amrom[1,2], J. Lavoie[4,5], M. Veilleux[2,6], F. Andermann[2,6,7].* 1) Neurogenetics Unit, Montreal Neurological Hospital and Institute, Montreal, PQ, Canada; 2) Department of Neurology & Neurosurgery, McGill University; 3) Department of Human Genetics, McGill University; 4) Cytogenetics Laboratory, Montreal Children's Hospital; 5) Department of Pathology, McGill University; 6) Epilepsy Service and Seizure Clinic, Montreal Neurological Hospital and Institute; 7) Department of Pediatrics, McGill University.

Purpose: Chromosome (chr) 6q deletion syndrome encompasses three distinct phenotypes corresponding to proximal (6q11-16), interstitial (6q15-25) and terminal deletions (6q25-qter). Epilepsy has rarely been reported in 6q interstitial deletions. We report the clinical, epilepsy, and array CGH data in a woman with interstitial 6q deletion, febrile seizures and absences, and compare it to our previously reported patient with interstitial 6q deletion and adult onset of myoclonic epilepsy (Andermann E et al., Epilepsia 2008,49(Suppl.7):309-310). Methods: Detailed review of medical records; oligonucleotide microarray of genomic DNA; and fluorescence in situ hybridization (FISH) to confirm the deletions. Results: A 22-year-old woman had febrile seizures at age 3, speech delay at age 4 and later absence attacks. Evaluation showed mild mental deficiency, generalized epileptiform discharges, and at age 13 mild left occipital periventricular leukomalacia. At age 22, she had upslanting eyes, notched eyebrows, micrognathia, microcephaly, mild mental retardation, and absences poorly controlled by valproic acid and topiramate. Karyotype at 4 years revealed a chr6q deletion. Microarray analysis detected a single copy loss of 360 oligonucleotide probes at 6q22.1-22.33 (12.8 Mb, at least 32 OMIM genes), confirmed by FISH. A 31-year-old man had a febrile seizure at age 8 months and developmental delay. At age 14, two hair whorls, small forehead with low frontal hairline, head circumference at P3, mild retrognathia, hyperextensible joints, and mild quadriparesis were recorded. In his late twenties, he developed stimulus-sensitive myoclonic jerks that increased in frequency. Evaluation showed no ictal or interictal epileptic abnormalities, and mild cerebellar vermian atrophy. Karyotype revealed a chr6q22.1-22.2 deletion. Microarray analysis detected a de novo single copy loss of 164 oligonucleotide probes at 6q21-22.31 (7.6 Mb, at least 18 OMIM genes), confirmed by FISH. Conclusions: Chr6q interstitial deletions may have a different epilepsy phenotype (febrile seizures, absences and myoclonus) from that seen with 6q terminal deletions. In one reported GEFS+ pedigree with 15 affected individuals, a novel locus has been mapped to chr 6q16.3-22.31 (Poduri A et al. Epilepsia 2008, 49(Suppl.7): 318-319). Our results suggest that this region might be narrowed to 6q22.1-22.31, and may represent a new locus for idiopathic generalized epilepsies.

## 2128/T/Poster Board #677

**High prevalence of abnormal genomic gains/losses in adults with unexplained intellectual disability.** *J. Jirikowic[1], C. Wells[1], M. Springer[2], K. Swisshelm[2], M. Taylor[1].* 1) University of Colorado Denver, Aurora, CO; 2) Colorado Cytogenetics Laboratory, Denver, CO.

**Purpose:** Array comparative genomic hybridization (aCGH) is now a widely used tool for the evaluation of intellectual disability. Meta-analysis of published data show positive findings in 10% of patients based largely on studies of modest-sized pediatric clinics or from larger clinical referral laboratories where the patient population is also biased towards pediatric cases. Adults with static, unexplained intellectual disability have not been systematically studied with aCGH. Here, we report our experience with aCGH testing on adults with unexplained intellectual disability referred to an adult genetics clinic. **Methods:** In 2006 we began applying clinically available aCGH testing to adults referred with an intellectual disability phenotype. As our laboratory's aCGH testing advanced from 2006-2009, our clinical testing progressed from an early-generation targeted array to a current genome-wide platform, which uses 5,500 clones to achieve an average resolution of 500Kb and targets 114 disease loci. All patients also underwent high-resolution karyotyping and molecular testing for Fragile X syndrome. **Results:** Our population was comprised of 40 patients (16 males, 24 females) with an average age of 35.3 years. All patients had unexplained intellectual disability ranging from mild to severe and only two had documentation of prior normal karyotypes; most had not been evaluated by genetics since childhood or had never undergone a genetic evaluation. Three subjects had abnormalities identified on initial high-resolution chromosome analysis. Twelve of the remaining 37 patients had genomic gains (4) and losses (8) identified only by aCGH. **Conclusion:** Abnormal copy number variation gains and losses detected by aCGH appear are prevalent in adults with unexplained intellectual disability. Our data showing abnormalities in 32% of cases with normal karyotypes suggest that the yield of aCGH in adults with this phenotype may be higher than in pediatric populations.

## 2129/T/Poster Board #678

**Characterization of human iPS cells established from Down syndrome patient-derived fibroblast cell lines.** *M. Hiratsuka[1], N. Uno[2], N. Imaoka[2], S. Masuda[2], K. Ueda[1], Y. Kazuki[2], M. Osaki[2], K. Higaki[3], K. Takahashi[4], S. Yamanaka[4], M. Oshimura[1,2].* 1) Molecular and Cell Genetics, Tottori University, Yonago, Japan; 2) Biomedical Science, Graduate School of Medical Science, Tottori University; 3) Functional Genomics, Research Center for Bioscience and Technology, Tottori University; 4) Stem Cell Biology, Institute for Frontier Medical Sciences, Kyoto University, Kyoto, Japan.

Down syndrome ( DS ) is caused by a whole, or occasionally partial, trisomy 21 resulting in complex and variable phenotypes. The most common phenotype of DS is characterized by mental retardation and late onset Alzheimer disease neuropathology. The mechanism by which trisomy 21 leads to DS phenotypes remains to be elucidated, although two hypotheses, developmental instability theory and gene-dosage hypothesis, are proposed. We have previously created chimeric mice from ES cells containing a single human chromosome 21 and demonstrated that this mouse could be used as a DS-model mouse with various phenotypic abnormalities including abnormal behavior. Furthermore, it has been demonstrated that these ES cells showed a higher incidence of apoptosis during early neural differentiation in vitro, in which some genes responsible for this phenomenon were identified. To validate whether this phenomenon also occurs in human cells, we established iPS clones ( DS-iPSs ) from four DS patient-derived fibroblast cell lines ( Coriell Institute ) by means of Yamanaka Protocol with either four or three factors. DS-iPSs, selected under the morphological criterion, showed the expression of pluripotent markers determined by both immunohistochemistry and RT-PCR analyses. DS-iPSs also exhibited differentiation potential, assessed by the methods of both embryoid body ( EB ) and teratoma formation. We are now under investigation of neural differentiation potential and apoptosis induction during this differentiation in DS-iPSs. Neural differentiation is performed by either co-culture with the mouse PA6 stromal cell line ( SDIA, stromal-derived inducing activity ) or EB formation. The possibility of trisomy 21 enhancing apoptosis of neural precursor cells will be discussed.

## 2130/T/Poster Board #679

**Large scale re-sequencing of autosomal synaptic genes reveals a high rate of de novo deleterious mutations in non-syndromic mental retardation.** *J. Michaud[1], F. Hamdan[1], J. Gauthier[2], S. Dobrzeniecka[2], A. Piton[2], H. Daoud[2], D. Spiegelman[2], M. Côté[2], E. Henrion[2], O. Diallo[2], C. Marineau[2], R. Lafrenière[2], P. Drapeau[3], J.-C. Lacaille[4], G. Rouleau[1,2].* 1) Research Center, CHU Sainte-Justine, Montreal, Quebec, Canada; 2) Research Center, Centre Hospitalier Universitaire de l'Université de Montréal, Montréal, Quebec, Canada; 3) Department of Pathology, Université de Montréal, Montréal, Québec, Canada; 4) Department of Physiology, Université de Montréal, Montréal, Quebec, Canada.

Mental retardation (MR) is a neurodevelopmental disorder affecting ~1-3 % of the general population. A large proportion of patients have the non-syndromic form of the disorder which is characterized by the absence of associated morphological, radiological or metabolic features. Very little is known about autosomal dominant non-syndromic MR (NSMR) genes, mainly because MR results in lower reproductive fitness, decreasing the likelihood of identifying families that are amenable to linkage analysis. In this study, we hypothesized that de novo mutations in genes implicated in synapse function represent an important cause of autosomal dominant NSMR. To identify such mutations, we re-sequenced the coding exons (and their intronic junctions) of 290 autosomal synaptic genes, selected based on functional criteria, in 95 patients with NSMR. We mainly chose sporadic cases with available healthy parents to increase our chance of finding de novo mutations. In total, we identified 12 de novo mutations, including 4 truncating, 2 splicing, and 6 missense mutations, in 9 different genes. Interestingly, de novo truncating mutations in SYNGAP1, which were considered pathogenic based on genetic and functional evidences, were identified in 3 patients, suggesting that haploinsufficiency of this gene may represent a common cause of NSMR. The other 3 truncating / splicing mutations, which were found in STXBP1 (n=2) and SHANK3 (n=1), were also predicted to be pathogenic. SYNGAP1 and SHANK3 have been shown to influence synaptic plasticity whereas STXBP1 is required for neurotransmission. More work is needed to determine whether the missense mutations have any clinical consequences. In conclusion, our study points to a high rate of de novo pathogenic mutations in NSMR, with at least 6 % of the studied patients carrying such mutations.

## 2131/T/Poster Board #680

**Characterization of the Lphn3 mutant mouse; a model for ADHD and addiction vulnerability?** *D. Wallis[1], D.S. Hill[2], L.C. Abbott[3], R.H. Finnell[1,2], P.J. Wellman[4], B. Setlow[4].* 1) Texas A&M Institute for Genomic Medicine, Texas A&M Health Science Center, Houston, TX; 2) Center for Environmental and Genetic Medicine, Institute of Biosciences and Technology, Texas A&M Health Science Center, Houston, TX; 3) Department of Veterinary Integrative Biosciences, College of Veterinary Medicine, Texas A&M University, College Station, TX; 4) Behavioral and Cellular Neuroscience Program Department of Psychology Texas A&M University College Station, TX.

Vulnerability to addiction and ADHD are frequently comorbid, suggesting a common etiology. The LPHN3 gene has already been correlated in linkage and association studies to both addictive phenotypes and ADHD independently. Lphn3 is a member of the LPHN subfamily of G-protein coupled receptors. LPHN3 has been implicated in modulating neurotransmitter release, although the endogenous ligand is unknown. We have utilized a gene-trap embryonic stem cell line to generate mice mutant for the Lphn3 gene. We report initial phenotypic characterization and analysis of this mutant. We have begun our studies by evaluating the Lphn3 expression pattern. We find Lphn3 in the adult amygdala, hypothalamus, hippocampus, subcommissural organ, and olfactory bulb. We have also evaluated differential gene expression between mutant and wildtype male littermates at postnatal day 0 in whole brain RNA. We have evaluated expression of genes commonly considered ADHD candidate genes through TaqMan gene expression assays as well as evaluated genes identified as "neurogenesis and neural stem cell marker" genes through the use of SABiosciences RT-PCR-array. Most notably, we find changes in dopamine and serotonin receptors and transporters (Dat1, Drd4, 5Htt, 5Ht2a), changes in neurotransmitter metabolism genes (Th, Gad1), as well as changes in neural developmental genes (Nurr, Ncam,). Additional preliminary data indicate that the null mice have a hyperactive phenotype in the open field. We are following up with additional behavioral characterization, as well as brain region-specific analyses of dopamine and serotonin levels, which appear to be increased in the dorsal striatum of the mutants. Alterations in energy metabolism of monoamines have been posited as a core deficit in ADHD. Such alterations in these mutants likely affect cognition, motor inhibition, and vulnerability to addiction.

## 2132/T/Poster Board #681

**Genetic Analysis of Korean Patients with Spinocerebellar Ataxia.** *G. Kim[1,2], J. Lee[1], S. Choi[1], B. Lee[1,2], H. Yoo[1,2].* 1) Med Gen Clinic & Lab, Asan Med Ctr, Seoul, Korea; 2) Genome Research Center for Birth defects and Genetic Diseases, Asan Medical Center, Seoul, Korea.

Spinocereballar ataxia (SCA) is characterized by progressive degeneration and dysfunction of the cerebellum, brainstem, and spinal cords. Autosomal-dominant SCA is a genetically heterogeneous disease entity. To date, more than 25 subtypes of SCA have been identified according to their causative chromosomal loci. Genetic testing for 13 subtypes (SCA1,2,3,5,6,7,8,10,12,13,14,17 and 27) are commercially available. In this study, we retrospectively analyzed cumulative data on molecular genetic testing results of SCA1, 2, 3, 6, and 7 in Korean patients. During the period of 1999 to 2008, 638 unrelated Koreans with the presumptive diagnosis of SCA have been referred to Medical Genetics Clinic & Laboratory in Asan Medical Center for genetic testing. The age at the test provided was 45±15 years old. TNR (trinucleotide repeat) copy number was determined by PCR and direct sequencing of the number of (CAG)s using ABI3130 Genetic analyzer. Totally, 128 patients (20.1%) were positive for the test; SCA1 (5, 3.9%), SCA2 (38, 29.7%), SCA3 (30, 23.5%), SCA6 (39, 30.5%), and SCA7 (16, 12.5%). The copy number of SCA1 was 45±8.53, SCA2 42±3.13, SCA3 71±5.39, SCA6 23±1.53 and SCA7 50±11.37. The TNR copy was inversely correlated with the onset age in SCA2, 6 and 7 (P=0.011, 0.001 and 0.043, respectively), but not in SCA 1 and 3. In summary, SCA 1,2,3,6 and 7 were genetically confirmed in 20 % of the Korean patients referred with presumptive clinical diagnosis of SCA, among which SCA 6, 2 and 3 were common subtypes in order. Excluding SCA 1 and 3, inverse correlation between age and TNR copy number was observed in most subtypes. Further study to explain these discrepancies among SCA subtypes and genetic testing of other subtypes of SCA for unclassified patients are necessary.

## 2133/T/Poster Board #682

**Investigating autosomal recessive cerebellar ataxias: clinical, biochemical and neuroimaging studies of 252 Brazilian patients.** *C. Lourenco[1,2], K. Dantas[2], C. Funayama[2], C. Sobreira[2], J. Pina-Neto[1], W. Marques Jr[2].* 1) Dept Med Gen, Univ Sao Paulo, Ribeirao Preto, Brazil; 2) Department of Neurology, Univ Sao Paulo, Ribeirao Preto, Brazil.

Autosomal recessive cerebellar ataxias (ARCAs) comprise a heterogeneous group of inherited neurodegenerative disorders that affect the cerebellum, the spinocerebellar tract and/or the sensory tracts of the spinal cord. They lead to progressive cerebellar ataxia in association with other neurological or extra-neurological signs. The epidemiological features and the relative frequency of such disorders are quite unknown yet. We prospectively studied 252 suspected ARCA patients from Brazil between 2005 and 2008. All patients were evaluated in the neurogenetics clinics with a standard evaluation, neuroimaging studies (CT scan, brain MRI with spectroscopy), ophtalmological and auditory evaluations, neurophysiological studies (EEG, ERG, BAER and EMG/NCV), hormone and biochemical tests, muscle biopsy with respiratory chain mitochondrial analysis, screening for inborn errors of metabolism (enzyme studies, peroxisomal and sterol panels, cholestanol dosage, organic acids, sulfatides and aminoacids chromatography, GAGs analysis), molecular studies for the FRDA expansion and, when indicated, nerve/skin biopsy for EM studies and karyotype. A conclusive diagnosis was established for 196 patients. The most frequent causes for the recessive ataxias seen in our cohort were Friedreich ataxia, vanishing white matter disease, Joubert syndrome (and related disorders), ataxia with oculomotor apraxia types I and II, mitochondrial disorders and neurolipidoses (Niemann-Pick type C and Tay-Sachs B1 variant). ARCAs are rare disorders witb a wide differential diagnosis. Recognition of the most frequent genetic causes of ARCA can lead to a sequential evaluation capable of establishing a definitive diagnosis in the majority of patients, avoid expensive testing and prevent delays in the initiation of treatment when available. .

## 2134/T/Poster Board #683

**Parental consanguinity and idiopathic generalized epilepsy in Hamadan, Iran.** *H. Pour-Jafari[1,2], M. Mazdeh[3], B. Pour-Jafari[2].* 1) Molec Med & Gen, Sch Med, Hamadan Univ Med Sci, Hamadan, Iran; 2) Research Center for Molecular Medicine, Hamadan Univ Med Sci, Hamadan, Iran; 3) Neurology Dept, Sch Med, Hamadan Univ Med Sci, Hamadan, Iran.

Idiopathic generalized epilepsies (IGEs) are a group of disorders determined by strict clinical and electroencephalogram (EEG) features proposed by the International League Against Epilepsy (ILAE) classification of epileptic syndromes. Most IGE patients display a complex pattern of inheritance. In this report the family history and types of paternal marriages in a groups of patients with IGE, in a referral center in Hamadan, Iran were studied and the importance of consanguinity and family history in the occurrence of this type of disease was investigated. In a cross sectional study all patients with epileptic seizer referred to neurology clinic, Farsh'chian Hospital, Hamadan, Iran, were investigated during a period of 6 months. In total, 95 unrelated patients (25 males and 70 females) were diagnosed with idiopathic generalized epilepsies adopted with ILAE classification. Their average age at the time of study was 25.44 (13 y min and 65 y max). The sex ratio (M/F) was 0.36. The types of their disease, family history and parental consanguinity were studied. The results were compared with the same indexes among general population in Hamadan, a city located in the west of Iran. The types of epilepsy among our cases in order of higher to lower frequencies were: Tonic-Clonic (82.1%), Myoclonic (13.7%), Absence (3.2%) and Tonic (1.1%) respectively. Family history was positive in 50.5 per cent of patients. Parental consanguinity was present in 34.7 per cent of cases. The most frequent type of consanguinity was first cousins (34.7%). The percentage of consanguinity marriages in the parents of epileptic individuals was statistically different from general population (chi2=16.14, p=0.000). Based to the results, it seemed that genetic factors, e.g. monogenic mutations, must be considered in idiopathic epilepsies. The results have confirmed that positive family history and paternal consanguinity lead genetic counselors to the role of genetic factors in such families. Also the importance of preventive programs such as school education and pre-marriage genetic counseling should be mentioned by the health organizations in developing countries.

## 2135/T/Poster Board #684

**Detection of large deletions/duplications in *NOTCH3* in CADASIL patients using MLPA.** *E.M.J. Boon[1], M.J. Pont[1], D. van Heusden[1], M.J. Vollebregt[1], P. Lakeman[2], M. Elting[2], S.A.M.J. Lesnik Oberstein[1], H.B. Ginjaar[1].* 1) Clinical Genetics, Leiden University Medical Center, Leiden, Netherlands; 2) Clinical Genetics, VU University Medical Center, Amsterdam, Netherlands.

Cerebral Autosomal Dominant Arteriopathy with Subcortical Infarcts and Leukoencephalopathy (CADASIL) is an adult-onset cerebrovascular disorder caused by mutations in the extracellular EGF-like domains of the *NOTCH3* gene. To date only pathogenic missense mutations and small deletions in *NOTCH3* have been described. To investigate whether large deletions or duplications play a role in CADASIL, we designed a multiplex ligation dependent probe amplification (MLPA) kit for all coding exons of *NOTCH3*. Sixty-one patients with a clinical suspicion of CADASIL were screened using direct sequencing and MLPA. In one patient a compound heterozygous mutation was detected consisting of a missense mutation in exon 13 and a deletion of exon 3-16 of the *NOTCH3* gene. These results show that deletions and/ or duplications are probably rare in CADASIL, but can now be detected using our home made MLPA kit and might play a role in the pathogenesis of CADASIL.

## 2136/T/Poster Board #685

**Single-Step Molecular Determination of Deletional and Non-Deletional Prader-Willi and Angelman Syndromes by Methylation-Specific Quantitative Melting Analysis.** *S.S. Chong[1,2,3], W. Wang[2], H.Y. Law[4].* 1) Department of Pediatrics, Yong Loo Lin School of Medicine, National University of Singapore, Singapore; 2) Children's Medical Institute, National University Hospital, Singapore, Singapore; 3) Molecular Diagnosis Center, Department of Laboratory Medicine, National University Hospital, Singapore, Singapore; 4) DNA Diagnostic and Research Laboratory, Department of Pediatric Medicine, KK Women's and Children's Hospital, Singapore, Singapore.

Prader-Willi syndrome (PWS) and Angelman syndrome (AS) are clinically distinct neurological disorders caused by lack of expression of oppositely imprinted genes in chromosomal region 15q11-13. The loss of expression can be due to parent-specific segmental deletions or can arise from non-deletional mechanisms such as uniparental disomy of chromosome 15 (UPD15) or defects in imprinting. Most of the current diagnostic methods for PWS/AS require separate amplification and detection steps, while current homogeneous assay strategies cannot distinguish between deletional and non-deletional PWS/AS. We have developed a single-step methylation-specific PCR (ms-PCR) assay to analyze methylation differences and copy number changes in PWS/AS. In this assay, bisulfite-modified DNA was subjected to duplex amplification of the *SNRPN* gene and a control amplicon from the *LIS1* gene, in the presence of the DNA binding dye EvaGreen. Qualitative melting curve analysis (MCA) distinguishes the maternal and paternal *SNRPN* amplicons based on their sequence differences after bisulfite modification. Quantitative ratio analysis of the maternal or paternal *SNRPN* peak height relative to the *LIS1* control fragment allows discrimination between deletional and non-deletional PWS and AS. Methylation-specific multiplex ligation-dependent probe amplification (MS-MLPA) was performed in parallel for comparison purposes. Results obtained from this relative quantitative melting curve analysis (RQ-MCA) strategy were completely concordant with the MS-MLPA genotyping results for all deletional and non-deletional PWS and AS samples. RQ-MCA represents a simple, rapid and robust alternative to MS-MLPA for the detection of, and discrimination between, deletional and non-deletional forms of PWS and AS.

## 2137/T/Poster Board #686

**Development of a predictive gene classifier for autism spectrum disorders based upon differential gene expression profiles between cases and controls.** *V.W. Hu.* Biochemistry and Molecular Biology, The George Washington University Medical Center, Washington, DC.

Autism is a neurodevelopmental disorder which is currently diagnosed solely on the basis of abnormal behavior as well as observable deficits in communication and social functioning. Although a variety of autism candidate genes have been identified on the basis of genetic analyses, none have been shown to be unequivocally diagnostic for idiopathic autism or to account for more than a few % of autism cases. DNA microarray analysis was employed to obtain the gene expression profiles of lymphoblastoid cell lines (LCL) of 87 autistic male individuals who were divided into 3 phenotypic subgroups (Hu et al., Autism Research, 2:78-97, 2009) based on cluster analyses of severity scores on the Autism Diagnostic Interview-Revised (ADI-R) assessment instrument (Hu and Steinberg, Autism Research, 2:67-77, 2009). We compared these expression profiles against that obtained from LCL of 29 nonautistic male control subjects. Using these datasets, we then utilized gene classification and cross-validation analysis software (TM4:MeV) to identify sets of differentially expressed genes that have a high statistical probability of predicting cases and controls. We have identified panels of selected genes (less than 30) which correctly classify samples according to affected/unaffected status with an accuracy exceeding 90%. When autistic samples are subtyped according to ADI-R cluster analyses prior to the gene expression and classification analyses, the accuracy of correct assignment to cases and controls exceeds 98%. High throughput quantitative nuclease protection assay of a subset of "classifier" genes (n= 14) for one of the ASD subtypes further confirms the ability of the selected differentially expressed genes to identify autistic and control subjects with an accuracy of ~80%. We suggest that such limited sets of genes may serve as useful biomarkers for diagnosis of idiopathic autism.

## 2138/T/Poster Board #687

**Peripheral blood transcriptome biomarkers to predict epilepsy during early latent period.** *N. Vi[1], A. Bragin[2], A. Mazarati[3], L.C. Kudo[1], S.L. Karsten[1,4].* 1) NeuroInDx, Inc., Signal Hill, CA; 2) Neurology, David Geffen School of Medicine at UCLA, Los Angeles, CA; 3) Pediatrics, David Geffen School of Medicine at UCLA, Los Angeles, CA; 4) Neuroscience, Los Angeles Biomedical Research Institute at Harbor-UCLA Medical Center.

Status epilepticus (SE) is a common cause of hippocampal neurodegeneration and synaptic reorganization that may or may not lead to the development of epilepsy. No effective prognostic tools exist to reliably predict whether chronic epilepsy would develop in post-SE patients. Therefore it is not known which post-SE patients should undergo antiepileptogenic preventive therapy, and for whom the therapy would be effective. We attempted to identify prognostic peripheral biomarkers of epilepsy using a microarray-based approach for the analysis of expression changes in the blood of two rat models of chronic epilepsy. Adult Wistar male rats (postnatal day 90) were subjected to SE induced by either systemic pilocarpine (n=25) or intrahippocampal kainic acid (KA; n=19). Peripheral blood was collected before status epilepticus to establish a baseline and one, three, seven and thirty days after SE. Isolated RNA was used for global transcriptome analysis using Agilent Rat Whole Genome microarrays. After SE, animals underwent continuous monitoring with both EEG and video for the occurrence, frequency and severity of spontaneous recurrent limbic seizures for six weeks. Seizure syndrome was retrospectively correlated with the changes in blood transcriptome profile. Identified gene expression changes were confirmed using semi quantitative RT-PCR and tested for effectiveness in independent group of post-SE kainic acid rats. Microarray data analysis revealed nearly 100 genes in each model associated with later occurring epilepsy. About 20% of the identified genes were regulated similarly in both models. This gene set is an initial class predictor/biomarker associated with later occurring chronic seizures. To further evaluate the effectiveness of the identified biomarkers, an additional group of post-SE animals (kainic acid model) was tested using custom designed prognostic microarray. We have demonstrated that the molecular signature preceding the development of epilepsy is present in the peripheral blood transcriptome, allowing the design of a prognostic biomarker chip that can be used to both screen and diagnose potential epilepsy patients, and to prospectively evaluate the effectiveness of antiepileptogenic therapy.

## 2139/T/Poster Board #688

**Single-tube methylation-specific PCR screen for *FMR1* CGG repeat structure and expansion in fragile X syndrome.** *C. Teo[1,2], C.G. Lee[3,4,5], S.S. Chong[1,2,6]*. 1) Department of Pediatrics, Yong Loo Lin School of Medicine, National University of Singapore, Singapore; 2) University Children's Medical Institute, National University Hospital, Singapore, Singapore; 3) Department of Biochemistry, Yong Loo Lin School of Medicine, National University of Singapore, Singapore; 4) Division of Medical Sciences, Humphrey Oei Institute of Cancer Research, National Cancer Center, Singapore, Singapore; 5) DUKE-NUS Graduate Medical School, Singapore, Singapore; 6) Department of Laboratory Medicine, National University Hospital, Singapore, Singapore.

Fragile X syndrome (FXS) is the most common heritable cause of mental retardation. It is predominantly caused by hyperexpansion and hypermethylation of a CGG trinucleotide repeat in the 5' untranslated region of the *FMR1* gene on chromosome Xq27.3. There are 4 allelic classes of *FMR1* CGG repeats: normal alleles (5 - 44 repeats), gray zone alleles (45 - 54 repeats), premutation alleles (55 - 200 repeats), and full mutation alleles (more than 200 repeats). Full mutation alleles are associated with FXS, while unmethylated premutation alleles have been associated with premature ovarian failure (POF) in females and with late-onset fragile X-associated tremor ataxia syndrome (FXTAS) in males, both of which are clinically distinct from FXS.

The most commonly used methods for analysis of *FMR1* repeats comprise of direct PCR amplification across the repeats, which is unreliable beyond the gray zone range due to the GC-rich nature of this locus, supplemented with Southern blot analysis to detect large repeat expansions, which is labor-intensive and time-consuming. Newer methylation-specific PCR (ms-PCR) methods require multiple reactions and cannot reliably detect all premutations. We describe a novel single-tube strategy involving fluorescent duplex ms-PCR and capillary electrophoresis that reliably distinguishes between all 4 allelic classes of CGG repeats in males and females. Triplet-primed PCR was performed simultaneously on methylated and unmethylated alleles of genomic DNA that had been subjected to sodium bisulfite conversion. The assay was validated on a panel of well-characterized male and female reference DNA samples with repeat lengths spanning the entire size spectrum. All genotype classes were accurately and easily determined based on their unique electropherogram patterns. Importantly, this approach reliably detects the presence of all premutation and full mutation alleles. The electropherogram patterns also inform on the repeat structures of the normal and gray zone alleles, which may aid in genetic counseling. Furthermore, this assay is able to detect skewed X-inactivation in premutation and full mutation females, which may be helpful in correlating with clinical findings. This simple single-tube strategy can serve as a rapid screening assay not only for FXS, but also for POF and FXTAS.

## 2140/T/Poster Board #689

**Virus-mediated gene silencing as a possible cause central nervous system disorders.** *T.C. Pereira, M.L.L. Moraes, I. Lopes-Cendes.* Dept of Medical Genetics, School of Medicine, State University of Campinas, Campinas, SP, Brazil.

Rationale: Human herpesvirus 6B (HHV-6B) was recently associated with a specific type of epilepsy in some pacients; these same individuals showed a significant reduction of EAAT2 messenger RNA. However the mechanism through which EAAT2 is repressed is unknown, as well as whether it is the cause or consequence f HHV-6B replication in affected cells. This is an interesting finding since several viruses can trigger a phenomenon known as virus-mediated gene silencing (VIGS), in which the pathogen represses a certain transcript through siRNAs. Objective: We set out to analyze whether some viruses could promote silencing through VIGS of certain genes expressed in the central nervous system (CNS). Methods - Pairs composed of viral genomes/genes were analysed using softwares (blast; strand analysis, gene runner) to identify viral regions potentially able to promote silencing of the corresponding gene. Results: To date, we have performed 36 complete surveys (3 viruses versus 12 genes). Although six of these presented no evidence of VIGS, most of them (29) showed regions (i.e. siRNAs) with potential for promoting VIGS. Remarkably, one pair: HHV-6B and doublecortin (DCX) showed a region with full complementarity. In addition, we found that the Huntington disease (HD) gene is complementary to regions in several viruses searched. Conclusions: Our computational survey provides evidence for VIGS of DCX by HHV-6B, which should now be investigated through molecular assays for confirmation. As for the HD data one can speculate that VIGS could be one of the postulated non-genetic factors acting as modifiers of the disease phenotype which could be influencing clinical characteristics such as age at onset.

## 2141/T/Poster Board #690

**Gene-Environment Interactions in Parkinson's Disease: CYPs and Pesticides.** *S.L. Rhodes[1], J.M. Bronstein[2], B. Ritz[1].* 1) Dept Epidemiology, UCLA Sch Public Hlth, Los Angeles, CA; 2) Dept Neurology, UCLA Sch Medicine, Los Angeles, CA.

Enzymes of the cytochrome (CYP) P450 superfamily metabolize drugs, endogenous molecules, and exogenous chemicals. Metabolic activity of CYPs varies between individuals and has been attributed to different haplotypes. We investigated CYP2 variants with demonstrated differences in metabolic activity for association with Parkinson's disease (PD) and for impact on PD-pesticide associations in the population-based Parkinson's Environment and Genes (PEG) study. PEG is unique in its assessment of pesticide exposure: an unbiased GIS-based computer model incorporates state-mandated reports of commercial agricultural pesticide use, historical land use maps, and residential addresses to estimate pesticide-specific exposure from 1974 to 1999 for each subject. 361 cases and 368 controls were genotyped for poor metabolizer (PM) variants: CYP2C9*2 and *3, CYP2C19*2 and *3, and CYP2D6*3 and *4. Maneb, paraquat, chlorpyrifos, and diazinon were investigated for interaction with CYP PM genotypes in age, sex, smoking adjusted logistic regression. No 'main effect' associations were observed between CYP PM variants and PD. 1.5- to 2-fold increases in risk were observed for the combination of maneb and paraquat (Mb/Pq; p=0.0045), chlorpyrifos (p=0.01), and diazinon (p=0.07), but not for paraquat alone (p=0.9). We observed no change in PD risk (OR=0.90 [0.11-7.18] p= 0.9227) by Mb/Pq exposure for subjects with the PM genotype of CYP2D6, but observed an increase in risk for subjects exposed Mb/Pq and possessing the wild type (WT) genotype (2.73 [1.58-4.75] p=0.0003) when compared to subjects exposed to neither pesticide. Similar associations were seen for CYP2C9 and CYP2C19 WT with Mb/Pq exposure (2.02 [1.21-3.38] p= 0.0074; 1.89 [1.11-3.21] p=0.0195, respectively). We observed suggestive negative association for CYP2D6 PM genotype (0.53 [0.11-2.55] p=0.4289) and significant risk association for the WT genotype (1.88 [1.28-2.76] p= 0.0014) in subjects exposed to the organophosphate (OP) chlorpyrifos, but not the OP diazinon, compared to unexposed subjects of the same genotype; this association remained after adjusting for Mb/Pq. These findings are in contrast to prior studies. Our frequency of CYP2D6 PM is low (5%) and our interaction analyses likely under-powered. Our results suggest that mechanisms underlying pesticide-gene interactions in PD are complex. Future GxE investigations should concentrate on high quality, unbiased exposure assessment over appropriate time periods.

## 2142/T/Poster Board #691

**Neuropathy target esterase mutations in individuals with sporadic ALS.** *S. Rainier[1], B. Bentley[1], T. Siman-Tov[1], T. Tobin[1], J. Moore[1], R.H. Brown, Jr.[2], J.K. Fink[1,3].* 1) Department of Neurology, University of Michigan, Ann Arbor, MI; 2) Neurology, University of Massachusetts School of Medicine; 3) the Geriatric Research, Education, and Clinical Center, Ann Arbor Veteran's Affairs Medical Center, Ann Arbor, MI.

Neuropathy target esterase (NTE) is a widely distributed membrane phospholipase that is implicated in the pathogenesis of both organophosphorus compound induced delayed neuropathy (OPIDN) and autosomal recessive motor neuron disease (NTE-MND). In the case of OPIDN, a disorder that includes progressive spastic paraplegia and peripheral neuropathy, organophosphorylation of NTE's active site serine leads to inhibition of NTE esterase activity and formation of toxic or "aged" NTE. NTE-MND is an autosomal recessive MND characterized by progressive spastic paraplegia and wasting of distal upper and lower extremity muscles and is similar to that of OPIDN. Individuals with NTE-MND have homozygous or compound heterozygous mutations involving NTE's esterase (NEST) domain. Finding that NTE is implicated in both a neurotoxin induced motor neuron disorder (OPIDN) and a form of autosomal recessive MND raises the possibility that abnormalities involving NTE or its biochemical pathways may contribute to other motor neuron disorders including amyotrophic lateral sclerosis (ALS). We investigated this possibility by examining the NTE coding sequence in subjects with ALS. We focused our analysis on the ten exons (exons 22 through 32) that together encode NTE's esterase domain because this was the location of NTE-MND mutations. We used heteroduplex analysis and DNA sequencing to analyze NTE exons 22 through 32 in DNA samples from 100 individuals with apparently sporadic ALS and an equal number of control subjects. Three ALS subjects were found to be heterozygous for novel, amino acid substituting mutations that disrupted inter-species conserved residues in NTE's esterase domain: Q756R, G942A and H1023Y. One of these subjects had an additional heterozygous, novel, amino acid substituting mutation in an exon outside of NTE's esterase domain (V19A). Each of these mutations was absent in at least 105 control individuals and is predicted to be not tolerated by SIFT analysis. Analysis of the biochemical and functional consequences of NTE mutations in ALS subjects is in progress. Our findings support the importance of NTE in motor neuron biology; and support the possibility that genetic variation in NTE is a contributing factor to the development of "apparently sporadic" ALS.

**Mutation Analysis of GIGYF2 Gene in Chinese Patients with sporadic late-onset Parkinson's Disease.** *JF. Guo[1,3], BS. Tang[1,2,3], L. Wang[1], WW. Zhang[1].* 1) Department of Neurology, Xiangya Hospital, Central South University, Chagsha, Hunan, China; 2) National Laboratory of Medical Genetics of China, Changsha, Hunan 410008, PR China; 3) Neurodegenerative disorders research center, Central South University, Changsha, Hunan 410008, PR China.

Objective:Establish a technical platform by using Polymerase Chain Reaction (PCR) and DNA sequencing to detect the mutations of GIGYF2 gene in Chinese patients with sporadic late-onset Parkinson's Disease, to make clear the mutation characteristics of GIGYF2 gene in Chinese PD patients. Methods:Mutation analysis of GIGYF2 gene in 300 unrelated Chinese patients with late-onset PD was performed using DNA sequencing. Results:We found 8 allele changes of GIGYF2 gene in 300 Chinese patients with sporadic late-onset PD, which were not found in DNA sequencing reports of the 200 controls. They are as follows: c.G766A,c.-C1130A,c.C1417T,c.C1555T,c.GG1474-1475AA, c.C1738A, c.C2935T, c.G3208C. All of them were new mutations according to bdSNP data. The mutation frequency of GIGYF2 gene among Chinese Han patients with sporadic late onset PD is 2.7%. In our research we did not find any mutations which had been reported. Conclusion:The mutations of GIGYF2 gene might be the etiological factors of Chinese sporadic late-onset PD.

## 2144/T/Poster Board #693

**Depression in Alzheimer's disease - the role of life events, epigenetics and genetics.** *P. PROITSI[1], J. MILL[2], JP. POWELL[1].* 1) NEUROSCIENCE, MRC CNR, KING'S COLLEGE LONDON, INSTITUTE OF PSYCHIATRY, LONDON, LONDON, United Kingdom; 2) SGDP, KING'S COLLEGE LONDON, INSTITUTE OF PSYCHIATRY, LONDON, LONDON, United Kingdom.

Many patients with Alzheimer's disease (AD) have depressive symptoms with serious consequences for patients and caregivers. Interactions between stressful life events (SLE), polymorphisms in the serotonin transporter (SERT) and brain-derived neurotrophic factor (BDNF) genes and depression have been described in children and adults, though this has not yet been studied in AD. The expression of the BDNF gene is highly complex with multiple promoters subject to epigenetic modification. BDNF and SERT act in concert to regulate neuronal plasticity and may be both compromised in aging and age-related neurodegenerative disorders making them good candidates for depression in AD. Our aim was to examine the relationships between epigenetic modification in the BDNF gene, polymorphic variation in the BDNF and SERT genes, and SLE in AD patients with depression. The HTTLPR and STin2 polymorphisms of the SERT gene and the Val66Met polymorphism of the BDNF gene were genotyped for ~1000 probable AD patients including 40 autopsy confirmed AD brains (and 5 controls) from the UK with full behavioural data including the Cornell Scale for Depression. Demographic data was used to quantify SLE. Three CpG islands regions from the BDNF promoter were investigated, capturing more than 100 CpGs, using the Sequenom MassARRAY EpiTYPER platform. DNA was extracted from 7 different brain regions (BA8, BA9, BA10, BA46, Entorhinal Cortex, Superior Temporal Gyrus and Occipital Cortex) and methylation analysis was performed on each area and genomic lymphocyte DNA from all 45 samples as well as an additional 150 lymphocyte DNA samples. A significant association was identified between the number of SLE and depression (p=0.005) in the whole dataset. No significant associations between the examined polymorphisms and depression in AD were identified. A very significant association between hypermethylation in a CpG island approximately 800bp upstream the major transcription start site and higher levels of depression ($R^2$=0.679, p=0.002) was seen in lymphocyte DNA. No interaction was identified with BDNF Val66Met polymorphism or/and SLE. Results from patients' brain tissue provide an indication on different methylation patterns of different tissues. Investigation of the interaction of genetics, epigenetics and environment allow us to examine the possibility of detecting a peripheral biomarker for depression and life events in AD.

## 2145/T/Poster Board #694

**Glucocerebrosidase gene mutations and Parkinson disease in Chinese population.** *BS. Tang[1,2,3], JF. Guo[1,3], QY. Sun[1].* 1) Department of Neurology, Xiangya Hospital, Central South University, Changsha, Hunan 410008, PR China; 2) National Laboratory of Medical Genetics of China, Changsha, Hunan 410008, PR China; 3) Neurodegenerative disorders research center, Central South University, Changsha, Hunan 410008, PR China.

Objective: To evaluate the association between Parkinson disease (PD) and mutations in the glucocerebrosidase gene (GBA) in Chinese population. Background: Mutations in the glucocerebrosidase (GBA) gene have recently been identified as contributing to the development of Parkinson disease (PD) in several populations. Methods: PCR restriction enzyme assay and DNA sequencing of four GBA common mutations (L444P, F213I, R353W and N370S) were carried out in 402 Chinese patients with PD and 413 age- and sex-matched controls. Results: Among the 402 Chinese Parkinson disease patients, we found eleven patients (2.74%) who carried a heterozygous mutant GBA allele. The eleven heterozygotes have the L444P mutation. The average age at disease onset of the eleven patients was 54.64 years, comparable to the disease onset in the total patient group (54.79). All eleven patients carrying a GBA mutation presented with a typical parkinsonian phenotype and had a good or excellent response to levodopa. No heterozygotes were found among the 413 age- and sex-matched controls. We compared the frequency of heterozygotes for GBA mutations among PD patients (11/402) and the control group (0/413) by means of the chi-square test. The difference was statistically significant ( 2=11.456,P=0.001). Conclusions: Our results demonstrate that the GBA gene mutations appear to be a risk factor for Parkinson disease in China .

## 2146/T/Poster Board #695

**Influence of Variations in Two Serotonin Genes and Gender Differences on Learning and Memory.** *E. Vitale[1], P. Khanna[2], C. Myers[2], M.A. Gluck[2].* 1) Institute of Cybernetics, CNR, Pozzuoli (NA) - Italy; 2) Center for Molecular and Behavioral Neuroscience Rutgers University - Newark.

There has been a long-standing debate on whether the basis for individual differences in performing behavioral tasks is rooted in nature or nurture, or more simply put, genetics or environment. In other words, it is still unclear if differences in human learning and memory principally reflect genetic factors, environmental factors or both. We used two polymorphisms of serotonin related genes to address this question. One, a 44-nucleotide insertion/deletion in the promoter region of the serotonin transporter gene (5HTTLPR), already implicated in deficits in different areas of personality measures and learning. The other, a single nucleotide polymorphism of the serotonin 2a receptor gene (His452Tyr), associated with deficits in delayed verbal memory. Our study investigates the relationship of these specific genetic variations to reward and punishment learning, and to personality traits assessed using Cloninger's Tridimensional Personality Questionnaire (TPQ). This study showed that the polymorphism of the serotonin receptor gene does not play a role in underperformance in delayed recall of words. However, males carrying one or more of the Tyr allele scored lower on both the Beck Depression Index and the Harm Avoidance personality trait of the TPQ than males carrying two His alleles. Both genetic and gender differences were found to significantly affect reward learning, where males outperformed females. In addition, individuals carrying both the Long-Tyr and Short-His genotype outperformed individuals carrying both the Short-Tyr and Long-His genotype. Interestingly, the Reward Dependence trait of the TPQ was influenced by the serotonin transporter polymorphism, where females with the long genotype tended to score higher than females with the short genotype. This study shows that both environmental and genetic factors play a major role in differences in learning and memory in healthy individuals.

## 2147/T/Poster Board #696

**The research on the association between C2264T,G4883C,G7153A variants in LRRK2 gene and sporadic Parkinson's disease in Han population.** *LY. Yao[1], BS. Tang[1,2,3], JF. Guo[1,3], L. Wang[1].* 1) Department of Neurology, Xiangya Hospital,Central South University, Changsha, Hunan, China; 2) National Laboratory of Medical Genetics of China, Changsha, Hunan 410008, PR China; 3) Neurodegenerative disorders research center, Central South University, Changsha, Hunan 410008, PR China.

Background: The LRRK2 mutation and single nucleotide polymorphism (SNP) vary among different ethnicities. Recent researches discovered that certain SNP in LRRK2 gene may increase the risk for Parkinson's disease, and may differentiate patient subgroups and influence future individualized therapeutic strategies. Objective and Method: We conducted a case-control study to determine the prevalence of C2264T(Pro755Leu), G4883C(Arg1628Pro)and G7153A(Gly2385Arg) variants in LRRK2 gene in 401 patients with sporadic PD and 398 unrelated healthy controls in Han population in central part of China, and carried out an association analysis among these three SNPs. We utilized restricted fragments length polymorphism and DNA sequencing methods to identify genotype of these three variants. Result: 1: There is no statistical difference in genotype or allele frequencies of C2264T variant in LRRK2 between sporadic PD patient group and healthy control group(genotype: $\chi2$ =0.657, P=0.686; allele: $\chi2$ =0.654, P=0.687) 2. There is no statistical difference in genotype or allele frequencies of G4883C variant in LRRK2 between sporadic PD patient group and healthy control group(genotype: $\chi2$ =2.02, P=0.248; allele: $\chi2$ =2.02, P=0.248) 3. There is no statistical difference in genotype frequencies of G7153A variant in LRRK2 between sporadic PD group and healthy control group ($\chi2$ =3.71, P=0.156), yet there is statistical difference in allele frequencies of G7153A variant in LRRK2 between sporadic PD patient group and healthy control group ($\chi2$ =3.92, P=0.048, OR=1.66, 95%CI: 1.00-2.76). 4. C2264T, G4883C and G7153A variants in LRRK2 are independent respectively without linkage disequilibrium.(all values of r2 equal to zero) 5. Logistic regression analysis reveals that the regression model admitting age, gender, and genotype of G7153A as independent variables is statistically significant (P<0.05) and age is an independent risk factor for PD(OR=1.997, 95% CI: 1.474-2.706, P<10-3). Conclusion: Neither C2264T(Pro755Leu) or G4883C(Arg1628Pro)in LRRK2 gene is a risk factor for the onset of PD in Han population in central part of China. Both of them are rare in Han population in central part of China. G7153A(Gly2385Arg) in LRRK2 gene is a risk factor for PD in Han population in central part of China. C2264T, G4883C and G7153A variants in LRRK2 gene are independent respectively without linkage disequilibrium.

## 2148/T/Poster Board #697

**Mutant TBP reduces the expression of HSPB1 through abnormal interacting with the NF-Y transcription factor.** *s. huang, M. Roberts, X. li, S. Li.* Department of Human Genetics, Emory University School of Medicine.

Expansion of the polyglutamine (polyQ) tract in human TATA-box binding protein (TBP) causes spinocerebellar ataxia 17 (SCA17),one of the nine polyQ neurodegenerative diseases. It remains unclear how the polyQ tract regulates normal protein function and induces selective neuropathology in SCA17. We generated conditional SCA17 conditional knock-in (KI) mice using mouse endogenous promoters to express mutant TBP at the endogenous level via Cre/loxP recombination system. These mice showed progressive weight loss, neurological symptoms, and neurodegeneration. We found that mutant TBP aggregates co-localized with the components of the NF-Y transcriptional factor in vitro and in transgenic mouse brain. Compared to normal TBP, mutant TBP shows enhanced interaction with one isform of the NF-Y transcriptional factors, NF-YA. Our lab previously reported that, in SCA17 transgenic mice, the small heat shock protein HSPB1, a potent neuroprotective factor, was downregulated. The luciferase reporter assay using mutant TBP and HSPB1 reporter expressed in HEK293 cells showed decrased luciferase intensity. These data indicate that mutant TBP seqesters NF-Y to reduce HSPB1 gene expression and causes transcriptional dysregulation in SCA17 mouse brain, providing insight into the molecular pathogenesis of SCA17. Supported by NIH grants NS045016. Norminator for ASHG trainee awards Xiao-Jiang Li, Membership ID:44111, E-mail:xli2@emory.edu.

**The carboxy-terminal fragment of $\alpha$1A -calcium channel preferentially aggregates in human spinocerebellar ataxia type 6 cerebella.** *T. Ishiguro, K. Ishikawa, H. Mizusawa.* Dept Neurology and Neurological Science, Tokyo Medical & Dental Univ, Tokyo, Japan.

Spinocerebellar ataxia type 6 (SCA6) is an autosomal dominant neurodegenerative disease caused by an expansion of polyglutamine (polyQ) tract in the carboxyl(C)-terminal cytoplasmic domain of $\alpha$1A voltage-dependent calcium channel protein (Cav2.1). It remains controversial whether the main toxicity depends on the loss change of P/Q type Ca channel function, or gain of function mechanism accompanied by accumulation of misfolded protein because of relatively small polyQ expansions compared with other polyQ diseases. We conducted this study to clarify how a small expansion alters Cav2.1 expression pattern in human SCA6 brains. Two new antibodies against the Cav2.1 C-terminus were applied in western blotting and immunohistochemical analyses. First, we showed that C-terminal fragments (CTF) of Cav2.1 (75~85 kDa size) were present in human brains. Second, we could segregate the CTF from purified cytoplasmic aggregates and also found the CTF with polyQ in the nucleus in SCA6 cerebella. On the other hand, we detected the CTF only in cytoplasm in normal control cerebella. In accord with these data, we demonstrated that CTF with small polyQ(Q28) formed oligomers and visible aggregates in cultured cells. We conclude that a small polyQ expansion, within normal length in other polyQ diseases, could confer propensity for protein aggregation on the CTF. SCA6 could have aspects disorders of protein misfolding and oligomer formation similar to other polyglutamine diseases.

## 2150/T/Poster Board #699

**Clinical heterogeniety and gene mutation frequencies in spinocerebellar ataxias with only predominant cerebellar features.** *K. Ishikawa, T. Amino, N. Sato, T. Ishiguro, M. Takahashi, M. Ohbayashi, H. Mizusawa.* Dept Neurology, Tokyo Med & Dental Univ, Tokyo, Japan.

Spinocerebellar ataxia (SCA) is a group of heterogeneous conditions both clinically and genetically. It may not be difficult to predict which gene mutations patients have, when their clinical presentations are typical. However, predicting gene mutations would be difficult on patients without obvious neurological symptoms except for cerebellar dysfunctions (i.e., predominant cerebellar features). This study was conducted to clarify clinical features of patients with predominant cerebellar features useful for predicting gene mutations. Sixty-five consecutive patients who were referred to our facility for genetic testing were studied. After molecular diagnosis, clinical features characterizing SCA subtypes were retrospectively searched. Among enrolled patients, 35% of patients were SCA6, and 30% were the chromosome 16q22.1-linked autosomal dominant cerebellar ataxia (16q-ADCA). Machado-Joseph disease (MJD) was the third frequent (10%) subtype of pure cerebellar syndrome. SCA14, SCA15 or SCA8 were not seen in our cohort. The remaining 25% of patients were patients without known mutations. Clinically, age of onset was higher in 16q-ADCA than SCA6 (SCA6: 45 years vs 16q-ADCA 60 years), and MJD had a mild limitation on upward gaze. We conclude that among patients with predominant cerebellar features, age-of-onset and eye signs could be good predictors for molecular diagnosis.

**Analysis of SCA2 and SCA3/MJD repeats in Parkinson's disease in mainland China, genetic, clinical, and PET findings.** *W. Junling[1,2], B. Xiao[1,2], X.X. Cui[1,2], J.F. Guo[1,2], L.F. Lei[1,2], X.W. Song[1,2], L. Shen[1,2], H. Jiang[1,2], X.X. Yan[1,2], Q. Pan[3], Long. Zhigao[3], Xia. Kun[3], Tang. Beisha[1,2,3].* 1) XiangYa Hospital Central South University, ChangSha, 86., China; 2) Neurodegenerative Disorders Research Center, Central South University,-ChangSha,86,China; 3) National Lab of Medical Genetics of China, Changsha, 86. China.

Background: Recent reports suggest that CAG triplet expansions of spinocerebellar ataxia type 2 and 3 (SCA2 and SCA3/MJD) genes (ATXN2 and MJD1) are the cause of typical levodopa-responsive Parkinson's disease (PD), several of which were found in patients of Chinese ethnicity. It is unclear whether ethnicity (or founder effects within certain geographical region) alone can explain such an association. Objectives: To investigate the prevalence and clinical feature(s) of SCA2 and SCA3/MJD in patients with Parkinsonism in a Mainland Chinese population and to find the difference in the SCA2 and SCA3/MJD mutations between ataxic and parkinsonian phenotypes. Patients and Methods: CAG triplet repeat expansions of ATXN2 and MJD1 genes were analyzed in a cohort of 452 Mainland Chinese patients affected by typical Parkinsonism, including 386 sporadic and 66 familial forms. Cloning and direct sequencing of the expanded allele was performed in patients positive for the ATXN2 and MJD1 expansion. Striatal dopamine transporter (DAT) was evaluated in one SCA2 and one SCA3/MJD-positive family members using carbon (C 11) [11C]-radiolabeled-CFT positron emission tomography (PET). Results: We found two patients in one familial PD (FPD) family (1.5%) and two sporadic PD patients (0.5%) with expanded CAG repeats in the ATXN2 locus, The expansions ranged from 36 to 37 repeats and were interrupted by CAA as (CAG)n(CAA)(CAG)8 in all the ATXN2 expansion-positive patients. Meanwhile, we found four patients in two FPD families (3%) and another three sporadic PD patients (0.8%) in the MJD1 locus, The expansions ranged from 58 to 73 repeats and were not interrupted by CAA or other variants. All patients had levodopa-responsive Parkinsonism without obvious cerebellar signs. [11C]-CFT PET in affected members in SCA2 and SCA3/MJD families showed decrements of 11C-CFT uptake in all patients listed above. Conclusions: A mutation in SCA2 or SCA3/MJD is one of the genetic causes of PD, specifically FPD, in Mainland China. Parkinson's disease patients, especially those with a family history of PD are strong candidates for routine screenings of SCA2 and SCA3/MJD mutations. [11C]-radiolabeled-CFT PET can provide a useful way to evaluate the degree of nigrostriatal dopaminergic damage in SCA2 and SCA3/MJD-related Parkinsonism.

## 2152/T/Poster Board #701

**Development and analysis of an expanded ataxia protein interaction network that contains CACNA1A and Ataxin-7 and their partners.** *J.J. Kahle[1], N. Gulbahce[2,3], J. Lim[1], C.A. Shaw[1], A.L. Barabasi[2,4], H.Y. Zoghbi[1,5,6,7,8].* 1) Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX 77030, USA; 2) Center for Cancer Systems Biology and Department of Cancer Biology, Dana-Farber Cancer Institute, 1 Jimmy Fund Way, Boston, MA 02115, USA; 3) Department of Physics and Center for Complex Network Research, Northeastern University, Boston, MA 02115, USA; 4) Center for Complex Network Research and Department of Physics, University of Notre Dame, 225 Nieuwland Science Hall, Notre Dame, IN 46556, USA; 5) Department of Pediatrics, Baylor Col Medicine, Houston, TX 77030, USA; 6) Division of Neuroscience, Baylor Col Medicine, Houston, TX 77030, USA; 7) Program in Developmental Biology, Baylor Col Medicine, Houston, TX 77030, USA; 8) Howard Hughes Medical Institute, Baylor College of Medicine, One Baylor Plaza, Houston, TX 77030, USA.

Several inherited Spinocerebellar ataxias (SCA) are caused by expansion of CAG repeats encoding polyglutamine (polyQ) tracts in proteins of diverse functions. Our lab generated a protein interaction network for ataxia-causing proteins using a high-stringency yeast 2-hybrid screen. Two key ataxia-causing proteins, CACNA1A and Ataxin-7, were not well represented in the network because we failed to identify their interacting partners. We hypothesized that using fragments of the coding region for each of these proteins would prove more successful for identifying interacting partners, and that placing these two proteins and their partners in the network would provide insight about their functions. CACNA1A, the alpha1A subunit of the P/Q-type calcium channel has two predominant splice forms: the MPI isoform contains the CAG repeat in-frame and encodes a polyQ tract in the C-terminus, whereas the MPc isoform lacks the polyQ tract. We screened a human brain cDNA library using baits for both isoforms and identified 86 interacting proteins, 15 of which interact exclusively with the MPI isoform. We also generated overlapping protein-fragment baits for Ataxin-7, a component of a chromatin-remodeling complex, and identified 49 interacting partners. We tested over 30%; of the interactions in mammalian cells by co-affinity purification and validated 77%; of them. We integrated CACNA1A , Ataxin-7, and their partners in the ataxia network and found high connectivity of the ataxia-causing proteins. We next used the ataxia network and Medicare patient data to examine gene-disease interactions for proteins that are in the network and diseases that are comorbid with ataxia. We found the relative risk of macular degeneration (MD) is significantly higher (2.35 fold increase) if a patient has ataxia. We therefore scrutinized the ataxia network and discovered a subnetwork that contains two MD associated proteins. These MD proteins interact with proteins not previously studied in the retina. We tested all of the novel components of the subnetwork and found that all are expressed in the retina. This type of analysis on the ataxia network provided insight into the functional relationship of the ataxia proteins, their interacting partners, gene-disease relationships and comorbidity.

## 2153/T/Poster Board #702

**Activation of p38MAPK and decreased expression of HSP70 in transformed lymphoblastoid cells from patients with Machado-Joseph disease.** *H. Tsai[1], C. Chan[1], W. Lee[2], T. Chen[3].* 1) School of Medical Laboratory and Biotechnology, Chung Shan Medical University, Taichung, Taiwan; 2) Feng Chia University, Taichung, Taiwan; 3) National Taichung Institute of Technology, Taichung, Taiwan.

Machado-Joseph disease (MJD, also called spinocerebellar ataxia type 3) is an autosomal dominant neurodegenerative disorder caused by an expansion of unstable CAG repeats in the coding region of MJD gene (chromosomal locus 14q24.3-q31). This disease is also associated with an accumulation of abnormal proteins, including expanded polyglutamine-containing proteins, molecular chaperones, and the ubiquitin-proteasome system. In this study, two MJD lymphoblastoid cell lines (LCLs) were utilized to examine the effects of polyglutamine expansion on heat shock proteins. Interestingly, under basal conditions, Western blot and semi-quantitative RT-PCR analyses showed a significant decrease of HSP70 protein expression in cells containing expanded ataxin-3, as compared with that of the normal LCL. The heat shock protein HSP70 had strong anti-apoptotic properties and functioned at multiple steps of the apoptotic-signaling pathway. The role of p38MAPK which plays an important role in coordinating genetic responses to various stresses, were subsequently analysis from expanded ataxin-3 and control cells by Western blot analysis with a phospho-p38MAPK antibody. Our data revealed that the expression of expanded ataxin-3 resulted in elevation of p38MAPK phosphorylation. The above results suggested that the activation of p38MAPK may be responsible for the increased cell death observed in expanded ataxin-3 expressing cells. Moreover, interfering with p38MAPK phosphorylation could rescue cells from polyglutamine-induced toxicity. Taken together, our results indicate that expanded ataxin-3 which leads to neurodegeneration can significantly impair the expression of HSP70 proteins and ultimately result in an increase of stress-induced cell death.

**A neuropathological study of two autopsy cases of early-onset spinocerebellar ataxia 6.** *X.J. Wang[1,2], B.S. Tang[1,2], H. Wang[1,2], H. Jiang[1,2], L. Shen[1,2,3].* 1) Xiangya Hospital, Central South University, ChangSha, Changsha, China; 2) Neurodegenerative Disorders Research Center,Changsha,China; 3) National Lab of Medical Genetics of China,Changsha,China.

Background: Spinocerebellar ataxia type 6 (SCA6) is a late onset autosomal dominantly inherited ataxic disorder, and is among the known CAG-repeat diseases. The permanent and progressive character of the cerebellar deficit mainly starting in the third to fifth decade of life led many researchers to consider SCA6 as a 'pure' cerebellar ataxia of late onset. Patients and Methods: Here, we describe a family with spinocerebellar ataxia type 6, characterized by an earlier onset and a more rapid course. Results: In the two patients we observed more severe neurodegeneration in cerebellum, dentate nucleus and olivary nuclei, furthermore, we show the evidences of synaptic modification in the cerebellar cortex. Conclusions: Morphologically, these findings confirm the mechanisms underlying neurodegeneration in inferior olivary complex and dentate nucleus, which interpreted as the retrograde transsynaptic degeneration and the anterograde transsynaptic degeneration secondary to the cerebellar cortical lesion. **TP-PCR Revisited.** *J. Warner, M.E. Porteous.* S.E. Scotland Genetic Service, Western General Hosp, Edinburgh, United Kingdom.

In 1996 we published a generally applicable method for the amplification of tandemly repeated tri-nucleotide sequences (1). The original fluorescent "Triplet Repeat Primed PCR" assay was designed to analyse the 3'UTR CTG repeat of the DMPK gene which is expanded in myotonic dystrophy (DM1). Derivations and extensions of this assay have been used with great success in this and other laboratories for the many different tandemly repeated units involved in disease. Nearly all published assays re-use our original tail primer sequences and tail repeat combinations. We present a series of improved DM1 TP-PCR assays with optimal reaction component and primer choices. We outline a general set of primer design rules for the selection of flanking primers, tails and tail primers leading to improved peak ladder length and uniformity for any tandem repeat unit. We demonstrate how TP-PCR copes well with template heterogeneity arising from mitotic instability or mosaicism giving a better estimate of average expansion size than long range PCR methods. We demonstrate how the "boundary lock" effect which gives maxima within the ladder of peaks at true alleles <100 repeats arises. We show how boundary locking can be manipulated to reduce preferential amplification of smaller alleles. Using these simple rules TP-ladders in excess of 1kb in size are achievable. Adoption and extension of these principles should ultimately lead to the demise of the diagnostic Southern blot for the tri-nucleotide repeat disorders. (1) J Med Genet 1996, 33: 1022-1026.

## 2156/T/Poster Board #705

**Alterations in alternative splicing in a knockin mouse model of FXTAS.** *J.N. Galloway[1], R. Willemsen[2], B.A. Oostra[2], D.L. Nelson[1].* 1) Baylor College of Medicine, Houston, TX; 2) Erasmuc MC, Rotterdam, The Netherlands.

Fragile X-associated Tremor/Ataxia Syndrome (FXTAS) is a late onset neurodegenerative disorder which primarily affects male Fragile X premutation carriers. We and others have shown that expanded noncoding CGG containing repeat RNAs are toxic to neurons. The current molecular model for FXTAS suggests the pathogenic RNA can sequester RNA binding proteins as well as other known and unknown cellular proteins into intranuclear inclusions preventing these proteins from performing their normal cellular functions and thus leading to clinical features of FXTAS. This model is very similar to the disease model for the myotonic dystrophies where one of the downstream effects of protein sequestration to pathogenic RNAs is misregulated alternative splicing. Using an expanded knockin mouse model of FXTAS we have performed a biased screen for changes in known splicing events in brain, heart and skeletal muscle. We find that at least two genes, Agrin and Protein tyrosine phosphotase receptor, type F (*Ptprf*) exhibit altered splicing patterns showing increased exclusion of exon 31 and increased inclusion of exon 19a respectively. Additionally, we observe increased expression of *Fxr1* fetal isoform C in expanded skeletal muscle. These results suggest that misregulated splicing events may be the link to disease phenotypes in FXTAS. Ongoing efforts to characterize splicing events on a genome-wide level using microarrays and deep sequencing will help us to have a better understanding of genetic changes which lead to neurodegeneration.

**Correlation of nuclear accumulation of expanded polyglutamine and dysregulation of sodium channel β4 subunit in Huntington disease transgenic mice.** *F. Oyama[1,2], H. Miyazaki[2], M. Yamada[2], M. Kurosawa[2], Y. Kino[2], N. Nukina[2].* 1) Dept Applied Chemistry, Kogakuin Univ, Hachioji, Tokyo, Japan; 2) Lab Structural Neuropathology, RIKEN BSI, Saitama, Japan.

Nuclear accumulation (NA) of the expanded polyglutamine has been identified before the onset of neuropathology and neurological phenotypes in the Huntington Disease (HD) mice. Transcriptional dysregulation is a main pathological feature of HD. However, the role of NA in the transcriptional dysregulation remains unclear. We identified sodium channel β4 subunit (β4) as an early affected gene in HD mice. To assess the correlation between NA formation and dysregulation of β4, we developed several β4 promoter-Venus (a variant of GFP) transgenic mouse lines which showed distinct expression patterns of the transgene. They were crossed with HD mice and analyzed at the presymptomatic stage. In double transgenic mice, we observed that Venus expression was reduced in NA bearing cells, whereas it was preserved in non-NA bearing cells. These results suggest that NA modulates the gene expression of β4 in HD mice through the promoter dependent manner.

**Analyses of conditional mouse models of SCA3 reveal reversibility of symptoms.** *J. Boy[1], T. Schmidt[1], H. Wolburg[2], M. Böttcher[1], S. Nuber[1], U. Schumann[1], A.F. Mack[3], I. Schmitt[4], F. Zimmermann[5], C. Holzmann[6], A. Servadio[7], T.B. Leergaard[8], F. Odeh[8], J.G. Bjaalie[8], O. Riess[1].* 1) Medical Genetics, University of Tuebingen, Tuebingen, Germany; 2) Institute for Pathology, University of Tuebingen, Tuebingen, Germany; 3) Institute for Anatomy, University of Tuebingen, Tuebingen, Germany; 4) Clinic for Neurology, University of Bonn, Bonn, Germany; 5) Center for Molecular Biology, University of Heidelberg, Heidelberg, Germany; 6) Medical Genetics, University of Rostock, Rostock, Germany; 7) Telethon Institute of Genetic and Medicine, Naples, Italy; 8) Center for Molecular Biology and Neuroscience and Institute of Basic Medical Science, University of Oslo, Oslo, Norway.

Spinocerebellar Ataxia Type 3 (SCA3) is an autosomal dominantly inherited neurodegenerative disorder caused by the expansion of a CAG stretch in the MJD1 gene. In order to analyze whether symptoms caused by ataxin-3 with expanded polyglutamine repeats are reversible, we generated inducible transgenic mouse models using the "Tet-Off system". This system is based on two constructs: The promoter construct controls the expression of the so-called tTA gene product. The binding of tTA to a TR element in the responder construct induces the transcription of the gene of interest. The expression can be blocked by the addition of doxycycline which allosterically inhibits the tTA. For the ataxin-3 responder mouse lines, a full length construct containing an expanded repeat with the pathological length of 77 glutamine repeats was used. The use of two different promoter mouse lines with known expression in the brain (prion protein (Prp) promoter, Ca2+/calmodulin-dependent protein kinase II (CamKII) promoter) allows us to target the transgene expression to different brain regions. Using the CamKII promoter, the trangene is targeted mainly to the frontal brain and mice display first symptoms at the age of six months. However, when we use the Prp promoter, the transgene is widely expressed in the brain with pronounced expression in the cerebellum and the brain stem. In these mice, first motor symptoms can be detected at the age of two months. We then stopped the expression of the transgene by treatment with doxycycline and compared treated and untreated mice at different levels: Performing immunohistochemical analyses of brain sections, we studied the expression of the transgene and neurodegenerative processes in the brain. Behavioural studies revealed that turning off the pathogenic transgene in an early disease stage led to the reversibility of motor symptoms. Comparable approaches in human patients -if available- would therefore require early initiation.

## 2159/T/Poster Board #708

**Expression of mutant huntingtin in astrocytes causes neurological phenotypes in HD mice via glutamate transporter defects.** *J.W. Bradford[1,2], J.Y. Shin[1], M.A. Roberts[1], S. Li[1], X.J. Li[1].* 1) Dept Human Gen, Emory Univ, Atlanta, GA; 2) Program in Genetics and Molecular Biology, Emory Univ, Atlanta, GA.

Huntington's disease (HD) is the most common of nine inherited neurodegenerative disorders caused by an expanded glutamine tract in the N-terminus of the huntingtin (htt) protein. An expansion of over 37 glutamines in htt results in the late onset of HD symptoms, including movement disorders, body weight loss, cognitive deficits, and eventually death 15-20 years following onset. Although mutant htt is expressed ubiquitously in various types of cells, including glia, how mutant htt in glia contributes to the pathology of HD remains unknown. We generated an HD mouse model that expresses N-terminal human mutant htt with either 98 or 160 polyglutamine repeats under the glial fibrilary acidic protein promoter (GFAP), which drives gene expression in astrocytes. Electron microscope analysis showed mutant htt expression only in astrocytes in the brains of these transgenic mice. Astrocytes, which are the most numerous type of glial cell, express glutamate transporters that remove extracellular glutamate to protect neurons against glutamate excitotoxicity. Mice expressing mutant htt in astrocytes show age- and polyglutamine repeat-dependent neurological phenotypes, including body weight loss, rotarod deficits, and early death when compared to WT littermates or GFAP-23Q control mice. Moreover, double transgenic mice expressing mutant htt in both neurons and astrocytes endure more severe neurological symptoms and earlier death than HD mice that express mutant htt primarily in neurons. Using co-immunoprecipitation with primary astrocyte lysate, we found that mutant htt binds more Sp1 transcription factor than WT htt. ChIP analysis further showed reduced association of Sp1 with the promoter of glutamate transporter. Both of these factors may contribute to the decreased expression of glutamate transporter seen in the brains of these mice. These results challenge the classic cell autonomous view of neurodegeneration by implying an important role for glial mutant htt in HD pathology. These findings also suggest that new possibilities for HD treatment might involve astrocytes. Supported by NIH grants AG019206, NS041669, and NS045016.

## 2160/T/Poster Board #709

**An ordered-subset linkage analysis of niacin skin flush response in schizophrenia.** *W.J. Chen[1,2,3], S.S. Huang[1], C.M. Liu[2], Y.J. Lien[1,3], S.H. Lin[1,3], P.C. Hsiao[3], S.V. Faraone[4], M.T. Tsuang[5,6], H.G. Hwu[1,2].* 1) Institute of Epidemiology, National Taiwan University, Taipei, Taiwan; 2) Department of Psychiatry, College of Medicine and National Taiwan University Hospital, National Taiwan University, Taipei, Taiwan; 3) Genetic Epidemiology Core Laboratory, Division of Genomic Medicine, Research Center for Medical Excellence, National Taiwan University, Taipei, Taiwan; 4) the Genetics Research Program and the Department of Psychiatry and Behavioral Sciences, SUNY Upstate Medical University, Syracuse, NY; 5) Department of Psychiatry and the Center for Behavioral Genomics, University of California, San Diego, CA; 6) Harvard Institute of Psychiatric Epidemiology and Genetics, Harvard Departments of Epidemiology and Psychiatry, Boston, MA.

Previous studies suggested that the attenuation of flush response to topically applied niacin was specific to patients with schizophrenia, showed familial aggregation in families of patients with schizophrenia, and was more impaired in both patients and non-psychotic relatives from families with higher familial loading for schizophrenia. This study aimed to evaluate the linkage signal for schizophrenia in genome scan by means of ordered subset analysis on the basis of the impaired niacin flush response. Subjects of this study were part of the participants of the Taiwan Schizophrenia Linkage Study, which collected a nation-wide family sample with at least two siblings fulfilling the DSM-IV criteria for schizophrenia or schizoaffective disorder, depressive type. The genotyping was conducted by the Center for Inherited Disease Research, with 369 microsatellite markers spaced at an average of 9-cM intervals. Among these families, 197 had at least one member with information on the niacin skin test and were included for this study. The mean niacin flush response score averaged over all the family members with the niacin skin test information was used as the covariate for each family. A series of ordered subset linkage analyses was then conducted to increase the homogeneity of the samples by ranking families according to the mean niacin flush response scores in each family, and generate a new maximum nonparametric linkage z (NPL-Z) score on each chromosome for each subset of families. The statistical significance for a subset-derived increase in linkage signal was evaluated using permutations to obtain a chromosome-wide p value. Two chromosomal regions were found to have significant increases in NPL-Z score by ranking families in descending order of niacin flush score, including 5q35.2 (NPL-Z = 3.65, an increase of 2.97, empirical $p = 0.006$) and 15q26 (NPL-Z = 3.08, an increase of 2.11, empirical $p = 0.047$). Another region with significant increases in NPL-Z score was found on chromosome 22q13.1 (NPL = 2.26, an increase of 2.09, empirical $p = 0.043$) by ranking families in ascending order of niacin flush score. Meanwhile, there was little evidence of linkage on these regions in the original genome wide scan for the whole sample. These results suggest that the flush response to niacin may be a marker of underling heterogeneity in schizophrenia and potentially useful to demarcate subgroups of the disorder with different susceptibility genes.

## 2161/T/Poster Board #710

**BACHD transgenic rats with full-length mutant huntingtin exhibit early phenotypic abnormalities.** *H. Nguyen[1], L. Yu[1], S. Metzger[1], J. Ehrismann[1], T. Ott[1], X. Gu[2], M. Gray[2], W. Yang[2], A. Weiss[3], P. Paganetti[3], O. Riess[1].* 1) Department of Medical Genetics, University of Tuebingen, Tuebingen, Germany; 2) Department of Psychiatry & Biobehavioral Sciences, UCLA, Los Angeles, USA; 3) Neuroscience Research, Norvatis Institutes for BioMedical Research (NIBR), Basel, Switzerland.

Our group has previously generated and characterized transgenic rats, which express a fragment of mutant huntingtin (htt), as model of Huntington's disease (HD) in detail. This rat model mirrors many aspects of HD, but it lacks the full-length mutant htt protein and therefore some aspects of the human condition might be imperfectly replicated. In order to overcome this potential disadvantage, we aimed to generate transgenic rats, which express full-length mutant human htt in the same developmental and tissue- and cell-specific manner seen in patients with the disease. To achieve this, bacterial artificial chromosomes (BACs) containing human genomic DNA spanning the full-length gene with 97 CAG/CAA repeats including all regulatory elements were used. Twenty-three founders were analysed for copy number of BAC insertion, integrity of transgene and size of CAG repeats. In F1 transgenic rats of each line the level of RNA and protein expression in brains was measured and the number of integration sites was determined. Western blot result show that the majority of BACHD rat lines expressed full-length htt at various levels. Two lines were then selected for detailed phenotyping. First results already indicate robust and early progressive motor deficits, impaired motor skill learning, reduced activity as well as reduced drinking and feeding and accumulation of N-terminal htt fragments in the line with the highest expression level of mutant htt.

**Characterization of N-terminal Huntingtin Fragments that Accumulate in the Nucleus.** *L. Smith[1, 2], XJ. Li[1], SH. Li[1].* 1) Department of Human Genetics, Emory University, Atlanta, GA; 2) Graduate program in Genetics and Molecular Biology, Emory University, Atlanta, GA.

Huntington's disease (HD) is an autosomal dominant, late-onset neurodegenerative disorder characterized by the expansion of a polyglutamine (polyQ) repeat located in the N-terminal region of the huntingtin (htt) protein. Wild-type htt consists of less than 36 glutamine repeats whereas the mutant version of the protein has an expanded polyQ repeat of greater than 37 glutamines. Htt is normally a cytoplasmic protein but in HD, N-terminal fragments of mutant htt localize to the nucleus to form inclusions. In the nucleus, mutant htt has been shown to aberrantly interact with various proteins such as the transcription factors Sp1 and TAFII130. The nuclear toxicity of mutant htt is indicated by the fact that mutant htt preferentially accumulates in the nuclei of striatal neurons, which are most vulnerable in HD. However, the mechanism for the nuclear accumulation of mutant htt remains to be investigated. We first aimed to identify the size of the mutant htt fragment that can accumulate in striatal nuclei. We transfected HEK 293 cells with N-terminal htt fragments of various lengths (212, 300 and 500 amino acids). Using immunocytochemistry and nuclear fractionation techniques, we analyzed whether each of the fragments could accumulate in the nuclei. We found that the smaller fragment of 212 amino acids showed more nuclear accumulation than larger fragments of 300 and 500 amino acids. Next we aimed to determine how phosphorylation of the N-terminus may affect nuclear accumulation of htt. We mutated phosphorylatable sites in the N-terminus of htt to create unphosphorylatable and phosphomimic mutants. We expressed these mutants in HEK293 cells and found that phosphorylation enhances nuclear accumulation and aggregation of mutant htt. Supported by NIH grants NS 045016 and NS41669 Nominator for ASHG trainee award: Xiao-Jiang Li (Membership ID 44111), E-mail: xli2@emory.edu.

## 2163/T/Poster Board #712

**Dentatorubral-Pallidoluysian Atrophy (DRPLA) in an Australian family of Chinese descent.** *K.H.C. Wu[1], R. Beran[2], P. Procopis[3], M. Davis[4], A. Colley[1].* 1) Clinical Genetics Dept, Liverpool Hospital, Liverpool, Sydney, Australia; 2) Neurology Dept, Liverpool Hospital, Sydney, Australia; 3) Neurology Dept, Children's Hospital at Westmead, Sydney, Australia; 4) Neurogenetics Unit, Anatomical Pathology Dept, Royal Perth Hospital, Perth, Australia.

**Purpose:** Dentatorubral-pallidoluysian atrophy (DRPLA) is a rare autosomal dominant neurodegenerative disorder caused by CAG trinucleotide repeats in the Atrophin-1 gene on chromosome 12p13.31. To date, only three Chinese kindreds, one in Taiwan and two in Hong Kong, have been reported. Here we report three affected members over two generations in an Australian family of Chinese descent with DRPLA. One member was diagnosed retrospectively from stored sample. "Birth-order effect" previously reported in two Chinese families was not observed. **Methods:**Case report on clinical presentations, electroencephalographic (EEG) and cerebral magnetic resonant imaging (MRI) features, and molecular genetic studies; and compare these with previously published reports. **Results:** The proband had migrated from China when young. He presented at 49 years of age with wide-based ataxic gait, which progressively deteriorated and he was wheelchair bound in six years. During this interval, he developed cognitive decline and aggressive behaviour. His EEG showed no epileptic activity. His MRI showed generalised cerebral atrophy. His eldest son, at 2 years of age (12 years prior to proband's presentation), presented with severe mental retardation and myoclonic epilepsy, was wheelchair-bound in childhood and died at 12 years of age with an unknown cause. The proband's youngest daughter presented, at age 7 years (4 years prior to the index presentation) with learning difficulties. She later developed epilepsy at age 12 years, and startle myoclonus at age 16 years. Her EEG showed generalised epileptiform activities. Molecular genetic studies showed CAG repeats of 58, 70, and 66 in the proband, his son, and his daughter, respectively. The proband's mother is in her 80's and is well. The proband's father died in South American as a young adult. **Conclusion:** Our family demonstrates genetic anticipation between the two generations, and correlation between the disease severity, age of onset and the number of triplet repeats, consistent with the literature. It however does not support the "birth-order effect" proposed to be due to the effect of advancing paternal age on meiotic instability, as demonstrated in two other Chinese families. Further, it may be speculated that the proband's father either had a "high-end" normal allele that subsequently expanded into pathogenic size in the proband, or had a "low-end" pathogenic expansion and therefore did not manifest the disease prior to his death.

## 2164/T/Poster Board #713

**Identification of novel early-onset progressive cerebellar ataxia gene in Finnish Hound dogs.** *K. Kyöstilä[1,2,3], S. Cizinauskas[4], P. Syrjä[2], E. Suhonen[5], J. Jeserevics[4], A. Sukura[2], H. Lohi[1,2,3].* 1) Department of Medical Genetics, University of Helsinki, Finland; 2) Department of Basic Veterinary Sciences, University of Helsinki, Finland; 3) Department of Molecular Genetics, Folkhälsan Institute of Genetics, Finland; 4) Referral Animal Neurology Hospital Aisti, Vantaa, Finland; 5) Small Animal Clinic Kontiolahti, Kontiolahti, Finland.

Human hereditary ataxias belong to a heterogeneous group of disorders characterized by progressive degeneration of the cerebellum and its connections. Although several causative genes have been identified in human ataxias the precise molecular mechanisms that cause the neuronal degeneration are still poorly understood. Recent annotation of the canine genome and development of the related genomic tools for gene mapping provides us a new animal model to identify novel ataxia genes. Ataxia-causing cerebellar cortical abiotrophies (CCAs) have been described in several dog breeds with breed-specific age of onset and disease progression. We report here the identification of a homozygous mutation in a novel ataxia-causing gene segregating with an early-onset progressive CCA disorder in Finnish Hounds (FH). We also provide clinicopathological characterization for the disease. Affected FH puppies develop sings of motor incoordination at the age of 4 to 12 weeks and after this the disease progresses fairly quickly. Magnetic resonance imaging (MRI) shows reduction in cerebellar size in 9 out of 10 clinically examined affected puppies. Histopathological examination reveals marked degeneration and loss of Purkinje cells in the cerebellar cortex. To map the disease locus we genotyped 14 affected puppies and 20 healthy family members using Illumina's canine 24K SNP chip arrays. The genotyping data was analyzed with PLINK software using both case-control and family-based association methods which identified a 1Mb disease associated region at CFA8 ($P_{raw}$ = 1.83E-6, $P_{genome\text{-}wide}$ = 0.00774). The associated region included 5 genes of which one plausible candidate was selected for mutation screening. Sequencing of the coding regions of the gene revealed a homozygous missense mutation in the affected dogs resulting in a single amino acid change in the encoded protein. Mutation and segregation was confirmed by genotyping 241 randomly selected FHs, which indicated a 10% carrier frequency in the FH population in Finland. The identified gene has not been previously associated with inherited ataxias in any species and we are currently sequencing the human ortholog in early-onset ataxia patients with similar clinical symptoms and unknown genetic background. Identification of the novel ataxia gene will cast more light to the pathogenesis of cerebellar neurodegeneration and will improve our understanding of the disease mechanisms in both species.

## 2165/T/Poster Board #714

**The Autism Genome Project: Dissecting the genetic and genomic etiology of autism.** *S. Ennis on behalf of the Autism Genome Project Consortium (AGP).* Medical Genetics, School of Medicine and Medical Sciences, UCD, Dublin, Ireland.

Autism and autism spectrum disorders (ASD) are neurodevelopmental disorders affecting approximately 1 in 150 individuals and characterized by deficits in reciprocal social interaction, communication and patterns of repetitive behaviors and restricted interests. Evidence to date supports high heritability and a complex genetic architecture. The Autism Genome Project (AGP) was formed to facilitate gene identification by uniting investigators and family data. We will present results from genome-wide association (GWA) analyses from close to 3000 families. Thus far we have results from over 1500 ASD families, roughly half of the families we will analyze during this three-year phase of the AGP. At 1500 families, the sample represents the first stage of the two stage process for screening the genome for CNVs and SNP loci affecting risk for ASD. Our principal GWA analysis is the additive model and our principal partitions of the data split along two axes: ancestry narrow (European) versus all; and inclusive diagnostic group (any ASD) versus narrow (autism). At this point our results implicate only one gene from our main analyses, namely MACROD2 ($p < 2.910^{-8}$). Intriguingly, a strong consistent but smaller signal for association for strict/European covers the gene *SLC25A12* on chromosome 2. This gene has been evaluated extensively in autism data sets because it falls in a linkage region and has been shown to be associated with autism in some but not all smaller data sets. However the signal for association occurs across 25 SNPs spanning a 350Kb region that encompasses *DYNC1I2*, *SLC25A12*, *HAT1* and the 5' region/first exon of *MAP1D*. The minimum p-value, $5.510^{-6}$, occurs for rs6731562 in *HAT1*. Other genes are implicated by various splits of the data. For example, for verbal ASD individuals, a p-value of $1.110^{-8}$ occurs in gene *PLD5* at rs2196826 whereas for non-verbal subjects no SNP in this gene generates an association p-value less than 0.01. Another notable result ($8.110^{-8}$) is for paternal transmission of alleles in *RASAL1*, a gene encoding a RAS-GTPase-activating protein and falling on 12q24.13. The largest test statistic and smallest p-value, $8.110^{-8}$, occurs for rs12422659, a synonymous exonic SNP. Insofar as we are aware, however, there is no evidence for *RASAL1* being imprinted. Whether these loci remain intriguing and whether new loci are implicated will be determined by analyses to be presented at the 2009 ASHG meeting by using a larger number of samples.

**Genome-wide association study on early-onset bipolar disorder.** *S. Jamain[1], S. Cichon[4,5], B. Etain[1,2], T.W. Muhleisen[4,5], A. Georgi[6,7], N. Zidane[1], S. Herms[4,5], M. Mattheisen[4,5], L. Priebe[4,5], F. Mathieu[1], C. Henry[1,2,3], D. Zelenika[8], I. Gut[8], W. Maier[7], M. Albus[6], T. Schulze[6,9], F. Bellivier[1,2,3], M. Rietschel[6,7], M.N. Noethen[4,5], M. Leboyer[1,2,3].* 1) Dept Genetics, INSERM U955, EQ 15, Creteil, France; 2) Faculty of Medecine, University Paris 12, Creteil, France; 3) Dept of Psychiatry, H. Mondor-A. Chevenvier group, Creteil, France; 4) Institute of Human Genetics, University of Bonn, Bonn, Germany; 5) Dept of Genomics, Life ans Brain Center, University of Bonn, Bonn, Germany; 6) Dept of Genetic Epidemiology in Psychiatry, Central Institute of Mental Health, Mannheim, Germany; 7) Dept of Psychiatry, University of Bonn, Bonn, Germany; 8) Commissariat à l'Energie Atomique, Genomic Insitute, Centre National de Genotypage, Evry , France; 9) Unit on the Genetic Basis of Mood and Anxiety Disorders, National Institute of Mental Health, National Institutes of Health, US Department of Health and Human Services, Bethesda, MD, USA.

Many genome-wide association studies (GWAS) have been recently performed on bipolar disorder, leading to discrepant results and difficulties in replication between independent samples. One possible explanation could come from a lack of common genetic variation influencing the vulnerability to bipolar disorder in general, but different susceptibility genes might influence clinical subsets of the disease. Thus, we focused our study on potentially more homogenous and more familial sub-forms of bipolar disorder in order to unravel heterogeneity of the classical categorical entity bipolar disorder and to identify genetic susceptibility genes. We carried out a genome-wide association study using 313,952 single nucleotide polymorphisms (SNPs) on 468 patients with early age at onset or familial history of bipolar disorder and 2832 controls. The strongest association was observed on chromosome 15 ($P$=4.4 x $10^{-7}$) for the whole sample. An additional analysis, including only patients with an early age at onset (N=318), identified several regions for which the association was stronger despite a smaller sample size. Among them, two SNPs located on chromosomes 12p12 and 5p13 ($P$=2.7 x $10^{-7}$ and $P$=3.6 x $10^{-6}$, respectively) are located in genes encoding proteins playing a role in phosphoinositide signalling pathway, which is consistent with the hypothesis that several genes in one pathway may be involved in the pathophysiolgy of bipolar disorder. Our results suggest, at least for bipolar disorder, that the phenotype issue remains an important challenge to identify susceptibility genes.

**Association of common variants at 7p21 with Frontotemporal Dementia with TDP-43 Inclusions.** *P.M.A Sleiman[1], V.M. Van Deerlin[2,3], M. Martinez-Lage[2], A. Chen-Plotkin[2,4], L.S Wang[2], G. Schellenberg[2,3], H. Hakonarson[1,5], J.Q. Trojanowski[2,3], V.M.Y Lee[2,3], International Consortium on Frontotemporal Dementias.* 1) Center for Applied Genomics, Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Center for Neurodegenerative Disease Research, Department of Pathology and Laboratory Medicine, University of Pennsylvania School of Medicine, Philadelphia, PA; 3) Institute on Aging, University of Pennsylvania School of Medicine, Philadelphia, PA; 4) Department of Neurology, University of Pennsylvania School of Medicine, Philadelphia, PA; 5) Division of Pulmonary Medicine and Department of Pediatrics, The Children's Hospital of Philadelphia, University of Pennsylvania School of Medicine.

Frontotemporal dementia (FTD) is the second most common cause of dementia in individuals under age 65. The most frequent neuropathological correlate of FTD is frontotemporal lobar degeneration with TDP-43 inclusions (FTLD-TDP), many cases of which are familial. Mutations in the progranulin gene (GRN) account for approximately 20% of cases, genetic risk factors for the remaining 80% of cases have yet to be identified. We assembled an international consortium to identify common genetic susceptibility loci for FTLD-TDP by genome-wide association (GWA). The GWA included 515 cases and 2509 controls. Following standard quality control, cases were matched to controls by 'genetic matching' to reduce population stratification and Cochran-Armitage trend tests calculated for each SNP. Three SNPs mapping to a single LD block on chromosome 7p21 reached genome-wide significance (P-value 1.08x$10^{-11}$; OR 0.61) and replicated in a separate cohort of FTLD-TDP cases (P-value 2x$10^{-4}$). In addition to the three genome-wide significant SNPs nine others also showed significant association with FTLD-TDP, all of which mapped to a 68 Kb interval. The 7p21 variants were also shown to contribute to the genetic risk for FTLD-TDP in a subset of the patients who harbored pathogenic progranulin mutations. To further characterize the candidates we carried out expression data in the brain tissue of patients and controls to identify either phenotype associated differential expression or genetic transcriptional regulators. Our data implicate variants at 7p21 as the first common genetic susceptibility factors for FTLD-TDP.

## 2168/T/Poster Board #717

**Identification of Loci Influencing Age-At-Onset in Late-Onset Alzheimer Disease Implicates Variation on Chromosome 12p.** *A.C. NAJ[1], G.W. Beecham[1], E.R. Martin[1], M.A. Slifer[1], E.H. Powell[1], P.J. Gallins[1], I. Konidari[1], P. Whitehead[1], J.R. Gilbert[1], J.L. Haines[2], M.A. Pericak-Vance[1].* 1) Institute for Human Genomics, University of Miami, Miami, FL; 2) Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

Alzheimer Disease (AD) is the leading cause of dementia among the elderly with 50%; risk of occurring after 85 years of age. AD is also highly genetic (estimated $H^2$~70%), and susceptibility loci for AD may contribute to earlier age-at-onset (AAO) of disease, as do the *APOE* ε3/ε4 alleles. To identify risk loci for late-onset AD (LOAD), we performed a genome-wide association study (GWAS) of AAO of AD and subsequently of risk for LOAD. We analyzed data on 1,169,331 SNPs genotyped and/or imputed among 1,474 AD cases by combining three GWAS datasets, and imputing non-overlapping SNPs. Initially, we tested SNP associations with AAO among all AD cases in the dataset, following up on associations of P<$10^{-5}$ by testing association with LOAD risk among cases and 1,331 cognitive controls. We observed associations with AAO of SNPs near *APOE* (e.g., rs11672085, P=4.12×$10^{-5}$). We also identified a number of signals with P<$10^{-4}$ that clustered on chromosome 12, specifically 26 SNPs near 33.1-33.2Mb, that demonstrated associations of P<$10^{-5}$ with AAO, the strongest being rs10047666 (P=1.40×$10^{-6}$) genotyped in two of three datasets, though none of these SNPs demonstrated statistically significant association (P<0.05) with LOAD risk. These signals fell ~200kb upstream of the synaptotagmin X gene (*SYT10*), which encodes a presynaptic protein that may contribute to memory performance; *SYT10* expression has been associated with spatial memory loss in mice. Additionally, two independent SNPs strongly associated with AAO (rs7970175 on chromosome 12, P=7.65×$10^{-6}$; rs10944728 on chromosome 6, P=7.73×$10^{-6}$) also showed significant or strong associations in subsequent analyses of LOAD risk (rs7970175, P=1.01×$10^{-9}$; rs10944728, P=1.23×$10^{-5}$), however neither SNP is located in/near known biological candidate genes for AD. Combining three GWASs of LOAD, we observed novel associations of multiple SNPs on chromosome 12 with AAO of Alzheimer Disease. In addition, we observed associations of chromosome 6 and 12 SNPs with AAO and with LOAD, however potential roles for these SNPs remain uncertain and merit further investigation.

**A Novel focal idiopathic epilepsy locus identified in Belgian Shepherd dogs.** *E.H. Seppala[1,2,3], A. But[1,2,3], I. Baranowska[4], M. Berendt[5], C.H. Gulløv[5], S. Cizinauskas[6], A. Short[7], W. Ollier[7], K. Lindblad-Toh[8,9], M. Fredholm[10], H. Lohi[1,2,3], CNG genotyping platform.* 1) Department Medical Genenetics, University of Helsinki, Finland; 2) Department of Basic Veterinary Sciences, University of Helsinki, Finland; 3) Department of Molecular Genetics, Folkhälsan Institute of Genetics, Finland; 4) Department of Animal Breeding and Genetics, Swedish University of Agricultural Sciences, Sweden; 5) Department of Small Animal Clinical Sciences, University of Copenhagen, Denmark; 6) Referral Animal Neurology Hospital Aisti, Vantaa, Finland; 7) Centre for Integrated Genomic Medical Research, School of Translational Medicine, University of Manchester, UK; 8) Broad Institute of Harvard and Massachusetts Institute of Technology, Cambridge, MA; 9) Department of Medical Biochemistry and Microbiology, Uppsala University, Sweden; 10) Department of Basic Animal and Veterinary Sciences, University of Copenhagen, Denmark.

Idiopathic epilepsies are common genetic disorders in both human and dogs. Most of the known epilepsy genes have been found in rare monogenic Mendelian forms of epilepsy syndromes and the genetic background of common idiopathic epilepsies has remained largely unknown. Epilepsy is the most common neurological disorder in dogs and they provide natural disease models for human epilepsies, with several discovered epilepsy genes being orthologs of the corresponding human epilepsies, suggesting that novel genes are likely to also contribute to the development of human epilepsy. The aim of this study was to map the epilepsy locus in Belgian Shepherds (BS). The prevalence of epilepsy among BS dogs is estimated to be almost 10% and previous studies have shown that a single locus with a large effect on the incidence of seizures is segregating in this population. Majority of the affected BSs suffer from focal idiopathic epilepsy with possible secondary generalization. We performed a genome wide association study by genotyping 40 cases and 44 matched controls from Finland and Denmark. Samples were genotyped on the Affymetrix v2 canine SNP array (50k) and association was analyzed with PLINK software. We mapped the disease locus to 3-Mb locus at CFA37 ($P_{raw}$= 1.34E-06 and $P_{genome\text{-}wide}$= 0.017) containing 25 genes. None of them are known to be associated with epilepsy. By sequencing a non-ion channel candidate gene, a coding variation resulting in Arg>His change was detected. By genotyping additional (n= 97) BSs we found that 73% of the epileptic dogs (n=37) were homozygous for the mutation compared to 23% of the healthy controls (n=60; OR=8.6; 95% CI 3.4-23.1; P=1.53E-6). However, the same variant was also present in 27 other breeds studied suggesting that it is a common polymorphism which is likely in a close LD with an actual disease-causing mutation. Further fine-mapping and sequencing of the associated region continues in 100 epileptic and 110 healthy control BSs and other breeds. These results indicate that we have mapped and confirmed a novel focal idiopathic epilepsy locus in a dog breed and the identification of the mutation will lead to the discovery of a novel non-ion channel epilepsy gene that can be studied in human focal epilepsy patients.

## 2170/T/Poster Board #719

**Genome-wide significant confirmation of SNPs in SNCA and the MAPT region as common risk factors for Parkinson disease.** *T. Edwards[1], W.K. Scott[1], C. Almonte[1], A. Burt[1], E.H. Powell[1], G. Beecham[1], L. Wang[1], S. Zuchner[1], I. Konidari[1], G. Wang[1], M. Pericak-Vance[1], J. Haines[2], J. Vance[1], E.R. Martin[1].* 1) Miami Institute for Human Genomics, Miller School of Medicine, University of Miami and the Dr. John T. Mcdonald Foundation Dept of Human Genetics; 2) Center for Human Genetics Research, Vanderbilt University Medical Center, Vanderbilt University.

Parkinson disease (PD) is a chronic neurodegenerative disorder with a cumulative prevalence of greater than one per thousand. While several rare Mendelian forms of PD have been described, the genetic factors underlying idiopathic PD have been elusive. Three independent genome-wide association studies (GWAS) have previously investigated the genetic susceptibility to PD using various study designs and genotyping platforms. These studies implicated several genes as PD susceptibility loci with strong, but not genome-wide significant, associations. In the current study, we combined and imputed data for joint analysis from two previously published GWAS, obtained from dbGAP, with our new GWAS with 605 cases and 621 controls genotyped at 491,590 SNPs. Genotyped SNPs in SNCA (rs2736990 genome-wide empirical p = 0.0109, OR = 1.29 95%CI 1.17-1.42 G vs. A allele, PAR% = 12%) and the MAPT region (rs11012 genome-wide empirical p = 0.0079, OR = 1.42 95%CI 1.25-1.61 C vs. T allele, PAR% = 8%) were statistically significant at the genome-wide level after adjustment for multiple tests. No other SNPs were close to genome-wide significant in this analysis, though several biologically implicated genes (RORA, NPAS3, WIPF1, DBC1, GFPT2) were replicated in at least two of three data sets at the 0.05 level with consistent direction of effects across independent samples. These genes are being further investigated in a fourth PD dataset. This study confirms that SNCA and the MAPT region are major genes influencing risk for most PD patients as they have been consistently observed to significantly associate with PD here and in other studies, and these exposures combined explain at most 20% of PD cases.

## 2171/T/Poster Board #720

**DISC1 conditioned genome-wide association study of psychosis proneness in a large birth cohort.** *L. Tomppo[1,2], J. Ekelund[1,2,3], D. Lichtermann[4], J. Veijola[5], S. Gabriel[6], MR. Järvelin[7], N. Freimer[8], W. Hennah[1,2,9], L. Peltonen[1,2,6,10].* 1) Institute for Molecular Medicine Finland FIMM, University of Helsinki, Helsinki, Finland; 2) Public Health Genomics Unit, National Institute for Health and Welfare, Helsinki, Finland; 3) Department of Psychiatry, University of Helsinki, Helsinki, Finland; 4) Café Ersatz, Bonn, Germany; 5) Department of Psychiatry, University of Oulu, Oulu, Finland; 6) Broad Institute, Cambridge, MA; 7) Imperial College, London, United Kingdom; 8) UCLA, LA; 9) Medical Genetics Section, University of Edinburgh, Edinburgh, United Kingdom; 10) Wellcome Trust Sanger Institute, Cambridge, United Kingdom.

DISC1 is currently one of the most promising candidate genes for schizophrenia and other major mental illnesses. We have previously detected association between DISC1 and measures of social and physical anhedonia in the large birth cohort of Northern Finland 1966 (NFBC66). We studied four psychometric scales that are intermediate phenotypes for psychosis, and function as proxies for positive and negative aspects of psychosis. Significant association was observed between previously reported combinations of three DISC1 SNPs and the Revised Social Anhedonia Scale (SAS). In the present study, we performed a genome-wide association study conditioned on these previously recognized DISC1 variants in this cohort, for the outcome measures Revised Social Anhedonia Scale and Revised Physical Anhedonia Scale (PHAS). From the original individuals (N = 12 058), 4 561 individuals attended a 31-year follow up and provided data for the present study. The sample has been genotyped using the Illumina Infinum Assay and HumanHap 370K marker set. Carriers of risk and protective DISC1 variants were analyzed separately (N = 3 054 and N = 962 respectively). The remaining individuals not carrying either of the variants were analyzed as one group (N = 545). No markers were significant at the genome-wide level. However, we noted suggestive evidence for association on several chromosomal regions. These included chromosomes 1q23.1 (risk model, best P = 4.38E-06) and 16q22.1 (protective model, best P = 5.30E-06) for SAS and 2q21.3 (risk model, best P = 1.84E-06) and 12q24.21 (neutral model, best P = 2.24E-06) for PHAS. With these genetically more homogeneous stratified samples we are more likely to recognize variants with small effect sizes that are related to psychosis proneness and potentially interact with DISC1. This approach of using quantitative phenotypes assessed in large population cohorts can be a powerful way of identifying genes that predispose to related clinical disorders, in this case psychosis.

## 2172/T/Poster Board #721

**Runs of homozygosity associated with autism in females: novel candidate gene TMEM47 undergoing recent positive selection?** *P. Lin[1,2,3], J. Albert[3], J. Wortman[3].* 1) Dept Psychiatry, National Taiwan Univ Hosp, Taipei, Taiwan; 2) Maryland Psychiatric Research Center, Catonsville, MD, USA; 3) Dept Medicine, Univ of Maryland School of Medicine, Baltimore, MD, USA.

Previous evidence has suggested that several candidate genes associated with risk of psychiatric disorders, such as schizophrenia, have undergone recent positive selection. One of the lines of evidence for recent positive selection of genetic variants is extended homozygous haplotypes (EHH). A common variant with a recent origin may reflect recent positive selection. Such a common variant may be characterized by ancestral haplotypes identical by descent, which may result in EHH. In the current study, we used Affymetrix 500K SNP arrays to search for EHH associated with common variants in 770 female individuals affected with autism spectrum disorder (ASD) and 300 unaffected female siblings. The EHH was defined as at least 100 contiguous SNPs with homozygous genotypes. EHH where deletions were speculated according to the probe intensity ratio data in the same regions were excluded in the analysis. To interrogate the associations between EHHs and ASD, logistic regression analysis with generalized estimation model to adjust for intra-sibship correlation was performed. The results reveal several chromosome regions that contained EHH that were over-represented in either ASD individuals or unaffected siblings. One of the most interesting findings was obtained in a 157.6 Kb region located on chromosome Xp11 that contains the transmembrane protein 47 (TMEM47) gene, which was found to be more frequent in affected individuals than unaffected siblings (OR = 3.04; p-value = 0.0003). Previous studies suggest that the TMEM47 gene might be associated with mental retardation. Additionally, the TMEM47 gene has been found to be highly expressed in some brain regions, such as prefrontal cortex, amygdale, and hypothalamus, etc. We then queried this gene using the webtool HAPLOTTER and found this gene might have been subject to recent positive selection (p-value = 0.023). Taken together, the TMEM47 gene may undergo recent positive selection and play a role in pathogenesis of ASD.

## 2173/T/Poster Board #722

**Genome-wide association study in Schizophrenia families.** *L. Rodriguez Murillo[1], J.L. Roos[2], J.A. Gogos[3,4], G.R. Abecasis[5], M. Karayiorgou[1].* 1) Department of Psychiatry, Columbia University Medical Center, New York, NY; 2) Department of Psychiatry, University of Pretoria, Pretoria, RSA; 3) Department of Physiology & Cellular Biophysics, Columbia University Medical Center, New York, NY; 4) Department of Neuroscience, Columbia University Medical Center, New York, NY; 5) Department of Biostatistics, Michigan University, Ann Arbor, MI.

Schizophrenia is a severe psychiatric complex disorder characterized by psychotic symptoms that include delusions and hallucinations, apathy, altered emotional reactivity and cognitive deficits as impairments in executive function, attention and working memory. It is estimated that around 1 % of the worldwide population suffer from schizophrenia. Multiple genetic and environmental factors may be interacting to cause the expression and development of the disease. Currently, genome-wide association studies (GWAS) are being used extensively to discover common genetic factors implicated in complex disorders. We performed a genome-wide association study in the Afrikaners, a founder population from South Africa of European descent. In this association study we are using a family-based approach studying families formed by at least one affected individual. Family-based association studies are advantageous over the case-control approach mainly because they are robust to population stratification effects. We genotyped 1376 individuals from 363 families for ~500,000 single nucleotide polymorphisms (SNPs) with the Affymetrix 5.0 GeneChip array. Following stringent quality-control filtering, preliminary analyses performed with LAMP showed SNPs associated with Schizophrenia with P-values in the order of $10^{-6}$. Some of the SNPs with the lowest P-values are located within genes likely to be involved in the disease pathobiology. Furthermore, we performed meta-analysis of our strongest association signals with data publicly available from other GWAS in Schizophrenia.

## 2174/T/Poster Board #723

**Gene variants associated with schizophrenia in Norwegian genome-wide study are replicated in a large European cohort.** *L. Athanasiu[1, 2, 3], M. Mattingsdal[1, 3], A.K. Kähler[1, 2, 3], A. Brown[3, 4, 5], O. Gustafsson[1], I. Agartz[3, 6], I. Melle[1, 3], V.M. Steen[7, 8], S. Djurovic[1, 2, 3], O.A. Andreassen[1, 3], The SGENE consortium.* 1) Department of Psychiatry, Oslo University Hospital - Ulleval, Oslo, Norway; 2) Department of Medical Genetics, Oslo University Hospital - Ulleval, Oslo, Norway; 3) Insitute of Psychiatry, University of Oslo, Oslo, Norway; 4) Department of Biostatistics, University of Oslo, Oslo, Norway; 5) Department of Matemathics, University of Oslo, Oslo, Norway; 6) Department of Psychiatric Research, Diakonhjemmet Hospital, Oslo, Norway; 7) Dr. Einar Martens Research Group for Biological Psychiatry, Department of Clinical Medicine, Univeristy of Bergen, Bergen, Norway; 8) Center for Medical Genetics and Molecular Medicine, Haukeland University Hospital, Bergen, Norway.

Genome-wide association studies (GWASs) have successfully identified susceptibility genes for various complex disorders. However, despite an estimated heritability of 0.8, few common variants have been identified in schizophrenia. Scandinavian populations are generally reckoned well suited for genetic studies, pertaining ethnically homogenous populations, only recently subjected to non-Caucasian immigration. This notion is ensured in our study as all study subjects are born in Norway and the vast majority has two Norwegian-born parents. Furthermore, since the Norwegian health care system is run by the government, participating hospitals in this study are the only psychiatric health care providers in the catchment area. This has enabled inclusion of a representative and unselected patient sample. We undertook a genome-wide association study (GWAS) of schizophrenia in a Norwegian discovery sample of 201 cases and 305 controls (TOP study) with follow-up analysis in a larger European replication sample of 2,663 cases and 13,780 control subjects (SGENE- study). Firstly, the discovery sample was genotyped with the Genome- Wide Human SNP Array 6.0 (Affymetrix Inc, Santa Clara, CA, USA) and 572,888 markers were tested for schizophrenia association. Secondly, we selected the top 1,000 markers in the discovery GWAS, and tested these (or HapMap- based surrogates) for association in the replication sample. Sixteen loci were associated with schizophrenia (nominal Cochrane Mantel Haentzel P value < 0.05 with concurring OR) in the replication sample. Secondly, we combined findings from these two studies in a meta-analysis using Fischer's combined probability test. The strongest evidence for SNP-schizophrenia associations from the meta-analysis (P < 0.00001) was provided for markers rs7045881 on 9p21, rs433598 on 16p12 and rs10761482 on 10q21. The markers are located in *PLAA*, *ACSM1* and *ANK3* respectively. *PLAA* is not previously described as a susceptibility gene, but the 9p21 is an implied schizophrenia linkage region, potentially harboring vulnerability genes. *ACSM1* on 16p12 is also part of implied schizophrenia linkage region, but the locus is not previously associated with schizophrenia. The association of *ANK3* with schizophrenia is intriguing in light of recent associations of *ANK3* with bipolar disorder, and supports the hypothesis of an overlap in genetic susceptibility between these psychopathological entities.

## 2175/T/Poster Board #724

**More is worse? Genome-wide expression analysis in Williams syndrome.** *L. Dai[1], R. Weiss[2], U. Bellugi[3], D. Mills[4], J. Korenberg[1].* 1) Brain Inst, University of Utah, Salt Lake City, UT; 2) Department of Human Genetics, University of Utah, Salt Lake City, UT; 3) Salk Inst for Biol. Studies, La Jolla, CA; 4) School of Psychology, Bangor University, Gwynedd, United Kingdom.

Williams syndrome (WS) is a rare disorder associated with striking deficits in visual-spatial function, relatively preserved language and a "gregarious" personality, Caused by the deletion of ~25 genes on chromosome 7, WS provides a unique opportunity to link these genes to developmental and functional defects in WS. In a previous study, we applied genome-wide expression analyses to a cohort of 19 subjects with WS and 8 normal controls using Affymetrix Exon 1.0 ST arrays. These arrays allow high resolution exon and gene-level analysis by comprehensive coverage of the genome, including empirically supported and predicted transcribed sequences. We found that rank products analysis revealed a 25-50% reduction in expression levels across WS region transcripts as among the most significant genome-wide reductions between WS and normal. In the current report, we expand the study to a cohort of 34 subjects with WS and 18 normal controls. We first confirmed 179 WS region exons as differentially expressed, and validated the fold change of 8 genes in the WS region by qRT-PCR. Unexpectedly, we found subsets of genes located outside the WS region are over or under-expressed. The top 25 differentially expressed genes outside WS deletion region were validated using qRT-PCR. These results redefine WS as due in part to a deletion and consequent gene over- or under-expression acting through development and in the adult, but also reveal a subset of genes that act downstream of the deletion and represent the first steps to a understanding the network interactions that may mediate the biology WS phenotypes. To further discover the underlying biological pathways, we applied Gene Set Enrichment Analysis (GSEA) and identified, besides the genes in WS region, gene sets involved in cytoskeleton-actin, cell adhesion, membrane trafficking and other cytoskeleton signal pathways. Interestingly, most of the genes in cytoskeleton-actin pathway are over-expressed in WS. They play important roles in neuroblast migration, particularly in the rostral migratory stream, the source of adult neurogenesis, and at the dendritic spine, which suggest a striking dataset leading to models for synaptic function and treatments. In summary, expression analysis of WS implies for the first time the possible genome-wide network effects that are due to the deletion of WS region genes, and we may gain insights into the biological mechanisms of the altered development and adult function in WS.

## 2176/T/Poster Board #725

**Genome-wide association study in the Amish indicates non-APOE genetic effects for dementia.** *A. Davis[1], L. Jiang[1], R. Laux[1], L. McFarland[1], P. Gallins[2], L. Caywood[2], M. Creason[2], D. Fuzzell[2], C. Knebusch[2], C. Jackson[3], W. Scott[2], M. Pericak-Vance[2], J. McCauley[2], J. Haines[1].* 1) Dept CHGR, MPB, Vanderbilt Univ, Nashville, TN; 2) Miami Institute for Human Genomics, University of Miami, Miller School of Medicine, Miami, FL; 3) Scott and White, Temple, TX.

Late Onset Alzheimer's disease (LOAD) is the leading cause of dementia in the elderly. While evidence for an underlying genetic etiology of AD is strong, it has proven to be quite challenging to elucidate. The APOE gene accounts for less than half of the susceptibility and thus other genetic factors are likely to be involved. Genetic heterogeneity is a major complicating factor hindering further gene identification. To overcome this problem and maximize our power to identify AD risk genes, we are studying the genetically isolated and well-defined Amish populations of middle Ohio and northern Indiana. To date we have enrolled over 1850 Amish individuals with 132 of these having either probable or possible dementia. We performed a genome-wide association study (Affymetrix Human SNP Array 6.0) and successfully genotyped 830 Amish individuals (125 with AD). Following QC, 453,389 SNPs were analyzed. We performed parametric and nonparametric 2-pt linkage analysis (Merlin) after using PedCut to divide our large pedigree into smaller, more computationally feasible sub-pedigrees. A lod score of 4.5 was calculated under a recessive model on chromosome 6 at rs4235857, which is ~93 Kb from the EPHA7 gene, known to be involved in the development of the nervous system. Five additional SNPs (4 of which were identified under a recessive model), on chromosomes 3, 6, and 9, had lod scores > 4.0 assuming either a dominant or recessive model. Under a dominant model 4 additional SNPs had lod scores >3.6, and under a recessive model 11 additional SNPs had lod scores >3.6. Because of the relatedness of these individuals, we employed a novel test of association using the MQLS test (Thornton & McPeek). The lowest MQLS p-value (1.7 x 10-7) was calculated for rs6468852 on chromosome 8 ~57 Kb from ATP6V1C1, which encodes a subunit of vacuolar ATPase. Three other SNPs (chromosomes 3, 9, and 11) had p-values <1 x 10-6, and an additional 90 SNPs had p-values <1 x 10-4. Further detailed analysis will clarify these initial results, which suggest novel non-APOE genetic effects for LOAD in our Amish dataset.

## 2177/T/Poster Board #726

**Genome-wide association study of schizophrenia using STR markers.**
*Y. Fukumaki[1], K. Yamamoto[2], Z. Sun[1], A. Oka[3], H. Inoko[3], T. Arinami[4], N. Iwata[5], N. Ozaki[6], H. Shibata[1].* 1) Div. Hum. Mol. Genet., Res. Ctr. Genet. Info., Med. Inst. Bioreg., Kyushu Univ. Fukuoka, Japan; 2) Div. Mol. Population Genet., Med. Inst. Bioreg., Kyushu Univ. Fukuoka, Japan; 3) Dep. Mol. Life Science, Tokai Univ. School of Med., Isehara, Japan; 4) Dep. Med. Genet., Graduate School of Comprehensive Hum. Sciences, Univ. of Tsukuba, Tsukuba, Japan; 5) Dep. Psychiatry, Fujita Health Univ. School of Med., Toyoake, Japan; 6) Dep. Psychiatry, Nagoya Univ. Graduate School of Med., Nagoya, Japan.

Schizophrenia is a devastating neuropsychiatric disorder with a multifactorial background. To search for schizophrenia susceptibility loci, we conducted a case-control study using about 30,000 STR markers distributed across the entire genome (average spacing 108 kb; average heterozygosity 0.67). To overcome type I errors due to multiple testing, we designed three sequential steps of screening using independent pooling sample sets. The first screening using pooled samples of 157 case-control pairs revealed 2,966 (10.6%) markers to be significantly associated with the disorder ($p < 0.05$). After the second and third screening steps using pooled samples of 150 pairs each, 52 markers remained to be associated with the disorder. Total 1,536 tagging SNPs in the vicinity of about 200 kb from the 52 positive STR markers were used for an additional genotyping of all screening samples. Significant association was observed for 167 SNPs. We selected 31 SNPs based on levels of $p$ values and conducted a confirmatory association study using large independent samples (2444 - 2475 cases and 2451 - 2479 controls). One SNP located upstream of *SLC23A3* showed the marginal $p$ value (0.054) and significant association with the disorder ($p = 0.004$) in cumulative samples (2891 - 2922 cases and 2946 - 2977 controls). Additional 6 SNPs near the relevant one were employed for genotyping of the cumulative samples. One SNP located between *SLC23A3* and *C2orf24*, and another within *C2orf24* showed significant association with the disorder ($p = 0.026$ and 0.012, respectively). These results suggest *C2orf24* as a candidate for schizophrenia susceptibility in the Japanese population.

## 2178/T/Poster Board #727

**Genome-wide association study for depressive symptom.**
*J. Heo[1], M. Park[1], B. Keam[1], H. Kim[2], S. Chung[3], J. Lee[1], J. Lee[1].* 1) Center for Genome Science, National Institute of Health, Korea Centers for Disease Control and Prevention, Seoul, Korea; 2) Division of Child and Adolescent Psychiatry, Department of Neuropsychiatry, Seoul National University Hospital, Seoul, Korea; 3) Department of Psychiatry, University of Ulsan College of Medicine, Asan Medical Center, Seoul, Korea.

Background: Depressive disorder is currently one of the leading causes of disease burden in the world. Despite the high prevalence and social impact of depressive disorder, a little is known about the genetic and pathophysiological mechanism. The aims of this study were 1) to identify the association between SNPs and depressive symptom by genome-wide approach with high resolution chip, and 2) to find a new candidate gene for depressive symptom. Methods: The study samples were drawn from the Korean Genome and Epidemiology Study which is an ongoing prospective community-based epidemiology study. In order to measure depressive symptom, we used the Beck Depression Inventory (BDI) score, which is the most widely used self report instrument for measuring the severity of depression. We finally obtained completed BDI questionnaires from 3,203 subjects. Individual genotyping was conducted using the Affymetrix Genome-Wide Human SNP array 500K chip. A total of 324,185 SNPs met quality control criteria and were included in the final analysis data set. We used a linear regression analysis to test for association of SNPs with depressive symptoms using PLINK program. Results: In this genome wide association study for depressive symptom, we found that 20 SNPs demonstrated a significant association with significance level of p<10-4. The identified SNPs were located in the following genes: SFPQ, SDK1, ITPR2, ACCN1, NLGN1, DST, MTHFD1L, HUS1, EXT1, GARNL3, COL5A1, LOC644860, and LOC728602. Among these SNPs, three SNPs in ACCN1 and one SNP in NLGN1 were reported in associated with autism. Conclusion: We have identified several SNPs associated with depressive symptom. For confirming these associations, we will investigate the further biologic and functional annotations.

## 2179/T/Poster Board #728

**Genome-wide association study for Parkinson's Disease in the midwestern US Amish.**
*L. Jiang[1], A. Davis[1], R. Laux[1], L. McFarland[1], P. Gallins[2], L. Caywood[2], D. Fuzzell[2], C. Knebusch[2], C. Jackson[3], W. Scott[2], M. Pericak-Vance[2], J. McCauley[2], S. Lee[4], J. Haines[1].* 1) Ctr Human Gen Res, Vanderbilt Univ, Nashville, TN; 2) Miami Institute for Human Genomics, University of Miami, Miller School of Medicine, Miami, FL; 3) Scott and White, Temple, TX; 4) Dartmouth College, Hanover, NH.

Parkinson's Disease (PD) is the second most common neurodegenerative disorder of adults. Previous evidence has shown that PD is heritable. Mutations in five known genes ($\alpha$-synuclein (PARK1, PARK4), Parkin (PARK2), PINK1 (PARK6), DJ-1 (PARK7), and LRRK2 (PARK8) cause Mendelian inheritance of PD, while consensus regions from GWAS studies implicate MAPT and SNCA. Other regions have been identified but the genes remain unknown. Genetic heterogeneity complicates the verification of likely genes and the identification of other susceptibility genes. Our approach to overcome the problem of heterogeneity is to study a population isolate, the midwestern Amish communities of Ohio. To date we have enrolled over 1850 Amish individuals with 38 of these diagnosed with PD. In this dataset we see a higher average kinship coefficient among our cases (.016) compared to the rest of our dataset (.012), suggesting that PD is heritable in the Amish. We have undertaken a genome-wide association study (Affymetrix-Genome-Wide Human SNP Array 6.0) and genotyped 900 Amish individuals (33 with PD). Through the use of the Anabaptist Genealogy Database (AGDB), we have determined the family structure for our collected individuals. Following QC, 453,389 SNPs and 827 individuals were analyzed. Because of the relatedness of these individuals, we employed a novel test of association using the MQLS test (Thornton & McPeek). Initial results identified 288 SNPs with p-values less than 1 x 10-4. Five SNPs, located on chromosomes 19, 15, and X, reached genome-wide significance level (< 1 x 10 -7). The most significant result was found on chromosome 19 at rs10402506 with a p-value of 9.0 x 10-9. The closest gene, LILRA2 (Leukocyte immunoglobulin-like receptor) is less than 1 Kb away from this SNP. Within the most significant regions, determined by the MQLS results, we searched for stretches of homozygosity preferentially occurring in affected individuals. Three such regions were identified on chr 13 , 15, and X, implicating the TLN2 and GLuR3 genes. Further analysis will confirm these results which indicate possible identification of novel PD-susceptibility genes.

## 2180/T/Poster Board #729

**Genome-wide Association of Cerebrovascular and Neurodegenerative Quantitative MRI Traits in Alzheimer Disease.**
*A. Parrado[1], M. Logue[1], K.L. Lunetta[2], L.A. Cupples[2], C. DeCarli[3], C.T. Baldwin[1], L.A. Farrer[1], MIRAGE Study.* 1) Genetics Program, Boston University, Boston, MA; 2) Department of Biostatistics, Boston University School of Public Health, Boston MA; 3) University of California, Davis Center for Neuroscience, Davis, CA.

Most genetic association studies of Alzheimer disease (AD) have focused on the dichotomous AD diagnosis outcome. However, the AD phenotype is suboptimal because of likely subject misclassification and underlying genetic complexity. With the exception of APOE, genome wide scans of AD conducted to date have not identified significant associations which are sustained in replication studies. Recently, using a candidate gene approach we showed significant associations between SORL1 (a robustly confirmed AD locus) and MRI-based semi-quantitative measures of white matter hyperintensities (WMH), generalized cerebral atrophy (CA) and hippocampal atrophy (HA), thus encouraging use of these endophenotypes for AD. To identify additional genes related to AD, we performed a genome-wide association analysis of WMH, CA, and HA measured in a Caucasian sample of 288 affected and 313 cognitively healthy members of 209 sibships from the MIRAGE Study who were genotyped using the Illumina HumanCNV370-Duo and the Human610-Quad BeadChips. Genotypes for a total of 1.39 million HapMap SNPs were imputed with the MaCH software using the CEU HapMap subjects as a reference panel. Association analyses were performed using Generalized Estimating Equations to account for sib correlations and adjusted for age at MRI, sex, disease duration, genotyping panel version, ancestry measured by genetic principal components, and APOE $\varepsilon 4$ status. Although no results were genome-wide significant, p-values < 1 x $10^{-6}$ were observed for several SNPs with CA (FLI32682), HA (NFIB), and WMH (LOC100131576, GJA9, RHBDL2, LOC100130627, ARHGAP26 and SUSD1). While the veracity of these associations awaits confirmation and the relationships of these loci to AD requires further study, a SNP in NCSTN showed a noteworthy association with HA (p=3.2 x $10^{-6}$, OR 1.9, 95% CI 1.4-2.4). NCSTN encodes the protein nicastrin which binds presenilin and was previously associated with AD in several but not all studies. The hippocampus is the primary early target of neuronal loss in AD. A replication study using an independent group of more than 600 MIRAGE subjects is currently in progress. These results emphasize the potential importance of neuroimaging endophenotypes as biological markers for discovering genes influencing the etiology of AD.

## 2181/T/Poster Board #730

**An Irish Genomewide Association Study of Schizophrenia.** *B. Riley[1], The Irish Schizophrenia Genomics Consortium, The Wellcome Trust Case/Control Consortium.* 1) Virginia Institute for Psychiatric and Behavioral Genetics, Virginia Commonwealth Univ, Richmond, VA; 2) Dept. of Psychiatry, Trinity College Dublin, Dublin, Ireland; 3) Division of Psychiatry and Neuroscience, Queens University Belfast, Belfast, Northern Ireland; 4) Depts. of Genetics, Psychiatry, & Epidemiology, University of North Carolina-Chapel Hill, Chapel Hill, NC; 5) Mental Health Service Line, Washington VA Medical Center, Washington DC, USA; 6) Health Research Board, Dublin, Ireland; 7) Center for Biomarker Research and Personalized Medicine, School of Pharmacy, Virginia Commonwealth Univ, Richmond, VA.

The genomewide association study (GWAS) is a powerful, systematic and unbiased approach to the study of the common disease/common variant (CDCV) hypothesis of complex disorders like schizophrenia. We have assembled a sample of 2357 narrow diagnosis Irish cases and 2000 Irish population controls, and can access 6000 additional UK controls. All cases meet narrowly defined schizophrenia or poor-outcome schizoaffective disorder diagnoses, were assessed directly with a structured clinical interview and had final diagnoses made using consensus criteria. This sample provides ≥80% power to detect allelic odds ratios (ORs) 1.2-1.3 with minor allele frequency (MAF) 0.2-0.3, and is also completely ethnically homogeneous, which should increase its power to detect association further. We have completed 1 million SNP data collection in the second round of the Wellcome Trust Case/Control Consortium, and the SNP genotype dataset is entering analysis at the time of abstract submission. Primary analysis of copy number variation data and of the SNP genotype data with the CA Trend test will be complete for presentation by 10/09. Additional planned analyses (some of which may be complete by 10/09) include 1) weighted FDR analysis using the results of 3 other large GWAS of schizophrenia, 2) analyses of additional phenotypic and clinical data, 3) analysis of evidence for biological or statistical interactions, 4) analyses of pathways and systems and 5) analysis of co-expression.

## 2182/T/Poster Board #731

**Genome-wide association study identifies common variants on two novel loci, α-synuclein, and upstream LRRK2 as genetic risks for Parkinson's disease.** *W. Satake[1,2], Y. Nakabayashi[1], I. Toda[1].* 1) Div Molecular Brain Science, Kobe Univ Grad Sch Med, Kobe, Hyougo, Japan; 2) Department of Neurology, Osaka University Graduate School of Medicine, Suita 565-0871, Japan; 3) Center for Genomic Medicine, RIKEN, Yokohama 230-0045, Japan; 4) Department of Neurology, Graduate School of Comprehensive Human Sciences, University of Tsukuba, Tsukuba 305-8575, Japan; 5) Division of Neurology, Tohoku University Graduate School of Medicine, Sendai 980-8574, Japan; 6) Department of Neurology, Tottori University Faculty of Medicine, Yonago 683-8504, Japan; 7) Department of Neurology, Sagamihara National Hospital, Sagamihara 228-8522, Japan; 8) Division of Clinical Immunology, Graduate School of Medical Sciences, Kitasato University, Sagamihara 228-8555, Japan; 9) RIKEN Brain Science Institute, Saitama 351-0198, Japan; 10) Department of Epidemiology, Research Institute for Radiation Biology and Medicine, Hiroshima University, Hiroshima 734-8553, Japan; 11) Department of Neurology, Kagawa Prefectural Central Hospital, Takamatsu 760-8557, Japan; 12) Department of Neurology, Juntendo University School of Medicine, Tokyo 113-8421, Japan; 13) Department of Neurology, National Center Hospital of Neurology & Psychiatry, Kodaira 187-8551, Japan; 14) Human Genome Center, Institute of Medical Science, University of Tokyo, Tokyo 108-8639, Japan.

Parkinson's disease (PD) is one of the most common neurodegenerative diseases worldwide, affecting 1-2% of individuals aged ≥65 years. To identify susceptibility variants for PD, we performed a GWAS and two replication studies in a total of 2,011 PD cases and 18,381 controls in the Japanese population. In the GWAS stage, we genotyped 561,288 SNPs on autosomal and sex chromosomes using the HumanHap550 array (Illumina). The GWAS stage included 1,078 cases and 2,628 controls in the Japanese population. After SNP and sample quality control analyses, we used high quality genotype data of 435,539 SNPs in 988 cases and 2,521 controls in the GWAS stage. We observed a close match to that expected under the null distribution (genomic inflation factor $\lambda_{GC}$ = 1.055 for PD). This indicates minimal overall inflation of genome-wide statistical results due to population stratification. For fast-track replication, we selected the 337 most associated SNPs (Cochran-Armitage trend; P ≤0.000533) from analysis of GWAS data and genotyped them in two case-control sample sets (Replication 1 and 2) that were independent of each other: the first sample set (Replication 1) consisted of 612 cases and 14,139 controls and the second one (Replication 2) consisted of 321 cases and 1,614 controls. We identified a novel and strong susceptible locus for PD (Novel Locus 1; P = $1.52 \times 10^{-12}$, OR = 1.30) and designated this region as PARK16. A novel and strong association with PD was also detected (Novel Locus 2; P = $3.94 \times 10^{-9}$, OR = 1.24). The two regions contain interesting genes for PD etiology. We detected a strong disease association at SNCA on 4q22 (rs11931074; P = $7.35 \times 10^{-17}$, OR = 1.37) and LRRK2 on 12q12 (rs1994090; P = $2.72 \times 10^{-8}$, OR = 1.39), both causative genes for autosomal dominant forms of parkinsonism (AD-parkinsonism). The MAPT locus was not identified significant in our study, because, unlike Caucasian, the MAPT H2 haplotype was absent in East Asians. This reflects population differences in the genetic heterogeneity of PD etiology. Our data show 4 genes associated with increased risk of PD, including 2 novel ones. Our data also show involvement of causal genes of AD-parkinsonism in typical PD and highlight population differences underlying genetic heterogeneity in PD.

**Genome-wide association study of Gilles de la Tourette Syndrome in European ancestry samples and four population isolates.** *J.M. Scharf[1], B.M. Neale[1,2], S. Service[3], A. Tikhomorov[4], J. Fagerness[1], A. Pluzhnikov[4], D. Yu[1], J. Crane[1], M. State[5], J. Tischfield[6], D. Cath[7], G. Rouleau[8], A. Ruiz-Linares[9], C. Mathews[10], C. Sabatti[3], S. Purcell[1,2], N. Freimer[3], N. Cox[4], D.L. Pauls[1], GTS GWAS Consortium.* 1) Psychiatric Neurodevelopmental Genetics Unit, Massachusetts General Hospital, Boston, MA; 2) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA; 3) Center for Neurobehavioral Genetics, University of California, Los Angeles, CA; 4) Department of Human Genetics, University of Chicago, Chicago, IL; 5) Yale Child Study Center,Yale University, New Haven, CT; 6) Department of Genetics, Rutgers University, Piscataway, NJ; 7) Department of Psychiatry, University of Utrecht, Netherlands; 8) Center for the Study of Brain Disorders, University of Montreal, Canada; 9) Department of Genetics, Evolution and Environment, University College London, England; 10) Department of Psychiatry, University of California, San Francisco, CA.

**Introduction:** Gilles de la Tourette Syndrome (GTS) is a highly heritable neuropsychiatric disorder, though no unequivocal GTS susceptibility genes have been identified. Here, results from the first genome-wide association study (GWAS) of GTS in 1,749 cases and 4,410 ancestry-matched controls will be reported. **Methods:** Cases included 983 GTS subjects of European ancestry (EA) as well as 766 GTS subjects from four population isolates (French Canadian (FC), Ashkenazi Jewish (AJ), Antioquia Colombian (CO) and Central Valley Costa Rica (CR). Diagnoses were made using DSM-IV-TR criteria. Case samples and population isolate controls from FC and CO were genotyped on the Illumina Human610Quad Beadchip; EA and AJ controls were previously genotyped on the Illumina Human550K and Human317K Beadchips, respectively. QC and stratified analyses in each population were performed in PLINK. **Results/Conclusions:** Preliminary results are presented based on analysis of 95% of the data. After standard QC to remove poorly performing SNPs and individuals, 1552 cases and 4027 controls remained. To control for population substructure, multi-dimensional scaling was performed and population outliers were excluded. Data were analyzed using logistic regression under an additive model with significant MDS axes included as covariates. Resulting $\lambda_{GC}$ after correction for the first four MDS axes were as follows: EA cases, 1.11; AJ 1.02; FC 1.02; CO 1.01; CR 1.04. Preliminary association analysis identified 8 loci with genomic control-adjusted p-values in the $10^{-7}$-$10^{-9}$ range (seven in the European ancestry sample and one in the Ashkenazi sample). The most significant autosomal locus in the EA sample was located 10 kb downstream of *CACNA1B* (OR 1.47; p=5x$10^{-8}$), which encodes the pore-forming subunit of the N-type calcium channel. In the AJ sample, the strongest signal was found in a 1 Mb gene desert on chromosome 8; the closest gene, *KCNU1*, encoding a voltage-gated potassium channel, lies 250 kb proximal to this locus (OR= 3.0; p=9.5 x $10^{-9}$). In the FC and CR/CO populations, no loci had GC-adjusted p<$10^{-6}$. Meta-analysis across the five populations identified multiple, additional loci with concordant signals across the populations, though none reached genome-wide significance. Results of analyses from the complete case sample will be presented as well as from imputation of all HapMap SNPs. Additional genotyping in a replication sample will be needed to confirm these results.

## 2184/T/Poster Board #733

**A Genome-wide Association Study of Quantitative Traits Related to ADHD.** *A.K. Smith[1], J.F. Cubells[1,2], D.J. Cutler[2].* 1) Psychiatry & Behavioral Sci, Emory University , Atlanta, GA; 2) Dept of Human Genetics, Emory University , Atlanta, GA.

The discovery of candidate genes is often challenging, especially when the etiology of a phenotype is as complex as the development of childhood psychopathology. Still, an emerging literature supports the heritability of several behavioral traits and disorders commonly diagnosed in children, including Attention Deficit Hyperactivity Disorder (ADHD). This study performed a genome-wide association analysis on the publically available GAIN dataset on ADHD, to identify SNPs associated with the dimensions of the Strength and Difficulties Questionnaire (SDQ), which assesses emotional symptoms, inattention/hyperactivity, conduct problems, peer problems, and prosocial behavior. Samples with call rates <90, duplicate samples, and subjects with heterozygosity inconsistent with gender on the X chromosome were eliminated. SNPs were eliminated if they had: a genotyping error rate >1.5 in any one of three genotype classes, a missing data rate >10 for any genotype class, an overall missing data rate of >1/5 the minor allele frequency or any departure from HWE significant at p<0.0001 in the parents of the probands. After removing the SNPs that did not meet QC criteria, 474,959 SNPs were examined using FBAT. Notably, associations were observed between emotional problems and 17 SNPs (6.70x$10^{-7}$ < p < 0.041) in *diacylglycerol kinase, beta* (*DGKB*), which is expressed intensely in the caudate putamen and participates in dopamine-mediated regulation of movements and learning. Twenty-six SNPs in *neuronal PAS domain protein 3* (*NPAS3*), a gene previously associated with biopolar disorder and schizophrenia and involved in hippocampal neurogenesis, were associated with hyperactivity (6.8x$10^{-5}$ < p < 0.047). Conduct problems were associated with 8 SNPs (1.9x$10^{-6}$ < p < 0.022) in *death-associated protein kinase 1* (*DAPK1*), an epigenetically regulated gene associated with Alzheimer's disease. Twenty SNPs in *SRY (sex determining region Y)-box 5* (*SOX5*), which postmitotically regulates migration, postmigratory differentiation, and subcortical projections of neurons, were associated with peer problems (1.7x$10^{-5}$ < p < 0.045). Also, 16 SNPs in *cadherin 4* (*CDH4*), a gene involved in brain segmentation and neuronal outgrowth, were associated with prosocial behavior (5.5x$10^{-6}$ < p < 0.050). This approach has resulted in the identification several genes that warrant further investigation into their associations with child behavior and the development of childhood psychopathology.

**Genome-wide association study of schizophrenia in a Chinese population.** *H.C. So[1], R.Y.L. Chen[1], E.Y.H. Chen[1], E.F.C. Cheung[4], S.S. Cherny[1,2,3], T. Li[5], P.C. Sham[1,2,3].* 1) Department of Psychiatry, University of Hong Kong, Hong Kong; 2) Genome Research Centre, University of Hong Kong, Hong Kong; 3) The State Key Laboratory of Brain and Cognitive Sciences, University of Hong Kong, Hong Kong; 4) Castle Peak Hospital, Hong Kong; 5) Division of Psychological Medicine and SGDP Centre, Institute of Psychiatry, King's College, London, UK.

Schizophrenia is a severe psychiatric disease with a lifetime risk of approximately 1%. Although the heritability of schizophrenia is high, very few susceptibility genes have been identified to date. Genome-wide association study (GWAS) has proved to be a powerful tool in dissecting the genetic basis of complex diseases. To date, most GWAS on schizophrenia were conducted on Caucasians. However, allele frequencies, linkage disequilibrium patterns and genetic or environmental backgrounds may differ among populations, rendering some variants more readily discovered in one population than the other. We have performed a GWAS on schizophrenia with 400 cases and 1311 controls in a Chinese Han population. Samples were genotyped using the Illumina Human610-Quad BeadChip. After quality control procedures, the dataset consisted of 477354 SNPs from 396 cases and 1286 controls. In total 67 SNPs achieved nominal p-values less than 1E-4. We also extracted the association results of SNPs lying within 30 candidate genes listed in the SZgene database. The QQ plot however shows no evidence of enrichment of significant variants within these candidate genes. The most significant SNP in the candidate gene analysis belongs to the DISC1 gene with a p-value of 8.21E-4. We plan to perform a replication study in an independent sample of family trios from Chengdu, China. In addition to selecting SNPs reaching the highest significance levels in the whole-genome scan, we also plan to select top SNPs in the linkage hotspots suggested by a recent meta-analysis. We will adopt a more liberal threshold for SNPs lying within linkage regions than the other SNPs in the genome, as the former group probably has stronger prior evidence for association.

**A genome-wide association study of obsessive-compulsive disorder.**
*E. Stewart[1,2], B.M. Neale[2], J.A. Fagerness[2], C. Mathews[3], J. Knowles[4], P. Arnold[5], G. Hanna[6], D. Cath[7], D. Denys[8], A.G. Hounie[9], M. Wagner[10], C. Lochner[11], M.C. Cavallini[12], H. Nicolini[13], D. Murphy[14], G. Nestadt[15], S. Purcell[2], D. Pauls[1,2], Obsessive-Compulsive Foundation Genetics Collaborative.* 1) Psychiatry, Harvard Medical School, Boston, MA; 2) Psychiatric and Neurodevelopmental Genetics Unit, Massachusetts General Hospital; 3) Psychiatry, University of California San Francisco; 4) University of Southern California; 5) Department of Psychiatry and Program in Genetics and Genomic Biology, Hospital for Sick Children, Toronto, Ontario, Canada; 6) Department of Psychiatry, University of Michigan; 7) Utrecht University, Department of Clinical and Health Psychology; Anxiety Outpatient Program, Altrecht, Utrecht; 8) Department of Psychiatry, Academic Medical Center, University of Amsterdam; Institute for Neuroscience, Amsterdam, The Netherlands; 9) Department of Psychiatry, University of San Paulo, Brazil; 10) Bonn; 11) MRC Unit on Anxiety Disorders, Department of Psychiatry, University of Stellenbosch, South Africa; 12) Fondazione Centro San Raffaele del Monte, Tabor, Italy; 13) Genomic Center, Universidad Autónoma de la Ciudad de México; 14) NIMH, Bethesda; 15) John Hopkins University, Department of Psychiatry and Behavioral Science, Baltimore, MD.

Introduction: Obsessive-Compulsive Disorder (OCD) is a complex genetic illness. This first genome-wide association study (GWAS) of OCD included European ancestry cases & family trios from international sites of the OCF Genetics Collaborative. Methods: Cases included 1558 OCD subjects of European ancestry as well as 477 OCD affected probands & their parents. Diagnoses were made using DSM-IV-TR criteria. Case & familial trio samples were genotyped on the Illumina Human610Quad Beadchip; 3,212 European ancestry 'iControl' samples were previously genotyped on the Illumina Human550K Beadchip. QC & stratified analyses were performed in Plink. TDT & case-control samples were weighted by their power to detect association. GPC based non-centrality parameters were employed. A weighted Z approach was used to transform P into Z-values for combining the two samples. Results/Conclusions: Preliminary results are presented. After standard QC to remove poorly performing SNPs and individuals with low call rate (<97%), excess heterozygosity, sex discordance, or unexpected duplications/cryptic relatedness, 1558 cases remained. Further checks for familial relationship confirmation and Mendel errors left 477 trios in 458 nuclear families. In addition, 3,212 iControl samples with >5% minor allele frequency, <5% missingness at SNP and individual levels, HWE and IBD sharing thresholds of p=10-3 HWE & 0.15 remained. Multi-dimensional scaling (MDS) was performed & population outliers were excluded. Data were analyzed using logistic regression under an additive model with significant MDS axes included as covariates. The resulting genomic control $\lambda$ from the case-control component was 1.084 & for the familial trio (TDT) sample was 1.039. Combining these two datasets yielded a $\lambda$ of 1.09. Preliminary, genomically controlled association analyses identified two loci with p-values in the 10-7 range & 12 loci with p-values in the 10-6 range. Four of the top 14 associated genes are involved in glutamate neurotransmission (GRK4, GRID2, GRIN2B and DLGAP1), consistent with current theories regarding OCD pathophysiology. Furthermore, GRIN2B & genes in the GRK & DLGAP families were previously reported in candidate gene studies of OCD. Although the results of this first GWAS study of OCD were promising, with multiple biologically plausible associated loci, results fell short of genome-wide significance. Additional genotyping in independent samples will be necessary to confirm these findings.

## 2187/T/Poster Board #736

**Genome-wide patterns of genetic variation in individuals with autism spectrum disorders from Croatia.** *L. Wang[1,4], D. Hranilovic[7], K. Wang[6], L. Yurcaba[5], Z. Petkovic[8], N. Gidaya[2], B. Jernej[9], H. Hakonarson[3,6], M. Bucan[2,4].* 1) Pathology and Lab Medicine, University of Pennsylvania, Philadelphia, PA; 2) Genetics, University of Pennsylvania, Philadelphia, PA; 3) Pediatrics, University of Pennsylvania, Philadelphia, PA; 4) Penn Center for Bioinformatics, University of Pennsylvania, Philadelphia, PA; 5) Neuroscience Graduate Group, Biomedical Graduate Studies, University of Pennsylvania, Philadelphia, PA; 6) Center for Applied Genomics, The Children's Hospital of Philadelphia, Philadelphia, PA; 7) Faculty of Science, University of Zagreb, Zagreb, Croatia; 8) Psychiatric Hospital for Children and Youth, Zagreb, Croatia; 9) Laboratory for Neurochemistry and Molecular Neurobiology, Institute Rudjer Boskovic, Zagreb, Croatia.

Genome-wide association studies of complex diseases require genotype analysis of a large global population samples, including cases and control subjects. However, individuals with different ethnic origins may differ in genetic variation, leading to spurious associations. As a first step in the analysis of susceptibility to autism spectrum disorder (ASD) in Croatia, we characterized genetic variation in a sample of 103 subjects with ASD and 200 control individuals. All subjects were genotyped using the Illumina HumanHap550 BeadChip platform. Distance-based phylogeny analysis together with several previously published populations revealed that Croatian subjects cluster, as expected, with Southern Europeans; in addition, individuals from the same geographic region within Croatia cluster together. Croatian subjects are separated from a sample of 600 healthy control subjects of European origin from North America, while Croatian ASD cases and controls are well mixed. A comparison of runs of homozygosity indicated the number and the median length of regions of homozygosity was higher for ASD subjects than for controls. The analysis of this small sample of 103 ASD individuals did not reveal a genome-wide significant ASD susceptibility loci, although among 728 rare CNVs found in Croatia cases and controls, 118 rare CNVs in ASD candidate regions were found in affected subjects. Moreover, three CNVs, including deletion of ACCN1 on Chr 17q11.2-q12, deletion of upstream region of LRRC4C on Chr 11p12-p11.2, and HSFX1 duplications on Chr X, were detected in affected individuals from Croatia and in a large cohort of 900 ASD cases from the USA, but not in corresponding control subjects.

## 2188/T/Poster Board #737

**Pathway analysis of multiple GWAS datasets implicates genes in the extracellular matrix - receptor interaction pathway with autism risk.** *B.L. Yaspan[1], J.S. Sutcliffe[1], M.A. Pericak-Vance[2], J.L. Haines[1], the Autism Genome Project.* 1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Miami Institute for Human Genomics, University of Miami, Miami, FL.

Autism is a common neurodevelopmental disorder characterized by deficits in language, reciprocal social interaction and patterns of rigid compulsive behaviors. Twin and family studies indicate that autism has a predominantly genetic etiology, and the presence of broader autism phenotype features in first degree relatives further supports heritability. Substantial progress has been made identifying rare copy number variants associated with autism, but most common allelic associations fail replication; possibly a function of locus heterogeneity and small effect sizes at individual loci. An exception is the recently reported association at 5p14.1, implicating cell adhesion molecules CDH9 and CDH10. As rare variants in autism tend to cluster in specific pathways, we hypothesized that common alleles of modest effect might also cluster in specific pathways to collectively affect risk. We conducted a pathway-based analysis using the KEGG database on the recently published Collaborative Autism Project (CAP) GWAS (487 trios) for exploration and on the larger Autism Genome Project (AGP) GWAS (1442 trios) for replication. If multiple genes in a pathway have an additive effect, statistical association for each SNP might be modest. Thus, known genes (±50kb) containing 2+ SNPs with nominal $p \leq 0.05$ and an $r^2 \leq 0.8$ were included in the analysis (n= 8884 Ensembl gene IDs; 185 KEGG pathways). We tested for enrichment (En) of observed: expected number of genes in each pathway. After multiple testing correction, 10 pathways were significantly overrepresented; strongest being the extracellular matrix-receptor interaction (ECM-RI) pathway (En=2.09, p=1.12E-6). We applied similar SNP and gene inclusion methods to the AGP dataset. Both strict and autism spectrum proband strata were highly significant when testing the ECM-RI pathway (strict En= 5.81,p=4.20E-13;spectrum En=4.54;p=2.17E-10). Further analysis of both datasets showed related signaling pathways focal adhesion and cell adhesion molecules (with CDH9, CHD10) were also significant (adj p from 0.003-1.86E-12). Ongoing analyses will explore the effect of potential biases such as gene and pathway size on these results. However, these preliminary results suggest that variation within genes of the ECM-RI pathway may collectively conspire to increase risk of autism and warrant further investigation.

## 2189/T/Poster Board #738

**Genome-wide survey for genetic loci underlying noise phobia in herding breed dogs.** *J.S. Yokoyama[1], M.L. Chang[1], K.L. Overall[2], N. Branson[2], S. Juarbe-Diaz[2], D.J. Dyer[2], S.P. Hamilton[1].* 1) Neurogenetics Laboratory, Department of Psychiatry and Institute for Human Genetics, University of California, San Francisco; 2) Center for Neurobiology and Behavior, Department of Psychiatry, University of Pennsylvania.

**Purpose**: The domestic dog is an excellent model for the study of complex behavioral phenotypes. Dogs exhibit naturally occurring behavioral pathologies that are analogous and probably homologous to human psychiatric disorders. Noise phobia, characterized by panic responses to sounds such as thunder, gunshots, and fireworks, is clinically similar to specific phobia in humans, is enriched in certain breeds, and can adversely affect quality of life for both dogs and owners. The distribution of noise phobia within and between canine families and populations suggests an underlying genetic basis for this pathology. The history and homogeneity of individual breeds facilitate efforts to detect associations between genes and complex behaviors that would be challenging in human populations. **Methods**: We conducted a genome-wide survey for SNPs associated with noise phobia in a sample of 183 dogs across 27 breeds using the Affymetrix Canine v2.0 array. Our sample included multigenerational pedigrees of Border Collies and Australian Shepherds that segregate noise phobia and a subset of unrelated cases and controls from several breeds. We filtered markers using standard quality control statistics and assessed phenotypes for noise phobia using a behavioral questionnaire that was developed by our group. We performed allelic association tests between single breed cases and controls and examined cases and controls across multiple breeds via Cochran-Mantel-Haenszel association test, allowing stratification by genetic background to avoid confounding. **Results**: Our case-control analyses yielded associations of markers and affected status on chromosomes 7, 10, 26, 27 and 34 that were supported by preliminary regional fine-mapping. All analyses supported similar findings and withstood permutation to correct for multiple comparisons. **Conclusion**: We have discovered several genomic regions of large genetic effect associated with noise phobia in our sample, suggesting that multiple genetic loci underlie this disorder across breeds. This is the first genome-wide association study in non-human animals focusing on a complex behavioral disorder, and the first to survey any species for markers associated with specific phobia. Future goals include expanding the sample, replicating findings in new samples, incorporating family data into our analyses, and exploring the implications of our results for human psychiatric research.

## 2190/T/Poster Board #739

**Genome-wide screen for rare copy-number variants in Amyotrophic Lateral Sclerosis.** *H. Blauw[1], J.H. Veldink[1], M.A. Van Es[1], P.W.J. Van Vught[1], L.a. Kiemeney[2], S.H. Vermeulen[2], K. Estrada[3], F. Rivadeneira[3], A.G. Uitterlinden[3], S. Cronin[4], O. Hardiman[4], W. Robberecht[5], P.M. Andersen[6], R.A. Ophoff[7,8], L.H. Van Den Berg[1].* 1) Neurology, UMC Utrecht, Utrecht, Netherlands; 2) Department of Epidemiology, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands; 3) Department of Epidemiology, Erasmus Medical Center Rotterdam, Rotterdam, The Netherlands; 4) Department of Neurology, Beaumont Hospital, Dublin, Ireland; 5) Department of Neurology, University Hospital Leuven, University of Leuven, Leuven, Belgium; 6) Institute of Clinical Neuroscience, Umeå University Hospital, Umeå, Sweden; 7) Department of Medical Genetics and Rudolf Magnus Institute, University Medical Center Utrecht, Utrecht, The Netherlands; 8) UCLA Center for Neurobehavioral Genetics, Los Angeles, USA.

Amyotrophic Lateral Sclerosis (ALS) is an invariably fatal neurodegenerative disease, caused by the selective death of motor neurons in the cerebral cortex and spinal cord. There is no curative treatment. The majority of cases are sporadic and the etiology is considered to be multifactorial, with both environmental and genetic components contributing to disease susceptibility with an estimated heritability of 0.38-0.85. Copy-number variants (CNVs) contribute to genetic and phenotypic variation and can occur as frequent copy number polymorphisms (CNPs) in the population or as rare events with an allele frequency of <1%;. It is thought that these rare structural variants are generally highly penetrant events with deleterious effects. Indeed, several CNV loci containing rare CNVs have been associated to disease phenotypes such as autism and schizophrenia. In this study, we sought to identify rare genomic loci that show association for ALS susceptibilty. 1881 ALS cases and 8760 controls were included. SNP intensity data were derived from different datasets using Illumina 300k, 370k and 550k arrays, and to make the different sets comparable we only used probes common to all arrays. We first applied Loess normalization to the intensity data and used PennCNV software for CNV calling. We applied strict quality control measures based on the per sample data quality and filtered data based on CNV call characteristics. We tested each gene for association with overlapping CNV segments. The gene that yielded the lowest p value was *DPP6* (dipeptidyl peptidase 6): p = 0.0035 (Fisher's exact test). The frequency of CNVs detected in cases was 0.5%;, while the frequency in controls was 0.1%;. The effect was almost entirely due to duplications: when analysing duplications and deletions separately, $p_{duplications} = 0.006$, while $p_{deletions} = 0.32$. *DPP6* encodes a dipeptidyl peptidase-like protein which is predominantly expressed in the brain. Interestingly, an intronic SNP within *DPP6* was significantly associated with ALS susceptibility in three independent association studies. Our results do not survive Bonferroni correction as such, so caution is warranted when examining these results. We are currently making efforts to replicate these findings in independent study populations.

**Biology of autism revealed through analysis of complex genotypes in GWAS data.** *C. Harris, J. Burns.* Exagen Diagnostics, Inc., Houston, TX.

**Background:** Autism spectrum disorders (ASD) are among the most prevalent and most heritable of neurodevelopmental disorders. While studies have identified many genetic loci as being associated with ASD, the complex genetics underlying the disease remains to be unraveled. We propose generally that reliance on univariate measures of association limits our understanding of complex genetic disease. Moreover, we specifically demonstrate that, for a particular ASD GWAS dataset, an analysis that seeks to identify associated complex genotypes yields results significantly overlapping those compiled from previous studies. **Methods:** Marshall et al. (Am J Hum Genet. 2008 Feb;82(2):477-88) collected genome-wide family SNP data, a portion of which, consisting of the genotypes for approximately 500,000 SNPs for each of 335 ASD cases and 232 parent cases, was made publicly available (http://www.ncbi.nlm.nih.gov/geo/ accession GSE9222). A genetic algorithm-based search was used to identify combinations of SNPs across the affected and parent samples that best discriminated the two groups. Over 5 billion 5-SNP combinations were evaluated. The significance of these was assessed using a permutation test. Reasonable throughput required the use of high performance computing resources. **Results:** We identified 25,116 significant (p<.05) 5-SNP combinations consisting of 4,296 unique SNPs. Genes overlapping or near these SNPs are significantly enriched for genes previously implicated in ASD. Of the 154 genes listed in the AutDB database (http://www.mindspec.org/autdb.html) of genes reported to be associated with autism, 57 were identified by our analysis (p=2.0X10-13). The SNP set was also evaluated using the DAVID functional annotation tools (Dennis G, et al. Genome Biol. 2003;4(5):P3). Significantly enriched biological process and cellular component terms include 'cell adhesion' (p=5.2X10-7, all DAVID p-values Benjamini-corrected), 'axongenesis' (p=8.3X10-4), 'synaptic transmission' (p=1.6X10-2), 'synapse' (p=2.1X10-4) and 'postsynaptic membrane' (p=1.1X10-3). Additional DAVID tools enable identification of associated pathways and tissues. The 'neuroactive ligand-receptor interaction' and 'axon guidance' KEGG pathways were identified (p=4.0X10-4 and p= 3.0X10-3, respectively), as was 'fetal brain tissue' (p=7.9X10-5). A univariate analysis identified 5 SNPs as associated with ASD. In contrast, these did not overlap with AutDB genes and were not enriched for any DAVID terms.

## 2192/T/Poster Board #741

**Genome-wide association study of migraine in Australian twins.** *D.R. Nyholt[1], S.D. Gordon[2], B.P. McEvoy[4], M. Campbell[3], A. Henders[2,3], A.C. Heath[5], G.W. Montgomery[3], N.G. Martin[2].* 1) Neurogenetics Lab, QIMR, Brisbane, Australia; 2) Genetic Epidemiology Lab, QIMR, Brisbane, Australia; 3) Molecular Epidemiology Lab, QIMR, Brisbane, Australia; 4) Queensland Statistical Genetics Lab, QIMR, Brisbane, Australia; 5) Department of Psychiatry, Washington University School of Medicine, St. Louis, MO.

Typical migraine, is a frequent, debilitating and painful disorder that normally affects people during their most productive years (up to 25% of females and 7.5% of males). The World Health Organization recently identified migraine among the world's top 20 leading causes of disability, with an impact that extends far beyond the suffering individual, to the family and community. Although migraine is highly prevalent in our society, its aetiology remains relatively obscure and there are no laboratory based diagnostic tests that identify those who suffer from the disorder. Twin studies indicate that migraine has a significant genetic component, with heritability estimates of 33-65%. Therefore, in an effort to identify the molecular mechanisms underlying the disorder, we are performing a genome-wide association (GWA) study of migraine in a large sample of Australian twins. Although genotyping is still underway, preliminary GWA results utilising 1088 unrelated migraine cases and 2849 unrelated controls have already identified two novel loci reaching genome-wide significance. Up-to-date results from our migraine GWA encompassing genotypes from both additional individuals and imputation, along with our experience in combining data across multiple projects, arrays and platforms will be presented.

## 2193/T/Poster Board #742

**Genome-wide association analysis of sleep length reveals new genes and pathways controlling sleep homeostasis.** *H.M. Ollila[1,2,3], T. Partonen[2], E. Kronholm[2], S. Männistö[2], J. Lönnqvist[2], V. Salomaa[2], L. Peltonen[2,4], M. Perola[2], T. Porkka-Heiskanen[1], T. Paunio[2,3].* 1) Department of Physiology, Institute of Biomedicine, University of Helsinki, Helsinki, Finland; 2) National Institute for Health and Welfare; 3) Department of Psychiatry, University of Helsinki and Helsinki University Central Hospital, Helsinki, Finland; 4) Wellcome Trust Sanger Institute, Cambridge, UK.

The genetic component in sleep homeostatic and circadian regulation is high. Disturbances in sleep have also been linked to mood disorders like major depression or bipolar disorder. Furthermore, especially short sleep predisposes to metabolic syndrome and may induce weight gain. However, the genes affecting sleep pattern or mood are not yet well understood. In order to further elucidate the genetic component behind sleep length and seasonal variation we performed a genome-wide DNA association analysis of 2200 Finnish individuals from the national Health2000 project. The individuals were genotyped with altogether over 600 000 single nucleotide polymorphism (SNPs)by Illumina 610 K and characterized for total sleep length per night (TSL) as well as evaluated for depressive symptoms and variation in mood due to seasonal changes. In addition to straight-forward search for association of the single polymorphsisms, Wewe also studied whetherexamined if there were enriched associations of variants from genes single genes from certain molecular pathways were enriched in our dataset. We found several new genes and variants that showed statistically significant association to TSL, which affect sleep length, while some of the genes from sleep regulation also gave suggestive signals for association. Interestingly, the gene ontology analysis showed that sleep length and seasonal changes in mood share common molecular pathways, which belong to brain development, neural, synapse and tyrosine kinase signaling pathways. Altogether we have identified new genes for sleep homeostasis and found potential candidate genes for studying the pathological aspects of both sleep disturbances and mood disorders.

## 2194/T/Poster Board #743

**Genome-wide linkage using the Social Reciprocity Scale (SRS) in Utah autism pedigrees.** *H. Coon[1], M. Villalobos[1], R. Robison[1], D. Cannon[1], K. Allen-Brady[1], M.F. Leppert[2], J. Miller[1], W. McMahon[1].* 1) Dept Psychiatry, Univ Utah, Salt Lake City, UT; 2) Dept Human Genetics, Univ Utah, Salt Lake CIty, UT.

Autism Spectrum Disorders are phenotypically heterogeneous, characterized by impairments in communication and social behavior, and the presence of repetitive behavior and restricted interests. Dissecting the genetic complexity of ASDs may require phenotypic data reflecting more detail than is offered by categorical clinical diagnosis. We present genome-wide results for 64 multiplex and extended families ranging from 2 to 9 generations with phenotypes measured by the Social Reciprocity Scale (SRS). The SRS is a continuous, quantitative measure of social ability giving scores that range from significant impairment to above average ability, therefore allowing us to use information from 518 pedigree subjects, including affected and unaffected relatives. When analyzed as a qualitative trait, results replicated a previous affected-only genome scan using clinical affection status on these families, with findings on chromosomes 7q31.1-q32.3 (HLOD=2.55), 15q13.3 (HLOD=4.09), and 13q12.3 (HLOD=2.23). Additional positive qualitative results were seen on chromosomes 3, 6, and 10. When analyzed as a quantitative trait, results replicated a previous scan of quantitative SRS scores, with results on chromosome 11p15.1-p15.4 (HLOD=2.77) and chromosome 8q13.3 (NPL score=2.56). Additional positive quantitative results were seen on chromosomes 9, 14, 16, 17, and 19. Our results suggest that the information from the SRS provides a useful tool to identify chromosomal regions that may contain autism susceptibility loci.

## 2195/T/Poster Board #744

**Brain and peripheral gene expression changes in rats after two weeks of exposure to antidepressant drugs.** *K. Doudney[1], J.A. Harley[2], X.Y. Deng[1], M. Allington[1], H.J. Waldvogel[3], R.L.M. Faull[3], P.R. Joyce[2], M.A. Kennedy[1].* 1) Department of Pathology, University of Otago, Christchurch, New Zealand; 2) Department of Psychcological Medicine, University of Otago, Christchurch, New Zealand; 3) Department of Anatomy with Radiology, Faculty of Medical and Health Sciences, The University of Auckland, Auckland 1023, New Zealand.

Antidepressants are an effective treatment for sub-classes of mood disorders including major depressive disorder, although we still don't know the molecular basis of their action. One approach to understanding the molecular effects of these drugs is to expose cultured cells and rodent models to antidepressants and observe protein or RNA expression changes as a measure of the biochemical and genetic processes involved. We have identified a number of antidepressant responsive genes and proteins in proteomic analyses of embryonic stem cell derived neural cells and rat hippocampus (1,2). Additionally, microarray analysis in these systems, and in the serotonergic cell line RN46A, have provided further antidepressant-specific gene expression differences (3,4). To further evaluate these observations, we have compared the immunohistochemical signals of several candidate proteins including PHB, PVALB, HIF1A, PDIA3 and SPR in treated and untreated rat brain sections from animals exposed to paroxetine, citalopram, haloperidol and vehicle only. We present preliminary data showing the differential expression patterns of PHB, PVALB and PDIA3. In parallel with this immunohistochemical study, we are also exploring potential differences in peripheral gene expression patterns in these animals by microarray analysis of cDNA extracted from total peripheral blood. Arrays have been completed on all animals and the results are currently being analysed. Data from these experiments should add to our knowledge of the molecular actions of antidepressants, and provide potential peripheral gene expression markers that may be used to guide or further explore clinical responses to antidepressant therapy. 1. ## 2196/T/Poster Board #745

**A combination of gene expression and tissue microarrays for the identification of human disease biomarkers: application for amyotrophic lateral sclerosis.** *S.L. Karsten[1], L.C. Kudo[2], L. Parfenova[1], N. Vi[2], K. Lau[1,3], J. Pomakian[4], H.V. Vinters[4], M. Wiedau-Pazos[3].* 1) Neuroscience, Los Angeles Biomedical Research Institute at Harbor-UCLA Medical Center, Torrance, CA; 2) NeuroInDx, Inc., Signal Hill, CA; 3) Neurology, David Geffen School of Medicine at UCLA, Los Angeles, CA; 4) Pathology and Laboratory Medicine, David Geffen School of Medicine at UCLA, Los Angeles, CA.

The identification of functionally relevant human disease modifying genes and proteins is essential for the design of novel therapeutic approaches. Advances in genomics and proteomics permitted the analysis of thousands of molecules in parallel to quickly identify disease relevant genes and proteins. However, this process still faces multiple challenges. Among them are global differences between animal models and human disease, high discordance between DNA and protein expression data, and a lack of experimental models which would represent human complex diseases accurately. The complexity and inaccessibility of brain tissues create additional obstacles when dealing with neurological disorders. To overcome some of these limitations, we developed an integrative approach that takes advantage of multiple animal models, post-mortem human material and a combination of high-throughput technologies to identify novel molecular markers of a human neurodegenerative disorder, amyotrophic lateral sclerosis (ALS). We used laser capture microdissection coupled with microarray based gene expression analysis to identify transcriptome changes that occur specifically in spinal cord motor neurons or surrounding glial cells in two different mouse models of familial motor neuron disease, SOD1G93A and TAUP301L transgenic mice. The experiments were performed at the presymptomatic stage to exclude identification of false positives due to reactive changes in the advanced disease stage. Identified gene expression changes were mainly model-specific. Then, to investigate the relevance of identified genes in sporadic ALS (SALS), corresponding protein products were examined by high throughput immunoassays using tissue microarrays constructed of human SALS postmortem spinal cord tissues. This large scale gene and protein expression study identified several new SALS biomarkers including Ccl19, Cnga3, Crb1, Mmp14 and established that TAU- and SOD1-induced motor neuron degeneration have distinct molecular mechanisms.

## 2197/T/Poster Board #746

**Puromycin sensitive aminopeptidase (PSA) as a modifier of amyotrophic lateral sclerosis that acts on SOD1.** *L. Parfenova[1], K. Lau[1,2], N. Vi[3], J. Pomakian[4], H.V. Vinters[4], L.C. Kudo[3], S.L. Karsten[1].* 1) Neuroscience, Los Angeles Biomedical Research Institute at Harbor-UCLA Medical Center, Torrance, CA; 2) Neurology, David Geffen School of Medicine at UCLA, Los Angeles, CA; 3) NeuroInDx, Signal Hill, CA; 4) Pathology and Lab. Medicine, David Geffen School of Medicine at UCLA, Los Angeles, CA.

Accumulation of abnormally folded proteins and peptides is a key feature of many neurodegenerative diseases, including Alzheimer's disease, Huntington disease and Amyotrophic Lateral Sclerosis (ALS). Puromycin sensitive aminopeptidase (PSA or NPEPPS) was recently identified as a novel modifier of TAU-induced neurodegeneration with neuroprotective effects via direct proteolysis of TAU protein (Karsten et al, 2006; Sengupta et al, 2006). Another recent report identified PSA as the major peptidase that digests polyglutamine sequences that may be an underlying cause of several polyglutamine diseases including Huntington's disease (Bhutani et al, 2007). These evidences suggest that PSA may be part of a natural neuroprotective mechanism that acts on potentially neurotoxic substrates through proteolytic activity. Here, we report the first evidence of PSA'sinvolvement in the progression of familial and sporadic ALS through interaction with SOD1 (Cu/Zn superoxide dismutase-1). Mutant SOD1 aggregation is observed in familial ALS, in SOD1 transgenic mice, and in some sporadic ALS cases (Boillee et al, 2006; Shaw and Valentine, 2007). To examine the effects of PSA overexpression in vivo, we generated multiple independent lines of PSA transgenic mice using bacterial artificial chromosome (BAC) mediated technology. Immunohistochemical analysis of these mice revealed that SOD1 protein expression is decreased in the brain stem and spinal cord in the adult. On the other hand, Western blot analysis performed on the protein lysates extracted from spinal cord of SOD1-G93A transgenic mice demonstrated that PSA is significantly ($P<0.01$) reduced in the spinal cord of presymptomatic (2-month old) and symptomatic (4-month old) animals. Further, a high-throughput immunohistochemical analysis on human tissue microarray containing sporadic ALS (SALS) postmortem CNS tissue samples showed significant decrease of PSA protein expression in the SALS motor neurons. Our work revealed a potential involvement of PSA in SOD1 metabolism and possibly ALS progression. An ongoing research on the physical interactions between PSA and SOD1 proteins is in progress.

## 2198/T/Poster Board #747

**ADHD in children with Autism Spectrum Disorders: Effect of family history, age, gender, and race.** *R. Abramson[1], A. Hall[2], S. Ravan[1], M. Cuccaro[3], J. Gilbert[3], M. Pericak-Vance[3], H. Wright[1].* 1) Dept Neuropsychiatry & Behav, USC Sch Med, Columbia, SC; 2) Dept. Communication Sciences, USC Sch Public Health, Columbia, SC; 3) Miami Inst. Human Genomics, U Miami School Med, Miami, FL.

**Introduction**: Attention Deficit Hyperactivity Disorder (ADHD) symptoms are reported by parents in a subgroup of children with Autism Spectrum Disorder (ASD). ADHD symptoms are currently considered a part of ASD. ADHD can be inherited (Biederman, 2005). Few studies examine differences in children with ASD+ADHD and a family history of ADHD (FH+) versus children with ASD+ADHD and no family history of ADHD (FH-). This study examines ADHD in children with ASD+ADHD (FH+) and children with ASD+ADHD (FH-). **Purpose**: To evaluate ADHD symptoms in children with ASD+ADHD (FH+) versus children with ASD+ADHD (FH-) by gender, race, and age using the SNAP IV(Bussing et al 2008). **Methods**: Children (n= 285, ages 4-21) with idiopathic ASD (PDD=6, Autism (AUT)=232, Asperger's (ASP)=53) diagnosed by ADI-R criteria(Lord, 1994) and expert clinicians were enrolled from a genetic study. The SNAP IV (a parent report measure) was used to determine the presence of ADHD symptoms in the sample. It has 3 scales: inattention (IN), hyperactivity (HYP) and Oppositional Defiant Disorder symptoms (ODD). Three categories of first degree relatives were included: (1) no ADHD, (2) suspected ADHD, and (3) diagnosed ADHD. **Results**: ANOVA indicated significant differences among AUT+ ADHD family history groups (none, suspected, diagnosed) on IN ($F(2,226)= 4.918$, $p= 0.008$), HYP ($F_{(2,226)}=4.068$, $p=0.018$) and ODD ($F_{(2,226)}=4.307$, $p=0.015$) with higher scores for ADHD FH+. ANOVA showed higher scores for children with ASP+ADHD than AUT+ADHD on IN ($F_{(1,284)}=13.140$, $p=0.000$), HYP ($F_{(1,284)}=6.015$, $p=0.015$, and ODD($F_{(1,284)}=72.970$, $p=0.000$). A 2x2 gender and race ANOVA showed significant main effects on HYP by gender ($F_{(1,238)}=5.044$, $p=0.026$) and race ($F_{(1,238)}=8.570$, $p=0.004$) and a gender by race interaction ($F_{(1,238)}=4.376$, $p=0.038$) and a main effect on IN by gender ($F_{(1,238)}=8.013$, $p=0.005$) and a gender by race interaction ($F_{(1,238)}= 5.859$, $p=0.016$). Overall, nonwhites had lower scores than whites on HYP and girls had lower HYP and IN scores. The interaction showed the nonwhite females scored lower on HYP than the other groups and lower on IN than the male groups. As expected, children age 4-11 had higher HYP scores ($F_{(1,289)}=6.748$, $p=0.010$) and lower ODD scores, $F_{(1,238)}=6.970$, $p=0.009$. **Conclusions**: ADHD symptoms in children with ASD differ in severity based on family history of ADHD, race, gender, and age. These factors need to be further examined as the FH+ subgroup was 18.1% of the sample.

## 2199/T/Poster Board #748

**The effect of family history, age, and gender on parent report of ADHD behaviors in children with ASD.** *A. Hall[1], R. Abramson[2], S. Ravan[2], M. Cuccaro[3], J. Gilbert[3], M. Pericak-Vance[3], H. Wright[2].* 1) Communication Sciences & Disor, Univ South Carolina Sch Public Health, Columbia, SC; 2) Dept Neuropsychiatry, USC Sch. Med, Columbia, SC; 3) Miami Inst. Human Genomics, U Miami School Med, Miami, FL.

**Introduction**: Hyperactivity, impulsivity and inattention are behavioral features of a subset of individuals with Autism Spectrum Disorders (ASD). However, a diagnosis of Attention Deficit Hyperactivity Disorder is not made if ASD is present (DSM-IV-TR). ADHD can be inherited (Biederman, 2005). Few studies thus far have examined the differences in ADHD behaviors in children with ASD and a family history of ADHD (FH+) versus ADHD behaviors in children with ASD and no family history of ADHD (FH-). This study examines ADHD behaviors in children with ASD+ADHD (FH+) and children with ASD+ADHD (FH-). **Purpose**: To evaluate ADHD symptoms of hyperactivity/impulsivity in children with ASD+ADHD (FH+) versus children with ASD+ADHD (FH-) by gender, and age as measured by the Aberrant Behavior Checklist (ABC) (Aman 1985a,b) **Methods**: Children (n=348, ages 4-21) with idiopathic ASD diagnosed by ADI-R criteria (Lord, 1994) and expert clinicians were enrolled from a genetic study. Hyperactivity/impulsivity is measured by the Aberrant Behavior Checklist subscale for hyperactivity (ABC-H). Two categories of first degree relatives were included: (1) no ADHD (ADHD FH-, n=241) and (2) suspected/diagnosed ADHD (ADHD FH+, n=107). **Results**: ANOVA indicated significant differences among age groups (4-11 vs. 12 and over) on the ABC-H subscale, $F_{(1,363)}=12.628$, p= 0.000. Children ages 4-11 had significantly higher ABC-H scores than those 12 yrs and above, (x=19.93 and x=15.40 respectively). A 2x2 (gender and family history) ANOVA showed a significant main effect of family history ($F_{(1,347)}=13.979$, p=0.000), and a significant gender by family history interaction effect ($F_{(1,347)}=11.653$, p=0.001). The results indicate ADHD FH+ parents reported more hyperactivity/impulsivity in their children than ADHD FH- parents reported. The interaction effect was quite interesting. It suggested girls from ADHD FH- had significantly lower hyperactivity/impulsivity scores than the boys from ADHD FH+. There were no significant differences among the ADHD FH+ girl group and the two male groups. **Conclusions**: ADHD symptoms in children with ASD differ in severity based on family history of ADHD, gender, and age. The age effect was expected. The significant interaction between gender and family history was not expected. While the ABC-H results by gender differ from the SNAP IV, both measures indicate the importance of family history of ADHD in assessing children with an ASD.

## 2200/T/Poster Board #749

**Web-based family recruitment for autism genetic study.** *H. Lee[1], B. Merriman[1], J. Piggot[2], PA. Law[3], JN. Constantino[4], SF. Nelson[1].* 1) Dept Human Gen, Univ California, Los Angeles, Los Angeles, CA; 2) Dept Child and Adolescent Psychiatry and Psychology, Univ California, Los Angeles, Los Angeles, CA; 3) Dept of Medical Informatics, Kennedy Krieger Institute, Baltimore, MD; 4) Dept Psychiatry, Washington University in St.Louis, St.Louis, MO.

The genetic basis of autism has been well established over the last 20 years, based on twin studies and the high relative risk of autism in siblings. Numerous linkage, association, and candidate gene studies have been performed to search for the underlying genes, yet at most a few percent of the genetic component of risk has been identified. This suggests that autism is caused by a large number of distinct genetic risk factors, each with relatively small explanatory power, either in the form of many rare variants, or common variants with small genetic relative risk. In order to have good power to identify such factors, we need tens of thousands of affected individuals. At present, only 3-4,000 European descent autism families are currently available for genetic study. The present project proposes to double this autism sample set in one year. The slow sample collection rate is largely due to the difficulty and expense of clinic-based assessment of the phenotype. The current project employs several novel resources and findings to overcome the obstacle of a lengthy, costly recruitment process. First is the Interactive Autism Network(IAN) registry that has over 10,000 families with autistic children of whom less than 5% have ever participated in any genetic studies, even though they indicate willingness to participate. This database is growing at 300 individuals per month, providing us with a resource for recruitment. Second is that there is strong evidence that the reports given by the parents on their children's affection status are highly correlated with more rigorous clinical assessment. IAN has implemented two standard parent-report questionnaires, SRS (Social Responsiveness Scale) and SCQ (Social Communication Questionnaires). Third is that blood collection can be readily done almost anywhere in the US. Combining these three factors will allow us to perform light phenotyping and rapid blood sample collection for genetic studies. We have launched our first phase of the study to sample a small number of families from IAN registry, perform thorough clinical assessment and compare with the IAN parent-report. Second phase of the study, soon to be launched, will test the blood collection mechanism. We view this web-based recruitment as a complementary and synergistic approach to the current comprehensive assessment approaches and will be a critical component in the comprehensive search for genetic variants contributing to autism risk.

## 2201/T/Poster Board #750

**A Unified Theory of Autism Revisited: Linkage Evidence Points to the IL1RAPL1 Gene using a High-Risk Subset of AGRE Families.** *K. Allen-Brady, D. Cannon, R. Robison, W.M. McMahon, H. Coon.* Utah Autism Research Project, Department of Psychiatry, Univ Utah, Salt Lake City, UT.

Zhao et al. (Proc Natl Acad Sci 2007;104:12831-6) hypothesized that incidence of autism in males could be explained by essentially two types of family structures: low risk autism families with de novo mutations that account for the majority of autism cases, and high-risk multiplex families, where the risk to male offspring approximates 50% consistent with a dominant model and high penetrance, and explains only a minority of autism cases. Using the Autism Genetic Resource Exchange (AGRE) dataset, Zhao et al. identified 86 high-risk families with likely dominant transmission. As genotype data is now available for many members of the AGRE resource, the objective of this abstract was to determine if dominant linkage evidence for an autism predisposition gene exists in these specific 86 high-risk families. HumanHap550K Illumina SNP data was available for 92% of 455 total family members in these 86 high-risk families. We performed a linkage analysis using a pruned subset of markers where markers in high linkage disequilibrium were removed. We observed a single suggestive peak (HLOD 2.08) under a dominant model on chromosome Xp21.3 encompassing part of the IL1RAPL1 gene. Mutations or deletions in IL1RAPL1 have been previously reported in three families with autism. In our study, fourteen families contributed nominally (p<0.05, HLOD > 0.588) to the chromosome X peak. Through follow-up of these 14 families we hope to shed further light on the role of IL1RAPL1 gene and autism. Furthermore, these results demonstrate the potential of using family structure to identify, localize, and further our understanding of autism predisposition genes.

## 2202/T/Poster Board #751

**Genome-wide linkage analysis of bipolar disorder in a Latin American population isolate confirms previous candidate regions on chrs 1p31, 16p12 and 21q21-22 and identifies a novel locus on chr 12q.** *B. Kremeyer[1], J. Garcia[2], H. Muller[1], M.W. Burley[1], I. Herzberg[1], E. Boucher[1], J. Pivard[1], M.V. Parra[3], C. Duque[3], J. Vega[3], V. Reus[4], G. Bedoya[3], C. Lopez[2], J. Ospina-Duque[2], N. Freimer[5], A. Ruiz-Linares[1,3].* 1) Genetics, Evolution and Environment, University College London, London, United Kingdom; 2) Departamento de Psiquiatria, Facultad de Medicina, Universidad de Antioquia, Medellin, Colombia; 3) Laboratorio de Genetica Molecular (Genmol), Facultad de Medicina, Universidad de Antioquia, Medellin, Colombia; 4) Department of Psychiatry, University of California, San Francisco, USA; 5) Center for Neurobehavioral Genetics, Semel Institute for Neuroscience and Human Behavior, University of California, Los Angeles, USA.

Bipolar disorder (BP) is a severe and complex psychiatric condition characterised by alternating episodes of depression and mania, which ranges among the top ten causes of morbidity and life-long disability world-wide. There is ample epidemiological evidence for a genetic contribution to the aetiology of the disorder; however, progress in the identification of disease-causing variants has been slow, most likely due to significant genetic and clinical heterogeneity. The study of a rigorously phenotyped pedigree collection from a population isolate can help reduce this heterogeneity. We have previously performed a whole-genome linkage scan on six pedigrees segregating severe BP from the well-characterised population isolate of Antioquia, Colombia (Herzberg et al. 2006, Hum Mol Genet 15:3146-53). We recently collected genotypes for the same set of 382 autosomal microsatellite markers in nine additional Antioquian BP pedigrees. Here, we report the analysis of the combined pedigree set, which altogether comprises 90 cases of BP-I, 22 cases of major depression (MD), and one case each of BP-II and schizophrenia. All diagnoses were made via a best estimate procedure. Linkage analysis under a narrow model considering only BP-I as affected ("narrow model") was conducted using both parametric and non-parametric approaches. To explore possible aetiological overlaps across different psychiatric diagnostic categories, non-parametric analyses were also conducted for a broader phenotype comprising BP-I, BP-II and MD ("broad model"), as well as for a psychosis as a phenotype ("psychosis model"). Under both narrow and broad phenotypic models, the most significant signal was found for chromosome 12ct-q14 (NPL = 2.55/2.35, respectively). This locus has not previously been identified as a candidate region for BP, making this a novel and interesting finding. Additional signals with LOD/NPL scores > 2 were found on chrs 1p22-31 (narrow and broad models) and 21q21-22 (narrow model). Importantly, both regions have repeatedly been implicated in BP susceptibility; the present study strengthens these findings. Analysis under the psychosis model resulted in NPL scores > 2 for candidate regions on chr 2q24-31 and 16p12-q12. The finding on chr 16p is noteworthy because the same locus has been highlighted in the Wellcome Trust CCC GWAS study of BP (WTCCC 2007, Nature 447:661-78), making it an interesting candidate for further follow-up.

## 2203/T/Poster Board #752

**Meta-analysis of 15 genome-wide linkage scans of smoking behavior.**
*S. Han[1], J. Gelernter[1,2,3,4], BZ. Yang[1,4].* 1) Department of Psychiatry, Division of Human Genetics, University School of Medicine, New Haven, CT 06511, USA; 2) Department of Genetics, University School of Medicine, New Haven, CT 06511, USA; 3) Department of Neurobiology, University School of Medicine, New Haven, CT 06511, USA; 4) VA CT Healthcare Center 116A2; 950 Campbell Avenue; West Haven, CT 06516.

A genetic contribution to smoking behavior, presumably through the mechanism of nicotine dependence (ND), is well established. To identify loci that increase the risk for smoking behavior, many genomewide linkage scans have been performed using various smoking behavior assessments. A number of putative susceptibility loci have been identified, only a few of which have been replicated in independent studies. In current study, we used genome scan meta-analysis (GSMA) to identify potential risk loci which are independent of specific smoking behavior assessments by pooling all available independent genome scan results on smoking behavior. Additionally, to minimize locus heterogeneity, subgroup analyses of the smoking behavior measured by Fagerstrom test for nicotine dependence (FTND) and maximum number of cigarettes smoked in a 24-hour period (MaxCigs24) were performed. A total number of 15 genome scan results were available for analysis, including 3404 families with 10,253 subjects. Overall, the primary 30 cM bin width GSMA across all smoking behavior identified suggestive linkage in chromosome 17q24.3-q25.3 ($P_{SR}$=0.001). Ten regions (2p, 3q, 5q, 6q, 7q, 11p, 12p, 16p, 17q and 20q) with nominal significance ($P_{SR}$ < 0.05) achieved "aggregate" genomewide significance ($P$=0.044), indicating some or all of these 10 regions were likely to harbor risk loci for smoking behavior. Subgroup analysis of FTND did not identify any genomewide suggestive or significant linkage. Subgroup analysis of MaxCigs24 identified a genomewide significant linkage in 20q13.12-q13.32 ($P_{SR}$=0.00041, $P_{OR}$= 0.048), where a strong ND candidate gene, *CHRNA4*, is located. Although genomewide association design has greater power to detect weak effect common variants, linkage analysis has the advantage of detecting diverse genetic effects that segregate in families, including multiple rare variants within one locus or copy number variations. The regions identified in the current study might deserve close attention and will be helpful to facilitate candidate gene identification or to target resequencing studies in the future.

## 2204/T/Poster Board #753

**Executive dysfunctions in nonpsychotic relatives of patients with schizophrenia in different familial loadings: heritability and recurrence risk ratio analyses.**
*S. Lin[1,2], C. Liu[3], S. Liu[3,4], T. Hwang[3], M. Hsieh[3], S. Faraone[5], M. Tsuang[6,7], H. Hwu[1,3,8], W. Chen[1,2,3].* 1) Institute of Epidemiology, College of Public Health, National Taiwan University, Taipei, Taiwan; 2) Genetic Epidemiology Core Laboratory, Division of Genomic Medicine, Research Center for Medical Excellence, National Taiwan University, Taipei, Taiwan; 3) Department of Psychiatry, National Taiwan University Hospital and National Taiwan University College of Medicine, Taipei, Taiwan; 4) Far Eastern Memorial Hospital, Taipei, Taiwan; 5) Departments of Psychiatry and Neuroscience and Physiology, SUNY Upstate Medical University, Syracuse, NY, USA; 6) Department of Epidemiology and Psychiatry, Harvard Institute of Psychiatric Epidemiology and Genetics, Harvard Medical Center, Boston, Massachusetts, USA; 7) Department of Psychiatry, Center for Behavioral Genomics, University of California, San Diego, La Jolla, California, USA; 8) Department of Psychology, College of Science, National Taiwan University, Taipei, Taiwan.

Impaired performance on the Wisconsin Card Sorting Test (WCST) has been found in patients with schizophrenia, and poorer performance was also found in their relatives compared with controls with a small effect size. However, these analyses did not address the magnitude of familial aggregation directly and whether different familial loadings of schizophrenia would affect this estimate. This study was aimed to examine whether there was familial aggregation on a variety of performance indexes of the WCST in the families of patients with schizophrenia by means of the heritability estimates and recurrence risk ratio analyses, and the estimates were compared between those from simplex families and those from multiplex ones. Participants were patients with schizophrenia and their nonpsychotic first-degree relatives from 149 simplex families (149 probands, 205 parents, and 77 siblings) and 583 multiplex families (985 probands, 601 parents, and 283 siblings) as well as 440 healthy controls. A computerized version of the WCST was administered for each subject and nine performance indexes were calculated according to the WCST manual. The adjusted z scores of the WCST indexes were obtained with adjustments for sex, age, and education against a group of 440 healthy controls. Both the heritability for continuous scores and the recurrence risk ratios for binary scores with a series of cut-off points in the nonpsychotic relatives of patients with schizophrenia were estimated. The heritabilities ranged from 0% (Nonperseverative Errors and Learning to Learn) to 17% (Perseverative Errors) in simplex families and from 0% (Learning to Learn) to 21% (Perseverative Responses) in multiplex families. The greatest risk ratios were 4.4 in simplex families and 6.3 in multiplex families using the cut-off point of -1 for Failure to Maintain Set. Most risk ratios estimated from multiplex families were higher than their counterparts from simplex families, and the differences were better revealed on the indexes of Perseverative Responses and Perseverative Errors. Our findings suggest that there exist a small-to-modest familial aggregation on the WCST performance in families of patients with schizophrenia, and higher familial loading of schizophrenia is associated with both a greater heritability and greater recurrence risk ratio. Nevertheless, the small magnitude of the familial aggregation in the WCST performance may limit its application as an endophenotypic marker for schizophrenia.

## 2205/T/Poster Board #754

**Consanguinity and increased risk for Schizophrenia in Egypt.** *H. Mansour[1,2], W. Fathi[2], L. Klei[1], K. Chowdari[1], A. Watson[1], A. Eissa[2], A. Yassin[2], H. Salah[2], S. Tobar[2], H. El-Boraie[2], H. Gaafar[2], M. Elasy[2], I. Ibrahim[2], N. Ibrahim[1], K. Kandil[1], W. El-Bahaei[2], M. Alatrouny[2], F. El-Chennawi[3], B. Devlin[1,4], V. Nimgaonkar[1,4].* 1) Department of Psychiatry, University of Pittsburgh School of Medicine, Western Psychiatric Institute and Clinic, Pittsburgh, Pennsylvania; 2) Department of Psychiatry, Mansoura University School of Medicine, Mansoura, Egypt; 3) Department of Clinical Pathology, Mansoura University School of Medicine, Mansoura, Egypt; 4) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, Pennsylvania.

Background: Prior studies have suggested increased consanguinity rates may exist among families of patients with psychoses in certain Middle Eastern populations. Our earlier studies showed elevated parental consanguinity rates among patients with bipolar I disorder (BP1) compared with independent Egyptian controls. We extended our anlayses to include patients with Schizophrenia (SZ). Methods: A case-control study involved 75 patients with SZ, 126 screened adult controls, and available parents was conducted at Mansoura University Hospital, Egypt. The control sample was enlarged from our BP1 study. The inbreeding coefficient/ consanguinity rate was estimated from family history data ('self report') followed by DNA analysis using randomly selected short tandem repeat polymorphisms (STRPs, n = 63) ('DNA-based' rate). Results: Self reported consanguinity rates were elevated among SZ patients (consanguinity rates, SZ: 0.43, controls: 0.15, OR 4.2, 95% CI 2.15, 8.18; p = 0.0001, 1 d.f.). These differences were confirmed using estimates for coefficients of inbreeding from DNA-based analyses (mean inbreeding coefficients ± standard error of the means, cases: 0.058 ± 0.007, controls: 0.022 ± 0.003, test statistic=-6.76, p = 6.6 E-12). Conclusion: Self reported consagunity confirmed by DNA analyses showed elevated parental consanguinity rates are among Egyptian SZ patients in the Nile delta region, compared with controls. These results are compatible with recessively inherited risk factors. The consistent results with BP1and SZ raise public health concerns.

## 2206/T/Poster Board #755

**Loci on four autosomes modify age-at-onset of Alzheimer's disease in early-onset PSEN2 families.** *E.E. Marchani[1], T.D. Bird[1, 2, 3], E.J. Steinbart[4,5], G.D. Schellenberg[6], E.M. Wijsman[1, 7, 8].* 1) Division of Medical Genetics, Unversity of Washington, Seattle, WA; 2) Department of Neurology, Veterans Affairs Puget Sound Health Care System, Seattle, WA 98108; 3) Department of Neurology, University of Washington, Seattle, WA; 4) Division of Gerontology and Geriatric Medicine, University of Washington, Seattle, WA; 5) Geriatric Research Education and Clinical Center, Veterans Affairs Puget Sound Health Care System, Seattle, WA; 6) Department of Pathology and Laboratory Medicine, University of Pennsylvania, Philadelphia PA; 7) Department of Biostatistics, University of Washington, Seattle, WA; 8) Department of Genome Sciences, University of Washington, Seattle, WA.

Alzheimer's disease (AD), the most prevalent form of dementia, has a complex genetic etiology. APOE is the only gene consistently associated with late-onset AD, but the risk allele is neither necessary nor sufficient to cause the disease. Three additional genes (APP, PSEN1, PSEN2) are associated with rare early-onset forms of the disease (EOAD). These genes only describe a fraction of the variance in age-at-onset (AGE) within families, and other analyses have suggested that additional loci remain to be found. We increased our power to detect these additional modifier loci by analyzing AGE among 11 Volga German EOAD families representing 269 individuals. These families share a single PSEN2 mutation, thus eliminating mutation heterogeneity, and their early AGE reduces the amount of missing data typical of AD data sets. We performed a genome-wide scan on AGE among these families using Bayesian oligogenic segregation and linkage analysis. This approach allowed us to analyze a censored trait while inferring missing data, controlling for segregating PSEN2 and APOE variants, and varying the number and type of quantitative trait locus models proposed. Empirical significance of results was obtained using marker resimulation. Four linkage signals were found to be empirically significant: chromosome 17p (p= 0.0002), chromosome 1q (p<0.001), chromosome 7q (p=0.017), and chromosome 11p (p=0.017). Simultaneous analysis of these four chromosomes maintained strong evidence of linkage to chromosomes 17p, 1q, and 7q. Inclusion of APOE as a covariate proved essential to detect these linkage signals, as all signals decreased when it was excluded from the model. The four regions all coincide with previous linkage signals, associated SNPs, and/or candidate genes identified in other AD study populations. This type of replication establishes several candidate regions for further analysis and emphasizes the oligogenic nature of this disease.

## 2207/T/Poster Board #756

**Genomewide linkage analysis on comorbid depression and cocaine dependence.** *B. Yang[1,4], S. Han[1], HR. Kranzler[5], L. Farrer[6], J. Gelernter[1,2,3,4].* 1) Dept Psychiatry, Yale Univ Sch Med, West Haven, CT; 2) Dept Genetics, Yale Univ Sch Med, West Haven, CT; 3) Dept Neurobiology, Yale Univ Sch Med, West Haven, CT; 4) VA CT Healthcare Center, West Haven, CT; 5) Univ CT Health Center, Farmington, CT; 6) Boston Univ School Med, Boston, MA.

Both illicit drug abuse and depression are common psychiatric disorders in the United States. According to the 2006 National Survey on Drug Use and Health, 6 million Americans age 12 and older had abused cocaine in any form. Major depressive disorder currently affects ~14.8 million American adults. High comorbidity between substance use disorders, including cocaine dependence, and depression in clinical samples has been reported widely. There are many factors involved; the shared genetic liability that contributes to this comorbidity is understudied. To explore this issue, we conducted a multipoint non-parametric linkage analysis for major depressive episode (MDE), and comorbid MDE and cocaine dependence (MDE+CD) in 2,128 individuals from 384 African American (AA) and 350 European American (EA) families who were genotyped for 5,863 SNP markers at CIDR. In AAs, we identified one region on chromosome 7 at 183.5 cM showing suggestive linkage for MDE with a peak lod score of 2.82. A genomewide significant linkage lod score of 3.54 (genomewide empirical p=0.017) was obtained at the same map position for the phenotype of MDE+CD. In EAs, we found evidence for suggestive linkage to MDE on chromosomes 3 (peak lod score = 2.02 at 1.0 cM) and 16 (peak lod score = 1.83 at 76.3 cM). Notable linkage peaks for MDE+CD were also identified in this group of families on chromosomes 5 (peak lod score = 2.25 at 14.3 cM), 10 (peak lod score = 2.18 at 153.5 cM), 16 (peak lod score = 2.11 at 76.3 cM), 3 (peak lod score = 1.84 at 1.0 cM) and 18 (peak lod score = 1.78 at 109.7 cM). In summary, we report a genomewide linkage scan of MDE and comorbid CD and MDE in the two major US populations on the basis of a dense SNP map. These findings can provide useful information to the search for genes jointly influencing comorbid MDE and CD in the AA and EA populations.

## 2208/T/Poster Board #757

**MicroRNA expression in hipocamppal tissue from patients with temporal lobe epilepsy.** *D.B. Dogini[1], T.C. Pereira[1], C.S. Rocha[1], C.L. Yasuda[2], H. Tedeschi[2], E. de Oliveira[2], C.V. Maurer-Morelli[1], F. Cendes[2], I. Lopes-Cendes[1].* 1) Dept Medical Genetics,Campinas, FCM - UNICAMP, Sao Paulo, Brazil; 2) Dept Neurology, Campinas, FCM-UNICAMP, São Paulo, Brazil.

MicroRNAs are a new class of small RNA molecules (21-24 nucleotide-long) that negatively regulate gene expression either by translational repression or target mRNA degradation. It is believed that about 30% of all human genes are targeted by these molecules. miRNAs are involved in many important biological processes including cell differentiation, embryonic development and central nervous system formation. We carried out the present study in order to investigate the possible role of miRNA regulation in temporal lobe epilepsy (TLE). Total RNA was isolated with Trizol of hippocampal tissue from 4 patients with TLE who underwent selective resection of the mesial temporal structures for the treatment of clinically refractory seizures. In addition we used control samples from autopsy (n=4) for comparison. RNA samples were used in real-time PCR reactions with TaqMan MicroRNA assays (Applied Biosystems) to quantify 157 miRNAs in human hippocampal tissue. Bioinformatics analyzes identified three miRNAs species which were differently expressed in patients as compared to controls: let7a was over expressed in patients (4 fold increased), miR-29b and miR-30d were down- regulated in patients (2.5 fold and 0.5 fold decreased, respectively). Possible target genes for let-7a are NME6 and NCAM1 (which would be down-regulated in patients); for miR-29b is MCL-1 and for miR30d are CTNND2, LGI1 and SON (which would be up-regulated in patients). We have identified three miRNA species differently expressed in tissue form patients with TLE. Gene functions related to the possible miRNA targets are involved mainly with cell proliferation, neurogenesis, cell adhesion and apoptosis. Our results reveal new targets which should be explored in additional studies addressing miRNA regulation in TLE.

## 2209/T/Poster Board #758

**An Animal Model to Investigate the Genetics of Hyperthymic Temperament.** *R. Plaetke[1], W. Byerley[2], S. Gosling[3].* 1) Department of Anthropology, University of Alaska, Fairbanks, AK; 2) Department of Psychiatry, University of California, San Francisco, CA; 3) Department of Psychology, University of Texas, Austin, TX.

Signs & symptoms of bipolar disorder, often described on qualitative scales, are now considered to be parts of continua that belong to traits also occurring in well individuals. Already Kretschmer[1] proposed such a relationship. However, Akiskal[2] included genetics & the aspect of evolution: *"The affective temperaments represent the most prevalent phenotypic expression of the genes underlying bipolar disorder: the disorder itself is an aberration & exists simply because the genes themselves, ..., are useful for evolutionary ends &, in principle, should be demonstrable in other species."*Similarly, Kraepelin[3] described a manic temperament that he originally termed *"constitutional excitement."* He considered the manic temperament as a *"link in the long chain of manic-depressive disposition"* that in its less severe form could still be considered normal. Akiskal et al[3,4] characterized the most discriminatory features of what they named the *"hyperthymic temperament,"* representing the softest expression of Kraepelin's manic type. This temperament, occurring in a variety of well people, is characterized as being exuberant, upbeat, over-energetic, & overconfident. Based on Akiskal's hypothesis, we propose a study to investigate the genetics of hyperthymic temperament in an animal model, the Alaskan Husky (sled) dog. Chromosomal regions & candidate genes identified in this animal model, can be considered to be "biomarkers" for bipolar disorder in humans. This study is unique in its design: **(1)** It aims for determining genes & chromosomal regions by analyzing normally occurring phenotypic expressions in a dog population to investigate the etiology of a psychiatric disorder in humans. **(2)** Dogs will be investigated in a non-invasive & observational way, & in their natural environment. **(3)** A behavioral assay measuring temperament in dogs will be developed by transferring temperament definitions in humans to an animal model, & therefore uses Darwin's[6] theory of the continuum of traits in humans & animals as its framework. We will present study rational, design, goals, & preliminary results supporting our approach. **References:** **1.** Kretschmer 1936, Physique & Character. **2.** Akiskal 2003, American Psychiatric Association 156th Annual Meeting. **3.** Kraepelin 1921, Manic-Depressive Insanity & Paranoia. **4.** Akiskal et al 1979, Psychiatr Clin North Am 2:527. **5.** Akiskal et al 1998, J Affect Disord 59 (Suppl 1):5s. **6.** Darwin 1872, The Expression of the Emotions in Man & Animals.

## 2210/T/Poster Board #759

**A role for the Insulin pathway in an inducible Drosophila model of Alzheimer's disease.** *O. Sofola, F. Kerr, L. Partridge.* Genetics, evolution and environment, University College London, London, United Kingdom.

Alzheimer's disease (AD) is the leading cause of dementia in the ageing population. Alois Alzheimer observed plaques and tangles in the brains of AD patients. The plaques are comprised of amyloid beta and the tangles of tau protein. Several studies have been initiated to understand the underlying mechanism of disease progression and possible biological pathways in AD. We are primarily focused on the role of the Insulin pathway in Alzheimer's disease (AD), due to the strong association between diabetes and AD, the effect of diet on AD, and the involvement of GSK-3 (a component of the Insulin pathway) in AD. In a C.elegans model of AD, daf-2 (Insulin receptor) RNAi in worms expressing amyloid abeta 42 reduced the paralysis and increased the life span of abeta expressing worms. We plan to determine the effect of insulin pathway on AD in Drosophila. Importantly, we will express the abeta protein in the brain of adult flies using an inducible ELAV-GAL4 system, in the presence or absence of intact insulin signalling, and compare the pathology of these flies. This will enable us gain insight of the involvement of the Insulin pathway in AD, in the ageing brain. Our results show that adult expression of abeta leads to toxicity in these flies by altering their motor performance ability. Furthermore, preliminary results suggest that by disrupting a component of the insulin pathway, we are able to delay toxicity in these flies. We are confirming these results and plan to investigate the underlying molecular mechanisms involved.

## 2211/T/Poster Board #760

**Gene Screening in two French-Canadian Families with Primary Lateral Sclerosis.** *V.V. Belzil[1], P.N. Valdmanis[1,2], J. St-Onge[1], N. Dupre[3], G.A. Rouleau[1].* 1) Center of Excellence in Neuromics of Universite de Montreal, CHUM Research Center and the Department of Medicine, University of Montreal, QC; 2) Department of Human Genetics, McGill University, Montreal, Quebec, Canada; 3) Departement de sciences neurologiques, CHAUQ Enfant-Jesus, Quebec City, Quebec, Canada.

**Background**: Primary lateral sclerosis (PLS) is a neurodegenerative disease characterized by a progressive spinal and bulbar spasticity due to the degeneration of upper motor neurons. Generally, the lower extremities are first affected, followed by the upper extremities and the bulbar muscles. The neuronal degeneration of PLS is confined to long descending pathways with no involvement of lower motor neurons, as opposed to amyotrophic lateral sclerosis (ALS) involving both upper and lower motor neurons. Although most cases of PLS are sporadic, we previously described a new autosomal dominant syndrome in a French-Canadian family of 10 individuals affected with PLS. A locus on chromosome 4 between the telomere and marker D4S2928 was identified after performing a 550 marker genome scan and confirming a disease haplotype present in all 10 affected individuals. This region spans 10.2 Mb and encompasses about 130 genes. Interestingly, a second small family with PLS has been recently identified with two affected individuals. **Objective**: The goal is to identify and characterize the gene responsible for a familial form of primary lateral sclerosis (PLS) located at the PLS1 locus. **Methods**: The 14 most interesting candidates in the PLS1 locus have been prioritized and screened. One of the candidate was the *huntingtin* gene, playing a role in protein trafficking, vesicle transport,post-synaptic signalling, transcriptional regulation, and apoptosis. Markers encompassing the PLS1 locus were also tested for the newly identified family. **Results**: All the exons of the 14 genes were screened without the detection of a coding mutation. S35 genotyping for the *huntingtin* gene revealed that none of the patients had an expanded CAG repeat which is causative for Huntington's disease. A copy number variant test was also performed for *huntingtin*, and no major deletion or duplication was identified. RNA for *huntingtin* was also analyzed without the detection of significant variations. Three members of the second family seemed to share the same haplotype as the affected members of the first family. **Conclusions**: More genes in the locus are currently being screened and linkage analysis will soon be performed for the second family, which would help narrow the candidate interval. The identification of mutations in a gene responsible for PLS will help provide insight into the causes and the mechanisms involved in PLS.

## 2212/T/Poster Board #761

**REGULATION OF ALZHEIMER'S PRESENILIN-1 MUTATIONS BY AATF IN NEURONAL APOPTOSIS.** *Q. Guo, J. Xie.* Department of Physiology, University of Oklahoma Health Sciences Center, Oklahoma City, OK 73104.

Most autosomal dominant inherited forms of early onset Alzheimer's disease (AD) are caused by mutations in the presenilin-1 (PS-1) gene on chromosome 14. PS-1 is an integral membrane protein localized mainly in endoplasmic reticulum (ER). We have found in transfected neural cells as well as in neurons from PS-1 mutant knockin mice that PS-1 mutations may sensitize neurons to apoptotic death via calcium-dependent pathways. Apoptosis antagonizing transcription factor (AATF) was initially identified as an interaction partner of DAP-like kinase, a member of the DAP (Death Associated Protein) kinase family of pro-apoptotic kinases. We now report that levels of AATF expression in cortical neurons were significantly altered in neuronal cells transgenic for Alzheimer's mutant PS-1. In these neurons, RNAi-mediated silencing of AATF exacerbated, while overexpression of AATF ameliorated mitochondrial dysfunction, calcium dysregulation, oxidative damage, and apoptotic death induced by mutant PS-1. AATF also reduced production of Abeta accumulation, a pathological hallmark of AD. Recently, we performed in vitro phosphorylation assays, and found that AATF is a phosphorylation substrate of Akt1/PKB$\alpha$, a serine/threonine protein kinase that plays important roles in promoting cell survival and inhibiting apoptosis. Furthermore, we found that phosphorylation of AATF by Akt1 significantly ameliorated apoptotic cell death. These results suggest that AATF is a novel regulator of cellular actions of PS-1 mutations, and that phosphorylation of AATF by Akt1 may represent a critical mechanism of signal transduction mediated by Akt1 in regulating neuronal survival in AD.

## 2213/T/Poster Board #762

**Puromycin Sensitive Aminopeptidase reduces TAU protein levels in vivo.** *L.C. Kudo[1], K. Lau[2,3], N. Vi[1], L. Parfenova[2,3], M. Hui[4], M. Gray[5], X.W. Yang[5], M. Wiedau-Pazos[2], K.S. Hui[4], S.L. Karsten[2,3].* 1) NeuroInDx Inc., Signal Hill, CA; 2) Neurology, David Geffen School of Medicine at UCLA, Los Angeles, CA; 3) Neuroscience, Los Angeles Biomedical Research Institute at Harbor-UCLA Medical Center, Torrance, CA; 4) Nathan S.Kline Institute for Psychiatric Research, Orangeburg, NY; 5) Psychiatry and Biobehavioral Sciences, David Geffen School of Medicine at UCLA, Los Angeles, CA.

Recently, we have identified a novel pathway of TAU protein processing involving puromycin sensitive aminopeptidase (PSA), and demonstrated the ability of PSA to protect from tau-induced neurodegeneration in vivo in the fly (Karsten et al, 2006; Sengupta et al, 2006). The role of human PSA as a TAU aminopeptidase was confirmed in a cell-free system. To examine the effects of PSA overexpression on the progress of TAU-induced neurodegeneration in vivo in the mammalian system, we generated multiple independent lines of PSA transgenic mice and crossed them with a TAU-P301L transgenic mouse model (Lewis et al, 2000). PSA mice were generated using bacterial artificial chromosome (BAC) mediated technology. PSA transgenic mice are born normal, breed normally and do not reveal any gross anatomical or behavioral abnormalities, suggesting that low levels of PSA activation might not have any deleterious physiological effects. Expression and activity of PSA are elevated in the brain of hemizygous PSA mice at 2- to 3-fold. In addition, PSA mice do not show any changes in enkephalin turnover/ degradation, supporting the notion that PSA is not an enkephalinase. PSA/ TAU double transgenic mice were characterized at ages 10 weeks, 4 months, 6 months, 9 months and 12+ months. Immunohistochemistry for TAU antibodies raised against phosphorylated TAU C-terminus (V-20, Santa Cruz) and PHF-TAU phosphorylated at Thr181 (AT270, Pierce) showed reduced levels of hyperphosphorylated TAU in the hippocampus, brain stem, cortex, and cerebellum of double transgenic TAU/PSA mice. These combined data suggest that PSA activation can ameliorate accumulation of hyperphosphorylated and toxic tau. Therefore, increasing PSA activity may be a feasible therapeutic approach to inhibit or/and block tau-induced neurodegeneration and thus may provide an effective means to treat tauopathies including Alzheimer's disease.

## 2214/T/Poster Board #763

**A common transcriptional regulatory pathway for genes involved in spastic paraplegia.** *R.D. Nicholls[1,2], W. Zhu[2], K. Hardaway[1], M. Stefan[1,2].* 1) Dept Pediatrics, Birth Defects Labs, Children's Hospital of Pittsburgh of UPMC, Pittsburgh, PA; 2) Dept Human Genetics, University of Pittsburgh, Pittsburgh, PA.

Hereditary spastic paraplegias (HSP) are a set of clinically diverse neurodegenerative disorders characterized primarily by progressive spasticity in the lower limbs due to axonal degeneration of the corticospinal tract (CST). HSP may be pure or complex, the latter found with additional neurological features such as mental retardation and epilepsy. Dominant inheritance accounts for ~70% of HSP and mutations in one gene, *SPAST* (*SPG4*), are the cause of over 40% of these cases. Nevertheless, to date 45 assigned gene symbols exist for autosomal dominant and recessive, and X-linked, gene loci that are chromosomally linked to HSP pathogenesis but the etiological gene mutations have been identified to date for only 17 or 18 of these. Known spastic paraplegia genes (SPG) encode proteins involved in a multitude of distinct biochemical pathways, attesting to the diverse molecular mechanisms that can affect function and trafficking in long axons, but making selection of new candidate genes difficult. We hypothesize that many SPG loci are co-regulated in order to express the encoded functions in proper CST spatiotemporal patterns. By bioinformatics analyses of human genome sequences we found that the promoters or 5' regulatory regions for 9 of 16 autosomal HSP genes have one or more binding site motifs for the transcription factor (TF) Nuclear Respiratory Factor-1 (NRF1), including *SPG4*, *SPG5*, *SPG6*, *SPG7*, *SPG8*, *SPG11*, *SPG13*, *SPG20* and putative *SPG33*. These sites are evolutionary conserved in all or most eutherian mammals and for some sites, in the marsupial and monotreme. Remarkably, the mammalian *SPG7* promoter is comprised of an array of one to six NRF1 sites and no other conserved TF motifs. We confirmed that NRF1 binds *in vivo* at these regulatory elements using chromatin immunoprecipitation with human and mouse neuroblastoma cell lines. Additionally, siRNA targeting *NRF1* mRNA downregulates expression of these SPG loci as well as luciferase reporter constructs for minimal promoters of the *SPG4* and *SPG6* loci. Since NRF1 sites occur in the promoters of ~5 to 6% of genes across the genome but we find these in ~55% of SPG promoters, we propose that NRF1 coordinates a gene regulatory network (GRN) comprising many of the genes involved in HSP pathogenesis. Further, we propose that identification of NRF1 target genes (and other TFs within the GRN) within large chromosomal domains linked to uncloned HSP loci will improve selection of candidate genes for mutation studies.

## 2215/T/Poster Board #764

**PAR-4-MEDIATED TRANSCRIPTION AND CYTOTOXIC PROPERTIES OF ALZHEIMER'S PRESENILIN-1 MUTATIONS.** *J. Xie, Q. Guo.* Department of Physiology, The University of Oklahoma Health Sciences Center, Oklahoma City, OK 73104.

Most autosomal dominant inherited forms of early onset Alzheimer's disease (AD) are caused by mutations in the presenilin-1 (PS-1) gene on chromosome 14. We have found in transfected neural cells as well as in primary neurons from PS-1 mutant knockin mice that PS-1 mutations sensitize neurons to apoptotic death. Par-4 (prostate apoptosis response-4) is a leucine zipper protein that promotes the death of neurons expressing PS-1 M146V mutation. Par-4-dependent cell-death seems to be mediated by decreased bcl-2 transcription. Overexpression of Par-4 effectively reduced the adaptive increase in Bcl-2 levels in the early stages of neuronal cell death. In pull down assays using specific sequence on the bcl-2 P1 promoter as bait, we found a significantly increased Par-4 binding to the bcl-2 promoter in cortical neurons transgenic for mutant PS-1. Apoptosis antagonizing transcription factor (AATF) is a member of the DAP (Death Associated Protein) kinase family of pro-apoptotic kinases. We found that AATF formed a complex with Par-4 via the leucine zipper domain, leading to a blockade of the pro-apoptotic signaling mediated by Par-4. Binding of Par-4 to the bcl-2 promoter was significantly reduced in neural cells transfected with AATF. These results suggest that Par-4 is directly involved in regulation of bcl-2 transcription in neurons expressing mutant PS-1, and that AATF/Par-4 complex formation may provide a novel neuroprotective pathway in AD.

## 2216/T/Poster Board #765

**Whole genome gene-expression profiling in schizophrenia patients.** *S. de Jong[1], M.P.M. Boks[2], W. Cahn[2], T.F. Fuller[3], S. Horvath[3,4], T. Rietkerk[2], C. Schubart[2], R.S. Kahn[2], R.A. Ophoff[1,3,5,6].* 1) Medical Genetics, University Medical Center, Utrecht, Netherlands; 2) Psychiatry, Rudolf Magnus Institute of Neuroscience, University Medical Center, Utrecht, Netherlands; 3) Human Genetics, David Geffen School of Medicine, University of California, Los Angeles, CA, USA; 4) Biostatistics, School of Public Health, University of California, Los Angeles, CA, USA; 5) Neurobehavioral Genetics, University of California, Los Angeles, CA, USA; 6) Rudolf Magnus Institute of Neuroscience, University Medical Center Utrecht, The Netherlands.

Schizophrenia is a severe psychiatric disorder characterized by delusions and hallucinations, in addition to a range of negative symptoms. Pharmacological treatment is often not sufficient and induces side effects. This disorder affects about 1% of the population and the genetic contribution is estimated to be around 80%. Therefore, gene-expression can help elucidate genetic mechanisms underlying schizophrenia. In this study, whole-genome gene-expression arrays were performed, using whole blood of schizophrenia patients. Patients were matched to healthy controls. Both medicated (n=200) and unmedicated (n=100) patient groups are included. For most subjects, genome-wide SNP and methylation data is also available. In addition to case-control comparisons using a FDR correction, this data was analyzed using a weighted gene co-expression method. Clustering was performed to create networks of co-expressed genes. This in turn resulted in reconstruction of a limited number of groups of genes ("modules") with highly similar expression profiles. Within the co-expression modules, the most connected genes are driving that group of genes and are considered to be most important. Differences in network structure and connectivity between cases and controls were found and will point to genes of interest in the etiology of schizophrenia. In addition, the effects of medication on gene-expression will be assessed. These effects can give insight into treatment-response and will be of importance in further studies in which medication-naive material is unavailable.

## 2217/T/Poster Board #766

**The genetic contribution of copy number variants to hereditary peripheral neuropathies.** *J. Huang[1], J. Price[1], G. Montenegro[1], G. Wang[1], X. Wu[2], J. Vance[1], M. Shy[2], S. Züchner[1].* 1) Miami Inst Human Genomics, Univ Miami, Miami, FL; 2) Department of Neurology, School of Medicine, Wayne State University, Detroit, MI.

Hereditary peripheral neuropathies present a group of clinically and genetically heterogeneous entities. All known forms, including the various forms of Charcot-Marie-Tooth disease (CMT) are characterized as Mendelian traits and over 30 genes have been identified thus far. It is well known that copy number variants (CNV) are involved in many diseases, including CMT type 1A. We speculate that hereditary peripheral neuropathy patients without missense mutations might instead carry rare CNVs in known genes, causing the disease phenotype. In this study, we performed the first high-density CNV study in CMT targeting 34 genomic regions harboring known genes for hereditary peripheral neuropathies, including the 17p12 duplication region. We screened a sample of 97 clinically heterogeneous index patients applying custom NimbleGen 4-plex 385K CGH arrays. All results were confirmed by qPCR. We identified six common and rare CNVs, of which three affect coding exons of CMT genes. A novel shorter form of a PMP22 duplication was detected in a CMT1A family previously tested negative in a commercial test. Moreover, we have evidence that this CNV represents a triplication of the PMP22 gene. Two other CNVs in MTMR2 and ARHGEF10 are likely not disease associated. Our results indicate that CNVs are a rare cause for CMT. Their potential relevance as disease modifiers remains to be evaluated. The present study design cannot rule out that specific CMT forms exist where CNVs play a larger role.

## 2218/T/Poster Board #767

**X-linked dystonia-parkinsonism: Effects of disease-specific single nucleotide change 3 (DSC3) within the *TAF1/DYT3* multiple transcript system in a cell system.** *U. Muller[1], T. Herzfeld[1], A. Gaarz[2], M. Grznarova[1], A. Staratschek-Jox[2], J.-L. Schultze[2], D. Nolte[1].* 1) Institut für Humangenetik, Justus-Liebig- Universität, D35392 Giessen, Germany; 2) LIMES-Institut (Life and Medical Sciences Bonn), Universität Bonn, D53115 Bonn, Germany.

X-linked dystonia parkinsonism (XDP) is caused by various disease specific single nucleotide changes (DSCs) within the *TAF1/DYT3* multiple transcript system. This transcript system is composed of 38 exons encoding *TAF1* plus 5 downstream exons (exons d1-d5) (1). While all DSCs, a deletion, and a SVA element observed in XDP patients lie within introns of *TAF1/DYT3*, one, DSC3, is located within an exon (exon d4). Exon d4 can be part of transcripts including *TAF1* exons or be part of a transcript driven by a specific promoter and encoded by d exons (exons d2, d3, d4) only (2). In order to investigate a possible effect of DSC3 at the cellular level we transfected neuroblastoma cells (SK-N-AS) with a construct overexpressing exons d2-d4 with exon d4 including either the wild-type or the mutated allele DSC3. Analysis of RNA extracted from these cells (performed in quadruplicates) on Illumina chips (HumanWG6_V3) revealed 68 genes that are differentially expressed in cells containing wild-type vs. DSC3 constructs. Of these 51 are downregulated at least two-fold in DSC3 vs. wildtype constructs. Seventeen are expressed at higher levels in DSC3 than in wildtype. In silico analysis of these genes using the Allen Brain Atlas revealed that 8 of the dysregulated genes are expressed in the mouse striatum. Potential roles of these genes in XDP are discussed. Although the mechanism of function of the d2-d4 transcript is not known it is intriguing that d4 encoded RNA forms a hairpin structure. This structure is disturbed by DSC3.

## 2219/T/Poster Board #768

**Mutational analysis of *FUS/TLS* in familial and sporadic amyotrophic lateral sclerosis in the Japanese population.** *Y. Takahashi, J. Goto, S. Tsuji.* Dept Neurology, Univ Tokyo, Tokyo, Japan.

[Objectives]To elucidate genetic epidemiology of familial and sporadic amyotrophic lateral sclerosis (ALS) with *FUS/TLS* mutations in the Japanese population and to describe clinical presentations of these patients. [Background]*FUS/TLS* has recently been identified as a causative gene for ALS6, an autosomal dominant familial ALS (FALS). It has been reported that the frequency of *FUS/TLS* mutations was approximately 5 % of FALS in the Western population. However, the genetic epidemiology of ALS with *FUS/TLS* mutations in the Japanese population remains unknown. [Materials and Methods] Sixteen genomic DNA samples of familial ALS (FALS) patients were used, where mutations of *SOD1*, *ALS2*, *DCTN1*, *VAPB*, *CHMP2B*, *ANG* and *TARDBP* were excluded using DNA microarray-based resequencing system. The mode of inheritance was autosomal dominant in 11 pedigrees, whereas 5 pedigrees were with affected siblings, in whom 4 were without consanguinity and 1 with consanguinity. In addition, 160 samples with sporadic ALS (SALS) patients and 260 control samples were used for this study. All the exons of *FUS/TLS* were amplified with genomic PCR using specific primers for each exon and further subjected to direct nucleotide sequencing method. Novel nonsynonymous variations were screened in 260 control samples. [Results] Two mutations consisting of a novel mutation K510M in exon 14 and a known mutation R521H in exon 15 were found in 16 families (12.5%) with FALS where mutations of other causative genes have been excluded. In addition, 2 mutations consisting of a novel putative pathogenic mutation G206S in exon 6, where another mutation has been reported, and a known mutation R521C were identified in 160 samples (1.3%) with SALS. The novel mutations were not found in 260 controls (520 chromosomes), located in mutation-clustered regions and conserved among species. The age at onset of patients with K510M, R521H, G206W and R521C were 41, 39, 72 and 39, respectively, raising the possibility that the mutation G206W was less damaging than the other mutations. [Conclusion]Mutations of *FUS/TLS* were relatively frequent in FALS in the Japanese population, indicating that the mutations are broadly identified in different ethnic backgrounds. In addition, mutations were also found in SALS, suggesting mutations with reduced penetrance or *de novo* mutations.

## 2220/T/Poster Board #769

**Inspecting verbal and visual episodic memory in childhood and in adulthood in affected kindreds: A generational paradigm in schizophrenia and bipolar-mood disorder.** *N. Rouleau[1,2], M. Maziade[2], C. Mérette[2], M. Battaglia[3], C. Marino[4], V. Jomphe[2], E. Gilbert[1], A. Achim[2], R.H. Bouchard[2], M.E. Paradis[2], M.A. Roy[2].* 1) School of psychology, Laval University, Quebec, Canada; 2) Centre de recherche Université Laval Robert-Giffard, Québec, Canada; 3) San Raffaele 'Vita Salute' University, Dept of Neuropsychiatric Sciences, Italy; 4) Eugenio Medea Institute, Depat of Child Psychiatry, Italy.

Episodic memory is one of the most prominent neurocognitive deficit observed in patients affected by schizophrenia (SZ) and bipolar/mood disorder (BP). Little is known about the pathological trajectory of memory impairments from childhood to adult clinical status in risk populations. We recently reported that young high-risk offspring (HR) of an affected parent were impaired in both verbal (VEM) and visual episodic memory (VisEM). Over 20 years, we followed up 48 kindreds affected by SZ or BP in the Eastern Québec population. After having characterized the DSM phenotypes, we undertook the phenotyping of cognition in three sub-samples in these kindreds and in controls (N=381): in the younger generations, 60 young HRs of a parent affected by SZ or BP and, in the adult generations, 92 non-affected adult relatives (NAARs) and 40 patients affected by SZ or BP. We used a cross-sectional generational stratification to compare the VEM and the VisEM cognitive profiles of the young non-affected HR offspring to the profiles of adult NAARs and patients. VEM was assessed with the California Verbal Learning Test (CVLT) and VisEM with the Rey complex figure. Compared to normal controls, VEM deficits of moderate to large effect sizes (ES) were observed in HRs (ES= -0.84, $p<0.0001$), in NAARs (ES= -0.59, $p<0.0001$) and in patients (ES= -1.08, $p<0.0001$). Effect sizes of similar magnitude were observed for VisEM in HRs (ES=-0.92, $p<0.0001$) and in patients (ES=-1.01, $p<0.0001$) but not in NAARs (ES=-0.22, NS). The memory impairments displayed by the young HR offspring of these kindreds in the years preceding disease onset were also observable in the adult generations. VEM and VisEM showed distinct generational patterns suggesting that a VisEM impairment in HRs was more likely to be a strong precursor of disease in adulthood whereas a VEM deficit would fit a model of intermediate phenotype (IP), i.e. a trait associated with SZ and BP and present in patients and in NAARs.

## 2221/T/Poster Board #770

**Gene expression, aging and Alzheimer's disease.** *D. Avramopoulos[1, 2], M. Szymanski[2], R. Wang[1].* 1) Dept Psychiatry, Johns Hopkins Univ, Baltimore, MD; 2) McKusick Nathans Institute of Genetic Medicine, Johns Hopkins Univ, Baltimore, MD.

Genome wide analysis of gene expression has been made possible by current microarray technologies allowing investigators to have a global view of the consequences of disease on gene expressio, or possibly the consequences of gene dysregulation on disease risk. Alzheimer's disease (AD) is a dementia with rare, Mendelian, earlier onset cases and more common, later onset cases with significant genetic contribution. Other than genes, age is one of the strongest risk factors for AD. We have performed a genome wide gene expression study on temporal lobe RNA from 26 brains from donors with confirmed late onset AD and 23 brains from donors without brain pathology. We used the Illumina Sentrix HumanRef-8 Expression BeadChips to interrogate 24,000 transcripts from genes across the genome. We examined the effects of age and sex in the expression of genes in the absence of pathology, as well as the expression differences in AD patients after controlling for these and other variables. We find that many genes have lower expression with increasing age and among them there is significant enrichment of genes involved in RNA processing and protein biosynthesis. Alzheimer's disease is also accompanied by significant expression changes for many genes independent of age. The set of genes with reduced expression in AD is enriched for those involved in neuronal activities including synaptic transmission. Genes expressed at higher levels in AD include an excess of transcription factors. Interestingly we find a highly significant overlap between genes whose expression changes with age in normal brains and genes whose expression changes in AD after controlling for age. This might reflect an accelerated aging process in the brain of people who develop AD or it might suggest that acceleration of age related changes in the expression of some genes increases the risk to develop AD.

## 2222/T/Poster Board #771

**Exploring gene regulation by antidepressant drugs.** *M.A. Kennedy[1], X.Y. Deng[1], K. Doudney[1], P.C. McHugh[1], P.R. Joyce[2].* 1) Dept Pathology, University of Otago, Christchurch, New Zealand; 2) Dept Psychological Medicine, University of Otago, Christchurch, New Zealand.

Antidepressant drugs are widely used but there is much about these drugs that is not well understood. It is now clear that antidepressants affect brain function in many ways beyond their immediate pharmacological actions, including stimulation of many cellular and molecular changes and promotion of neuronal survival and growth. As one approach to explore these diverse antidepressant actions, we used transient luciferase reporter gene assays with selected transcriptional promoters, in the neural cell line RN46A, to examine the chronic effects of antidepressant drugs (paroxetine, citalopram, nortriptyline) and control non-antidepressant CNS drugs (haloperidol and valproic acid). Among the 19 promoter constructs initially tested, six showed significantly increased gene expression following 14 days exposure to 0.5 uM paroxetine (ADM, GCHFR, PDIA3, GCH1, CREB1, and PHB). ADM and GCHFR promoter constructs were chosen for subsequent drug exposure experiments due to their most significant expression changes. Time-course analysis showed that paroxetine treatment led to an increase in gene expression within 48 hrs of exposure, peaking after 72 hrs drug exposure. A dose-response test confirmed 0.5uM as an appropriate concentration to use for drug exposure experiments. Both ADM and GCHFR promoters showed up-regulation by paroxetine, haloperidol and sodium valproate. This effect was specific to ADM and GCHFR, and did not occur with control promoters not thought relevant to antidepressant function. However, with extended experimentation we found that observed differences in expression of reporter constructs between treated and untreated RN46A cells were not consistently reproducible, with significant day to day variability in outcomes despite considerable care in experimental design and execution. Therefore, we are now applying real-time quantitative PCR (qPCR) as an alternative approach to evaluate antidepressant-induced gene expression changes in this cell line. Among the five candidate reference genes tested so far, ACTB, RNF4 and DAZAP1 are expressed relatively stably across all the treatments. We are now assessing the relative expression level of a wide range of candidate genes drawn from our prior work, and from the literature, in this cell culture model. It is our goal to identify a robust and easily manipulated model system for exploring regulation of genes by antidepressant drugs, to further our understanding of the molecular action of these substances.

## 2223/T/Poster Board #772

**A screen for genetic suppressors of Rett syndrome in the mouse.** *M. Justice, J. Shaw, F. Probst.* Dept Molec & Human Gen, Baylor Col Med, Houston, TX.

Mutations in the methyl CpG binding protein 2 (*Mecp2*) cause Rett Syndrome, an X-linked neurological syndrome that affects primarily girls. A large degree of variation in the severity of the disease is observed, which is often not correlated with the extent of X-inactivation, suggesting that modifier genes may affect the symptoms. Mouse mutants that eliminate Mecp2 function provide a good animal model for Rett Syndrome. Studies of the mouse model have shown that the mutant symptoms in male mice can be rescued by re-introduction of the Mecp2 gene and partially rescued by introduction of Brain derived neurotrophic factor (*Bdnf*), providing substantial evidence that the alleviation of symptoms is possible. Genetic modifier screens have been valuable in organisms such as the fruit fly, worms, yeast, and bacteria to reveal genes that act in a biological pathway. In the mouse, such screens are now feasible because of the availability of the complete genome sequence, which aids in the rapid identification of lesions induced by the supermutagen N-ethyl-N-nitrosourea (ENU). We are carrying out a genetic modifier screen of *Mecp2*-/Y males to uncover loci that may ameliorate or cure the symptoms of Mecp2 mutation. In a screen of over 1400 male mice, we have identified four mouse lines that carry suppressors of the disease symptoms. Our preliminary data show that some suppressors may be more effective than others, and reveal a map location for the first modifier. Identifying the suppressors at a molecular level will allow for the development of small molecules that may mimic the natural suppressor. Our ultimate goal is to discover and validate drug targets for the treatment of Rett Syndrome.

## 2224/T/Poster Board #773

**Polymorphisms in Interleukin 4 (IL4), Interleukin 13 (IL13) and IL 4 receptor (IL4R) are associated with Asthma Exacerbations in African Americans.** *S. Pillai, S. Yancey, L. Edwards, K. Sutton, S. Stinnett, H. Ortega, W. Anderson.* GlaxoSmithKline, RTP, NC.

Polymorphisms in IL4, IL13 and IL4R have been shown to be associated with asthma related phenotypes in African Americans. We assessed whether the polymorphisms in these genes have an effect on asthma exacerbations in an African American population. We conducted a retrospective pharmacogenetic analysis (N=322) of subjects in a 52-wk trial comparing exacerbation rates between fluticasone propionate (FP) plus salmeterol (FSC 100/50mcg BID) and FP 100mcg BID via Diskus®. At screening, while of steady state low dose ICS and after withholding bronchodilators, the $FEV_1$ was between 60-90% of predicted and subjects demonstrated ≥12% reversibility. Subjects received FP250 for 4 wks prior to randomization. Fifteen SNPs in the IL4, IL13 and IL4R genes were genotyped. Exacerbations were defined as worsening asthma requiring oral steroids, hospitalization, unscheduled urgent care, ≥30% decrease in $FEV_1$from baseline or ≥30% decrease in AM PEF on any 2 consecutive days. Analysis of exacerbations was conducted by three methods: logistic regression for occurrence of exacerbations, Poisson regression for the rate of exacerbations and Cox proportional hazards models for time to first exacerbation. Genotype, treatment, and treatment-by-genotype interaction were assessed adjusting for age, BMI, asthma duration, baseline $FEV_1$, reversibility, sex, and investigator region. A polymorphism in IL4R (rs1805010) was associated with occurrence (p=0.04) of exacerbations during the 52 week treatment period. Polymorphisms in IL4 (rs2243263, p =0.032) and IL13 (rs1295686, p=0.046) were associated with rate of exacerbations. A non-synonymous coding polymorphism, rs20541 (Arg144Gln) in IL13, which is in tight LD with rs1295686 was associated with time to first exacerbation (p=0.02) with significantly higher exacerbation rate and earlier time to first exacerbations in subjects homozygous for the variant allele. No genotype-by-treatment interactions were observed. These results suggest that polymorphisms in IL4, IL13 and IL4R, reported to be associated with asthma related phenotypes are also associated with asthma exacerbations in African Americans. (SFA103153).

## 2225/T/Poster Board #774

**Glycogen synthase kinase 3β polymorphisms and weight change during clozapine treatment.** *R.P. Souza[1,2], D.V. Rosa[1,3], M.A. Romano-Silva[3], H.Y. Meltzer[4], J.A. Lieberman[5], J.L. Kennedy[1,2].* 1) Neurogenetics Section, Centre for Addiction and Mental Health, Ontario, Canada; 2) Department of Psychiatry, University of Toronto, Ontario, Canada; 3) Laboratorio de Neurociencias, Universidade Federal de MInas Gerais, Minas Gerais, Brazil; 4) Departments of Psychiatry and Pharmacology, Vanderbilt University, Tennessee, United States; 5) Department of Psychiatry, Columbia University, New York, United States.

Antipsychotic medications are an important component in the medical management of many psychotic conditions. Although clozapine, the prototype atypical antipsychotic, has superior efficacy and fewer extrapyramidal effects compared with typical analogs, it is associated with increased prevalence of adverse, weight-gain effects. Search for predictors of drug-related morbidity is becoming increasingly important in persons with major mental illness. Weight gain, glucose and lipid abnormalities are observed more frequently in some novel antipsychotics. The mechanism underlying clozapine-induced body weight changes remain unknown. We examined 13 GSK3β markers (rs6805251, rs4688043, rs7624540, rs13319151, rs6438552, rs4072520, rs9878473, rs4491944, rs6772172, rs11919783, rs11923196, rs6779828, rs9846422, rs3755557) and two markers after the 3'-untranslated region of the gene (rs9846422, rs3755557). Genotyping was performed by GoldenGate assay (Illumina, San Diego, CA, USA) at The Centre for Applied Genomics at the Hospital for Sick Children in Toronto, Ontario, Canada. For the analyses on clozapine-induced weight gain, a total number of 67 subjects were recruited from Case Western Reserve (n=56; 38 males and 18 females, mean age 35±8) and from Hillside Hospital (n=11, 4 males and 7 females, mean age 33±6). Weight gain was expressed as a dichotomous variable in the whole sample at six weeks using as criteria a weight increase greater than seven percent from baseline at enrolment. The Food and Drugs Administration has established this threshold as producing a clinically meaningful and significant metabolic outcome. Individual SNP analyses of weight gain greater than seven percent (case) and absence of weight gain greater than seven percent (control) data and Hardy-Weinberg equilibrium assessment were performed using $\chi 2$ tests. Statistical Package for the Social Sciences, version 10.0.7, was used to access genotypic association and Haploview 4.0 for allelic association. Linkage disequilibrium was assessed using Haploview version 4.0. Haplotype analyses were performed using UNPHASED 3.0.10 and Haploview version 4.0. No allelic, genotypic or haplotypic significant association with clozapine-induced weight gain was found in our sample. Our results suggest that the GSK3β that may not affect susceptibility to gain weight induced by clozapine. Further analyses in this region are required to strengthen this negative finding.

## 2226/T/Poster Board #775

**Association of polymorphisms in transcription factor genes with variable bronchodilator response among asthmatics.** *Q.L. Duan[1], R. Du[1], J. Lasky-Su[1], A.J. Murphy[1], A.B. Partch[1], S.B. Liggett[2], A.A. Litonjua[1], K.G. Tantisira[1], S.T. Weiss[1,3].* 1) Channing Laboratory, Brigham and Women's Hospital and Harvard Medical School, Boston, MA; 2) Cardiopulmonary Genomics Program, University of Maryland School of Medicine, Baltimore, MD; 3) Partners Center for Personalized Genetic Medicine, Partners Health Care, Boston, MA.

Variability in transcription factor (TF) regulation has been associated with numerous human diseases and differential response to drug therapies including asthma medications such as leukotriene modifiers and corticosteroids. Recently, TFs have been shown to be regulated by proasthmatic cytokines (e.g. Interleukins 4 and 13, transforming growth factor-β, Leukotriene $D_4$) and exposure to a bronchodilator (isoproterenol) in human airway epithelial and smooth muscle cells. We hypothesized that variants in the genes encoding these TFs regulate their expression within these cells, which could contribute to asthma and variability in bronchodilator response (BDR). We identified 98 genes coding for 59 TFs that were differentially expressed (≥ 50% up- or down-regulated) in response to isoproterenol within these proasthmatic cells. A total of 1155 single nucleotide polymorphisms (SNPs) located across these genes and up to 20 kb of non-coding, flanking regions were genotyped in Caucasians participating in the Childhood Asthma Management Program (403 parent-child trios) by the Illumina HumanHap550v3 BeadChip. We tested each SNP for association with BDR, measured as the percent change in $FEV_1$ as result of bronchodilator administration, using family-based analysis (FBAT) of the trios and population-based analysis of the probands only, incorporated into generalized linear models in SAS (version 9.0; SAS Institute, Cary, NC). Analyses were adjusted for age, sex and baseline lung function. Under the additive model, 104 SNPs and 133 SNPs provided p-values < 0.1 using FBAT and population based analyses, respectively. Forty-six of these SNPs overlapped, covering 19 candidate genes, which are represented by 38 tag SNPs due to linkage disequilibrium (correlation coefficient ($r^2$) ≥ 0.8). Replication genotyping of these SNPs are ongoing in three asthma cohorts. Identification of genetic variants regulating BDR in this fashion could be used to predict asthma therapy outcomes and may represent a novel way to translate *in vitro* cellular drug response to bedside clinical management.

## 2227/T/Poster Board #776

**Effects of *UGT1A1* polymorphism on irinotecan-induced drug reaction and serum bilirubin levels.** *A. HIRASAWA[1], T. AKAHANE[1], T. TSURUTA[1], Y. KOBAYASHI[1], H. NOMURA[1], K. BANNO[1], H. TSUDA[1], K. SAITO[2], T. ZAMA[2], Y. TANIGAWARA[3], N. SUSUMU[1], D. AOKI[1].* 1) Dept. Gyne/Obst, Sch. of Med, Keio Univ., Tokyo, Japan; 2) Dept. Otolaryngol-Head/Neck Surg, Sch. of Med, Keio Univ; 3) Dept. Hospital Pharmacy, Sch. of Med, Keio Univ.

Irinotecan is metabolized to active form which is further conjugated and detoxified by the UGT1A1 enzyme. The severe toxicities in patients who receive irinotecan are related to its genetic variants, and the serum total bilirubin (BIL) levels are useful for the prediction of adverse reactions to irinotecan. However, the relationship between the specific *UGT1A1* genotype and BIL levels has not yet been confirmed. Then, we studied 443 cases with no history of liver dysfunction to explore their relationship. Genomic DNAs were extracted from peripheral leukocytes after the informed consent was obtained. The assays for genotyping the polymorphisms in the *UGT1A1* (*6, *27, *28, *60) were based on either Invader assay or direct sequencing. The frequencies of *28 and *60 variants were much lower than those published results for whites, while the frequencies of *6 and *27 variants were much higher. Furthermore, 89% (24/27) subjects with hyperbilirubinemia had *6, *28 or *60 variants. This study showed that several *UGT1A1* genotypes were significantly associated with the increased BIL levels. These findings will be useful for further pharmacogenomical studies on adverse reactions to irinotecan.

## 2228/T/Poster Board #777

**Discovery, replication and clinical validation of genetic variants associated with carboplatin-induced cytotoxicity in Caucasians.** *R. Huang[1], D. Ziliak[1], E. Gamazon[1], S. Duan[1], W. Zhang[1], E. Kistner[2], P. Chen[3], S. Mi[1], G. Chenevix-Trench[4], J. Beesley[4], S. Johnatty[4], A. DeFazio[5], S. Das[3], N. Cox[1], M. Dolan[1], Australian Ovarian Cancer Study.* 1) Dept Med, Univ Chicago, Chicago, IL; 2) Dept Health Studies, Univ Chicago, Chicago, IL; 3) Dept Human Genetics, Univ Chicago, Chicago, IL; 4) Queensland Institue of Medical Research, Australia; 5) Westmead Hospital, Australia.

Carboplatin is commonly used in treating cancers; however, a portion of patients do not respond to therapy while others develop severe treatment-induced toxicity. To gain a better understanding of the genetic variants associated with platinum sensitivity, we applied a genome-wide approach integrating genotypes, mRNA expression and cellular sensitivity to carboplatin using HapMap lymphoblastoid cell lines (LCLs). For discovery, 90 HapMap CEU LCLs were utilized while 52 unrelated non-HapMap CEPH LCLs were used as a replication set. Cell growth inhibition was determined in LCLs at increasing concentrations of carboplatin. The percent survival at different treatment concentrations along with carboplatin $IC_{50}$ (concentration required to inhibit 50% cell growth) were used as carboplatin sensitivity phenotypes. Genome-wide mRNA expression was determined using the Affymetrix GeneChip® Human Exon 1.0 ST Array. Genome-wide association studies were performed between the components of the model to identify genetic variants significantly associated with carboplatin sensitivity through their effects on mRNA expression. We identified 65 SNPs that are associated with at least one carboplatin sensitivity phenotype through the expression of 61 genes. Five of these SNPs were replicated in separate set of LCLs. In addition, we constructed a multi-SNP prediction model, utilizing risk allele counting and weighted risk allele counting, which take into account the effect of risk allele for each SNP, to predict carboplatin $IC_{50}$. A set of SNPs appear to consistently predict carboplatin $IC_{50}$ in the discovery and replication dataset. Furthermore, the replicated SNPs were genotyped in 543 Australian Ovarian Cancer Study patients treated with carboplatin and paclitaxel. A SNP was significantly associated with progression free survival ($P_{adjust}<0.05$) in all patients with a more pronounced effect in a subset of optimally debulked cases ($P_{adjust}=0.007$). This SNP is located in *NRG3* gene locus and is significantly associated with the expression of several other genes. We demonstrated the potential of utilizing a genome-wide approach in a cell-based model to identify SNPs predicting for survival in a clinical study. This work has important implications in the field of oncology where using cell-based models would be highly beneficial for pharmacogenomic discovery.

## 2229/T/Poster Board #778

**Pharmacogenetics of Pharmacotherapies for Smoking Cessation: Analysis of Placebo-Controlled Trials for Varenicline and Bupropion Efficacy and Side Effects.** *D. King[1], S. Paciga[1], E. Pickering[1], N. Benowitz[2], L. Bierut[3], D. Conti[4], J. Kaprio[5], C. Lerman[6], P. Park[7].* 1) Pfizer Global Research and Development, Groton/New London, CT; 2) Division of Clinical Pharmacology and Experimental Therapeutics, University of California at San Francisco, San Francisco, CA; 3) Department of Psychiatry, Washington University, St. Louis, MO; 4) Department of Preventive Medicine, Keck School of Medicine, Zilkha Neurogenetics Institute, University of Southern California, Los Angeles, CA; 5) Department of Public Health, University of Helsinki, Helsinki, Finland; 6) Department of Psychiatry, University of Pennsylvania, Philadelphia, PA; 7) Pfizer Global Pharmaceuticals, New York, NY.

**Background** Despite the availability of effective therapies to aid smoking cessation, most smokers find quitting difficult and the majority of successful quitters relapse. While there is considerable evidence to support a genetic risk for nicotine dependence, much less is known about the pharmacogenetics of successful smoking cessation. In the first pharmacogenetic investigation of the relative efficacy of varenicline and bupropion, we examined whether variation in genes important in the pharmacodynamic and pharmacokinetic effects of nicotine or drug treatment predicts medication efficacy and side effects. **Methods** Subjects participated in randomized, double-blind, placebo-controlled smoking cessation clinical trials, comparing varenicline, a nicotinic acetylcholine receptor (nAChR) partial agonist, with bupropion, a norepinephrine and dopamine reuptake inhibitor. DNA was obtained from 1476 consenting individuals in these trials, and primary analysis was performed on 1175 smokers of European ancestry (additional subjects were included in robustness analyses). We analyzed 785 SNPs representing 24 gene loci, which resolved into 245 LD blocks. Candidate genes of interest included nAChR subunits, varenicline transporter and additional targets, and genes involved in nicotine or bupropion metabolism. **Results** Analysis of baseline smoking (cigarettes/day) and nicotine dependence (Fagerstrom test) validated an association with a locus on chr15 that includes three nAChR subunit genes (*CHRNA5*, *CHRNA3*, *CHRNB4*) ($p<0.01$). Within the varenicline arm, continuous abstinence (weeks 9-12) was associated with *LOC123688* and nAChR subunit genes (*CHRNA4*, *CHRNA7*, *CHRNB2*) (OR=1.76; 95%CI=[1.23,2.52]) ($p<0.005$); within the bupropion arm, abstinence was associated with *CYP2B6* (OR=1.78;[1.27,2.50]) ($p<10^{-3}$). Incidence of nausea on treatment was predicted by SNPs in several nAChR subunit genes (OR=1.99;[1.43,2.78]) ($p<10^{-4}$) and time to relapse to smoking following therapy was associated with SNPs in *HTR3B* (HR= 1.97;[1.45,2.68]) ($p<10^{-4}$). **Conclusion** These data provide both novel and supporting evidence for genetic loci contributing to smoking cessation and therapeutic response. Importantly, different genetic signals are associated with varenicline vs. bupropion treatment response, suggesting that additional research may lead to clinically useful markers to guide treatment decisions, resulting in improved smoking cessation rates overall, and a reduction in smoking prevalence.

## 2230/T/Poster Board #779

**A Pharmacogenetic Study of Novel SNPs in *VKORC1* and *CYP2C9* in an African American Cohort: Implications in Warfarin Maintenance Dose.** *M.A. Perera[1], L.H Cavallari[2], S. Patel[2], T. Ramikie[1], M. Flynn[1], N.J. Cox[1]*. 1) Medicine, University of Chicago, Chicago, IL; 2) Pharmacy, University of Illinois, Chicago, IL.

Genetic factors have appeared as important markers in determining warfarin dose requirements. Common functional variants in *CYP2C9*, named *CYP2C9*2* and *CYP2C9*3*, significantly lower maintenance doses, and have higher risk of serious bleeds. Both of these alleles have a low allele frequency (~ 10%) in Caucasians; have a lower frequency in African Americans (2 - 5%). In addition to *CYP2C9*, variation in the *VKORC1* gene accounts for 20 - 30% of the observed population variation in warfarin dose. Warfarin dosing algorithms incorporating the variation in both these genes have been very successful in explaining large portions of the variability of warfarin dose in both Caucasians and Asian populations. However these SNPs do not fully incorporate the variation seen in African Americans, and therefore are not as predictive of dose in this population ($r^2 = 0.19$ in African Americans as compared to $r^2 = 0.40$ in Caucasians). To provide a comprehensive evaluation of variation that may contribute to warfarin dose in African Americans we used both comparative genomics and putative transcriptional binding factor prediction to target resequencing efforts around regions of highest interest in both *VKORC1* and *CYP2C9*. We then used a tagging SNPs approach to genotype novel variation as well as functional variation in both genes to determine association with warfarin maintenance dose in 300 African American anticoagulation subjects. Upon testing the functional variants in *CYP2C9*, only *CYP2C9*5* and **11* were shown to be significant, along with several novel SNPs All previously known *VKORC1* variants were found to be significant. However, we also identified several novel SNPs that contribute to warfarin dose, many of which are more highly associated than the known *VKORC1* variants (p = 0.0003). These SNPs were found upstream of *VKORC1*. From these initial associations we developed an African American specific dosing algorithm, which incorporated all variation that influenced warfarin maintenance dose in this population. We validated the predictive power of this algorithm in an independent African American cohort of 50 patients. This study is the first to look at novel variation in these genes in an African American population, which may lead to more comprehensive and predictive dosing in this population.

## 2231/T/Poster Board #780

**Polymorphisms in the UGT1A locus are associated with hyperbilirubinemia in pazopanib treated patients.** *B. Reck, Z. Xue, L. Huang, K. Baker, M. Chen, V. Mooser, L. Cardon, C. Spraggs, L. Pandite, CF. Xu.* GlaxoSmithKline Research and Develolpment; Harlow, UK, North Carolina, and Philadelphia, USA.

Pazopanib is an oral multikinase angiogenesis inhibitor which has demonstrated antitumor activity in several tumour types. While the safety profile of pazopanib was generally acceptable and tolerable, elevations in total bilirubin (TBL) have been observed in some patients treated with pazopanib. Although such elevations are generally asymptomatic, the aetiology and mechanism of TBL elevation in pazopanib treated patients remain unknown. To evaluate the potential genetic effect for the observed increases of TBL, pharmacogenetic analyses of markers from 280 candidate genes were performed on samples from Caucasian patients collected from two renal cell carcinoma clinical studies. Maximum on-treatment TBL was found to be associated (P<0.01) with 94 markers from 35 genes in the first study (N= 112). Of these, ten markers were found to also be associated (P<0.01) with maximum on-treatment TBL in the second dataset (N=124). All 10 markers were located on chromosome 2 in a region containing the gene encoding uridine diphosphate glucuronosyltransferase 1A1 (UGT1A1). Linkage disequilibrium analysis showed that these markers are strongly correlated with each other ($0.7 \leq r2 \leq 1$). Among them, the TA repeat polymorphism in the promoter of UGT1A1 (rs8175347) is a known valid biomarker that has been associated with plasma bilirubin concentration and drug induced hyperbilirubinemia. After adjusting for the effect of this polymorphism on TBL, no additional independent genetic associations were found between any of the other markers and TBL. It follows that the associations observed at this locus are likely to be a reflection of the same causative variant in the region. Accordingly, some cases of isolated hyperbilirubinemia in pazopanib treated patients are a manifestation of Gilbert's syndrome which is associated with the TA repeat polymorphism of the UGT1A1 gene.

## 2232/T/Poster Board #781

**Pharmacogenetic markers for cholinergic effects on nicotine addiction and smoking cessation.** *J. Sarginson[1], J. Killen[2], L. Lazzeroni[1], S. Fortmann[2], A. Schatzberg[1], G. Murphy[1].* 1) Psychiatry, Stanford University School of Medicine, Stanford, CA; 2) Stanford Prevention Research Center, Stanford University School of Medicine, Stanford, CA.

Stopping smoking is difficult even with treatment. Many patients prescribed pharmacologic treatments for smoking cessation experience side effects or lack of efficacy. We are performing a pharmacogenetic study of the efficacy and tolerability of bupropion and transdermal nicotine (TN), two treatments for smoking cessation. Samples are drawn from two smoking cessation studies. In the first study, 301 smokers received bupropion plus TN for 11 weeks, followed by 14 weeks of placebo or bupropion (MT1). In the second, 276 smokers received bupropion and TN for 8 weeks (MT2). The two studies used comparable selection criteria and recruited from the same community. We focused on 8 SNPs in the 15q24 region that contain the nicotinic cholinergic receptor subunits CHRNA5, CHRNA3 and CHRNB4. In other studies, this region has been implicated in several aspects of nicotine addiction and smoking cessation. Nicotinic cholinergic receptors are activated directly by TN and are present on neurons that are affected by bupropion. The primary clinical outcome measures in our studies were point-prevalence abstinence and time to relapse, but craving, withdrawal symptoms and adverse events due to the study drugs, including changes in weight and mood, were also considered. Analyses of baseline smoking quantity (SQ) and baseline addiction using the modified Fagerstrom score (mFTQ) were also undertaken. Analyses of baseline SQ and mFTQ were carried out on DNA samples from 577 individuals. The findings provided further support for a strong association between SQ and both the CHRNA5 SNP rs16969968 (D398N) and the CHRNA3 SNP rs1051730 (Y215Y), two SNPs that are in strong linkage disequilibrium (LD) in this cohort. Two further SNPs located in CHRNA3 and CHRNB4 appear to have independent associations with SQ. Pharmacogenetic analysis showed a strong association between rs8192475 (R37H) in CHRNA3, higher craving after quitting and increased withdrawal symptoms over time. This effect was seen in MT2 but not in MT1, suggesting that extended treatment may mitigate the pharmacogenetic effect. Additional markers for point prevalence abstinence in MT2 were also identified in CHRNA5 and CHRNB4. These results provide further support for the role of the CHRNA5/A3/B4 in determining number of cigarettes smoked. We have also identified markers for response to smoking cessation therapy. (Supported by the NIH and the California TRDRP).

## 2233/T/Poster Board #782

**NRXN1 variants are associated with behavioral difficulty in response to levetiracetam.** *T.J. Urban[1], N.M. Walley[1], P. Nicoletti[1], E.L. Heinzen[1], D. Ge[1], K.V. Shianna[1], R.A. Radtke[2], D.B. Goldstein[1].* 1) Center for Human Genome Variation, Institute for Genome Sciences and Policy, Duke Univ Medical Ctr, Durham, NC; 2) Department of Medicine, Division of Neurology, Duke Univ Medical Ctr, Durham, NC.

**Rationale:** The clinical use of levetiracetam (LEV) is limited in a subset of patients by neurobehavioral side effects including irritability and aggression, and more rarely, psychosis. The genetic basis for behavioral difficulty (BD) in response to LEV is entirely unknown.

**Methods:** A genome-wide association study (GWAS) of common single nucleotide polymorphisms (SNPs) and both common and rare copy number variants (CNVs) was conducted on a cohort of chronic epilepsy patients (n= 237) retrospectively assessed for BD following exposure to LEV. Patients were classified as cases if LEV was discontinued specifically due to BD, and controls if there was no mention in the patient history of BD after at least one year of continuous LEV treatment.

**Results:** No common SNPs were significantly associated with LEV-related BD after correction for multiple testing. However, the most strongly associated SNP was located in the NRXN1 gene (OR = 5.22, 95%CI: 2.5 - 10.9, $p = 8.2 \times 10^{-5}$), deletions in which had previously been associated with schizophrenia. Inspection of CNVs in the NRXN1 region revealed that three individuals carried deletions spanning coding exons of NRXN1, and these deletions were exclusive to cases (3/47 *vs.* 0/190, p = 0.007).

**Conclusions:** These results suggest that NRXN1, which is known to have a strong involvement in risk for schizophrenia, is also associated with LEV-related neurobehavioral side effects. These findings, however, require independent replication, which is an ongoing effort. Additional ongoing studies include targeted sequencing to uncover smaller-scale rare variants affecting antiepileptic drug response as well as shared risk factors between epilepsy and schizophrenia.

## 2234/T/Poster Board #783

**A Pharmacogenetic Test To Enhance Understanding of Molecular And Pharmacological Chaperones By Using START (Sapropterin Therapy Actual Response Test) With Mutation Analysis For BH4 Response Testing In Phenylketonuria (PKU).** *J.R. Utz[1], D. Markowitz[1], C.Pham Lorentz[1], K.D. Rudser[2], B.M. Diethelm-Okita[1], D.C.C. Erickson[1], C.B. Whitley[1].* 1) Department of Pediatrics , Univ Minnesota, Minneapolis, MN; 2) Division of Biostatistics and Office of Clinical Research, Univ Minnesota, Minneapolis, MN.

Background: Sapropterin (SAP), synthetic tetrahydrobiopterin (BH4) for BH4 responsive PKU, works as chemical chaperone of phenylalanine hydroxylase (PAH) to facilitate and stabilize active PAH fold conformation. Only 20-56% of patients responded to SAP in clinical trials. The high cost of response tests and lifelong therapy warrants better understanding of patients likely to benefit from SAP. No standard pharmacogenetic tests exist to identify responsive genotypes. Previous BH4 and SAP pharmacogenetic studies indicate genotypes do not consistently predict response, but are weakened by varied: 1) SAP/BH4 doses; 2) response definitions; 3) duration; 4) phenylalanine (PHE) test times at varied protein catabolic states; 5) methods to control and report dietary PHE. START is a double-blind, placebo-controlled, 4-week test to identify SAP response while avoiding confounders. Hypothesis: START with mutation analysis gives a pharmacogenetic test to find genotypes that consistently predict SAP response and augment understanding of molecular and chemical chaperones. Methods: START results were evaluated for response and genotype correlates and trends in molecular characteristics. Results: To date, 44/56 enrolled patients completed START. Of these 44, 24 (54.5%) are SAP responders, 31 mutations are known, 24 different genotypes are present, 18 genotypes deemed response predictive. Alleles singly associated with response prediction include Y414C (5/5 patients responsive, 3 genotypes) and R408W (12/13 patients, 10/11 genotypes non-responsive). R408W, located at the hinge of an activating fold site, contains bulky aromatic amine tryptophan substituted for aliphatic arginine. START found aromatic amines substituted for aliphatic chains were non-responsive with low residual PAH activity in 12/13 (92%) patients, 10/11 genotypes (91%). Higher molecular weight amino acids substituted by smaller in 14/15 patients (93%) were responsive with high residual PAH activity. Conclusions: START identified 18 genotypes predictive of SAP response and showed response is swayed by mutant locus at activating PAH fold sites and spatial folding changes incurred by substituted amino acid size/configuration. Bulky aromatic amines substituted for aliphatic chains are associated with non-response. Findings warrant ongoing study of BH4 response via START to elucidate genotype response and mutant molecular characteristics' impact on protein folding dynamics in molecular and chemical chaperones.

## 2235/T/Poster Board #784

**Novel genes governing platinum chemotherapy toxicity susceptibility using an unbiased genome-wide approach.** *P.H. O'Donnell, E. Gamazon, W. Zhang, M.E. Dolan.* The University of Chicago, Chicago, IL.

Clinical observations show that Asians experience greater toxicity from platinum-containing chemotherapy regimens compared to other populations, suggesting that Asians may represent a particularly informative population in which to study genetic causes of platinum susceptibility. We utilized well-genotyped, Epstein-Barr virus-transformed lymphoblastoid cell lines (LCLs) from 90 apparently healthy Asian individuals in the International HapMap project to determine in vitro cisplatin and carboplatin-cytotoxicity phenotypes for use in genome-wide association studies. First, drug-specific $IC_{50}$s were employed as dependent variables in a linear regression with genotypic data for each line. Assuming an additive genetic model, analysis was restricted to SNPs (~1.2 million) having a minor allele frequency of ≥ 5% and for which missing data was < 20%. This analysis resulted in a list of 479 SNPs for cisplatin and 199 SNPs for carboplatin that were significantly associated with cytotoxicity ($P < 10^{-4}$). Candidate SNPs were then linearly modeled against baseline gene expression (~50,000 transcripts) to determine SNP-gene associations. This identified SNPs associated with 119 genes for cisplatin and 32 genes for carboplatin which were significant (Bonferroni $P_c < 0.05$). Finally, baseline expression levels for these genes were evaluated for association with the original $IC_{50}$ phenotypes for each drug ($P < 0.05$). A resulting short list of genes, and associated SNPs, defining the "susceptibility signature" for each drug in Asians was identified. For cisplatin, 8 target genes (*MAGEC3, WRNIP1, RPS28, CL640, CAST, SIVA, PAIP1, C11ORF17*) were implicated. For carboplatin, 2 target genes (*WRNIP1, SIVA*) were identified. Notably, *WRNIP1* and *SIVA* were important for cytotoxicity of both drugs, suggesting a possible platinum drug-class effect. Evaluation of expression changes in the identified genes and the impact on platinum susceptibility is currently being evaluated in a replication Asian LCL cohort (HapMap Chinese in Denver) and in other ethnic HapMap populations. In summary, an unbiased genome-wide approach allowed identification of novel cisplatin and carboplatin susceptibility genes which deserve further testing as possible mediators of the unique susceptibility of Asians, and perhaps other individuals, to toxicities from these chemotherapies.

## 2236/T/Poster Board #785

**Genome-wide SNP Association for Clinical Pain Sensitivity in Humans.** *H. Kim, S. Smith, R. Dionne.* NINR/NIH, Bethesda, MD.

Aims of the investigation: Microarray-based genotyping technology allows genome-wide screening for single nucleotide polymorphism (SNP) association studies. The major advantage of this approach is that no specific functional genetic hypotheses are required prior to undertaking analysis. Given the presumably polygenic and complex nature of pain, SNPs genotyped across the whole genome is an appropriate tool in the search for responsible genetic variations for pain. We applied genome wide SNP genotyping to investigate the role of genetics in responses to clinically induced pain in humans. Methods: Normal subjects (112 European Americans and 39 African Americans) were evaluated at the National Institutes of Health following informed consent under a human research protocol approved by the Institutional Review Board. Subjects underwent a standardized minor surgical procedure under local anesthesia and were monitored up to 3 hours after the surgery. The maximum post-operative pain rating, post-operative pain onset time and the analgesic onset time after ketorolac administration were used as measures of clinical pain and the onset of NSAID analgesia. The samples were genotyped at ~500,000 markers using Affymetrix 500K SNP assay. Results: While 4 SNPs (rs2562456, rs7295290, rs10014562 and rs17011183) showed significant association with analgesic onset time (false discovery rate (FDR) range from $1.18 \times 10^{-4}$ to $2.93 \times 10^{-2}$) in European Americans, 2 different SNPs (rs2943024 and rs6725855) were associated with maximum post-operative pain rating (FDR range from $3.35 \times 10^{-3}$ to $1.13 \times 10^{-2}$) in African Americans. Conclusion: Genome wide association study found that genetic variations play a role in the individual variations in responses to analgesic drugs in European Americans but not in African Americans. On the contrary, genetic variations were associated with the amount of pain caused by minor surgery in African Americans only. These results suggest that genetic factors influence pain sensitivity and analgesia in humans in an ethnicity dependent manner. Acknowledgement: This study was supported by the Division of Intramural Research, National Institute of Nursing Research, National Institutes of Health, Bethesda, MD 20892, USA.

## 2237/T/Poster Board #786

**Characterization of genetic variants in the 3' UTR of organic cation transporter 3 (OCT3).** *L. Chen, A. Roomiani, S. Yee, K. Giacomini.* Department of Bioengineering and Therapeutic Sciences, UCSF, San Francisco, CA.

The organic cation transporter 3 (OCT3) is widely distributed in body tissues and mediates the transport of important endogenous and exogenous organic cations including histamine, norepinephrine, serotonin, metformin and oxaliplatin. Several genome-wide association studies (GWAS) indicate that OCT3 plays an important role in the development of prostate cancer and in cardiovascular disease. The goal of this study was to identify and characterize genetic variants in the 3' untranslated region (3'UTR) of OCT3, which is 3926bp in length. We identified 30 novel single nucleotide polymorphisms (SNPs) in DNA samples from 272 individuals from Chinese, European, African and Mexican ancestries. Genetic variants ranged in allele frequencies from singletons, identified one time on one chromosome to 46% in a single population. The OCT3 3' UTR was divided into five segments due to its unusual length and each segment was cloned into a pMIR-REPORT vector system. Genetic variants were generated by site directed mutagenesis and functional analysis using the dual luciferase assay was performed. Reporter plasmids were transfected into four cell lines: HepG2, HCT116 and two prostate cancer cell lines (DU-145, PC-3). Two of the genetic variants (457T/C and 514C/A, allele frequencies of 5%) showed a significantly reduced luciferase activity ($p < 0.01$) in all four cell lines when expressed in the full length 3'UTR. No significant change in luciferase activity was observed when the variants were present in truncated segments of the OCT3 3'UTR. Further studies are underway to determine the mechanism for the reduced activity of the two variants in the 3'UTR of OCT3. These variants may play a role in variation in drug disposition and response and may also be important in risk for human disease.

***In Vivo* Pharmacogenomic Characterization of Enhancers in Liver Membrane Transporters.** *M.J. Kim[1,2,3], P. Skewes-Cox[4], S. Hesselson[5], P.Y. Kwok[5], D.L. Kroetz[1], K.M. Giacomini[1], N. Ahituv[1,2]*. 1) Department of Bioengineering and Therapeutic Sciences, University of California, San Francisco, San Francisco, CA; 2) Institute for Human Genetics, UCSF; 3) Pharmaceutical Sciences and Pharmacogenomics, UCSF; 4) Biological and Medical Informatics Program, Department of Biochemistry, Microbiology and Medicine, Howard Hughes Medical Institute, UCSF; 5) Cardiovascular Research Institute, UCSF.

Liver membrane transporters play an important role in determining individual drug response due to their involvement in hepatic uptake and elimination. Numerous pharmacogenetic assays have demonstrated that nucleotide variation in the coding regions of these transporters and differences in their expression levels have a strong influence on drug response. However, little is known about how genetic variation in enhancers, sequences that regulate gene promoters, influence transporter expression and function and how they contribute to differences in drug response. In this study, we set out to identify enhancers that regulate liver membrane transporters and to investigate whether nucleotide variation in these enhancers can alter their expression levels. Using comparative genomics, we identified evolutionary conserved sequences (ECRs) surrounding nine liver membrane transporters (*SLC22A1, SLCO1B1, SLCO1B3, ABCC2, ABCB11, SLC22A7, SLCO2B1, SLC10A1, SLC47A1*) known to interact with commonly-used pharmaceuticals. These sequences were then ranked for the presence of liver-specific transcription factor binding sites and the top 50 ECRs were analyzed for enhancer activity *in vivo* using the mouse hydrodynamic tail vein assay. This assay utilizes a rapid intravascular injection of DNA into the mouse tail vein, leading to its specific expression in the liver. Eleven out of the 50 ECRs tested exhibited significant liver enhancer activity when compared to the control vector. Several of these positive enhancers were then sequenced in DNA samples from an ethnically diverse human population (N=250). Selected common variants were assayed for differential enhancer activity compared to the reference allele and several variants were found to affect activity. Assays to associate these variants with liver transporter expression levels in human liver tissues are currently on-going. Combined, these studies provide a model for elucidating how nucleotide variation in enhancer sequences can contribute to inter-individual differences in drug response. Furthermore, understanding how genetic variability in membrane transporters influences drug response and adverse drug effects will ultimately lead to more efficacious and efficient treatments.

## 2239/T/Poster Board #788

**Pharmacogenetics: In-vitro drug toxicity screening.** *T. Wiltshire[1], N. Butz[1], O. Suzuki[1], B. Steffy[1], D. Scoville[1], R. Thomas[2]*. 1) Sch Pharmacy, Univ North Carolina, Chapel Hill, NC; 2) The Hamner Institute for Health Sciences, Research Triangle Park, NC.

Pharmacogenetic studies have successfully identified genetic variants that contribute to variation in susceptibility to drug responses, but it is still a complex and challenging task to evaluate broadly across the human genome to identify the genetic components of response to drugs. Despite limitations there is a pressing need to identify genetic components that contribute to the efficacy and toxicity of drugs, across a wide spectrum of agents. We have proposed that using an alternative model population approach will provide many underlying mechanisms and pathways that are implicated in drug activity and responses. We have developed a platform of both in-vitro and in-vivo assays from genetically well defined mouse strains which will enable us to assess effects of toxicity and efficacy of current and novel agents in drug therapies. Here, we present a new strategy to identify genes and gene pathways that underlie susceptibility only to cellular-level adverse drug reaction. We have the ability to pinpoint genetic components that contribute to, or underlie, the toxicity phenotypes. We have screened 25 drugs (mostly anti-cancer agents) in whole well viability assays across 32 genetically well-defined primary cell lines. We have also screened the same cell lines with 50 toxicants/drugs in a high-content imaging screen that determines changes in specific cell-health status phenotypes (nuclear changes, membrane permeability, mitochondrial membrane potential and apoptosis). We can assess a high level of heritability (60-80%) for many of these phenotypes and have performed genome-wide association analysis to identify loci that underlie the toxicity traits. Although no targets have been fully validated yet we identify a number of potential candidate genes for specific drug toxicity phenotypes.

## 2240/T/Poster Board #789

**ABCC2 Genetic Variations and Carbamazepine Drug Response.** *S. Kim[1], W. Kim[2], J. Lee[1], J. Yi[1], Y. Cho[2], K. Heo[2], S. Lee[1], K. Kim[1], B. Lee[2], M. Lee[1]*. 1) Pharmacology, Yonsei University College of Medicine, Seoul, Korea; 2) Neurology, Yonsei University College of Medicine, Seoul, Korea.

ABCC2 (MRP2; multidrug resistance protein 2) is a primary active transporter that exports many chemical agents. Genetic variations in the ABCC2 located in brain endotheilium may affect individual drug responses to antiepileptic drugs such as carbamazepine. We investigated the association between ABCC2 polymorphisms and the drug response, including CNS side effects, of carbamazepine in Korean epileptic patients. Five tag SNPs(single nucleotide polymorphisms) in the ABCC2 gene were analyzed in 146 epilepsy patients. Patients were divided into two groups: those who experienced side effects of the CNS(central nervous system) (n=47) and those who did not (n=99). A nonsynonymous polymorphism, V417I (c.1249G>A), showed a strong association with CNS side effects caused by carbamazepine (P= 0.009). In the logistic regression analysis using multiple variables, the odd ratio of CNS side effects caused by carbamazepine was 5.32-fold higher in patients with the c.1249A allele (P=0.002). The functional study using a FACScan flow cytometer revealed that the V417I variation selectively reduced carbamazepine transport across the cell membrane. These results strongly suggest that the c.1247G>A polymorphism in the human MRP2 gene is associated with CNS side effects to carbamazepine. (This study was supported by grants 05132KFDA173 from the Korea Food & Drug Administration and A030001 from the Korea Health 21 R&D Project, Ministry for Health, Welfare and Family Affairs, Korea.).

## 2241/T/Poster Board #790

**ES cell derived hepatocytes are a useful model of drug toxicity.** *D. Dimmock[1], A. Buchaklian[1], K. Si-Tayeb[2], D. Helbling[1], S. Duncan[2]*. 1) Pediatrics, Medical College of Wisconsin, Milwaukee, WI; 2) Cell Biology, Neurobiology and Anatomy, Medical College of Wisconsin, Milwaukee, WI.

Several recent studies have demonstrated that hepatocyte cultures of human cancer origin may be a valuable model for predicating human hepatotoxicity and adverse drug reactions. However, the human hepatocellular carcinoma tissues do not reflect true hepatocyte drug response as they are lacking several key drug transport proteins. Hence, primary hepatocyte cultures are becoming a preferred vehicle for drug testing. These primary hepatocyte cultures have to be established from freshly harvested human livers, necessitating a biopsy or cadaveric sampling. Such harvesting is rarely an option in children with rare metabolic diseases as they seldom die at an equipped center with appropriate parental consent obtained. Since these cells can only undergo a very limited number of passages, the experiments that can be performed are limited by cell availability. It would be very valuable to have hepatocyte cultures which can be recurrently derived from the same individual, for instance from a stem cell, hence reducing intra-experimental variability to the condition being tested. These hepatocytes could be used to test for the therapeutic or toxic effects of pharmaceutical agents. Published reports in mammalian, including human primary hepatocytes demonstrate that, after exposure to acetaminophen, there is a dose dependent increase in apoptosis and cell death compared with vehicle treated cell lines. To evaluate ES cell derived hepatocytes as a model of such toxicity; we differentiated primary human ES cells using specific factors. Cultures were then incubated for 24 hours in media containing a final concentration of 5 or 10umol of acetaminophen or PBS vehicle. An alamar blue based dye (Resazurin) and a "live-cell" protease were used to measure resultant viability. The results demonstrate dose dependent toxicity of acetaminophen, consistent with the response of published human primary hepatocytes. This suggests ES derived hepatocytes have an equivalent pharmacodynamic response to toxins as primary hepatocytes and may serve as a useful model.

## 2242/T/Poster Board #791

**The Influence of SLCO1B1 Variants on Cerivastatin Drug Transport.**
*B. Tamraz[1], H. Fukushima[2], DL. Kroetz[2], PY. Kwok[1].* 1) Institute for Human Genatics, UCSF, San Francisco, CA; 2) Biopharmaceutical Sciences and Pharmaceutical Chemistry, UCSF, San Francisco, CA.

Drug metabolizing enzymes and membrane transporters work in concert to regulate the absorption, distribution, metabolism and excretion of drugs. Genetic variation in drug metabolizing enzymes and membrane transporters can modulate the beneficial as well as the deleterious effects of drugs. In a study of patients who developed rhabdomyolysis while taking the HMG-CoA reductase inhibitor, cerivastatin, we sought to identify genetic variants that might explain the high incidence of rhabdomyolysis associated with this medication. We re-sequenced several genes involved in the uptake and metabolism of cerivastatin and identified seven non-synonymous coding variants in SLCO1B1 which encodes the liver specific membrane drug transporter OATP1B1. Cerivastatin and other HMG-CoA reductase inhibitors are substrates of OATP1B1, leading to the hypothesis that SLCO1B1 variants may alter cerivastatin transport. To test this hypothesis, we stably transfected HEK293-FRT and MDCK-FRT cells with plasmids containing the variant cDNAs created by site-directed mutagenesis and measured the function of the transporter in an in vitro assay. To date a novel frameshift mutation in exon 9 of the SLCO1B1 gene discovered in this specific population group is determined to have a complete loss of function. The study of the remaining six nonsynonymous mutations on cerivastatin uptake is currently underway. The functional data characterizing the effect of all identified SLCO1B1 variants on cerivastatin uptake in stably transfected HEK293-FRT and MDCK-FRT cell lines will be presented. These results may shed light on risk factors for rhabdomyolysis, a serious side effect of statin drugs.

**ABCB1 Polymorphism is Associated with Side Effects of Methylphenidate in Attention Deficit Hyperactive Disorder.**
*J. Park[1], S. Kim[1], H. Hong[2], S. Lee[1], K. Yook[3], M. Lee[1].* 1) Department of Pharmacology, Yonsei University College of Medicine, Seoul, Korea; 2) Department of Psychiatry, College of Medicine, Hallym University, Pyeongchon, Korea; 3) Department of Psychiatry, College of Medicine, Pocheon Cha University, Sungnam, Korea.

P-glycoprotein (ABCB1; ATP binding cassette, subfamily B, member 1, MDR1; multidrug resistance protein 1) located at the luminal side of brain endothelial cell is a potent candidate to alter the pharmacokinetic values of psychotropic medications. We investigated the association between ABCB1 polymorphisms and side effects of methylphenidate, a brain stimulant known as a ABCB1 substrate mainly used in attention-deficit hyperactive disorder (ADHD). One hundred ninety two Korean patients who had been administered methylphenidate for their ADHD were divided into two groups according to the level of experiencing drug side effects at four weeks and genotyped with five tag SNPs (single nucleotide polymorphisms) of ABCB1. Our results showed that patients with T homozygote at G2677A/T have more side effects of methylphenidate at 4 weeks than patients with other alleles. The functional study using ATPase assay revealed that ABCB1 with 2677T allele had diminished methylphenidate transporting activity than 2677G or 2677A alleles. The side effects of methylphenidate have been regarded as one of major factors associated with drug compliance and treatment response in ADHD. Therefore, our results implied that the polymorphism of ABCB1 would be an important factor in prescribing methylphenidate in patients with ADHD. (This study was supported by grant A030001 from the Korea Health 21 R&D Project, Ministry of Health & Welfare, Korea).

## 2244/T/Poster Board #793

**Azathioprine induced severe Pancytopenia in one patient with Crohn's disease: identification of a novel Thiopurine S-Methyltransferase allelic variant IVS8-1G>A.**
*T. Adam de Beaumais[1], M. Fakhoury[1], B. Pigneur[2], S. Viola[2], Y. Medard[1], F. Broly[3], E. Jacqz-Aigrain[1].* 1) Department of Pediatric Pharmacology and Pharmacogenetics, Robert Debré Hospital, Paris, France; 2) Department of Pediatric Gastroenterology and nutrition, Trousseau Hospital, Paris, France; 3) UF Genopathy, Pharmacotoxicogenetics and Glycobiology, Biology and Pathology center, CHRU Lille, France.

INTRODUCTION Thiopurine S-methyltransferase (TPMT) polymorphisms are a major factor responsible for large individual variations in thiopurine toxicity due to excessive accumulation of cytotoxic metabolites. This present clinical observation describes a 14-year-old girl with Crohn's disease who developed severe pancytopenia during her Azathioprine (AZA) treatment. METHODS Red blood cell thioguanine nucleotides (RBC 6-TGN) and 6-methylmercaptopurine ribonucleotides (6-MMP) concentrations were measured by high-performance liquid chromatography. The open reading frame of TPMT gene (exons 3 to 10) and their consensus flanking sequences were sequenced (Applied Biosystems 3130 XL). RESULTS A 14-year-old girl with Crohn's disease treated by AZA was hospitalized for a wide pancytopenia highlighted by a routine blood analysis. Viral infections were excluded. Genotyping for the three predominant TPMT mutations (TPMT*2, TPMT*3B, TPMT*3C) showed a heterozygous TPMT*2 genotype but 6-TGN levels were unexpectedly elevated (3414 pmol/8*$10^8$RBC) and the concentration of 6-MMP was inferior to 20 pmol/8*$10^8$ RBC. Familial genetic analysis showed that the patient was carrier of a heterozygous composite TPMT genotype for two non-functional mutations. We identified a novel TPMT variant allele IVS8-1G>A corresponding to a G>A transition at the splice acceptor site of the intron 8 probably responsible of TPMT deficiency. CONCLUSION In cases of TPMT phenotype/genotype discordance concomitant with the occurrence of a severe adverse effect, sequence analysis of the complete open reading frame of the gene is interesting to identify rare inactivating variants. This case illustrates that TPMT genotype determination before treatment and measurement of 6-TGN and 6-MMP concentrations at steady-state remain important tools for thiopurines monitoring and clinical decision making.

## 2245/T/Poster Board #794

**CYP2C19 and CYP2D6 variation and response to citalopram treatment.**
*J.M. Biernacka[1,2], J.L. Black[2], D.J. O'Kane[3], J.M. Cunningham[3], S. Stevens[1], M.S. Drews[2], K.A. Snyder[2], R.M. Weinshilboum[4], D.A. Mrazek[2].* 1) Division of Biomedical Statistics and Informatics, Mayo Clinic, Rochester, MN; 2) Department of Psychiatry and Psychology, Mayo Clinic, Rochester, MN; 3) Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN; 4) Department of Molecular Pharmacology and Novel Therapeutics, Mayo Clinic, Rochester, MN.

Subjects in the Sequenced Treatment Alternatives to Relieve Depression (STAR*D) study were treated for major depressive disorder with citalopram. We used the STAR*D data to assess the association of genetic variation in two cytochrome P450 genes with drug response. Associations of remission and tolerance with CYP2C19 and CYP2D6 alleles were evaluated in a subset of 1074 white non-Hispanic patients using logistic regression models. In addition, CYP2C19 and CYP2D6 genotypes were used to classify subjects into categories based on known activity properties of the alleles (e.g. poor, intermediate, extensive and ultrarapid metabolizers), and association of these categories with treatment outcomes was assessed. Tolerance was defined based on study exit data. Patients who continued citalopram treatment in Level 2 of STAR*D were considered tolerant, while patients who refused to continue citalopram or left the study due to side effects were considered intolerant. Remaining subjects were classified as probably tolerant, probably intolerant, or intolerant based on the level of side effects at study exit as measured by the Global Rating of Side Effect Burden scale. The inactive CYP2C19 *2 allele was found to be associated with lower odds of tolerance (p-value = 0.02; OR = 0.67, 95%CI = (0.48,0.94). Similarly, CYP2C19 activity quantified from 1=poor metabolism to 6=ultrarapid metabolism demonstrated a trend of association with tolerance (p-value=0.06, OR = 1.15, 95%CI = (1.00, 1.32)). Furthermore, a significant association of remission with 2C19 activity classes was detected in the subgroup of tolerant subjects (p=0.03). Without consideration of the 2C19 genotype, there was no detectable association between 2D6 genotype and tolerance or remission. However, there was a significant interaction between the effects of CYP2C19 and 2D6 genotypes on remission (p=0.03). These findings suggest that variations of the CYP2C19 gene are associated with remission in white non-Hispanic depressed adults treated with citalopram. As the 2D6 enzyme does not play a primary role in the metabolism of citalopram, it is not surprising that CYP2D6 genotype is not as strongly associated with remission. However, the detected interaction between the effects of these two genes on tolerance and remission demonstrates that both enzymes appear to be playing a role, and the combination of a patient's genotypes at these two genes contributes to their response to citalopram treatment.

## 2246/T/Poster Board #795

**Genome-wide association study of response to warfarin in a UK prospective cohort.** *S. Bourgeois[1], A. Jorgensen[2], N. Soranzo[1], P. Whittaker[1], O. McCann[1], N. Hammond[1], S. Bumpstead[1], p. Williamson[2], P. Deloukas[1], M. Pirmohamed[2].* 1) Wellcome Trust Sanger Institute, Hinxton Cambridge, United Kingdom CB10 1SA; 2) Department of Pharmacology & Therapeutics, University of Liverpool, Sherrington Building, Ashton Street,Liverpool UK L69 3GE.

Warfarin is a widely prescribed anticoagulant drug to treat thromboembolic events that often give rise to stroke, deep vein thrombosis, and pulmonary embolism. Studies aimed at discovering the genetic and environmental determinants of warfarin dose requirements have been replicated in many cohorts, leading to the development of algorithms that can predict warfarin dose to within 20% of the actual dose in 55% of patients. Beyond CYP2C9 and VKORC1, in a recent genome-wide association study (GWAS) of 1000 Swedish patients we indentified CYP4F2 which accounts for just over 1% of the observed dose variation. In anticipation of no further common variants with large effects we set to explore clinically relevant outcome measures, such as dose stability, high INR during the first week of treatment, and time to bleeding event analyses. We genotyped a sample of 752 warfarin patients enrolled in a prospective study in Liverpool using Illumina's 610K QUAD chip. Post QC, data were first analyzed by linear regression; not surprisingly, only VKORC1, CYP2C9*2 and *3 were significant determinants of dose requirements, whereas we lacked power to detect a CYP4F2 effect. Interestingly, Cox regressions for time to stable INR, INR over 4 during first week of treatment, and bleeding events (classified according to several criteria) identified novel loci which may be implicated in patients' response to warfarin. A meta-analysis of the UK and Swedish scans for bleeding events is underway. The detailed phenotypic data allowed us to further dissect the influence of known and novel determinants of the inter-variability in response to warfarin, highlighting the great potential gains that can accrue from studying such phenotypes in addition to the dose. Such novel information is expected to further improve the utility of warfarin pharmacogenetics in the clinic. We acknowledge funding from the UK Department of Health.

## 2247/T/Poster Board #796

**Validation and Application of a Broad-Based ADME Genotyping Assay in Research and Clinical Trials.** *A.M.K. Brown[1,2], Y. Renaud[1], C. Ross[3], M. Hansen[4], U. Zanger[5], J-C. Tardif[1,2], M.S. Phillips[1,2].* 1) Genome Quebec & Montreal Heart Institute Pharmacogenomics Centre, Montreal, QC, Canada; 2) Université de Montréal, Montreal, QC, Canada; 3) University of British Columbia, Vancouver, BC, Canada; 4) Illumina, Inc. San Diego, CA; 5) Dr. Margarete Fischer-Bosch Institute of Clinical Pharmacology, Stuttgart, Germany.

Many medications show clear patient variability in terms of efficacy and undesired adverse side effects. Genetic variation in a well understood set of genes encoding enzymes and transporters involved in pathways affecting the Absorption, Distribution, Metabolism and Excretion (ADME) of drugs may directly contribute to the observed variation in patient response. To identify how ADME pathways affect drug response and safety, we have developed a broad-based ADME genotyping panel that encompasses the majority of the known variation present in the top ~180 ADME genes as ranked by several pharmaceutical companies. The genotyping panel, which consists both functional and haplotype tagged SNPs, is composed of ~3,000 SNPs that covers most of key functional variants that comprise the ADME "Core List" of genes. The assay was developed using Illumina's GoldedGate chemistry and the design has been optimized using novel strategies to overcome 3 identified failure modes; i) the presence of variants underlying oligo sequences, ii) assayed SNPs in close proximity, and iii) regions of high homology (including CNV and low complexity DNA). To validate the accuracy of the genotyping assays, we have screened samples that have known functional rare variants, HapMap samples to validate the haplotype tagging SNPs and a set of 150 liver DNA's (Institute of Clinical Pharmacology, Stuttgart) that have been extensively genotyped for many ADME variants and haplotype tags. Data from the Illumina broad-based panel has also been cross validated by comparing data from different technological platforms. Since the Stuttgart liver samples have been extensively characterized for ADME gene expression and enzymatic activity of many ADME proteins, these samples will be used to assess additional genotype/phenotype correlations that can be made using the broad-based panel over existing ADME data. To date, the assay has been used to screen patients involved in two clinical trials of drug response, as well as a research project on adverse drug reactions in children with promising results. We hope to continue to use this panel to screen subjects in clinical trials and research projects with the goal of identifying genetic variation in ADME genes responsible for variable drug responses.

## 2248/T/Poster Board #797

**Tacrolimus pharmacogenomics in kidney transplant: preliminary results from a 7 center consortium.** *P.A. Jacobson[1], A. Israni[2], S. Basu[3], T. Bergemann[3], R. Leduc[3], B. Julian[4], A. Matas[5], W. Oetting[1], DeKAF Investigators.* 1) Clinical Pharmacology, University of Minnesota, Minneapolis, MN; 2) Hennepin County Medical Center, Nephrology; 3) Biostatisics, University of Minnesota; 4) Unviversity of Alabama, Birmingham, AL; 5) Transplant Surgery, University of Minnesota.

There are conflicting data on the influence of single nucleotide polymorphisms (SNPs) on the pharmacokinetics of tacrolimus (TAC), a calcineurin inhibitor, which is the mainstay immunosuppressant in solid organ transplantation (tx). Methods: TAC pharmacogenetics were studied through a 7-center consortium in the U.S. and Canada in 680 kidney transplantation subjects. TAC trough concentrations were determined in each patient as part of clinical care twice in weeks 1-8 posttx and then once in each of months 3, 4, 5 and 6 posttx. Trough TAC concentrations were adjusted for TAC dose and weight. TAC doses were adjusted to maintain blood concentrations in the therapeutic range as defined by center. Recipient DNA was genotyped using a customized Affymetrix SNPChip containing 3500 SNPs of which 1000 were drug absorption, distribution, metabolism and excretion SNPs. Results: Mean±SD age and weight of the recipients were 49.5±12.7 yrs and 82.2±19.6 kg, respectively. 545 recipients were nonAA (African American) and 135 were AA. TAC mean daily dose requirements were higher in AA (7.6±3.4 mg) than nonAA (5.6±3.3 mg). Mean TAC troughs were lower in AA (6.7±3.4) than nonAA (8.6±3.4 ng/mL). Repeated measures analyses were performed to examine the effect of individual SNPs on adjusted troughs. In univariate analyses when adjusted for race, 30 SNPs were highly significant ($p \leq 0.0002$) towards TAC troughs. The top SNP was cytochrome P450 (CYP) 3A5*1 (rs776746) with a p=4.2x10-37. Troughs (adjusted for daily dose and weight) were 177.8±53.4 for individuals with 3A5*3/*3, 93.4±72.7 for 3A5*3/*1 and 72.9±71.9 for 3A5*1/*1. After adjustment for CYP3A5*1, five other SNPs (2 from CYP3A4 and 1 each from MDM2, ATF6 and COMT genes) remained significant ($p<0.0005$). The CYP3A4, MDM2 and ATF6 increased TAC troughs whereas the COMT SNP was associated with lower TAC concentrations. Conclusion: We found that the CYP 3A5*1 allele was significantly associated with lower TAC concentrations in a large, ethnically diverse population. Multiple previously unexplored polymorphisms were identified. These variants may further explain the substantial interpatient variability in TAC concentrations and will be validated with intensive pharmacokinetic evaluation in patients specifically recruited with these genotypes.

## 2249/T/Poster Board #798

**Association of polymorphisms of CYP2D6 and other PK-related genes on recurrence-free survival in Japanese breast cancer patients receiving adjuvant tamoxifen therapy.** *K. Kiyotani[1], T. Mushiroda[1], M. Sasa[2], T. Yamakawa[3], K. Hirata[4], M. Okazaki[5], S. Ohsumi[6], Y. Takatsuka[7], Y. Bando[8], I. Sumitomo[2], T. Tsunoda[9], N. Hosono[10], M. Kubo[10], Y. Nakamura[1,11], H. Zembutsu[11].* 1) Lab for Pharmacogenetics, RIKEN Center for Genomic Med, Yokohama, Japan; 2) Department of Surgery, Tokushima Breast Care Clinic, Tokushima, Japan; 3) Yamakawa Clinic, Kochi, Japan; 4) First Department of Surgery, Sapporo Medical University School of Medicine, Sapporo, Japan; 5) Department of Surgery, Sapporo Nyusen Clinic, Sapporo, Japan; 6) Department of Breast Oncology, National Hospital Organization Shikoku Cancer Center, Ehime, Japan; 7) Department of Surgery, Kansai Rosai Hospital, Hyogo, Japan; 8) Department of Molecular and Environmental Pathology, Institute of Health Biosciences, The University of Tokushima Graduate School, Tokushima, Japan; 9) Lab for Medical Informatics, RIKEN Center for Genomic Medicine, Yokohama, Japan; 10) Lab for Genotyping Development, RIKEN Center for Genomic Medicine, Yokohama, Japan; 11) Lab of Molecular Medicine, Human Genome Center, Institute of Medical Science, The University of Tokyo, Tokyo, Japan.

The clinical efficacy of tamoxifen has been suggested to be influenced by the activity of metabolizing enzymes and transporters that involved in the formation, detoxification and elimination of tamoxifen and its active forms, 4-hydroxytamoxifen and endoxifen. We investigated the effects of polymorphisms in the genes possibly associated with pharmacokinetics (PK) of tamoxifen and its metabolites in 283 breast cancer patients who were received adjuvant tamoxifen monotherapy. Kaplan-Meier estimates showed that CYP2D6*10 were significantly associated with recurrence-free survival (log-rank P = 0.00029). Multivariate Cox proportional hazard analysis demonstrated that the CYP2D6 genotype was one of the independent factors affecting recurrence-free survival (P = 0.00055; adjusted hazard ratio (HR), 9.36; 95% CI, 2.63-33.29 for CYP2D6*10/*10, and P = 0.037; adjusted HR, 3.79; 95% CI, 1.08-13.22 for CYP2D6*1/*10 compared to patients with CYP2D6*1/*1). We then investigated the association of polymorphisms in tamoxifen PK-related genes, including other P450 isoforms, UDP-glucuronosyltransferases (UGTs) and sulfotransferases (SULTs). However, no polymorphisms in these genes tested in this study were significantly associated with recurrence-free survival of patients receiving tamoxifen monotherapy (P > 0.05). The present study suggests that the CYP2D6 genotype should be considered when selecting adjuvant hormonal therapy for breast cancer patients.

## 2250/T/Poster Board #799

**Warfarin dose variation and VKORC1/CYP polymorphisms.** *M.K. Kringen[1], K.B.F. Haug[1], R.M. Grimholt[1], C. Stormo[1], A.P. Piehler[1], I. Seljeflot[2], J.P. Berg[1], O. Børs[1].* 1) Department of Medical Biochemistry and Clinical Pharmacology, Oslo University Hospital, Ullevål, Oslo, Norway; 2) Center for Clinical Heart Research, Department of Cardiology, Oslo University Hospital, Ullevål, Oslo, Norway.

Background: Warfarin dosage has traditionally been a challenge to clinicians because of its narrow therapeutic range and patient variability in clinical response. Polymorphisms affecting both warfarin pharmacokinetics and pharmacodynamics have been in focus, especially the impact of CYP2C9, VKORC1 and now recently, the CYP4F2 gene. Previously we have found VKORC1*2 (rs9934438) to account for 24.5%, and CYP2C9*2 and CYP2C9*3 combined (rs1799853 and rs1057910), to account for 7.2% of the warfarin dose variation in patients from the Warfarin Aspirin Reinfarction Study (WARIS-II). In this study we investigated whether VKORC1*3 (rs7294), VKORC1*4 (rs17708472) and CYP4F2 (rs2108622) were associated with warfarin dose requirements in the same patient group. Methods: The patients (n=105) in this study were a subgroup of the WARIS-II study who had been assigned to either warfarin alone or warfarin in combination with aspirin after acute myocardial infarction. DNA from patients was genotyped for VKORC1*3, VKORC1*4 and CYP4F2 (rs2108622) by real-time PCR. Genotyping of VKORC1*2, CYP2C9*2 and CYP2C9*3 were done previously. Results: None of the SNPs deviated from the Hardy-Weinberg equilibrium (exact test). Multivariate regression of CYP4F2 (rs2108622), adjusted for age and treatment group, showed a weak association on warfarin dose for the heterozygous CYP4F2 variant (P=0.05). However, adding this polymorphism into our main regression model together with our previously reported data on the VKORC1*2, CYP2C9*2 and CYP2C9*3 genotypes, age and treatment group, gave no significant associations for neither of the CYP4F2 genotypes and reduced the $R^2$. There was a significant association between warfarin dose and VKORC1*3 and VKORC1*4 when adjusted for age and treatment group only (P<0.001 and P=0.003, respectively). They did not, however, add more information when included into the main regression model, and the associations between warfarin dose and VKORC1*3 and VKORC1*4 were lost. Conclusion: In our study of patients with myocardial infarction, up to 32% of the variability in warfarin dose requirements could be explained by VKORC1*2, CYP2C9*2 and CYP2C9*3. The addition of VKORC1*3, VKORC1*4 or CYP4F2 (rs2108622) into the main regression model did not explain more of the variability in warfarin dose requirements, indicating that genotyping of CYP2C9*2, CYP2C9*3 and VKORC1*2 is sufficient for warfarin dose prediction.

## 2251/T/Poster Board #800

**Teststrip-based genotyping to assist in the prediction of anticoagulant dose requirement.** *H. Puehringer[1], G. Klose[2], B. Schreyer[2], W. Krugluger[3], R.M. Loreth[2], C. Oberkanins[1].* 1) ViennaLab Diagnostics, Vienna, Austria; 2) Clinical Haemostaseology, Westpfalz-Klinikum GmbH, Kaiserslautern, Germany; 3) Institute of Laboratory Medicine, Donauspital, Vienna, Austria.

Background: Coumarin derivatives (warfarin, phenprocoumon) are the most widespread oral anticoagulant drugs for the prevention and treatment of thromboembolic disorders. However, these vitamin K antagonists have a narrow therapeutic range and a wide interindividual variability in dose requirement. Despite adjustment for clinical variables, adverse events are frequently encountered during the initial phase of therapy. Genetic polymorphisms in the drug-targeted vitamin K epoxide reductase complex 1 (VKORC1) and in the drug metabolizing enzyme CYP2C9 have been reported to account for the majority of variations in the therapeutic response to warfarin. Aims and Methods: A genetic test (StripAssay) for the simultaneous detection of two VKORC1 polymorphisms (-1639G>A, 3730G>A) and the functionally defective CYP2C9 variants *2 (430C>T) and *3 (1075A>C) was developed. The protocol is based on multiplex PCR and reverse-hybridization of biotinylated amplification products to allele-specific probes on membrane teststrips. The new StripAssay is currently being used in an ongoing clinical study to classify patients into high, intermediate and low dose responders to coumarin anticoagulants. Results: Preliminary data based on more than 170 patients treated with phenprocoumon (Marcumar) indicated a considerably lower stable dosage required for therapeutic anticoagulation in carriers of a combined VKORC1 -1639A and CYP2C9 *2 or *3 genotype compared to carriers of a single variation or wildtype alleles. The VKORC1 3730G>A polymorphism seemed to have no additional predictive power for phenprocoumon dose variability. Summary and Conclusions: The new diagnostic assay and the results obtained during our study will assist clinicians to achieve a safer and more individualized anticoagulant therapy. (oberkanins@viennalab.co.at).

## 2252/T/Poster Board #801

**Validating a novel hepatocyte culture platform for *in vitro* pharmacogenomics.** *M. Saito[1,2], C. Cotsapas[1,2], S. Khetani[3], S. Katz[3], E. Liu[3], J. Yeh[3], S. Gupta[2], M. Mino-Kenudson[4], R. Gould[5], S. Bhatia[3,5], M. Daly[1,2].* 1) CHGR, Massachusetts General Hospital, Boston, MA; 2) Medical and Population Genetics, Broad Institute of MIT and Harvard, 7 Cambridge Center, Cambridge MA, 02142; 3) Laboratory for Multiscale Regenerative Technologies, MIT, 77 Massachusetts Ave. Building E19-502d, Cambridge MA, 02139; 4) Department of Pathology, Harvard Medical School and Pathology, Massachusetts General Hospital, 55 Fruit St. Boston MA, 02114; 5) Novel Therapeutics Platform, Broad Institute of MIT and Harvard, 7 Cambridge Center, Cambridge MA, 02142.

Population variation in drug metabolism leading to adverse toxic events is a major medical burden, resulting in the withdrawal of several widely prescribed pharmaceuticals. Understanding the genetic underpinnings of this variation is crucial to prevention efforts and to incorporating variation response assays earlier in the drug development process. Such efforts have been hampered by the absence of suitable *in vitro* models of human liver, as hepatocytes lose the ability to induce metabolic enzyme production in response to chemical stimulus within hours of isolation from tissue. We have developed an *in vitro* hepatocyte culture system which preserves this ability for several weeks [Khetani and Bhatia, Nat Biotech 2008]. This provides the first realistic platform in which to quantitatively screen metabolic response to therapeutics in humans, potentially enabling us to perform large-scale pharmacogenomic assays. Here, we describe a comparison of *in vivo* and *in vitro* responses to two drugs in mice, in which we calibrate the ability of our platform to recapitulate *in vivo* biology and perform pharmacogenomics experiments in humans. We administered therapeutically equivalent doses of acetaminophen (APAP) and 5`-fluorouracil (5FU) to pools of four C57Bl/6J male mice. We measured gross response with serum chemistry and microscopic liver histopathology after 24 hours of drug administration; to look for more subtle responses, we also performed gene expression profiling of RNA prepared from the liver. In parallel, we exposed hepatocyte co-cultures from drug-naïve mice to equivalent doses of APAP and 5FU for 24 hours. We performed serum chemistry tests on the culture media and expression profiling on RNA prepared from the cells. We detected dose-dependent elevations in alanine and aspartate aminotransferases (ALT and AST) both *in vivo* and *in vitro*, with elevations occuring at the same dosage levels. We have also been able to determine dose-dependent *in vivo* gene expression signatures unique to each drug compared to control samples. We are currently exploring the overlap between these signatures and those obtained *in vitro*. Our initial results indicate substantial correlation, suggesting our hepatocyte culture system is able to recapitulate *in vivo* events. We are therefore hopeful that our platform will allow us to execute pharmacogenomic experiments on human hepatocytes to uncover the molecular processes underlying response to therapeutics.

## 2253/T/Poster Board #802

**A Pharmacogenetic Approach to Pharmacological Chaperone Therapy for Fabry Disease.** *X. Wu[1], E. Katz[1], K. Mascioli[1], K. Chang[1], R. Khanna[1], S. Sitaraman[1], D. Palling[1], R. Schiffmann[2], D. Lockhart[1], K. Valenzano[1], E. Benjamin[1].* 1) Pharmacology, Amicus Therapeutics, Cranbury, NJ; 2) Baylor Research Institute, Dallas, TX.

Fabry disease is an X-linked lysosomal storage disorder caused by mutations in the gene that encodes $\alpha$-galactosidase A ($\alpha$-Gal A), and is characterized by pathological accumulation of globotriaosylceramide (GL-3). More than 600 mutations have been reported of which more than 60% are missense. The iminosugar AT1001 (migalastat hydrochloride) is a pharmacological chaperone that selectively binds $\alpha$-Gal A, increasing physical stability, lysosomal trafficking, and total cellular amount and activity. To identify AT1001-responsive $\alpha$-Gal A mutant forms, each of 394 known Fabry disease-causing missense mutations and small in-frame insertion and deletion mutations were engineered and expressed in HEK-293 cells. Incubation with AT1001 for 4-5 days increased $\alpha$-Gal A levels for 60% of the mutant forms as measured by using a 4-MU-$\alpha$-D-galactopyranoside hydrolysis enzyme activity assay and by Western blot. The HEK-293 cell assay results were consistent with those obtained in an *ex vivo* Fabry patient-derived T-cell assay and the *in vivo* white blood cell response dataset from the AT1001 Phase 2 clinical trials. Based on the HEK-293 cell assay results, criteria for the selection of Fabry patients most likely to respond to AT1001 were developed. Based on these criteria, the responsive mutant forms evaluated in the Phase 2 clinical trials were generally representative of the larger set predicted to be responsive. Concomitantly, $\alpha$-Gal A-deficient mice that express a responsive human mutant form (R301Q) showed significant increases in $\alpha$-Gal A and decreases in GL-3 levels in multiple tissues and plasma after daily or less frequent (4 days on/3 days off) oral administration of AT1001 for 28 days. Collectively, these results indicate that genotype is predictive of cellular $\alpha$-Gal A response to AT1001, and may be used to identify the patients most likely to benefit in further clinical evaluation of AT1001 as a treatment for Fabry disease.

**TIMP2 REGULATES EXPRESSION OF TGF- AND IL-4 IN HEPATIC STELLATE CELLS CULTURE.** *Y. Sánchez-Toscano[1], M.R. Bueno-Topete[1], A.B. Martínez-Rizo[1], L. Sánchez-Orozco[1], J. Armendáriz-Borunda[1,2], R. Troyo-Sanromán[3].* 1) Instituto de Biología Molecular en Medicina y Terapia Génica, Universidad de Guadalajara, Guadalajara, Jalisco, Mexico; 2) OPD Hospital Civil de Guadalajara, Universidad de Guadalajara, Jalisco, México; 3) Coordinación de Investigacion, Universidad de Guadalajara, Guadalajara, Jalisco, México.

Background: TGF-β is the most relevant pro-fibrogenic cytokine during the process of liver fibrosis. Nevertheless, novel studies shown an induction in the expression of collagen type I, III and IV in response to the signaling route IL-4/STAT6, almost with the same intensity as TGF-β. Knock-down of TIMP-2 expression decreases liver fibrosis in experimental models, but the interrelationship between TIMP-2 and the signaling route of TGF-β e IL-4 is unknown. Aim: To decrease the gene expression of TIMP-2 using small interfering RNAs (siRNA) and to evaluate the key molecules participating in the signaling route of TGF-β and IL-4, in culture hepatic stellate cells Methods: Human (HSC180) and rat (8B) hepatic stellate cells were cultured. Transfection studies were performed using siRNA/TIMP-2(100nM)/lipofectamine once the stellate cells reached a confluency of 70%. After 48 hr of transfection, total RNA and proteins were collected to evaluate the gene expression of TIMP-2 by real time RT-PCR and the protein levels of TGF-β, Smad2P, Smad7 and IL-4 were determined by Western blot. Results: Knock-down of TIMP-2 expression significantly decreased 95% compared with the control, using siRNA 100nM. Interestingly, the protein levels of TGF-β, Smad2P, Smad7 and IL-4 were decreased (>70%) compared with the controls. Conclusion: TIMP-2 obliteration drastically decreases the over expression of pro-fibrogenic molecules involved in the progression of liver fibrosis.

**Legal Liability and Incidental Findings in Clinical Pharmacogenetic Testing.** *P.C. Kuszler[1], W. Burke[2], K.B. Shutske[3], S.B. Haga[4].* 1) Law, University of Washington, Seattle, WA; 2) Bioethics and Humanities, University of Washington, Seattle, WA; 3) Institute for Public Health Genetics, University of Washington, Seattle WA; 4) Institute for Genome Sciences and Policy, Duke University, Durham, NC.

Pharmacogenetics offers the promise of tailored drug therapy that will improve safety and efficacy. However, many pharmacogenetic tests reveal information beyond that relevant to the therapeutic question for which testing is done. These incidental findings present challenges to informed consent and raise questions about when disclosure is appropriate and necessary. A provider may face liability either from the failure to disclose the risk of incidental findings in the process of informed consent or from failure to adhere to the standard of care in ordering, interpreting or acting on test results that present as incidental risk findings. A systematic search of electronic case law databases (Westlaw, Lexis; date range 1999-2009) reveals no case law on pharmacogenetic testing. There is however, case law evolving from analogous clinical technologies, notably imaging technologies. Several scholars, notably Wolf, et al., (J Law Med Ethics. 2008) have posited a decision tree addressing incidental findings in genetic research. Drawing upon this work and our study of case law, we propose a decision-making framework for disclosure in pharmacogenetic testing in clinical practice. This framework provides for a tiered approach to disclosure of incidental findings and posits a high level of duty when the information has the potential to reduce morbidity or mortality and a diminished duty as the utility of the information becomes increasingly clinically ambiguous. Patient factors are also relevant: While the duty to disclose incidental information seems clear when the information will offer a patient the opportunity to prevent future illness, it may be of less moment if co-morbidities would prevent the patient from pursuing or benefiting from preventive measures. On the other end of the spectrum, information that has no known utility may, with growing knowledge of gene-disease associations, become significant, clinically useful information. This dynamic may challenge the traditional legal parameters of duty in the provider/patient relationship, particularly if usual practice includes electronic recording of pharmacogenetic test information for future use. These issues raised by pharmacogenetics are likely to represent the first wave of growing obligations for clinicians related to the incidental information deriving from genome-based testing in health care.

## 2256/T/Poster Board #805

**Who Are Adopters of Pharmacogenomics among U.S. Physicians?** *E.J. Stanek[1], C.L. Sanders[1], J.R. Teagarden[1], K.A. Johansen[2], R.E. Aubert[1], B.C. Agatep[1], M. Khalid[1], A. Patel[1], F.W. Frueh[1], R.S. Epstein[1].* 1) Medco Health Solutions, Inc., Franklin Lakes, NJ; 2) American Medical Association, Chicago, IL.

Background: Information about pharmacogenomics (PGx) is evolving rapidly, but little is known about how US physicians perceive and use PGx testing. Methods: We conducted an anonymous, cross-sectional survey of US physicians in late 2008. The fax-based survey solicited demographic and professional profile elements, as well as PGx education, beliefs, practices, and preferred information sources. Respondent characteristics were compared to the American Medical Association MasterFile to assess generalizability. Factors associated with early and future adoption of PGx were tested for statistical significance with chi-square and multivariate logistic regression analyses. Results: We surveyed 397,832 physicians and 10,303 (3%) completed surveys were returned. Respondent characteristics were similar to the overall US physician population. Overall, 98% of respondents agree that patient genetic profiles may influence drug therapy, and 26% have prior PGx education. However, only 10% feel adequately informed about PGx testing. Early adopters (those ordering a PGx test in the previous 6 months) accounted for 13% of respondents, and future adopters (those anticipating ordering a PGx test in the next 6 months) accounted for 26%. Ten percent of respondents reported that PGx tests had benefited their patients by improving drug effectiveness and 10% reported their patients benefited from reduced toxicity. Early adopters are more likely to be oncologists, 15-29 years from medical school, and recipients of formal PGx education. They are also more likely to feel adequately informed about the availability of genetic testing, and believe that tests have benefited their patients by improving drug effectiveness, reducing drug toxicity, or increasing patients' understanding of therapy. Physicians who had not yet adopted PGx testing, but anticipated doing so, were more likely to be male, older, and educated about PGx. They also believe that a patient's genetic profile influences drug therapy and that the use of PGx tests benefit patients by improving drug effectiveness or reducing toxicity. Conclusions: An estimated 13% of US physicians have adopted PGx testing, while 26% anticipate adoption. Surprisingly, almost all believe that a patient's genetic makeup influences drug therapy. The contrast between acceptance of PGx as a therapeutic modifier and actual adoption rate highlights the need to clearly demonstrate patient benefit and the importance of physician education.

## 2257/T/Poster Board #806

**A GENETIC VARIANT SIGNIFICANTLY ASSOCIATED WITH RESPONSE TO ANTIEPILEPTIC MEDICATION IN TEMPORAL LOBE EPILEPSY.** *M.S. Silva[1], E. Bilevicius[2], R. Secolin[1], F. Cendes[2], I. Lopes-Cendes[1].* 1) Dept Medical Genetics, FCM - Unicamp, Campinas, Sao Paulo, Brazil; 2) Dept Neurology, FCM-Unicamp, Campinas, São Paulo, Brazil.

Rationale: Mesial temporal lobe epilepsy (MTLE) is associated with a high proportion of patients who do not respond well to treatment with antiepileptic drugs (AEDs). There is functional evidence that genetic variation, such as single nucleotide polymorphisms (SNPs), can affect the expression of drug transporter genes. In addition, there is a previous report of a significant association between an SNP in the ABCB1 gene and pharmacoresistance in a group of patients with different types of epilepsy; however, this study was not further replicated. The purpose of our study was to evaluate whether SNPs in drug-transporter genes could be associated with pharmacoresistance to AEDs in a large group of patients with MTLE. Methods: Consecutive patients with clinical-EEG diagnosis of MTLE were ascertained at the epilepsy clinic of our University Hospital. We included a total of 138 drug-resistant patients and compared with 88 drug-responsive patients who were seizure free on AEDs. We genotyped 30 dbSNPs in 4 different genes (RALBP1, ABCB1, ABCC2, ABCC4). Genotyping was carried out using the TaqMan system (Applied Biosystems). The significance of allelic association was assessed using logistic regression (logistf function in R environment). P-values were corrected by Bonferroni. In addition, we analyzed the genetic structure of both population groups using Fst and AMOVA with Arlequin v.3.11. Results: Genotypic frequencies for all SNPs genotyped were in Hard-Weinberg equilibrium in both groups. Sample power calculation showed a statistical power of 0.98 for the sample studied. The mean Fst was 0.00111 between drug-responsive and drug-resistant patients. Genetic variance between groups was 0.11 and within groups was 99.88. Logistic regression showed no significant association between any of the SNPs studied in RALBP1, ABCB1 and ABCC4 and pharmacoresistance. However, we found a significant association between an exonic SNP rs3740066 (Ile1324Ile), at the ABCC2 gene and pharmacoresistance (p=0.0368); OR = 1.51, IC (1.01:2.29). Conclusion: We found that both populations, drug-resistant and drug-responsive patients with MTLE, are very similar in their genetic structure. In addition, they show a large amount of genetic variability within the groups. We exclude the association between pharmacoresistance to AEDs in patients with MTLE and SNPs in the ABCB1 gene; by contrast, we found a significant associating between a SNP in the ABCC2 gene and this phenotype.

## 2258/T/Poster Board #807

**Identification of novel variants in the *CYP2D6* gene in Mestizo and Amerindian populations of Mexico.** *A. Contreras, I. Silva-Zolezzi, T. Monge, L. Alfaro, S. Hernandez, H. Miranda, K. Carrillo, G. Jimenez-Sanchez.* National Institute of Genomic Medicine (INMEGEN), Mexico City, Mexico.

Genetic variants of drug metabolizing enzymes play a critical role on interindividual differences in drug response and adverse reactions. The *CYP2D6* gene, a member of Cytochrome P-450 family, has a central importance in the metabolism of a large number of commonly prescribed drugs, including antidepressants, antipsychotics and antihypertensives. *CYP2D6* shows a high degree of interindividual genetic variability that influences its expression and function. In addition, population studies have shown a wide range in the frequency of *CYP2D6* polymorphisms. For example, frequency of the *CYP2D6*10* allele ranges from 1.5% in Caucasian population to 52.5% in Chinese population. Mexicans have a specific ancestry which includes Amerindian, European, and in a lesser extent, African populations. To characterize genetic variation in the *CYP2D6* gene in Mexican population, we resequenced *CYP2D6* including 1.6 kb 5' flanking region, and its 9 exons and 8 introns in 96 Mexican Mestizos; 50 from Guerrero (GUE) and 46 from Sonora (SON). We observed 55 different genetic polymorphisms, including 14 novel: 13 SNPs and a *CYP2D6/2D7* gene conversion. The wild-type *CYP2D6*1* allele was to the most frequent (50.0%) and included a new version of it which contains rs1081004 (3.12%). The second most frequent (25.5%) was allele *CYP2D6*2*, included 3 novel haplotypes (18.22%). Allele *CYP2D6*4* (14.15%), characterized by a splicing defect (1846G>A), included a version with a novel non-synonymous SNP in exon 9 (C4160A; Ala449Asp). In addition, another non-synonymous SNP (G3251C; Arg330-Pro) was identified in exon 7. A novel *CYP2D6/2D7* gene conversion in exon 2 was identified in GUE (4%), and was confirmed in additional Mestizo: Yucatan (3.4%) and Zacatecas (1.67%), and Amerindian populations: Mixtecos (5%), Tepehuanos (3.3%) and Mayas (1.67%). Our results contribute to the characterization of *CYP2D6*, which will facilitate the development of pharmacogenetics for the Mexican population.

## 2259/T/Poster Board #808

**Prediction of irinotecan toxicity and response in patients with advanced colorectal cancer.** *M. Wadelius[1], H. Garmo[2, 3], A. Berglund[4], L. Fredriksson[1], H. Kohnke[1], H. Sørbye[5], B. Glimelius[4, 6].* 1) Dept Medical Sciences, Clinical Pharmacology, Uppsala University, Sweden; 2) Regional Oncologic Centre, Uppsala University Hospital, Sweden; 3) Division of Cancer Studies, School of Medicine, King's College London, UK; 4) Dept Oncology, Radiology and Clinical Immunology, Uppsala University, Sweden; 5) Dept Oncology, Haukeland University Hospital, Bergen, Norway; 6) Dept Oncology and Pathology, Karolinska Institutet, Stockholm, Sweden.

Introduction: Irinotecan and 5-fluorouracil (5-FU) are frequently used to treat metastatic colorectal cancer. Irinotecan's active metabolite is metabolised by UDP-glucuronosyl transferase 1A1 (UGT1A1), which is deficient in Gilbert's syndrome. Irinotecan and metabolites are transported by P-glycoprotein, encoded by ABCB1. 5-FU targets folate metabolism through inhibition of thymidylate synthase (TYMS). Methylentetrahydrofolate reductase (MTHFR) generates active folate necessary for normal haematopoiesis. Methods: We collected blood or normal colon biopsies from 140 Swedish and Norwegian colorectal cancer patients treated with irinotecan and 5-FU in a randomised clinical trial. We genotyped them for UGT1A1*28, UGT1A1*60, ABCB1 1236C>T, 2677G>T/A and 3435C>T, TYMS*2 and *3, and MTHFR 677C>T and 1298A>C using capillary DNA sequencing, real-time PCR and PCR with electrophoresis. Results: 25% of the patients experienced serious toxicity after one or two treatment cycles. Patients homozygous for UGT1A1*28 had an increased risk of early toxicity, OR 4.4 (95% C1 1.3 - 15.2), especially neutropenia, OR 21.3 (95% CI 2.0-225). The ABCB1 3435 variant genotype T/T increased the risk of early toxicity, OR 3.8 (95% CI 1.1-13.2). Compared with wild type patients, those homozygous for ABCB1 variant haplotypes were less likely to respond to treatment, OR 0.31 (95% CI 0.11-0.87) and survived shorter time, HR 1.97 (95% CI 1.06 - 3.65). Conclusion: We verified an increased risk of early toxicity, particularly neutropenia, in patients with Gilbert's syndrome. ABCB1 variant genotypes were associated with early toxicity, less response and shorter survival, but these findings need to be confirmed in future studies.

## 2260/T/Poster Board #809

**Admixture Analysis for Dissecting Pharmacogenetics Phenotypes in Psychiatry.** *V. De Luca, F. Panariello, J.L. Kennedy.* Dept Neurogenetics, Univ Toronto, Toronto, ON, Canada.

Despite the considerable amount of data from several studies in psychiatric pharmacogenetics, there is no agreement regarding the ideal cut-off for the quantitative phenotypes to determine people at risk for side effect and non-response to treatment. The aim of this study is to define the ideal cut-off for three common psychiatric phenotypes (antipsychotic response, weight gain and tardive diskinesia) by using admixture analysis, a common statistical procedure that has been applied to determine the cut-off for early onset of many psychiatric disorders. Admixture analysis was applied to identify model(s) of separate normal distributions of AOO characterized by different means, variances and population proportions in our sample of 204 patients with schizophrenia assessed for response (BPRS), tardive diskinesia (AIMS) and percentage weight change after antipsychotic treatment. Once the total sample was divided in different severity groups, we have also evaluated the demographic features of each subgroup. Regarding the weight gain, the model that best fits the observed distribution was a mixture of two gaussian distributions with three one-off points. The mean weight chnages estimated in this model were 2.61% (SD=3.73) and 8.65% (SD=8.75). The cut-off point was 8% weight change from baseline that is very close to the proposed 7% based on clinical evidence. When we analyzed the distribution of BPRS and AIMS in our sample, the admixture analysis program was unable to identify a cut-off that can be applied for analyzing genetic data. Our conclusion is that the admixture analysis can be employed to dissect certain pharmacogenetics phenotype such as antipsychotic-induced weight gain, however its application to other phenotypes should be further assessed in independent samples.

## 2261/T/Poster Board #810

**Variant discovery by targeted resequencing of "high-value" regions in drug pathways.** *E.T. Lam[1], K.M. Long[2], D.T. Okou[3], M.E. Zwick[3], P.-Y. Kwok[1], H.L. McLeod[2], M. Wagner[2].* 1) Institute of Human Genetics, University of California, San Francisco, San Francisco, CA; 2) Institute for Pharmacogenomics and Individualized Therapy, University of North Carolina at Chapel Hill, Chapel Hill, NC; 3) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA.

In order to realize the goal of personalizing medicine, markers associated with drug response need to be identified and validated. Recognizing that drug response, much like other complex phenotypes, is influenced by multiple genetic factors, we set out to identify novel variants in networks of genes that may contribute to the patient's overall response phenotype. The advent of massively parallel sequencing or next-generation sequencing (NGS) technologies promises to enable sequencing in an ultra high-throughput fashion and at a much lower cost. We aim to take advantage of these NGS technologies for targeted resequencing of candidate loci. Currently, target capture technologies that facilitate high-throughput and robust enrichment of regions of interest are being developed. In our pharmacogenetics study, we have used a microarray-based approach with NimbleGen capture arrays to capture loci involved in drug metabolism and activity of 5-fluorouracil (5FU), a compound commonly used in chemotherapy. We are particularly interested in regions with a high *a priori* probability of being functional. We have designed microarrays to target "high-value" regions that are either exonic or highly conserved across vertebrates. Our arrays target over 4200 regions from 95 genes, encompassing approximately 0.8 Mb. We have exploited CEPH lymphoblastoid cell lines for drug response measurements for chemotherapy agents otherwise not suitable for testing in normal subjects. Toxic response to 5FU for these cell lines was measured, and much variation in response was observed. DNA extracted from these cell lines were used in our capture experiments, and the captured DNA was sequenced on the Illumina GAII. Preliminary data analyses show high degree of enrichment of sequences of interest. We will present our framework of prioritizing the variants found for validation based on coverage and predicted functional significance and correlating genotype to phenotype.

## 2262/T/Poster Board #811

**CYP2D6 genotyping for functional gene dosage analysis by allele copy number detection.** *N. Hosono[1], M. Kato[1], K. Kiyotani[1], T. Mushiroda[1], S. Takata[1], H. Sato[1], H. Amitani[1], Y. Tsuchiya[1], K. Yamazaki[1], T. Tsunoda[1], H. Zembutsu[2], Y. Nakamura[1,2], M. Kubo[1].* 1) Center for Genomic Medicine,Riken, Yokohama, Kanagawa, Japan; 2) The Institute of Medical Science, University of Tokyo,Tokyo, Japan.

Cytochrome P450 2D6 (CYP2D6) is one of the most important drug-metabolizing enzymes and has been reported to have genetic variations that affect its enzymatic activity. For the pharmacogenetic study of CYP2D6, accurate measurement of its functional gene dosage is essential. However, current genotyping techniques are insufficient due to their inability to provide the exact copy number of functional CYP2D6 alleles. We developed three quantitative real-time PCR (qPCR) assays for estimating the total copy number of the CYP2D6 gene, as well as multiplex PCR-based real-time Invader assays (mPCR-RETINAs) for estimating the allele ratios at 24 variation-loci which were reported to have functional significance in vitro and/or in vivo. After determining the allele copy number at each locus, we estimated the frequencies of CYP2D6 alleles in a population and the diplotype in each individual by a CNV phaser. Among 455 Japanese individuals were examined, 42 (9.2%) had one CYP2D6 gene copy, 207 (45.5%) had two copies, 161 (35.4%) had three copies, 40 (8.8%) had four copies, and five (1.1%) had five copies of the CYP2D6 gene. We found 14 reported CYP2D6 alleles and their frequencies were similar to previous reports. Additionally, we found two novel CYP2D6 alleles (CYP2D6*10-*36-*36 and *10-*10-*36) and confirmed them by Southern-RFLP. In the diplotype analysis, we observed that CYP2D6*1/*1 and *1/*10-*36 were the most common diplotypes and we could precisely estimate the functional gene dosage in each individual. Our method is the first to determine the exact functional CYP2D6 gene copy number. We believe our method will facilitate the detailed pharmacogenetic analysis of CYP2D6.

## 2263/T/Poster Board #812

**Modeling the impact of improved prediction of type 2 diabetes using SNP-based score on the design of type 2 diabetes prevention trials.** *K. Song[1], x. Lin[2], D. Waterworth[1], M. Nelson[1], V. Mooser[1], J. Whittaker[1].* 1) Statistical Genetics Capability Development, GlaxoSmithKline; 2) Discovery Analytics, GlaxoSmithKline.

Several recent studies have shown that incorporation of genetic variants only offers a slight improvement in the prediction of T2D at the individual level over clinical predictors alone. Still, the benefits may be larger for groups, and in particular for reducing the duration and size of prevention T2D trials, which are driven by the number of recruited participants expected to develop clinically defined T2D throughout the clinical trial. Here, we proposed a targeted T2D design to evaluate the potential benefits and costs using genetic variants and clinical factors for patient selection. For comparison between the proposed targeted design and the traditional clinical trial design, we calculated the sample size required to detect 90% power. The result showed that a modest reduction in the number of subjects on trial can be achieved at the expense of screening larger numbers prior to enrollment compared to the traditional design. Assuming we wish to power the study to compare a treatment effect of 33% conversion rate to a control effect of 100% conversion rate, sample sizes required by two designs differed by 19% when the probability of developing T2D during the course of the trial (positive predictive value or PPV) was improved from 15% without genetic selection criteria to 25% with it and the negative predictive value (NPV) decreased from 85% to 80%. The difference in the number of patients to be enrolled increased by 64% with PPV = 35% and NPV = 90%. Although only modest improvements in our ability to predict T2D risk is needed to benefit prevention trials, we conclude that further studies are needed to validate these benefits and implementation for a selection strategy.

## 2264/T/Poster Board #813

**Genetical Basis of Variation in Induction of CYP3A4 Enzyme.** *N. Rahmioglu[1], J. Heaton[2], G. Surdulescu[1], N. Smith[2], T. Spector[1], K.R. Ahmadi[1].* 1) Department of Twin Research and Genetic Epidemiology, King's College London, London, UK; 2) Pharmaceutical Science Division, King's College London, London, UK.

Response to medication is highly variable and the current "one size fits all" approach to therapy is costly (adverse drug responses cost the NHS £466 million a year) and dangerous. Personalized treatment has the potential to increase efficacy and decrease toxicity if "response" can be predicted accurately. Formal studies are needed but anecdotal evidence suggests that (i) all drugs are more effective in some groups of the population whilst showing non-or minimal benefit to other groups; and (ii) there are myriad genetic and non-genetic influences affecting drug response. One family of genes known to be implicated are those encoding the Cytochrome P450s (CYPs) family of enzymes. Among the P450s, CYP3A4 is the most important enzyme metabolising more than 50% of all prescribed medications. Many ADRs or poor therapeutic responses are due to genetically and environmentally "induced" CYP3A4 activity which shows large inter-individual variation. As part of a systems biology investigation into one of the major causes of adverse drug reactions, namely induction and inhibition of the drug metabolising enzyme CYP3A4, we have setup a large cohort of 400 healthy identical and non-identical twin pairs (100MZ, 300DZ) phenotyped for baseline and induced CYP3A4 activity. Briefly, the study involved administering a standard dose of St John's Wort (SJW) a mild, herbal antidepressant but also a potent inducer of CYP3A4 to each twin 3 times a day for 14 days. On day 14, each twin was also administered one 300mg tablet of quinine, a probe drug metabolized exclusively by CYP3A4. Fasting blood and urine was collected on day 0 and 15 at visits to St. Thomas' Hospital from each twin. We used baseline and post-dose urine and plasma from each participant in conjunction with Ultra Performance Liquid Chromatography (UPLC) to obtain the CYP3A4 activity measurement, which is the ratio of the primary metabolite of quinine (3-Hydroxyquinine) to quinine. We are currently processing the data. We will present results from our heritability analysis, genome-wide association study, and candidate gene study and highlight the most important genetic variants responsible for variability in the induced CYP3A4 activity.

## 2265/T/Poster Board #814

**Genetic variations associated with warfarin resistance in the Japanese population identified through genome-wide association study.** *PC. Cha[1], T. Mushiroda[2], K. Nakazono[3], A. Takahashi[3], S. Saito[4], H. Shimomura[4], T. Suzuki[4], S. Minami[5], H. Zembutsu[1], N. Kamatani[3], Y. Nakamura[1,2].* 1) Lab. of Molecular Medicine, Human Genome Center, Institute of Medical Science, University of Tokyo, Shirokanedai, Tokyo, Japan; 2) Research Group for Pharmacogenomics, RIKEN Center for Genomic Medicine, Yokohama, Japan; 3) Laboratory for Statistical Analysis, RIKEN Center for Genomic Medicine, Tokyo, Japan; 4) Tokushukai Hospital Group, Tokyo, Japan; 5) Laboratory of Endocrinology and Metabolism, Department of Bioregulation, Nippon Medical School, Kawasaki, Japan.

Warfarin is a commonly-used anticoagulant that is hard to dose owing to its narrow therapeutic index and wide inter-individual variations in its therapeutic dose. Although age, body surface area (BSA), and genetic polymorphisms in the *CYP2C9* and *VKORC1* genes have been found to explain a part of these inter-individual variations, identification of additional factors influencing the dose is critically important for safer and more appropriate use of this drug. In this study, we successfully identified through genome-wide approach, two novel Asian population-specific SNPs that are likely to be associated with warfarin resistance in a Japanese population. We evaluated associations of these SNPs by using an independent Japanese population sample. Furthermore, we found that in the combined study, these SNPs achieved linear regression $P$ = 3.76E-10 and $P$ = 9.23E-06, respectively. Integrating genotype information of these SNPs into the Warfarin-responsive index (WFRI) model previously developed based on genotypes of only SNPs in the *VKORC1* and *CYP2C9* genes clearly distinguished subjects who confer warfarin resistance that may therefore have higher risk of cerebral infarction ($P$ = 1.44E-16). Additionally, incorporating genotype information of these SNPs had improved predictability of the warfarin dosing algorithm that considered only age, BSA, and genotypes of the *VKORC1* and *CYP2C9* genes. Although the biological significance of these two SNPs is yet unclear, our results may provide insights to improvement of warfarin treatment, particularly to patients who need a higher dose of warfarin. In addition to that, our study may also imply that common SNPs other than those in *CYP2C9* and *VKORC1* genes that show strong effect on therapeutic warfarin dose might not exist; yet, there might be other SNPs, most possibly rare SNPs or population-specific SNPs, that are influencing therapeutic warfarin dose with moderate or small effects.

## 2266/T/Poster Board #815

**A genome-wide association study on opioid analgesic sensitivity in patients undergoing painful cosmetic surgery.** 
*D. Nishizawa[1], K. Fukuda[2], S. Kasai[1], W. Han[1], J. Hasegawa[1], A. Nishi[1], M. Koga[3], T. Arinami[3], M. Hayashida[4], K. Ikeda[1].* 1) Molecular Psychiatry Research, Tokyo Institute of Psychiatry, Tokyo, Japan; 2) Oral Health and Clinical Science, Division of Dental Anesthesiology (Orofacial Pain Center/Suidoubashi Hospital), Tokyo Dental College, Tokyo, Japan; 3) Medical Genetics, Graduate School of Comprehensive Human Sciences, University of Tsukuba, Tsukuba, Japan; 4) Anesthesiology, Saitama Medical University International Medical Center, Hidaka, Japan.

**Objectives**: Opioids are commonly used as effective analgesics for the treatment of acute and chronic pain. However, considerable individual differences have been widely observed in sensitivity to opioid analgesics, which can lead to wide variability in the dose of opioid analgesics required to achieve adequate pain control. This study aimed at comprehensively identifying genetic polymorphisms that could contribute to individual differences in sensitivity to an opioid analgesic, fentanyl, by genome-wide association study (GWAS). **Methods**: Subjects were 121 healthy patients who were scheduled to undergo cosmetic orthognathic surgery for mandibular prognathism at Tokyo Dental College Suidoubashi Hospital and provided informed, written consent for the genetics studies. Patients with chronic pain, those taking pain medication, and those who had experienced Raynaud's phenomenon were excluded. Postoperative pain was managed with a bolus dose of 40 μg fentanyl on demand using a patient-controlled analgesia (PCA) pump when patients felt pain, with a lockout time set at 10 min. Postoperative PCA fentanyl use during the first 24-h postoperative period was recorded, whereas venous blood (10 ml) of the subjects was sampled for preparation of DNA specimens for genotyping. Whole-genome genotyping was performed with iScan System (Illumina K.K.) and the BeadChip Human1M v1.0 or Human1M-Duo v3. **Results and Discussion**: For quality control, markers with genotype call frequency for samles ≥ 0.95 and minor allele frequencies ≥ 0.15 were selected for the study. In association study for 527,753 markers that passed the criteria, several single nucleotide polymorphisms (SNPs) were identified to be significantly associated with postoperative PCA fentanyl use (μg/kg) during the first 24-h postoperative period. Association was also significant between some SNPs and perioperative fentanyl use (μg/kg), which was calculated as the sum of intraoperative fentanyl use and postoperative fentanyl use. These SNPs could serve as markers for predicting the analgesic requirements in patients. Although future replication studies with independent samples will be required to confirm the association identified in this study, this is the first GWAS to explore candidate polymorphisms affecting sensitivity to an opioid analgesic. Our findings will lead to satisfactory pain control for patients suffering intolerable pain and open a path for personalized pain treatment in the future.

## 2267/T/Poster Board #816

**Comparison of multiple instrument platforms with qPCR and Hi-Res Melting(R) capability for CYP2C9 and VKORC1 SNP genotyping performance.** 
*J.T. McKinney, C.N. Gundry, R. Lems, M. Wall, M. Poulson, D.H-F Teng.* Idaho Technology, SLC, US.

One immediate application of personalized medicine is reducing adverse drug reactions genetically-predicted dosage prediction. Idaho Technology has developed rapid genotyping assays using the single-labeled SimpleProbe chemistry to genotype the CYP2C9 *2 and *3 SNPs, as well as the VKORC1 c.1 G-1639A SNPs. The assays allow PCR amplification and produce melting curves characteristic of each genotype. The SimpleProbes match the expected variant and create a single base mismatch when the wildtype sequence is present. This results in a low temperature melting peak from the probe when the wildtype allele is detected, and a relatively higher probe melting peak when the variant allele is present. A single SimpleProbe detects both alleles, and because the probe is a perfect match to the variant allele, other rare sequence variants in close proximity to the *2 and *3 alleles can produce false positives using other probe technologies. Due to the design of the Idaho Technology probes, if these rare variants are present, a 2nd base-pairing mismatch is created under the probe. This additional mismatch results in even lower probe melting peaks than observed from the single-mismatched homozygous wildtype-to-probe hybrid. Ninety human genomic samples were extracted according to the same protocol and used at 5-15 ng per reaction. The LightCycler® 480, LightScanner®, LightScanner 32 (LS32), and Rotor-Gene® 6200 instruments produced equivalent genotyping results for the VKORC1 c.1 G-1639A and CYP2C9 *2 and *3 variants. Rare variants near both the CYP2C9 *2 and *3 loci were observed and create the aforementioned 2-bp mismatch within the probe-target hybridization region. These rare variants were observed on all instrument platforms, however, because the LS32 Hi-Res Melting fluorimeter does not detect the FAM fluorophore on the SimpleProbes, the melting data from the standard air chamber melt required higher analysis sensitivity settings to detect the rare variants. All other instruments generated Hi-Res Melting data and performed well. Despite reductions in the price per sequencing reactions, other technologies such as this probe technique are currently the most cost-effective way to genotype simple SNPs.

## 2268/T/Poster Board #817

**Analysing variation in *CYP1A2* in the peoples of Ethiopia and identifying evidence of purifying selection acting on the gene.** 
*S.L. Browning[1], A. Tarekegn[1,2], E. Bekele[2], N. Bradman[1], M.G. Thomas[3].* 1) The Centre for Genetic Anthropology, University College London, London, United Kingdom; 2) Addis Ababa University, Addis Ababa, Ethiopia; 3) Research Department of Genetics, Evolution and Environment, University College London, London, United Kingdom.

Cytochrome P450 *1A2* metabolizes a wide range of therapeutic drugs, including several used to treat diseases common in sub-Saharan Africa. Variation in the gene (*CYP1A2*) has been reported to be associated with differential efficacy of therapeutic drugs and adverse drug reactions. To gain a better understanding of the extent of variation in the coding and exon-flanking non-coding regions of *CYP1A2* we re-sequenced 762 chromosomes from members of five ethnic groups (Afar, Amhara, Anuak, Maale and Oromo) distributed in a rough north east to south west transect across Ethiopia. Ethiopian populations were expected to display substantial variation because: a) human genetic diversity is known to be greatest in sub-Saharan Africa and is reported to decrease with distance from Addis Ababa and b) there has been substantial migration of Semitic speaking peoples from the Arabian Peninsula into Ethiopia over the past few thousand years. We found 49 variable sites of different types overall, 30 of which are novel. Nine non-synonymous changes (seven of which are novel) and one synonymous change were found in the coding region. Haplotype analysis of the entire gene revealed 55 different haplotypes, only three of which were previously reported. When haplotypes were constructed using only non-synonymous polymorphisms, so as to restrict the haplotype set to those most likely to affect enzyme structure/function, ten haplotypes were identified, eight of which have not previously been reported. Comparing these data with those from publically available databases it appears that Ethiopian groups display much greater variation than do other populations (gene diversity using complete coding region haplotypes (non-synonymous variants only): Ethiopia = 0.17 ± 0.02; Rest of the World combined = 0.08 ± 0.03). Many haplotypes can be predicted to be of importance in the planning and provision of healthcare. In addition Ethiopian populations exhibit most of the common variation observed elsewhere. Analysis of these data, comparing gene diversities of the non-coding region and synonymous SNPs with those of non-synonymous SNPs, while controlling for variation due to differential demographic histories, supports the hypothesis that purifying selection has acted on the gene. This, in turn, supports the hypothesis that mutations affecting the CYP1A2 enzyme may be suitable candidates for complex disease association studies (e.g. several cancer types and coronary heart disease).

## 2269/T/Poster Board #818

**Pharmacogenetics of Risperidone Therapy in Autism: association analysis of eight candidate genes with drug efficacy and adverse drug reactions.** 
*C. Correia[1,2], J. Almeida[3], P. Santos[2], A.F. Sequeira[1,2], C. Marques[3], T. S. Miguel[3], R. Abreu[3], G. Oliveira[3], A.M. Vicente[1,2].* 1) Instituto Nacional de Saúde Dr.Ricardo Jorge, Lisboa, Portugal; 2) Instituto Gulbenkian de Ciência, Oeiras, Portugal; 3) Hospital Pediátrico de Coimbra, Coimbra, Portugal.

The atypical antipsychotic risperidone is used to control disruptive behaviors associated with autism. Little has been reported on the factors, genetic or other, that underlie the variability in individual response to risperidone, particularly for autism. In this study we simultaneously explored the effects of multiple candidate genes on clinical improvement and occurrence of adverse drug reactions (ADRs), in autism. Forty five autistic patients receiving monotherapy with risperidone up to one year were studied. Selected candidate genes were those involved in the pharmacokinetics (*CYP2D6* and *ABCB1*) and pharmacodynamics (*HTR2A*, *HTR2C*, *DRD2*, *DRD3*, *HTR6*) of the drug, and the *BDNF* gene, found to be relevant in other studies. Using the generalized estimating equation method these genes were tested for association with drug efficacy, assessed using the Autism Treatment Evaluation Checklist, and with safety and tolerability measures, including prolactin levels, body mass index, waist circumference and neurological adverse effects. Our results confirm that risperidone therapy was very effective in reducing some autism symptoms and caused few serious adverse effects. After adjusting for confounding factors, our results show that the *HTR2A* c.-1438G>A, *DRD3* c.25T>C (p.S9G), *HTR2C* c.-995G>A and *ABCB1* c.1236C>T polymorphisms were predictors for clinical improvement with risperidone therapy. The *HTR2A* c.-1438G>A, *HTR2C* c.68G>C (p.C33S), *HTR6* c.7154-2542C>T and *BDNF* c.196G>A (p.V66M) polymorphisms influenced prolactin elevation. The *HTR2C* c.68G>C and *CYP2D6* polymorphisms were associated with risperidone induced increase in BMI or waist circumference. Although association results should be taken as suggestive, given the small sample size, we identified for the first time several genes implicated in risperidone efficacy and safety in autism patients, therefore making a preliminary contribution to the personalized therapy of risperidone in autism.

**Human_CVD 50K SNP array analysis in the Drug-Induced Arrhythmia Risk Evaluation (DARE) Study.** *C. Dalageorgou[1], D. Zheng[1], V. Marshall[3], S. Shakir[3], A.J. Camm[2], S. Jeffery[1], E.R. Behr[2], Y. Jamshidi[1].* 1) Clinical Developmental Sci, St George's Medical Sch, London, United Kingdom; 2) Cardiac and Vascular Sciences, St George's Hospital Medical Sch, London, United Kingdom; 3) Drug Safety Research Unit, Southampton, United Kingdom.

The risk of pathologic prolongation of the QT interval (> 550 ms) and *Torsade de Pointes* (TdP) is the most common cause of withdrawal of commercially used drugs. TdP can be self-limited or can degenerate to fatal arrhythmias, such as ventricular fibrillation. Genes encoding cardiac ion channels have identified potential contributory variants in only <20% of patients with Drug-Induced Long QT Syndrome (dLQTS). As part of the Drug-Induced Arrhythmia Risk Evaluation Study (DARE), we analysed DNA samples from 89 Caucasian Subjects, experiencing drug-induced adverse proarrhythmic events, and 90 matched population controls, using the Illumina Infinium Human_CVD 50K Bead Array. The resulting association analysis, adjusted for -age and -sex, identified significant association with single nucleotide polymorphisms (SNPs) in a number of genes. The most highly associated SNPs were located in the Dopamine Receptor D3 (*DRD3*) gene, (most significant $P = 6 \times 10^{-5}$). Dopamine receptors are important in the regulation of cardiovascular function and interestingly anti-arrhythmic drugs such as amiodarone and verapamil have been shown to increase intracellular levels of both dopamine and L-DOPA. Our study identifies *DRD3* as a potentially novel gene which is significantly associated with the risk of drug-induced QT prolongation and consequent arrhythmias.

## 2271/T/Poster Board #820

**Location of lipid metabolism genes via oligogenic analysis in a pharmacogenetic familial clinical trial.** *E.W. Daw[1], I.B. Borecki[1], S. Ketkar[1], J.M. Ordovas[2], M.Y. Tsai[3], P.N. Hopkins[4], J. Hixson[5], M.A. Province[1], D.K. Arnett[6].* 1) Division of Statistical Genomics, Washington University, St. Louis, MO; 2) JM-USDA-HNRCA, Tufts University, Boston, MA; 3) Department of Laboratory Medicine and Pathology, University of Minnesota, Minneapolis, MN; 4) Department of Internal Medicine, University of Utah, Salt Lake City, UT; 5) Human Genetics Center, University of Texas Health Science Center at Houston, Houston, TX; 6) Department of Epidemiology, University of Alabama at Birmingham, School of Public Health, Birmingham, AL.

The GOLDN study is a clinical trial to examine the Genetics of lipid metabolism and response to treatment in 201 families, ranging in size from 53 to 3. This data is unusual in providing controlled gene by environment interaction data in families. 1027 subjects completed the initial Post-prandial Lipemia (PPL) arm of the study: after fasting, subjects were asked to drink a fatty shake and a variety of lipid levels (hdl, ldl, cholesterol, triglycerides, chylomicrons, particle sizes by nmr, etc.) were measured just prior to drinking the shake, at 3.5 hours, and at 6 hours after drinking the shake. Subjects were then placed on a 3-week fenofibrate trial and the PPL study was repeated at the end. To identify genes in the lipid metabolism network that influence PPL response, we analyzed each of the lipid measures at each time point, both pre and post fenofibrate trial, as well as the slopes between time points and the area under the curves. Growth curve (GC) models were applied to help control for the potentially noisy nature of lipid measurements. Since the GC models assume normality, all measures were tested for normality and those failing were log transformed. If a measure was still not close to normal after a log transform, a Box-Cox power transformation was considered. Microsatellite markers were typed in over 2000 family members, including markers typed in additional family members in the predecessor study, used here to improve meiotic inference. We conducted an oligogenic simultaneous segregation and linkage analysis with Monte Carlo Markov chain (MCMC) methods for each lipid measurement, and identified a number of linked regions. Chromosomes with regions of particular interest include 4 (near GGAA19H07), 7 (between GGAA3F06 and GATA13G11), 11 (between GATA23E06 and GATA64D03), 16 (near GATA71H05), and 17 (between GATA49C09 and ATA43A10). In some regions there are low-level linkage signals across a number of measures, possibly indicating genes that have a broad but small effect. In other regions there are stronger signals, but sometimes only in one of two measures. Both types of results offer a window into this complex network.

## 2272/T/Poster Board #821

**Coverage of the PharmaADME Consortium Core Marker List by TaqMan® DME and Copy Number Assays.** *T. Hartshorne, S. Desai, K. Li, T. Ceccardi.* Molecular Biology Systems, Applied Biosystems, Foster City, CA.

The PharmaADME Consortium (PharmaADME.org) is composed of individuals from academia and pharmaceutical and genomic technology industries, who together developed a consensus list of key genes involved in the absorption, distribution, metabolism and excretion (ADME) of drugs. The list includes phase 1 and 2 drug metabolizing enzymes and transporter genes. A core list of 184 putative functional genetic variants in 33 significant ADME genes, which likely impact the pharmacokinetics of drug metabolism, was also created. By providing this information to technology providers, products could be developed to support pharmacogenetic research, with the objective of improving the quality of pharmaceuticals available to consumers. We report here on our progress towards covering the core ADME marker list with TaqMan® Genotyping Assays. The ADME marker list includes 172 SNP and InDel polymorphisms, 11 copy number variants, and one microsatellite polymorphism. We first reviewed our available list of TaqMan® Drug Metabolism (DME) Genotyping Assays, which detect polymorphisms in coding and regulatory regions in 221 DME genes. We then focused on developing allelic discrimination assays to any SNP or InDel ADME marker for which we did not have an assay. Challenges for assay design included: assay specificity for targets with high homology to pseudogenes or gene family members, triallelic SNP targets, other SNPs in close proximity to the target, and repetitive target context sequences. All assays were tested on up to 180 gDNAs from four populations. For some challenging targets, several rounds of assay design and testing were required to obtain a robust TaqMan® DME Assay. At this time, 155 DME assays covering SNP and InDel ADME targets are available, including 8 assays to genotype 4 triallelic SNPs. Efforts are underway to develop assays for the remainder of the SNP and InDel targets. For the 11 copy number variants on the core ADME list, which include deletions and duplications of 6 total genes, TaqMan® Copy Number Assays were developed and tested on 180 gDNAs. In total, over 90% of the core ADME markers are covered by TaqMan® DME or Copy Number Assays, which offer a simple and scalable workflow for genotyping these important alleles in pharmacogenetic research.

## 2273/T/Poster Board #822

**Natural Variation in the 3'UTRs of 37 Human Membrane Transporter Genes.** *S. Hesselson[1], J. Eshragh[1], D. Stryke[2], D. Kroetz[3], K.M. Giacomini[3], P.Y. Kwok[1].* 1) Cardiovascular Research, UCSF, San Francisco, CA; 2) Department of Pharmaceutical Chemistry, UCSF, San Francisco, CA; 3) Department of Bioengineering and Therapeutic Sciences, UCSF, San Francisco, CA.

Genetic variation in membrane transporter genes can contribute to interindividual variation in drug absorption, distribution, and elimination. Most of the interest in membrane transporter pharmacogenetics has focused on the coding and promoter regions. In contrast, few studies have focused on genetic variation in the 3'UTRs of membrane transporters, which may also influence transporter expression and function. We sequenced 32,378 bp of the 3'UTRs of 15 ATP-binding cassette (ABC) and 22 solute carrier (SLC) membrane transporters in order to identify and estimate the minor allele frequency (MAF) of polymorphisms in healthy individuals. We sequenced DNA samples from 272 people from the SOPHIE cohort (68 African Americans, 68 Caucasians, 68 Chinese Americans and 68 Mexican Americans). We observed 433 polymorphisms in the 3'UTRs of these 37 transporter genes. The majority of these polymorphisms were SNPs, however, 30 were indels. More polymorphisms were observed in the 3'UTR (1/75 bp) than were observed in the exons of 24 previously sequenced membrane transporters (1/166 bp) and 107 previously sequenced ABC and SLC proximal promoters (1/85 bp). The average number of polymorphisms per base pair in the 3'UTRs and proximal promoters overall was similar, however in the 3'UTRs more polymorphisms were observed in ABC genes than SLC genes (ABC 1/52 bp, SLC 1/107 bp), while the opposite is true for proximal promoters (ABC 1/106 bp, SLC 1/75 bp). Of the polymorphisms observed in the 3'UTRs, 36% are population specific. The majority of these are singletons (62%). African American samples have the highest number of rare and common population specific alleles (46%). Asians have a similar number of singletons as African Americans, however the number of SNPs with a MAF higher than 1% was much higher in African American samples than the other 3 populations. Many 3'UTR polymorphisms with high frequency minor alleles have been observed: 74% have a MAF greater than 1% in at least one population, and 18% have a MAF greater than 10% in at least one population. In the future, polymorphisms observed in this sequencing effort will be functionally characterized to determine if they alter membrane transporter expression and function. The polymorphisms identified in this study will lead to a better understanding of how natural genetic variation effects drug transport and may help to identify individuals who will have an adverse reaction to commonly used medications.

## 2274/T/Poster Board #823

**The VKORC1 1173C/T polymorphism and warfarin maintenance dose in Asians and Caucasians: a meta-analysis.** *K. Huang.* Epidemiology, Pfizer Inc, New York, NY.

Background: Warfarin sodium (Coumadin) is the most frequently used oral anticoagulant. Warfarin inhibits vitamin K epoxide reductase that prevents vitamin K recycling and the subsequent gamma-carboxylation of clotting factors. Variants in the gene encoding Vitamin K epoxide reductase complex subunite 1 (VKORC1) may affect the response to warfarin. Objectives: To conduct a meta-analysis to determinate associations between VKORC1 1173 C/T polymorphism and mean weekly maintenance dose of warfarin in Asians and Caucasians. Methods: A search from the PubMed database (from inception to May 2009) was conducted and references identified from bibliographies were sought. Studies were considered if they evaluated an association between the VKORC1 1173 C/T polymorphism and mean weekly (daily) maintenance dosing of warfarin. Only studies published in the English language were included. 12 studies were identified and 8 studies meeting inclusion criteria were selected. Data was extracted from selected studies and additional information was obtained by contacting study authors. Hardy Weinberg equilibrium was tested across studies using the Wald-type test. Statistical heterogeneity was measured by means of Cochran's Q test. Pooled tests for the means weekly dose by the VORKC1 1173 C/T polymorphism in subgroups representing different races were performed by weighted linear meta-regression using a random-effects model. All statistical tests were two-sided. Results: This analysis comprised a total of 1,036 subjects, including 328 Asians and 708 Caucasians. Genotype frequency for CC was higher in Caucasians compared to Asians (36.3% vs. 1.8% respectively) while Asians had a higher TT genotype frequency compared to Caucasians (81.1% vs. 17.7%). Subjects with the CC genotype had the highest unadjusted mean weekly maintenance dose (46.9mg, 95%CI: 32.3-61.4 in Asians and 43.9mg, 95%CI, 38.8-49.0 in Caucasians). Subjects with the CT genotype and subjects with TT genotype required a lower unadjusted mean weekly maintenance dose that was 31mg, 95%CI: 25.9-36.2 in Asians and 22.8mg, 95%CI: 19.9-25.8 in Asians vs. 32.1mg, 95%CI: 27.1-37.2 in Caucasians and 21.4mg, 95%CI: 16.1-26.7 in Caucasians respectively. Conclusions: Results of this meta-analysis indcate that the VORKC1 1173 C/T polymorphism is associated with maintenance dose of warfarin in both Asians and Caucasians.

## 2275/T/Poster Board #824

**Association between common genetic variants in the *NOS1AP* (*CAPON*) gene in patients experiencing amiodarone-induced ventricular arrhythmias.** *Y. Jamshidi[1], D. Zheng[1], I.M. Nolte[3], C. Dalageorgou[1], H. Snieder[3], V. Marshall[4], S. Shakir[4], A.J. Camm[2], S. Jeffery[1], E.R. Behr[2].* 1) Clinical Developmental Sciences, St Georges Hospital Medical School, London, United Kingdom; 2) Cardiac and Vascular Sciences, St Georges Hospital Medical School, London, United Kingdom; 3) Department of Epidemiology, University Medical Center Groningen, University of Groningen, the Netherlands; 4) Drug Safety Research Unit, Southampton, United Kingdom.

Amiodarone is a potent anti-arrhythmic agent used to treat various types of tachyarrhythmias. It has multiple electrophysiological effects and is associated with a high incidence of side-effects, such as QT prolongation and bradycardia. Uncommonly QT interval prolongation can lead to the polymorphic ventricular tachycardia Torsade de Pointes which may be self-limited or degenerate to fatal arrhythmias such as ventricular fibrillation. Recent studies have shown consistent association between resting heart rate corrected QT interval (QTc) and common variants of the NOS1 regulator, *NOS1AP*. As part of the Drug-Induced Arrhythmia Risk Evaluation (DARE) Study, we have systematically collected a unique national cohort of patients experiencing drug-induced ventricular arrhythmias and severe QT prolongation as well as matched population controls. We postulated that variation within the *NOS1AP* gene differed between cases and controls. In order to test this hypothesis, we sequenced the *NOS1AP* gene in 30 Caucasian subjects treated with amiodarone who experienced a drug-induced arrhythmic event and 90 Caucasian control subjects. The sequencing assays included all coding regions of the gene. Additionally we have genotyped 198 single nucleotide polymorphisms (SNPs) with minor allele frequencies > 1% across the *NOS1AP* gene (500b upstream and 1 kb downstream) using Infinium Technology (Illumina). We found no novel coding mutations / polymorphisms. The resulting association analysis showed that thirty polymorphisms within the NOS1AP gene were associated with amiodarone-induced QT prolongation at a significance level of 0.05 (most significant P = $5 \times 10^{-5}$, OR=5.6 using an additive model). These did not include either of the SNPs rs10494366 and rs16857031 known to be associated with resting QTc nor SNPs that were in strong linkage disequilibrium with them. Our results suggest that common variations in the *NOS1AP* gene play a role in the pathogenesis of amiodarone-induced QT prolongation and consequent arrhythmias and these might be independent of the known association with resting QTc. Further studies are underway to confirm this finding in additional replication cohorts.

## 2276/T/Poster Board #825

**Genetic determinants of warfarin dosing and VKORC1 haplotype analysis.** *M.T.M. Lee, C.H. Chen, C.H. Chou, L.S. Lu, J.Y. Wu, Y.T. Chen.* Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan.

Background: Warfarin, a widely prescribed oral anticoagulant, is used for the prevention of thromboembolism. Polymorphisms in CYP2C9 and VKORC1 have been shown to associate with warfarin dose requirements. However, it is likely that other genes could also affect warfarin dose. In this study, we aimed to identify additional genes influencing warfarin dosing in the Han-Chinese population. VKORC1 haplotype also exhibit population differences, we also examined VKORC1 haplotype in six Asian populations. Methods: In this study, we screened for SNPs in 13 genes (VKORC1, CYP2C9, CYP2C18, PROC, APOE, EPHX1, CALU, GGCX, ORM1, ORM2, factor II, factor VII, and CYP4F2) and tested their associations with warfarin dosing with univariate and multiple regression analysis. In addition, frequencies and haplotype structure of six VKORC1 SNPs (-1639 G>A, 497 T>G, 1173 C>T, 1542 T>G, 2255 C>T, and 3730 G>A) were analyzed in six Asian populations (Han-Chinese, India, Indonesia, Philippine, Thailand, and Vietnam). Results: Results showed that CYP2C18, PROC and EPHX1 have small but significant association with warfarin dose. In multiple regression analysis, PROC and EPHX1 explained 3% of the dose variation. In VKORC1 haplotype analysis, rs2884737 (497 T>G) is only polymorphic in the Indian population. Remaining SNPs demonstrated high LD and have similar frequencies and haplotype structure in all but the Indian population. The Indian population is made up mostly the H7 haplotype (76%) while the rest of the recruited populations are consisted of the H1 haplotype (>80%).

## 2277/T/Poster Board #826

**Azorean pharmacogenetic study: the variability of 13 genes implicated in drug response.** *T. Pereirinha[1], S. Bulhões[1], P.R. Pacheco[1,2], M.J. Brilhante[1], R. Cabral[1,2], C.C. Branco[1,2], L. Mota-Vieira[1,2].* 1) Mol Gen & Pathol Unit , Hosp Divino Espirito Santo PD, EPE, Azores Islands, Portugal; 2) Instituto Gulbenkian de Ciência, Oeiras, Portugal.

Genetic polymorphisms in genes encoding for drug metabolizing enzymes, transporters and therapeutic targets have been recognized as one of the factors responsible for inter-individual differences in drug response. As incorrect dosages contribute to a high rate of adverse effects, there is clinical interest in improving strategies for the determination of the appropriate dose. In this study, we analyzed a total of 28 variants, in 13 genes (*MDR1*, *5-HT2C*, *5-HT2A*, *PDE6A*, *ADCY9*, *ADRB2*, *CYP2C9*, *CYP2C19*, *CYP2D6*, *VKORC1*, *TPMT*, *NAT2* and *UGT1A1*) in 170 healthy blood donors from the anonymized Azorean DNA bank. Polymorphisms genotyping was performed by real-time PCR and fragment analysis by capillary electrophoresis. Results demonstrated that in Azoreans the TPMT*3C and NAT2*14, two common variants in Africans, have relatively high frequencies (2.9% and 0.3%, respectively) when compared with Caucasians, and reveals statistically significant difference with mainland Portugal ($\chi^2$, p<0.001). This African trace corroborates previous studies of the Azoreans genetic background. The allelic frequencies of the remaining 26 pharmacogenetics variants are similar to those found in other Caucasian populations. Currently, we are analyzing the Azorean pharmacogenetic profiles of complex diseases, in order to help the drug therapy prescription and, consequently, to improve the establishment of personalized medicine. Funded by Azorean Government (M 1.2.1./I/002/2008).

## 2278/T/Poster Board #827

**Statin-Induced Myotoxicity Adverse Drug Reactions; Pharmacogenomic Evaluation of SLCO1B1 and Atrogin-1 in Statin Myotoxic Cohorts.**
*M.S. Phillips[1,2], A.M.K. Brown[1,2], M-P. Dubé[1,2], C. Johansen[3], R.A. Hegele[3], J-C. Tardif[1,2].* 1) Génome Québec & Montreal Heart Institute Pharmacogenomics Centre, Montreal, Quebec; 2) Université de Montréal; 3) University of Western Ontario, London, Ontario.

Pharmacogenomics is a powerful technique that has the potential to enhance drug safety and efficacy. HMG-CoA reductase inhibitors (statins) are widely prescribed and are an effective therapy for the lowering of plasma LDL-cholesterol. However, statin treatment has also been associated with a wide range of muscular side effects, from non-specific or atypical myalgias to the extreme rhabdomyolysis syndrome. We have recruited a statin myotoxicity cohort consisting of ~2,500 dylipidemic patients presenting clear rhabdomyolysis/muscular intolerance phenotypes along with ~2,000 dyslipidemic controls (~4,500 patients in total). In recent publications, the SEARCH collaborative group have identified variants in the solute carrier organic anion transporter 1B1 gene (SLCO1B1) that are associated with high dose simvastatin myotoxicity. Furthermore the atrogin-1 gene (FBXO32), a subunit of the ubiquitin protein complex, has been associated with increased muscle atrophy and implicated in statin-induced muscle toxicity. In order to test if these observations are present in our large myotoxic cohort, we have selected ~260 cases along with ~400 matched controls for genetic screening. We have genotyped them for the key functional and haplotype-tagged SNPs within the SLCO1B1 gene to see if the same association is observed with other statins and at lower doses. In our preliminary analysis, we have not observed significant association in our myotoxic patients with the SLCO1B1 variants when taking atorvastatin or simvastatin at lower doses. This could be due to several factors, including our statin intolerance phenotype definition, the type of statins being taken by the patient, and potential ascertainment or selection biases. We are replicating these observations in an independent cohort from a tertiary referral lipid clinic that consists of 126 patients with symptomatic statin-induced myopathy and 144 case-matched controls (London, Ontario). Furthermore, to evaluate if the atrogin-1 gene is involved with statin-induced myotoxicity, we have sequenced the gene in ~100 statin-induced phenotypic cases to identify any novel functional variants in this population. To date, we have identified >70 novel variants that we are screening in the larger cohort to access their involvement with statin-induced myotoxicity. With studies like these, we hope to identify potentially interesting biomarkers for the statin-induced clinical phenotype that can be developed into predictive tests.

## 2279/T/Poster Board #828

**Pharmacogenomics of the gastrointestinal safety of cyclooxygenase inhibitors.**
*T.S. Price[1], A. Jeyam[2], C. Molony[3], L.A. Garcia Rodriguez[4], B.J. Keating[5], E.E. Schadt[6], G.A. FitzGerald[5].* 1) MRC SGDP Centre, Inst Psychiatry, London, United Kingdom; 2) ENSAI, Bruz, France; 3) Rosetta Inpharmatics, Seattle, WA; 4) CEIFE. Madrid, Spain; 5) University of Pennsylvania School of Medicine; 6) Pacific Biosciences, Menlo Park, CA.

Traditional nonsteroidal anti-inflammatory drugs (NSAIDs) can cause gastrointestinal (GI) side effects. Selective inhibitors of COX-2 have a more favorable profile of GI tolerability. We hypothesize that genetic factors may contribute to individual susceptibility to GI side effects in response to either the NSAID diclofenac or the purpose developed selective COX-2 inhibitor etoricoxib. We genotyped over 6,000 subjects enrolled in the MEDAL program, a large drug trial comparing the GI safety of diclofenac and etoricoxib, using a custom 50,000 SNP genotyping array. Subjects were followed up for an average of over 18 months. After very stringent quality control, including removing all subjects of non-white ethnicity, we retained 4,441 subjects and 33,938 SNPs. We ran survival analyses to test association with predicted time to complicated and uncomplicated upper GI clinical events, stratified by drug. No analyses reached genomewide levels of significance.

## 2280/T/Poster Board #829

**Pharmacogenomic investigation in hypertensive patients using candidate genes approach and Genome Wide Association Study.**
*E. Salvi[1], C. Barlassina[1], C. Lanzani[2], L. Citterio[2], S. Lupoli[3], F. Torri[1], C. Cosentino[1], F. Taddeo[1], V. Tieran[1], A. Orro[4], D. Cusi[5], G. Bianchi[2], F. Macciardi[1,6].* 1) Dept Scence Biomedical Techn, Univ Milan, Milan, Italy; 2) University Vita Salute, San Raffaele Hospital, Milan, Italy; 3) INSPE, Scientific Institute San Raffaele, Milan, Italy; 4) ITB, CNR, Milan, Italy; 5) Dept. Nephrology, San Carlo Borromeo Hospital, Milano and Graduate School of Nephrology, University of Milano; 6) Department of Psychiatry and Human Behavior, University of California, Irvine, CA, USA.

Pharmacogenomic association studies help to identify DNA variants which impact on the individual response to drugs. The knowledge of sample variability in drug response can allow to personalize drug dosing and treatment regimes. The fundamental question concerns whether it is possible to differentiate the patients with potentially responses to the treatment (R) from those with the greatest risk of no response (NR). Our approach to these questions for the disease of interest, Hypertension, is to identify SNPs in hypertensive patients that segregate with drug efficacy either in candidate genes (CG) that relate to the mechanism of action of the specific drug or in other DNA regions detected with a Genome Wide Association Study (GWAS). SNPs identified from CG or GWAS could allow NR to be excluded from subsequent clinical trial studies, therefore allowing enriched, smaller, faster, less expensive clinical studies on patients with a better chance of responding favorably. Here, we present a real pharmacogenomic example: we adopted a genetic association design, where the phenotype of interest was measured as a quantitative trait (decrease of systolic blood pressure office after drug treatment) and the variables affecting the distribution of the phenotype are the SNPs, the therapy (drug or placebo) and the SNP*therapy interaction. Once we identified those SNPs, we developed an algorithm to detect the genotypic profiles that best discriminate R from the NR. In a final step, we merged the best predictive SNPs found from our GWAS strategy with those from a CG approach. Both categories of SNPs convey a specific predictive power that is magnified by their joint integration into a unified model.

**Effects of Cellular Confounding Variables in Epstein Barr Virus (EBV) Transformed Lymphoblastoid Cell Lines on Pharmacological Phenotypes.**
*A.L. Stark[1], W. Zhang[2], S. Mi[2], S. Duan[2], P.H. O'Donnell[2], R.S. Huang[2], CM. Beiswanger[3], M.E. Dolan[2].* 1) Dept Human Genetics, Univ Chicago, Chicago, IL; 2) Section of Hematology/Oncology, Dept Medicine, Univ Chicago, Chicago, IL; 3) Coriell Institute for Medical Research, Camden, NJ.

Publicly available genetic and expression data on lymphoblastoid cell lines (LCLs) comprising the International HapMap collection make them a unique resource for understanding the genetic underpinnings of cellular phenotypes. One use of these cell lines is for pharmacogenomic discovery and validation of clinical findings associated with drugs. However, variable cellular growth rate and EBV copy number can be confounders in such studies. Our objective is to examine the degree to which confounding variables affect pharmacological endpoints in LCLs. To this end, we evaluated the relationships between cellular growth rate/baseline EBV copy number and drug-induced cytotoxicity in LCLs exposed to daunorubicin, etoposide, carboplatin, cisplatin, cytarabine, pemetrexed, 5-deoxyfluorouridine, vorinostat, methotrexate, 6-mercaptopurine, and 5-fluorouracil. There was no significant correlation between baseline EBV copy number with drug-induced cytotoxicity or cellular growth rate. However, cellular growth rate and drug-induced cytotoxicity were significantly correlated for all drugs except vorinostat. We found that cellular growth rate is under appreciable genetic influence ($h2 = 0.30$-$0.39$) with five suggestive linkage regions having LOD scores above 1.5 across the genome. Not surprisingly, a portion of SNPs that significantly associate with drug cytotoxicity are also associated with cellular growth rate ($p \leq 0.0001$). We are currently also evaluating whether several independently-transformed LCLs from the same individual vary between each other with respect to cellular growth rate, EBV copy number, and drug-induced cytotoxicity. Studies using LCLs should consider that cellular growth rate is an important component of cytotoxicity phenotypes, and a portion of the genetic determination of cytotoxicity may be explained through heritable growth rate polymorphisms.

## 2282/T/Poster Board #831

**Factors accounting for the response variability in serum 25(OH)D in postmenopausal women.** *L.J. Zhao, J.P. Zhou, F.X. Bu, R.R. Recker, J.M. Lappe.* Osteoporosis Res Ctr, Creighton Univ Med Ctr, Omaha, NE.

Vitamin D deficiency is a common health problem. Serum 25-hydroxyvitmain D [25(OH)D] is the functional indicator of vitamin D status. Low circulating serum 25(OH)D values is associated with a higher risk of common cancers and other disorders. Vitamin D supplementation is the best approach for achieving adequate serum 25(OH)D levels. A wide range of response variation in serum 25 (OH)D was observed in previous vitamin D intervention trials. However, factors contributing to the response variation are unknown. In order to identify these unknown factors, we conducted retrospective data analyses in 318 unrelated postmenopausal women with age >55 years from eastern Nebraska (~41° N). These subjects were treated with vitamin D (1100 IU/day) for four years and their vitamin D intake compliance rates were >80%. Values of serum 25(OH)D were measured at baseline and again at each annual visit. The treatment-induced pair-wise serum 25(OH)D in 1-, 2-, 3-, and 4-year were highly correlated (r>0.6 for all pairs, p<10-6). The average serum (25OH)D increment is 25.59±16.5 nmol/L (mean±SD), but varied widely, with increments ranging from -29.99 nmol/L to +72.87 nmol/L. The percentage of subjects who did not raise their 25(OH)D to optimal serum level (80nmol/L) were 17%, 18%, 17%, and 26% in year-1, 2, 3, and 4, respectively. We estimated factors contributing to the response variability in serum 25(OH)D. Among the tested factors, baseline serum 25(OH)D was the most significant one, explaining 16% of total response variance. Other significant factors included total body fat, amount of trial vitamin D intake, concentration of serum bone specific alkaline phosphatase (BSAP), serum parathyroid hormone (PTH), and serum creatinine. Collectively, they explained 29.9%, 24.7%, 22.9%, and 32.2% of 1-, 2-, 3-, 4-year total serum 25(OH)D response variation, respectively. We further compared differences between responders and non-responders. Thirty responders and 30 non-responders were selected from the 318 subjects based on their baseline serum 25(OH)D (<80 nmol/L), increment of serum 25(OH)D, and vitamin D status after treatment. Serum PTH, BSAP, and calcium concentrations were significantly different between responders vs non-responders (P<0.05). Responders generally had lower serum PTH, higher serum calcium, and lower BSAP levels. Conclusion: Baseline serum 25(OH)D, PTH, and BASP levels were important for the change of serum 25(OH)D in response to vitamin D supplementation.

## 2283/T/Poster Board #832

**Reaction of human pulp cells to DNA damage induced by urethane dimethacrylate (UDMA), a component of dental restorative materials.** *J. Blasiak[1], E. Pawlowska[2], T. Poplawski[1], K. Loba[1], J. Szczepanska[2].* 1) Dept Molecular Genetics, Univ Lodz, Lodz, Poland; 2) Department of Pediatric Dentistry, Medical University of Lodz, Poland.

The use of new dental restorative materials with new chemistry, the etching the dentin, and the need to ensure complete polymerization and sealing of the restoration to the tooth have raised questions about the biological safety of new materials and techniques. The essential components of such materials are methacrylate resins, which, after polymerization, can release monomers into the oral cavity and pulp, from where they can migrate into the bloodstream reaching virtually all organs. The local concentration of the released monomers can be in the millimolar range, high enough to induce adverse biological effects. Genotoxicity of methacrylate monomers is of a special significance due to potential serious phenotypic consequences, including cancer, and long latency period. In the present work, we investigated cytotoxicity and genotoxicity of urethane dimethacrylate (UDMA) in the human pulp cells. UDMA at concentrations up to 1 mM evoked a concentration-dependent decrease in the viability of the cells up to about 80%, as assessed by flow cytometry. This agent did not induce strand breaks in the isolated plasmid DNA, but evoked concentration-dependent DNA damage in the human pulp cells evaluated by the alkaline and neutral comet assay. This damage included oxidative modifications to the DNA bases, as checked by DNA repair enzymes Endo III and Fpg as well as single DNA strand breaks. UDMA did not evoke double strand breaks. The cells exposed to UDMA at 750 μM were able to remove about 90% of damage to their DNA in 120 min. The drug evoked apoptosis and induced an increase in the G2/M cell population, accompanied by a decrease in the S cell population and an increase in G0/G1 cell population. Due to broad spectrum of UDMA genotoxicity and a potential long-lasting exposure to this compound, its use should be accompanied by precautions, reducing the chance of its release into blood stream and the possibility to induce adverse biological effects. This work was supported by the grant N N403 188134 from the Ministry of Science and Higher Education.

## 2284/T/Poster Board #833

**Confounding factors in ARVC caused by mutations in *TMEM43*.** *A.F.M. Haywood, K.A. Hodgkinson, N.D. Merner, J. Houston, A.D. Greenslade, S. Conners, P.S. Parfrey, T.L. Young.* Discipline of Genetics, Faculty of Medicine, Memorial University of Newfoundland, St. John's, Newfoundland and Labrador, Canada.

Arrhythmogenic right ventricular cardiomyopathy (ARVC) is an inherited cardiac disorder characterized by ventricular tachycardia, sudden cardiac death and fibrofatty replacement of cardiomyocytes. Predominantly mutations in desmosomal genes for example, *desmoplakin, plakophilin-2, desmoglein-2, desmocollin-2* and *plakoglobin* have been identified to cause ARVC, where cells are predicted to succumb to mechanical stress. We recently identified the latest ARVC gene, a non desmosomal gene *TMEM43/LUMA*, in which a S358L missence mutation causes a particularly lethal form of ARVC (*ARVD5*) in the Newfoundland population. The importance of this gene discovery has been validated by the identification of S358L and two new missense *TMEM43* mutations, R28W and R312W, which are deemed deleterious through bioinformatics and both segregate with affected patients from Ontario, Nova Scotia and the UK. Interestingly, *ARVD5* patients identified with the founder mutation (*TMEM43*; S358L) have clinical features that overlap with dilated cardiomyopathy. To see if mutations in *TMEM43* play a role in other cardiomyopathies, we screened 54 probands from Newfoundland diagnosed with dilated cardiomyopathy, hypertrophic cardiomyopathy, ARVC or sudden cardiac death (otherwise unspecified), for mutations in *TMEM43*. None of the 54 probands had the founder S358L mutation. However two probands were heterozygous for R312W mutation, one also carries a pathogenic *LMNA* mutation, and the other carries a separate *LMNA* mutation along with a large deletion in dystrophin. Several other *TMEM43* mutations were identified among the 54 probands including two other missense variants and a potential splice site mutation of unknown significance. These findings suggest that cardiomyopathies other than ARVC may be caused by mutations in *TMEM43* or the pathogencity of the previous variants indentifies in LMNA questionable or the multiple mutations underlie the disease phenotype. Interestingly, *TMEM43/LUMA* interacts with A and B type-lamins, some of which are produced from *LMNA* in the inner membrane of the nucleus. It may prove to be important when making diagnoses to look at the series of related genes together. This data suggests the need to expand the definition of cardiac disease caused by variations in *TMEM43*, and the need for this gene to be added to the genetic screening panel for ARVC.

## 2285/T/Poster Board #834

**Functional Analysis of 5-Lipoxygenase Promoter Variants.** *H. Allayee[1], S. Vikman[1], P. Armstrong[2], R.M. Brena[3], J. Hartiala[1], C.B. Stephensen[2].* 1) Dept Preventive Med, Univ Southern California, Los Angeles, CA; 2) Program in International and Community Nutrition, Univ Calif Davis, Davis, CA; 3) Dept Biochemistry and Molecular Biology, Univ Southern California, Los Angeles, CA.

Variants of a hexanucleotide repeat polymorphism in the promoter of the 5-Lipoxygenase (5-LO) gene have been associated with cardiovascular disease (CVD) traits in humans, which may be due, at least in part, to differential expression of the at-risk alleles. To more fully characterize these variants, we carried out gene expression and methylation studies in primary leukocytes from healthy individuals carrying various 5-LO promoter alleles. Regardless of genotype, 5-LO and 5-LO activating protein (FLAP) gene expression was highest in granulocytes compared to monocytes and lymphocytes whereas leukotriene A4 hydrolase (LTA4H) expression was highest in monocytes. In all three leukocyte populations, 5-LO mRNA levels were positively correlated with those of FLAP and LTA4H, with the highest correlation observed in granulocytes. In lymphocytes, individuals homozygous for the shorter 3 and 4 repeat alleles had between 20-35% higher 5-LO, FLAP, and LTA4H expression compared to homozygous carriers of the wildtype 5 repeat allele ($p = 0.03 - 0.0001$). Methylation analysis of four CpG islands in a 1500bp region encompassing the 5-LO promoter and the first ~100bp of intron 1 revealed relatively low overall DNA methylation across all genotypes and leukocyte populations. However, analysis of the promoter repeats themselves demonstrated that, regardless of cell population, the 4 allele was methylated approximately twice as much as the 3 allele ($p < 0.0001$). Our results demonstrate that, in lymphocytes, the shorter repeat alleles of the 5-LO promoter lead to higher gene expression, which may be regulated through differential methylation of the CpGs located within these repeats.

## 2286/T/Poster Board #835

**Melting Curve Analysis for Fine Mapping of Variants in 6 lipid-related genes: Implications for Improving Coronary Risk Classification.** *J.F. Carlquist[1,2], B.D. Horne[1,2], J. McKinney[3], N.J. Camp[2], J.B. Muhlestein[1,2], C.P. Mower[1], J.J. Park[1], Z.P. Nicholas[1], J.L. Anderson[1,2].* 1) LDS Hosp, SLC, UT; 2) Univ Utah, SLC, UT; 3) Idaho Technology Inc., SLC, UT.

Among the traditional risk factors for coronary artery disease (CAD), total cholesterol emerged as one of the earliest and bears some of the most important risk for CAD. Among 17,000 consenting subjects undergoing angiography and prospectively enrolled in the Intermountain Healthcare Collaborative Heart Study (IHCS), we sought to determine whether genetic variants in the principal lipid metabolic genes contribute to risk for CHD. Scanning was performed by melting curve analysis (MCA) for all exons including 20 bp 5' and 50 bp 3' (to capture coding and donor and acceptor splice variants) and untranslated regulatory regions for the following genes: LCAT, CETP, LIPC, LPL, SCARB1, and ApoF. Presumptive variants identified by MCA were confirmed by cycle sequencing. The multi-stage study design was comprised of a SNP discovery phase (62 healthy subjects), a haplotype and tagging SNP discovery phase (339 healthy subjects), and a CAD association phase (1,003 angiographic CAD cases and 510 angiographic controls). In all, 115 target sequences were scanned for each of the 62 individuals in the SNP discovery cohort for a total of 23,939 bases of interrogated sequence. Among the 6 genes, a total of 92 SNPs were identified; 19 (21%) were previously unreported variants. Thirty six of the variants were identified in exons; 18 of these (50%) were synonymous and 18 (50%), non-synonymous. Twenty nine (32%) of the identified SNPs were in intron-exon boundaries containing splice sequences and 27 (29%), in the 5' and 3' untranslated regions. In the haplotype discovery phase, 163 of 169 MCA presumptive variants and 419 of 420 MCA presumptive non-variants were confirmed by cycle sequencing (MCA sensitivity: 98.6%, specificity: 99.4%). Of the 91 SNPs, 38 (42%) were chosen as tagging SNPs and explained >90% of the intra-genic variation in the 6 genes. When applied to the disease association cohort, 10 SNPs were found to have associations of $p<0.20$ with lipid parameters and, thus, were carried forward for evaluation of CAD event phenotypes in subsequent studies. These findings demonstrate the feasibility, sensitivity, and specificity of MCA in SNP discovery and expand and complete the discovery effort for common (>5% MAF) SNPs and haplotypes for these 6 genes, excluding deep introns. Further, the genetic variants in these genes may be used to derive a genetic risk score for the potential reclassification of risk determined by traditional (Framingham) methods.

## 2287/T/Poster Board #836

**Searching for mutation casuing mitral valve prolapse in *MMVP3*.** *R. Durst, L. Maire, J. Null, R. Levine, S. Slaugenhaupt.* CHGR, MGH, Boston, MA.

Mitral valve prolapse (MVP) is a common cardiac disorder that exhibits a strong hereditary component. Its complications include congestive heart failure, endocarditis and atrial arrhythmias. Although MVP is associated with a wide array of genetic disorders, specific genes involved in its pathogenesis have eluded detection. Recently one X-linked and three autosomal MVP loci have been described. The first loci was reported on chromosome 16 (MMVP1) and we identified the remaining two: MMVP2 on chromosome 11p15.4 and MMVP3 on chromosome 13q31.3-32.1. The MMVP3 locus is defined as an 8.2 Mb region between the markers D13S794 and D13S786. Despite the fact that the MMVP3 region is so large, it contains only 17 single-copy genes. Five of these genes are particularly good biological candidates (UGCGL2, GPC5, GPC6, ITR and HS6ST3). Given the fundamental importance of the extracellular matrix components in MVP, UGCGL2 is a compelling candidate. UGCGL2 is a UDP-glucose ceramide glucosyltransferase which is likely to play a role in GAG biosynthesis.GPC5 and GPC6 are heparan sulfate proteoglycans that are anchored to the cell-surface via a covalent linkage to glycosylphospatidylinositol. Their main function is to regulate the signaling of Wnts, Hedgehogs, fibroblast growth factors, and bone morphogenetic proteins making these genes good candidates for a role in MVP. ITR (intimal thickness-related receptor) may play a role in vascular smooth muscle remodeling. HS6ST3 (heparan sulfate 6-O-sulfotransferase 3) is a 6-O-sulfation enzyme is part of the sulfation pathway of N-sulfoglucosamine. Knockout mice for HS6ST2, which is yet another enzyme in the same pathway, develop mitral valve prolapsed, making HS6ST3 a strong candicate in the MMVP3 region.Our search for the MMVP3 gene continues as we examine the SNPs identified in our initial gene screening and as we sequence the remaining candidate genes. Determination of the genetic basis of MVP is important because the disease often manifests clinically in the 5th or 6th decade of life through presentation as a severe cardiac event. Earlier intervention in genetically susceptible individuals, for example by reducing leaflet stresses, could potentially arrest or prevent progression to a clinically severe stage. Further, discovering the genetic basis of MVP is the first step towards understanding the cascade of cellular events that result in MVP.

## 2288/T/Poster Board #837

**Myocyte-specific enhancer factor-2A gene polymorphism and susceptibility to coronary artery disease.** *S. Elhawari[1], O. Al-Boudari[1], E. Andres[1], P. Muiya[1], B.F. Meyer[1], F. Al-Mohanna[2], M. Alshaid[3], N. Dzimiri[1].* 1) Genetics, King Faisal Spec. Hospital & Res. Ctr, Riyadh, Saudi Arabia; 2) Biological and Medical Research, King Faisal Spec. Hospital & Res. Ctr, Riyadh, Saudi Arabia; 3) King Faisal Heart Institute, King Faisal Spec. Hospital & Res. Ctr, Riyadh, Saudi Arabia.

The role of the myocyte-specific enhancer factor-2A (MEF2A) gene in coronary artery disease remains unclear. We first screened the exon and exon-intron junctions of the gene in 200 Saudi individuals for single nucleotide polymorphisms (SNPs), and then evaluated their role in 1156 CAD patients compared with 859 angiographed controls. More than 40 SNPs were detected in these regions of the gene. Of these, exon 11 displayed a very high degree of heterogeneity resulting from deletions of various (1-6) sets of tri-nucleotide (CAG)n chains encoding a polyglutamate (424QQQQQQQ430) sequence leading to absence of different sets of amino acids, as well as other single/multiple base deletions immediately following this chain. No significant difference was observed between patients and controls in the various sets of (CAG)n deletions. In contrast, one SNP, rs1059759G>C [Odds ratio (95% Confidence Interval) = 1.21(1.02-1.34); p =0.029] was associated, and another, rs34851361A>G [1.22(0.9-1.54); p=0.088] was only weakly associated with CAD. Three other SNPs rs325408 [0.74(0.61-0.91); p=0.004], rs3730059 [0.15(0.03-0.68); p=0.014] and rs12442844 [0.78(0.68-0.91); p=0.001] appeared to show protective properties. Additionally, in the region following the CAGs, we observed two types of changes, one comprising an nt146550:AGCAGC/- (deletion) in 8% of the population and another involving 7 sets of different stretches of deletions in the subsequent region nt146556CCGCCGA146562. The single and double nt deletions led to premature STOP codons at nt146635 and nt146645, respectively. However, none of these changes displayed noticeable difference between the two groups, possibly due to their low prevalence in our study population. Our results suggest that the polymorphic changes in exon 11 of the MEF2A may predispose individuals to CAD.

## 2289/T/Poster Board #838

**The role of Zhx2 in atherosclerosis, plasma lipid metabolism, and developmental regulation.** *A. Erbilgin[1], P.S. Gargalovic[1,2], O. Kohannim[1,2], J. Pagnon[1,2], X. Wang[1,2], L. Castellani[1,2], R. LeBeouf[3], A.J. Lusis[1,2].* 1) Department of Microbiology, Immunology, and Molecular Genetics, University of California, Los Angeles, CA 90095; 2) Department of Human Genetics, University of California, Los Angeles, CA 90095; 3) Department of Pathobiology, University of Washington, Seattle, WA.

We have recently identified a transcription factor, Zhx2, as a novel regulator of plasma lipid metabolism. An endogenous retroviral insertion within the coding region of this gene in BALB/cJ mice leads to severely reduced levels of transcript and protein, and corresponds to lower levels of total cholesterol and triglycerides. BALB/cJ mice carrying Zhx2 transgenes exhibit a correction of these plasma lipid phenotypes. We have now further characterized the role of Zhx2 by observing the contribution of this gene to atherosclerosis. BALB/cBy mice with the wild-type Zhx2 allele and BALB/cJ mice were placed on a low-density lipoprotein receptor null background. Significant differences in lipid profiles and atherosclerosis were observed when these mice were maintained on an atherogenic diet. Male BALB/cJ mice exhibited a 1.9-fold decrease in triglycerides and a 2-fold decrease in total cholesterol levels compared to BALB/cBy mice, accompanied by a nearly 13-fold decrease in atherosclerotic lesions. There is evidence that Zhx2 is involved in developmental regulation, and it is unknown whether this observed increase in atherosclerosis is due to the differences in lipid levels or the perturbation of another mechanism regulated by this transcription factor. Zhx2 is responsible for the post-natal repression of the $\alpha$-fetoprotein (AFP) and H19 genes in mice. In most strains of inbred mice, AFP is expressed at high levels in the mouse fetal liver but rapidly repressed at birth. In contrast, BALB/cJ mice maintain relatively high levels of AFP into adulthood due to the non-functional Zhx2 allele, which is normally highly expressed in the adult liver. In order to further explore the role of Zhx2 in this context, we are conducting a developmental curve study that compares the gene expression in the hearts and livers of BALB/cJ mice and congenic mice containing the wild-type Zhx2 allele. Samples from the heart and liver were collected at birth, 5 days, 14 days, and 25 days of age and gene expression differences were assessed using real-time quantitative PCR. These data show remarkable differential expression of lipoprotein lipase (Lpl) and Ear11 between the two strains at all time-points, in addition to other significant gene expression differences. We are currently assaying global expression through the use of microarrays on these samples in order to identify additional regulatory targets.

## 2290/T/Poster Board #839

***SCN5A* variation is associated with electrocardiogram traits in the Jackson Heart Study.** *J. Jeff[1], K. Brown-Gentry[1], S. Buxbaum[6], D. Sarpong[6], H. Taylor[6], J. Wilson[6], J. Payne[6], J. Maher[7], A. George[3,4], D. Crawford[1,2], D. Roden[3,5].* 1) Human Gen, Vanderbilt Univ, Nashville, TN; 2) Molecular Physiology & Biophysics, Vanderbilt Univ, Nashville, TN; 3) Pharmacology and Medicine, Vanderbilt Univ, Nashville, TN; 4) Institute for Integrative Genomics, Vanderbilt Univ, Nashville, TN; 5) Oates Institute for Experimental Therapeutics, Vanderbilt Univ, Nashville, TN; 6) Jackson Heart Study , Jackson State University, Jackson, MS 39213; 7) McDermott Center for Human Growth and Development, UT Southwestern, Dallas, TX 75309.

Understanding variation in the normal electrical activity of the heart, assessed by the electrocardiogram (ECG), may provide a starting point for studies of susceptibility to serious arrhythmias, such as sudden cardiac death during myocardial infarction or drug therapy. Recent genetic association studies of one ECG trait, the QT interval, have identified common variation in European-descent populations, but little is known about the genetic determinants of ECG traits in populations of African-descent. To identify such factors, we have undertaken a candidate gene study of ECG traits in collaboration with the Jackson Heart Study (JHS, n=5621). JHS is the largest longitudinal study to date that investigates the role genetic factors play in disease in African Americans ascertained from the Jackson, Mississippi area. Nine quantitative ECG traits were evaluated: the P,QT, QTc, T and QRS durations, V-rate, and the P, QRS and T axes. We genotyped 72 variations in the sodium channel, voltage-gated, type V, alpha subunit *(SCN5A)* gene, a member of a gene family that forms sodium channels abundant in the cardiac muscle. Three SNPs deviated from Hardy-Weinberg Equilibrium expectations and four had minor allele frequencies <0.05; these 7 SNPs were removed from further analysis. Using linear regression, we performed tests of association for 65 SNPs assuming an additive genetic model in unrelated individuals (n=3,334). Adjusting for age, sex, and European ancestry, significant associations (p<6.0x10-4) were observed for QRS and P-wave durations. Intronic rs3922844 ($\beta$=1.3; p=2.7x10-7) was associated with increased QRS duration while intronic rs7374138 ($\beta$=-1.2; p= 7.1x10-5) and rs7627552 ($\beta$=-1.1; p=4.8x10-4) were both associated with decreased QRS duration. Nonsynonymous rs7626962 (S1103Y) ($\beta$=-3.5; p=6.5x10-5), a variation observed in African-descent populations but absent or rare in other populations, is associated with decreased P-wave duration, and trends toward significance for the QRS duration ($\beta$=-1.30; p=.005). Intronic rs7692965 ($\beta$=-3.1; p=6.5x10-5), rs7637849 ($\beta$=-1.9; p=1.9x10-4), rs7627552 ($\beta$=-1.9; p=4.9x10-4), rs7624535 ($\beta$=-1.8; p= 2.0x10-4), and rs6763048 ($\beta$=-1.6; p=7.3x10-4) were all associated with decreased P-wave duration. These results suggest that the sodium channel candidate gene *SCN5A* contributes to ECG trait distributions in African Americans, and these same variations may be risk or protective factors associated with susceptibility to arrhythmias.

## 2291/T/Poster Board #840

**Sequence variation from the 5' region upstream of CETP associated with the tails of HDL and CETP concentration levels.** *T.J. Maxwell[1], X. Lui[1], L.C. Shimmin[1], A.G. Clark[2], T.J. Rea[3], A.R. Templeton[4], J.E. Hixson[1], E. Boerwinkle[1].* 1) Human Genetics Center, UT Houston Health Science Center, Houston, TX; 2) Department of Molecular Biology and Genetics, Cornell University, Ithaca, NY; 3) Department of Human Genetics, University of Michigan School of Medicine, Ann Arbor, MI; 4) Department of Biology, Washington University, St. Louis, MO.

Multiple studies have shown that genetic variation in the promoter region of the Cholesteryl Ester Transfer Protein gene (CETP) is associated with plasma high-density lipoprotein cholesterol concentrations (HDL-C) and CETP protein concentrations. To test the relationships between CETP promoter variants and trait variation, we sequenced a 6.3 kb region 5' upstream through intron 1 of CETP in individuals chosen separately from the upper and lower tails of HDL-C and CETP concentration distributions within race-gender strata. Individuals were chosen and sequenced (76 African Americans (AA) and 84 European Americans (EA) for HDL-C and 78 EA and 92 EA for CETP concentration) from the top and bottom 4% within each stratum. Thirteen other SNPs from the CETP gene region were available from previous studies. The upper and lower tail of each trait was used to create discrete phenotypes of interest. Logistic regression was used to test for differences in genotypic counts between tails. A permutation analog of the sequential step-down Bonferroni (Westfall and Young 1993) was used to obtain significance levels that incorporated the multiple tests and the correlations between them. The data show that, for 47 SNPs in AA and 37 SNPs in EA), over half of the SNPs in each group had a minor allele frequency (MAF) greater than 0.10 and about 10% of the SNPs had a MAF less than 0.01. The level of significance for SNPs in association with CETP concentration was much greater than that for HDL (nominal p-values of 10-8 vs 10-4). Seven SNPs were significant for EA HDL-C and no SNPs were significant for AA HDL-C. Seven SNPs were significant for EA CETP concentration and eight were significant for AA CETP concentration. Six of the SNPs significant for EA HDL-C were also significant for EA CETP concentration, including the four significant SNPs that were significant for CETP concentration in both the EA and AA populations (rs711752; rs183130; rs708272; rs17231506). Many of the SNPs that are associated with CETP concentration in both populations were associated with HDL-C levels in the EA populations but had no significant effect on HDL-C in the AA population. Only one SNP (rs183130) significant for CETP concentration in AA displayed evidence for an association with HDL-C concentration (nominal p-value of 0.0543).

## 2292/T/Poster Board #841

**Variants in NOTCH Pathway Genes Among Individuals with Left-Sided Cardiovascular Defects.** *K.L. McBride[1], G.A. Zender[1], S.M. Fitzgerald-Butt[1], J.W. Belmont[2].* 1) Molecular and Human Gen, Res Inst Nationwide Child Hosp, Columbus, OH; 2) Molecular and Human Gen Baylor Coll Med, Houston, TX.

Cardiovascular malformations (CVMs) are common birth defects that contribute to a large proportion of infant mortality. Evidence suggests that subgroups of CVMs share common genetic etiologies. Our previously published epidemiology and genetic data support this concept for one subgroup, the left-sided cardiac defects of aortic stenosis (AS) coarctation of the aorta (CoA) and hypoplastic left heart syndrome (HLHS). The Notch pathway is important in cardiac development. Ligand(Jagged, Delta) binding causes cleavage of the receptor(Notch1-4), releasing the Notch intracellular domain. It translocates to the nucleus and activates HES transcription factors. We previously screened *NOTCH1* in this subgroup, and discovered variants causing a functional disturbance of the Notch signaling pathway in 4/91 AS, CoA and HLHS individuals. The purpose of the present study was to expand the investigation to include downstream targets of NOTCH1 in a larger cohort of individuals than originally reported. A total of 455 individuals of north European ancestry affected with either AS, CoA, or HLHS, were screened for mutations in the genes *NOTCH1, HEY2* and *HEYL*. Initial screening was performed by dHPLC followed by Sanger sequencing to identify the exact change. Potentially harmful missense variants were defined as pedicted damaging by POLYPHEN and having a PANTHER deleterious probability of ≥0.50. We identified 2 potentially harmful variants in *HEY2* (S172P, n=1; P179L n=2), and 4 in *HEYL* (R141C, n=1; P173S, n=1; W177C, n=2; F179L, n=2). In addition to the previously noted *NOTCH1* variants, we found 2 more potentially harmful variants (V565M, n=1; R621H, n=1). Rare variants causing a synonymous substitution or causing a missense change predicted to be benign were also found in *HEY2* (7 variants in 11 people), *HEYL* (2 variants in 5 people) and *NOTCH1* (9 variants in 10 people); none are previously described SNPs. Combined with prior results we found rare variants in 5 /207 (2.4%) controls vs 32/455 (7.0%) cases for *NOTCH1* ($\chi^2$ p =0.017). Comparison of cases and controls for *HEY2* and *HEYL* awaits completion of the coding region sequencing in controls. This study demonstrates that rare variants in genes of the NOTCH signaling pathway are found among individuals with AS, CoA, and HLHS at a much higher rate than the general population. Combined with previous functional data for NOTCH1, the data suggests this pathway is involved in the pathogenesis of left sided cardiovascular defects.

## 2293/T/Poster Board #842

**The role of the BRAP gene for carotid atherosclerosis.** *Y. Pan[1], Y. Liao[2,3], S. Juo[1,2,4,5].* 1) Inst Med Gen, Kaohsiung Med Univ, Kaohsuing, Taiwan; 2) Dept Medicine, Kaohsiung Med Univ, Kaohsiung, Taiwan; 3) Dept Neurology, Taichung Veterans General Hospital, Taichung, Taiwan; 4) Dept Medical Research, Kaohsiung Med Univ Hospital, Kaohsiung, Taiwan; 5) Center of Excellence for Environmental Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan.

Background and Purpose The BRCA-1 associated protein (BRAP) gene was recently identified as a susceptible gene for myocardial infarction (MI) in Asian population. A functional variant at the BRAP gene was able to enhance BRAP expression, which in turns, modulate the NF-κB-dependent inflammatory pathway on the vascular walls. The purpose of present study was to test the BRAP genetic effect on stroke and subclinical carotid atherosclerosis. Methods Segment-specific intimal-medial thickness (IMT) and plaque index were obtained by carotid ultrasonography in 816 stroke- and MI- free healthy volunteers. Another 262 incident stroke patients were enrolled, including 51 large-artery, 21 cardioembolic, 85 small-vessel, and 105 cryptogenic strokes. Single nucleotide polymorphisms (SNPs) rs11066001 and rs3782886 were genotyped by TagMan method. Results These two SNPs were in strong linkage disequilibrium (D' = 0.99) and both were significantly associated with IMT values at the bifurcation (Bif). The rare allele of rs11066001 appeared to exert a detrimental effect on IMT and the average Bif IMT were 0.68 ± 0.15, 0.65 ± 0.13, 0.63 ± 0.12 in the rare homozygotes, heterozygotes and common homozygotes respectively (p = 0.015). Although the rare allele appeared to be over-represented in subjects with plaques (index ≥ 1), the difference did not reach statistical significance. We did not find any association between BRAP genotypes and stroke risks. Subgroup analyses on the stroke subtypes did not yield better result. Conclusions Our results supported the regulatory role of BRAP gene on carotid atherosclerosis. However, this gene may not be an important determinant of stroke susceptibility.

## 2294/T/Poster Board #843

**Population-based re-sequencing of endothelial lipase and zinc finger protein 202 genes in subjects at the extreme ends of HDL-C Distribution.** *H. Razzaghi[1], S. Santorico[2], J. Hokanson[3].* 1) Dept Med, Univ Colorado Denver, Aurora, CO; 2) Dept Mathematical and Statistical Sciences, Univ Colorado Denver, Denver, CO; 3) Dept Epidemiology, Uni Colorado Denver, Aurora, CO.

Multiple epidemiological studies have constantly shown an inverse relationship between elevated levels of high-density lipoprotein cholesterol (HDL-C) and the risk of CHD. Endothelial lipase (Gene: LIPG, Protein: EL) and zinc finger protein 202 (ZNF202) are two prime candidate genes in HDL metabolism. We sought to determine the genetic contribution of LIPG and ZNF202 to variation in HDL-C levels by re-sequencing both genes including the 2000 bp 5', all exons and introns, and 2000 bp 3' in selected individuals expressing the extreme phenotype of high (x=75.90 mg/dl, n=114) and low (x=31.24 mg/dl, n=121) HDL-C levels. 235 subjects were selected from a biethnic population of Whites and Hispanics. A total of 185 and 122 sequence variants were identified in LIPG and ZNF202 genes, respectively, which all are now available in the NCBI databases. In both genes, only two of the sequence variants were missense (T111I and N396S in LIPG; A154V and K259E in ZNF202) with the remaining in noncoding regions of the gene. This striking finding suggests the variation in HDL-C levels may be due to mutations affecting the gene regulation as opposed to the protein structure. We found several rare variants unique to either the low or high HDL groups in both genes. In Whites, there were 23 SNPs and 39 SNPs that had a rare variant seen only in the high and low HDL groups, respectively. In Hispanics, there were 14 SNPs and 28 SNPs that had a rare variant seen only in the high and low HDL groups. For LIPG, the proportion of unique variants differed between the high and low HDL groups in Whites (p=0.022) and Hispanics (p=0.017). Furthermore, the location of rare variants in Hispanics differed between the high and low HDL groups (p=0.018) with the low HDL group having more unique SNPs present in the introns and UTR regions than in exons. For ZNF202, the proportion of unique variants in the low and high HDL groups differed only in the Hispanics (p=0.021), and no relationship was found with SNP location. A comparison of haplotype frequencies based on tagSNPs as well as the missense SNPs revealed an association for LIPG in Hispanics (p=0.0073, $p_{adj}$=0.0582). Associations were also detected for ZNF202 for both ethnic groups [p(Whites)=0.0121, $p_{adj}$(Whites)=0.0129; p(Hispanics)=0.0246, $p_{adj}$(Hispanics)=0.0585]. In summary, our re-sequencing project identified many additional SNPs in both LIPG and ZNF202 genes and our analyses support the association of these two genes with HDL levels.

## 2295/T/Poster Board #844

**Screening of mutations in the sarcomere genes in a cohort of 205 cardiomyopathy probands of Japanese origin.** *M.A. Razzaque[1], T. Nishizawa[1], M. Furutani[1,2], M. Kurabayashi[3], K. Joh-o[4], J. Fukushige[5], Y. Ohta[6], S. Arai[1], N. Hagiwara[7], R. Matsuoka[1,2].* 1) IREIIMS, Tokyo Women`s Medical University 8-1, Tokyo, Tokyo, Japan; 2) Division of Pediatric Cardiology, Tokyo Women`s Medical University 8-1, Tokyo, Tokyo, Japan; 3) Department of Medicine and Biological Science Gunma University School of Medicine, Gunma,; 4) Department of Pediatrics, Kyushu Welfare Pension Hospital, Fukuoka, Japan; 5) Pediatric Cardiology, Fukuoka Children's Hospital, Fukuoka, Japan; 6) Ohta Children's Clinic, Hokkaido, Japan; 7) Department of Cardiology, Tokyo Women's Medical University, Tokyo, Japan.

Over the last two decades, a large number of mutations have been identified in sarcomeric proteins as a cause of hypertrophic cardiomyopathy (HCM) and dilated cardiomyopathy (DCM). Mutations associated with cardiomyopathy have been identified in sporadic as well as familial cases in the proteins of sarcomere, cytoskeleton, and the sarcolemma. Mutations in $\beta$-myosin heavy chain (MYH7), cardiac myosin binding protein C (MYBPC3), cardiac troponin T (TNNT2), cardiac troponin I (TNNI3), $\alpha$-tropomyosin (TPM1), myosin regulatory light chain (MYL2), myosin essential light chain (MYL3), cardiac $\alpha$-actin (ACTC) were reported as the major genes causing HCM and DCM. To report the frequency of single and multiple gene mutations in a Japanese cohort of patients with cardiomyopathy, we screened for mutation by direct sequencing in the MYH7, MYBPC3, TNNT2, TNNI3, TPM1, and ACTC in our cohort of 173 probands with HCM, 25 probands with DCM, and 7 probands with restrictive cardiomyopathy (RCM). We found 68 (39%) mutations in the probands diagnosed with HCM, 5 (20%) mutations in the probands with DCM and 4 (57%) mutations in the probands with RCM. In familial cardiomyopathy patients, 3 compound mutations in which 2 are novel and 4 double mutations in which 3 are novel were found in 7 HCM families (10%) out of 71 families, and a novel compound mutation was found in a DCM patient. Probands carrying either compound mutations or double mutations were shown to express a more severe clinical phenotype than single gene mutation patients. This suggests the importance of look into the phenotypic diversities among the family members and screening the entire panel of major genes causing HCM and DCM even after a single mutation has been identified.

## 2296/T/Poster Board #845

**Association of Ins/Del polymorphism of the angiotensin-I converting enzyme gene with nonfamilial atrial fibrillation in Koreans.** *D. Shin[1,3], A. Park[1], J. Im[1], N. Son[1], K. Lee[1], S. Kim[1], E. Shin[4], J. Lee[4], S. Lee[1,2], H. Park[1,2], Y. Jang[1,2].* 1) Cardiovascular Genome Ctr, Yonsei Col Medicine, Seoul, Korea; 2) Division of Cardiology, Yonsei University College of Medicine; 3) Yonsei University Research Institute of Science for Aging; 4) DNA Link Inc, Seoul, South Korea.

Atrial fibrillation (AF) is a common and serious clinic rhythmus disorder frequently accompanied by heart failure and thromboembolism. Recent studies have been reported renin-angiotensin system (RAS) may play a pivotal role in the pathogenesis of AF, and suggested that the development of AF has relation to activation of the RAS in the atria of humans and animal models of AF. These findings indicate that angiotensin II may be responsible for the mechanism of atrial structural and electrical remodeling, and angiotensin I-converting enzyme (ACE) inhibitors or angiotensin receptor anatagonists may reduce the risk of AF. We hypothesized that genetic variant in the ACE gene predicts risk condition of AF. The aim of this study was to elucidate whether the ACE I/D polymorphism is associated with nonfamilial AF. A total of 219 patients with documented nonfamilial AF, and age and sex-matched 250 controls without AF were recruited. All subjects were genotyped for ACE I/D polymorphism by polymerase chain reaction. The distribution of genotype and allele for I/D polymorphism was significantly different between the patients with AF and the controls in male group (p= 0.013 and 0.015, respectively). After adjustment for variables, the result of logistic regression analysis indicated that the ACE I/D polymorphism (DD+ID/II) was strongly associated with AF in the male subjects (OR, 0.455; 95% CI, 0.251-0.824, p = 0.009) and in all subjects (0.591, 0.371-0.940, p = 0.026), whereas no significant effect was observed in the female subjects. ACE II genotype predicts a decreased risk of nonfamilial AF. This study demonstrates the association of ACE I/D polymorphism with nonfamilial AF in males and this variant may influence effect of ACE inhibitors on AF.

**Evidence that the 9p21 locus confers susceptibility to coronary artery plaque vulnerability - The IBIS-2 and APPROACH studies.** *D.M. Waterworth[1], K. Song[1], X. Yuan[1], N. Lim[1], M. Mosteller[2], M. Dickson[3], C. Huang[4], H.M. Garcia-Garcia[5], P.W. Serruys[5], N.S. Kolatkar[6], A. Zalewski[7], L. Cardon[1], V.E. Mooser[1].* 1) Genetics, GlaxoSmithKline, King of Prussia, PA; 2) Genetics, GlaxoSmithKline, Research Triangle Park, NC; 3) Biomedical Data Sciences, GlaxoSmithKline, Harlow, UK; 4) Biomedical Data Sciences, GlaxoSmithKline, King of Prussia, PA; 5) Thoraxcenter, Erasmus Medical Center, Rotterdam, The Netherlands; 6) Medicine Development Center, GlaxoSmithKline, King of Prussia, PA; 7) Cardiovascular Clinical Science Unit, Novartis, East Hanover, NJ.

The mechanism whereby the GWAS-derived 9p21 locus confers an increased risk for coronary artery disease (CAD) of approximately 35% per risk allele independently of known cardiovascular risk factors remains elusive. We hypothesized that carriers of the 9p21 locus risk alleles may have larger coronary atherosclerotic plaques and therefore may respond better to LpPLA2 inhibition, as compared to non-carriers. To test this hypothesis, we investigated this locus in the IBIS-2 study, a phase II placebo-controlled clinical trial of darapladib (a Lp-PLA2 inhibitor), where intravascular ultrasound (IVUS) greyscale and IVUS virtual histology (VH) parameters of single plaques were available at baseline and after approximately one year of follow-up (up to n=258). We found that 9p21 risk alleles were associated with smaller rather than larger VH total plaque volumes (rs1075274 p=0.006) and a corresponding lower necrotic core volume (p=0.006) at baseline. IVUS greyscale measures of total plaque volume were less significant (p=0.015). No clear treatment by genotype effect was observed when changes from baseline in the two treatments were evaluated. In addition, MMP9 levels, a surrogate measure of plaque vulnerability, were higher in 9p21 carriers over the entire course of the study and in both treatment groups. To confirm these results, we genotyped the same 9p21 SNPs in the APPROACH study, a 18-month randomized trial of rosiglitazone or glipizide on atherosclerosis progression in patients with type 2 diabetes and CAD where IVUS greyscale but not VH data and MMP9 levels were available at baseline (up to n=342). The IVUS greyscale total plaque volume trended in the same direction as in IBIS-2, though was not significant. As in IBIS-2, risk allele carriers had elevated baseline MMP9 levels, especially in subjects with poor glucose control (rs1075274-HbA1c interaction p=0.006). In summary, the potential association between 9p21 SNPs with smaller atherosclerotic plaques on IVUS virtual histology parameters, and the robust association with MMP9 provide evidence that the 9p21 locus predisposes to coronary artery plaques that are more vulnerable and prone to rupture.

## 2298/T/Poster Board #847

**Association of polymorphisms in NPR1 and NPPA genes and essential hypertension: single gene and gene-gene interaction.** *S. Wu, W. Niu, P. Gao, D. Zhu.* Shanghai Institute of Hypertension, Shanghai, China.

Objectives: Previous studies show that natriuretic peptides have blood pressure lowering properties. Recently, a study found that common variants in NPPA and NPPB loci were associated with circulating natriuretic peptides and blood pressure. We aimed to identify the genetic variants in NPPA and the NPR1 gene and gene-gene interaction which might play role in occurrence of essential hypertension. Methods: We enrolled 1023 unrelated essential hypertensives and 1004 age-, gender-matched normotensives. Six single nucleotide polymorphisms were selected. Results: We found that genotype and allele frequencies of rs11264236 in NPR1 gene distributed significantly different between hypertensive and normotensive groups (P= 0.004 and P=0.04 for genotype and allele respectively). More importantly, in the recessive model AA genotype showed significant association with the risk of essential hypertension (P=0.002, OR=3.329). In addition, genotype of rs7552330 in NPPA gene shows significantly association with occurrence of essential hypertension (P=0.04). We did not find any association of haplotype in the two genes or gene-gene interaction with essenthila hypertension. Conclusion: Our study suggests that NPR1 might be an important factor for the etiology of essential hypertension. More SNPs will be included in the future study.

## 2299/T/Poster Board #848

**Genetic Variants in Angiotensinogen (*AGT*) are Associated with Plasma AGT Levels in Healthy Mexican.** *E. Balam[1,2], A. Esquivel-Villarreal[2], L. Alfaro[1], K. Carrillo[1], A. Elizalde[2], T. Gil[2], M. Urushihara[3], H. Kobori[3], G. Jimenez-Sanchez[1].* 1) National Inst Genomic Medicine, Mexico; 2) Central North Hospital, Petroleos Mexicanos, Mexico; 3) Tulane Univ, New Orleans, LA.

In Mexico, hypertension has a prevalence of 30.8%; in olders than 20 years. Different genetic variants including those in AGT are reported to be associated with hypertension. This study was performed to examine the association between AGT variants and plasma AGT levels in healthy Mexican. Sixty-one normotensive subjects (SBP/DBP <130/80 mmHg) were recruited and the following nine single nucleotide polymorphisms (SNPs) were genotyped: C-532T (rs5046), G-217A (rs5049), A-20C (rs5050), A-6C (rs5051), C3389T (rs4762), C4072T (rs699), G6309A (rs2493132), C11535A (rs7079), and A1240G (rs943580). Plasma AGT levels were determined by ELISA. we performed pairwise comparison between the AA genotype as reference group and others genotypes to further elucidate their association with plasma AGT. We observed differences in plasma AGT levels with genotypes of C3389T (CC: 25.3±5.3 vs. CT: 20.8±2.4 μg/ml, p= 0.003). Ten haplotypes covered 97%;; of the variability. The first haplotype was considered as the intercept for linear regression analysis. Significant associations detected by the single-SNP analyses were largely retained in the haplotype analysis. We observed that the seventh haplotype (CGCTCCCCG) is associated with high plasma AGT levels (6.9, 2.7-11.1, p=0.001). Furthermore, we observed that alleles of two SNPs are related to AGT plasma levels (A-20C: 6.9, 2.7-11.1, p=0.001 and C3389T: -11.1, -17.7--4.5, p=0.0009). These findings suggest putative interactions between haplotypes that contain these alleles (CGATCCCCG: 2.6 μg/ml and CGCTCCCCG: 6.9 μg/ml). The association of these haplotypes with plasma AGT levels remained after the full adjustment for covariates (age, abdominal circumference, and body mass index). Also, the total effect of significant haplotypes in plasma AGT level variance was 16.5%. We perform Likelihood Ratio Test (LRT) for haplotype-phenotype association adjusted for above covariates (X2=38.9 with 11 df, p=0.0005). These results support that the LTR are independent of allele frequency. Finally, we performed pairwise linkage disequilibrium (LD) analysis to determine the relationship between SNPs and found that A-20C and C3389T showed strong LD (D'=1.0, LOD= 0.98, 95% confidence bounds: 0.78-1, r2=0.76), suggesting unique locus with high degree of LD associated with plasma AGT level variance in healthy Mexican. While the present analysis only includes controls, other differences could be identified when patients with hypertension are included.

## 2300/T/Poster Board #849

**NIPBL is a Candidate Gene for Isolated Septal Heart Defects in an Inuit Population.** *D. Chai[1], L. Arbour[1], L. Brown[2], P. Eydoux[1,2].* 1) Med Gen, Univ British Columbia, Vancouver, Canada; 2) Pathology, Univ British Columbia, Vancouver, Canada.

The prevalence of congenital heart defects (CHDs) in the Inuit from Nunavut is higher than in the rest of the Canada . Although the rate of complex heart malformations decreased after folic acid fortification, the prevalence of ASDs and VSDs remained essentially unchanged. This high rate of cardiac septal defects could be related to other environmental or genetic factors. In search of a cause for this high rate of CHDs, we studied 15 trios (patients and their parents) using chromosome microarrays. Patients and parents consenting to the study were recruited because of an isolated auricular or ventricular septal defect (ASD, VSD) or association of both these malformations, confirmed with echocardiographic examination in each case. DNA was extracted, labeled and hybridized to the Affymetrix 6.0 array. Data generated from scanning the arrays were analyzed using the Affymetrix Genotyping Console software. In this sample, we found 2 probands with VSD carrying a de novo partial deletion of NIPBL: one deletion was 48,356 base pairs, the other one 114,132 base pairs in size. NIPBL encodes the delangin, a protein playing a role in chromatid cohesion, chromosome condensation and DNA repair. It is highly expressed in the developing heart. NIPBL frameshift, nonsense, splice-site and missense mutations, spanning most of the gene, are seen in ~50% of patients with Cornelia de Lange Syndrome (CdLS), a multisystem malformation syndrome with mental retardation. Up to 1/3 of individuals with CdLS have a CHD; VSDs and ASDs are the most frequent and are a significant cause of death in these patients. Missense mutations and absence of mutation seem to be associated with a milder disease. Deletions in this gene have not, to date, been reported in non-syndromic heart defects. In our Inuit patients, the two mutations, although different, deleted exon 2 to exon 9 included. Both leaved intact the distal, highly conserved part of the gene containing the 5 HEAT repeats. Most mutations resulting in CdLS described to date are distal to exon 9 and/ or are truncating mutations. Further studies in this population are underway to confirm the association of deletions in NIPBL to non-syndromic heart defects.

## 2301/T/Poster Board #850

**The M235T Polymorphism in the Angiotensinogen Gene is Associated with Susceptibility to Myocardial Infarction in the INTERHEART Study.** *N.M. Chami[1], S.W. Bailey[1], C. Xie[4], R. Do[1], G. Pare[2], A. Montpetit[2], T.J. Hudson[3], S. Yusuf[4], S. Anand[4], J.C. Engert[1] On behalf of the Interheart Individuals.* 1) Human Genetics, McGill University, Montreal, Quebec, Canada; 2) McGill Univ. and Genome Quebec Innovation Centre, Montreal, QC, Canada; 3) Ontario Inst. of Cancer Res., Toronto, ON, Canada; 4) Dept. of Medicine, McMaster Univ., Hamilton, O, Canada.

Hypertension is a well-known risk factor for cardiovascular disease and myocardial infarction (MI). Angiotensinogen (AGT) is a vasopressor agent and part of the renin-angiotenin system which plays an essential role in the regulation of blood pressure. Although many studies have shown a strong association between genetic variants of AGT and hypertension, there have been some conflicting results and only a few studies have investigated their role in cardiovascular disease. We assessed the association between the coding variant M235T and MI in INTERHEART, a global case/control study that has identified associations between a host of risk factors and MI among different countries, ethnicities, and socioeconomic groups. The study includes individuals from 52 countries. We genotyped a subset of 7232 individuals from the INTERHEART study and performed an association analysis with five different ethnicities (European, South Asian, Arab, Nepalese, and Iranian). Large differences in allele frequencies were observed for M235T between the different ethnicities. Specifically, the MAF ranged from 0.31in Nepalese to 0.48 in Europeans. In association analysis, we found that M235T is significantly associated with MI in all ethnicities combined (P<0.0002) as well as in Europeans (P< 0.04) and South Asians (P< 0.0004), the ethnicities with the largest number of samples. Interestingly, we observed greater significance in females (P< 0.0009) than in males (P< 0.01). In addition, we were able to replicate previous results and show that M235T is associated with hypertension (combined P value=0.02). These results confirm that M235T is involved in the pathogenesis of MI and at least part of that increased risk is probably mediated through hypertension.

## 2302/T/Poster Board #851

**High-density genome-wide linkage analysis of left-ventricular outflow tract obstruction.** *M.P. Dubé[1,2], L.P. Lemieux-Perreault[1,2], R. Gendron[3], G. Asselin[1], J.L. Bigras[3], M. Hitz[3], S. Yang[3], A. Richter[2,3], A. Montpetit[4], P. Chetaille[3], G.U. Andelfinger[2,3].* 1) Montreal Heart Institute, Research Centre, Montreal, QC, Canada; 2) Université de Montréal, Faculté de Médecine, Montreal, QC, Canada; 3) Centre Hospitalier Universitaire Sainte-Justine, Montreal, QC, Canada; 4) Genome Quebec Innovation Centre, Montreal, QC, Canada.

**INTRODUCTION**: Congenital heart disease is the most common birth defect and the second cause of infant mortality in North America. Left ventricular outflow tract obstruction (LVOTO) is a wide spectrum of congenital heart defects ranging from bicuspid aortic valve to aortic stenosis and hypoplastic left heart syndrome. The current lack of knowledge of the underlying aetiology limits our ability to modify disease course and develop primary or secondary prevention intervention strategies.

**METHODS**: We have recruited a large cohort of multiplex families with LVOTO. All individuals gave informed consent and underwent physical exam, ECG and echocardiography. We have chosen 42 highly informative families with 300 individuals for high-density genotyping on the Affymetrix 6.0 SNP array. Affection status was defined according to two phenotypes: LVOTO only (stringent) or LVOTO plus other cardiovascular malformation or arrhythmia (broad phenotype). Two-point and multipoint linkage analysis was carried out using MERLIN with parameters for an autosomal dominant disease. Unlinked SNPs were selected for multipoint linkage at a linkage disequilibrium threshold of $r^2 < 0.2$. We developed a new algorithm that converts Birdsuite's Fawkes integrated SNPs and copy number variants (CNV) into copy number polymorphisms (CNP) which we partitioned based on familial pedigree data and analyzed as multi-allelic markers for linkage. Run-of-homozygosity analysis was performed using GoldenHelix with a family-based case-control design. **RESULTS**: In the stringent phenotype scenario, we identified a novel locus on chromosome 3p26 (LOD score 2.95). 20/42 families were found to contribute to this locus. Linkage analysis of CNP shows that this locus is co-segregating with genomic structural variation. The broad phenotype scenario yields a locus on chromosome 16p12 (LOD score 3.15). 15/42 families contributed to this locus. Seven families contributed to both loci. No significant association with extended runs-of-homozygosity could be identified.

**CONCLUSIONS**: We provide the first high-density linkage scan of LVOTO, which identified two candidate loci in the French-Canadian population. Detailed haplotype analyses show conservation in a subset of families. We identified structural genomic variation that co-segregates with LVOTO. Ongoing work aims at evaluating positional candidates in LVOTO.

## 2303/T/Poster Board #852

**MicroRNA microarray expression profiling of human myocardial infarction patients revealed potential microRNAs involved in downregulation of cardiac sarcoplasmic reticulum calcium ATPase-2 (SERCA2).**
*D. Glavac, E. Bostjani.* Department of Molecular Genetics, Faculty of Medicine, University of Ljubljana, Ljubljana, Slovenia.

Using miRNA microarrays and bioinformatic tools, miRNA profiling was performed on human myocardial infarction (MI) , foetal hearts and healthy adult hearts. Of 719 miRNAs analyzed, ~50% were expressed in human hearts, 77 miRNAs were absent from all tested tissues and 68 were confidently dysregulated in at least one tested group. Some expression patterns appeared to be similar in MI and foetal hearts. Bioinformatic analysis revealed at least 15 novel dysregulated miRNAs not yet described in MI patients. On the other hand cardiac sarcoplasmic reticulum calcium ATPase-2 (SERCA2) plays a central role in myocardial contractility. SERCA2 mRNA and protein levels are reduced in various forms of heart disease, but a correlation between decreased SERCA2 mRNA and protein levels is not always observed. SERCA2 is regulated at post-translational level by phospholamban, but may be also regulated at post-transcription level. Since protein SERCA2 reduction may contribute to heart disease, we focused on miRNAs that could potentially involved in regulation of SERCA2 expression especially in human myocardial infarction (MI) patients. SERCA2 protein expression and microRNA expression were analyzed by Western blot and qPCR. MicroRNAs binding on SERCA2 mRNA was predicted using several in silico approaches. In infracted tissue when compared to remote myocardium, the protein SERCA2 was decreased, 64 miRNAs were dysregulated, and of these 21 miRNAs were upregulated. By combining miRNA microarray, target prediction, Western blot and Northern blot, we identified 8 miRNAs (miR-34a, miR-214, let-7i, miR-100, miR-122, miR-199-3p, miR-199-5p and miR-497) with a potential influence on SERCA2 regulation. In proportion of samples the up-regulation of miR-122 and miR-100 was confirmed by Northern blot and qPCR analysis. At the same time SERCA2 downregulation was observed by Western blot and qPCR. This results is in concordance with some other miRNA analysis obtained on cardiomyopathies and neonatal cardiomyocytes. Our results indicate that various miRNAs, in addition to phospholamban, may be involved in the regulation of SERCA2 in myocardial infarction patients.

## 2304/T/Poster Board #853

**Sequence variation in the APOA1 and APOA4 genes and their relationship with plasma HDL-cholesterol levels.**
*S.E. Hill[1], F.Y. Demirci[1], A.S. Dressen[1], C.M. Kammerer[1], C.H. Bunker[2], J.E. Hokanson[3], R.F. Hamman[3], M.I. Kamboh[1].* 1) Human Genetics, GSPH, Univ Pittsburgh, Pittsburgh, PA; 2) Epidemiology, GSPH, Univ Pittsburgh, Pittsburgh, PA; 3) Epidemiology, Colorado School of Public Health, Univ Colorado Denver, Aurora, CO.

Heart disease continues to be the leading cause of death in the United States, making it one of the foremost public health concerns. Many factors influence the risk to develop heart disease, including abnormal blood lipid levels. High levels of plasma high-density lipoprotein cholesterol (HDL-C) have been shown to have a protective effect. Genetic variation in *APOA1* and *APOA4* has been evaluated for association with HDL-C levels in multiple studies with somewhat inconsistent results. The aim of this study was to comprehensively investigate the role of both common and rare variation in these genes by first sequencing them (entire gene and flanking regions) in individuals having extremely low and high HDL-C levels in two epidemiological samples, non-diabetic U.S. Non-Hispanic Whites (NHWs) from the San Luis Valley Diabetes Study and African Blacks from Nigeria, and then screening the identified variants in the entire sample sets. The analysis of sequencing data from individuals with HDL-C levels in the upper $5^{th}$ percentile (47 NHWs and 48 African Blacks) and the lower $5^{th}$ percentile (48 NHWs and 47 African Blacks) revealed a total of 54 variants in *APOA1* and its flanking regions and 43 in *APOA4* and its flanking regions. The total number of identified sequence variants was higher in African Blacks as compared to NHWs. A dramatically higher number of coding region variants were detected in *APOA4* (n=17) versus *APOA1* (n=5). When individuals were compared between high and low HDL-C groups for carriership of rare variants unique to each group, the percentages were either similar or slightly higher in the high HDL-C group. The sequencing data also showed differences in minor allele frequencies of some common variants between low and high HDL-C groups that await confirmation by genotyping the entire sample sets. Genotyping of all identified rare variants and common tag SNPs in the entire NHW and Black samples is underway and will reveal the extent to which the *APOA1* and *APOA4* variants affect the HDL-C levels.

## 2305/T/Poster Board #854

**Genetic Risk Scores Weighted by SNP Effect on Intermediate Lipid Phenotypes for Application to Coronary Artery Disease Associations.**
*B.D. Horne[1,2], N.J. Camp[1,2], J.F. Carlquist[1,2], J.B. Muhlestein[1,2], C.P. Mower[1], J.J. Park[1], J.L. Anderson[1,2].* 1) Cardiovascular Dept, Intermountain Med Ctr, SLC, UT; 2) Genet Epidemiol/Cardiol, Univ Utah, SLC, UT.

Most single nucleotide polymorphism (SNP) associations with common, complex diseases have small risk effects. Genetic risk scores (GRS) aggregate SNP information from many genes but only our prior work has used weighting and not simply summed the number of risk alleles. This study evaluated SNPs that are candidates for low-density lipoprotein cholesterol (LDL-C), high-density lipoprotein cholesterol (HDL-C), or triglycerides (TG) and aggregated them into a GRS based on relative effects. GRS associations with coronary artery disease (CAD) were then tested. SNPs (total=54) were studied from a tagging SNP study of lipid genes (39 SNPs) and from genome-wide association studies (15 SNPs). Genotyping included untreated population normals (N=748) and patients undergoing coronary angiography (N= 2,950, 65% with CAD). Among normals, each SNP's risk allele was determined from LDL-C, HDL-C, and TG associations of $p \le 0.20$ (17 for LDL-C, 21 for HDL-C, and 12 for TG). GRS variables were computed separately for LDL-C, HDL-C, and TG. Deciles of GRS-LDL were associated with LDL-C (normals: p-trend=$3.8x10^{-6}$, but not in patients: p-trend=0.86), GRS-HDL with HDL-C (normals: p-trend=$1.3x10^{-12}$, patients: p-trend=$1.7x10^{-5}$), and GRS-TG with TG (normals: p-trend=$6.3x10^{-7}$, patients: p-trend=$1.4x10^{-6}$). GRS-LDL ranged from -24.9 to 22.6 mg/dL and for CAD had odds ratio (OR)=1.013 per mg/dL (95% CI=1.00, 1.03; p=0.055) for continuous values, while GRS-LDL deciles had OR=1.03 per decile (CI=1.00, 1.06; p-trend= 0.050). GRS-HDL ranged from -14.6 to 19.9 mg/dL and for CAD had OR= 0.991 per mg/dL (CI=0.97, 1.01; p=0.36) and OR=0.98 per decile (CI= 0.95, 1.02; p-trend=0.30). GRS-TG was measured in natural log-transformed values, with range=-0.66 to 0.05 and for CAD had OR=2.09 per natural log (mg/dL) unit (CI=0.99, 4.39; p=0.053) and OR=1.03 per decile (CI=1.01, 1.06; p-trend=0.042). GRS variables weighted by intermediate phenotype were associated with LDL-C, HDL-C, and TG in population normals and replicated in an independent sample of angiography patients for HDL-C and TG (failure of GRS-LDL to predict LDL-C in patients may be due to lipid-lowering treatment). Weak CAD associations existed for GRS-LDL and GRS-TG (but not GRS-HDL). Intermediate-phenotype weighted polygenic GRS metrics deserve further evaluation.

## 2306/T/Poster Board #855

**A novel stroke susceptibility locus in a pedigree from northern Sweden.**
*T. Janunger[1], S. Nilsson-Ardnor[1], P.G. Wiklund[2], P. Lindgren[1], S.A. Escher[1], K. Lackovic[1], A.K. Nilsson[1], B. Stegmayr[2], K. Asplund[2], D. Holmberg[1].* 1) Department of Medical Biosciences, Division of Medical and Clinical Genetics, Umeå University, Umeå, Sweden; 2) Department of Public Health and Clinical Medicine, Division of Clinical Medicine, Umeå University, Umeå, Sweden.

**Objectives** - The population of northern Sweden is characterized by reduced genetic diversity and a high incidence of stroke. We sought to reduce genetic variation further, using genealogical analysis in a set of nuclear families affected by stroke and we subsequently performed a genome wide scan to identify novel stroke susceptibility loci. **Methods** - Through genealogy, seven nuclear families with a common ancestor, connected over eight generations were identified. A genome wide scan, utilizing 449 microsatellite markers, was performed with subsequent haplotype analyses. **Results** -A maximum allele-sharing LOD score of 4.81 on chromosome 9q31-q33 was detected. Haplotype analysis identified a common 2.2 Mb interval in the chromosomal region in four of the nuclear families, where an overrepresentation of intracerebral hemorrhage was observed. **Conclusions** - We have identified a novel susceptibility locus for stroke. Haplotype analysis suggests that a shared genetic factor is of particular importance for intracerebral hemorrhage.

## 2307/T/Poster Board #856

**Association between genetic variants on chromosome 9p21 and aneurysmal subarachnoid hemorrhage.** *C. Jern[1,2], S. Olsson[1,2], L.Z. Csajbok[3], K. Jood[1], K. Nylén[1], B. Nellgård[4].* 1) Dept of Clinical Neuroscience and Neurorehabilitation, Institute of Neuroscience and Physiology, the Sahlgrenska Academy at Gothenburg University, Sweden; 2) Department of Clinical Genetics, Sahlgrenska University Hospital, Göteborg, Sweden; 3) Department of Anaesthesiology and Intensive Care, Sahlgrenska University Hospital, Göteborg, Sweden; 4) Department of Anaesthesia and Intensive Care, University Hospital Malmö, Sweden.

**Background:** Family studies have suggested a role for genetic factors in susceptibility to subarachnoid hemorrhage, but little is known about which genes are involved. Recently, genomewide association studies have identified a locus for risk for intracranial aneurysms (IA), coronary artery disease and ischemic stroke on chromosome 9p21. The aim of the present study was to examine the possible association between sequence variants at 9p21 and ruptured intracranial aneurysms, i.e. aneurysmal subarachnoid hemorrhage (aSAH), in a Swedish population. **Methods:** The study comprises 183 patients presenting with aSAH at the neurointensive care Unit at the Sahlgrenska University Hospital and 366 healthy age and sex matched population-based controls. Because the functional gene in the region on 9p21 remains to be identified, an approximately 44 kbp region on 9p21 (between position 22071397 and 22115503) was tagged using HapMap CEU data and haploview (r2=0.8 and MAF=0.1), resulting in 6 tag single nucleotide polymorphisms (SNPs). Genotyping was performed by TaqMan assays. **Results:** The mean age of patients and controls was 55 years and 74% were females. Two SNPs, rs10757278 and rs1333045, and one common haplotype showed significant association with aSAH in univariate analyses. As expected, hypertension and smoking were overrepresented among aSAH cases compared to controls. There is one study showing association between variants on 9p21 and arterial stiffness, and there are data indicating that arterial stiffness plays a role in the development of hypertension. Furthermore, there is evidence of an interaction between familial aggregation of intracranial aneurysms and smoking. Therefore associations between 9p21 and aSAH were also tested in multivariate analyses. After adjustment for hypertension and smoking, the association between aSAH and rs10757278 remained significant with an OR for aSAH of 1.42 (95% CI 1.08-1.87, p=0.01) for the uncommon G allele. We did not find a significant interaction between rs10757278 and smoking. **Conclusions:** We confirm earlier results showing that 9p21 is a susceptibility locus for intracranial aneurysms, and we show that this association is present in a Swedish sample restricted to ruptured intracranial aneurysms. For the first time we show that this association is independent of hypertension. Furthermore the present data do not suggest that there is an interaction with smoking.

## 2308/T/Poster Board #857

**Linkage and association analyses of platelet function following aspirin treatment measured by the PFA-100 closure time.** *Y. Kim[1], R.A. Mathias[2], L.R. Yanek[2], N. Faraday[2], L.C. Becker[3], D.M. Becker[2], A.F. Wilson[1].* 1) IDRB/Genometrics Sec, NHGRI/NIH, Baltimore, MD; 2) Division of General Internal Medicine , The Johns Hopkins University School of Medicine, Baltimore, MD; 3) Division of Cardiology, The Johns Hopkins University School of Medicine, Baltimore, MD.

Low-dose aspirin (ASA, 81mg/day) inhibits platelet function and is used as a preventive treatment for coronary artery diseases (CAD). The platelet function analyzer (PFA) - 100 test is used to assess the effects of ASA; it measures the time in seconds to shear stress-induced platelet plug formation with a collagen-epinephrine cartridge. In this study, three methods are used to screen for genetic effects contributing to PFA: 1) two-point genome-wide linkage analysis of 546 microsatellite markers, 2) multipoint linkage analysis in regions with evidence of linkage using single nucleotide polymorphisms (SNPs), and 3) tests of association in regions identified with linkage analysis. The study included 363 whites in 190 pedigrees and 255 blacks in 120 pedigrees with premature CAD but healthy. PFA values post ASA were adjusted for age, sex, and pre-aspirin values within each race. Two point linkage analysis was performed on the deCODE 550 STR markers (average spacing = 8 cM) with Haseman-Elston regression models in SAGE v5.1.0 (44/47 sibs in blacks and whites, respectively). A 10 Mb region on 5q35.2-3 suggested linkage ($P < 0.005$) in both races, and 4599 SNPs in this region were selected from the Illumina1M SNP chip for subsequent analyses. Multipoint linkage analysis modeling linkage disequilibrium (LD) was performed with these SNPs (median spacing = 1.5 kb) with Merlin v1.1.2. Association tests of each single SNP were performed using linear mixed effect models in SAS v.9.1.3 under an additive model. In blacks, 105 linkage signals with $P < 0.001$ clustered in the region between 176 - 178.5 Mbp on chromosome 5, 45 of which map to the COL23A1 gene. In association studies, there were four highly significant markers: rs4323245 (p =1.9e-4, MAF = 0.07), rs11953588 (p = 2.9e-4, MAF = 0.28), rs6898657 (p = 9.75e-5, MAF = 0.12), and rs7731035 (p = 7.05e-5, MAF = 0.14). However there was no evidence for association with the SNPs in whites. There are six genes of interest on 5q35.2-3. COL23A1 is a member of the transmembrane collagens. CPLX2, SNCB and CLTB are vesicle associated proteins, the first two of which play a role in platelet excocytosis/degranulation. PCDH24 is a calcium dependent cell adhesion molecule, and FGFR4 is fibroblast growth factor. In conclusion, we have identified a novel genetic locus on chromosome 5 using linkage and association analysis that may cause a modification of the responsiveness of platelets to ASA.

## 2309/T/Poster Board #858

**Kalirin: A novel genetic risk factor for ischemic stroke.** *T. Krug[1,2], H. Manso[1,3], L. Gouveia[4], J. Sobral[1,3], J. Xavier[1,2], I. Albergaria[3], G. Gaspar[3], M. Correia[5], M. Viana-Baptista[6], A.N. Pinto[7], R. Taipa[5], C. Ferreira[8], J.R. Fontes[8], M.R. Silva[9], J.P. Gabriel[9], I. Matos[10], G. Lopes[5], J.M. Ferro[2,4], A.M. Vicente[1,3], S.A. Oliveira[1,2].* 1) Instituto Gulbenkian de Ciencia, Oeiras, Portugal; 2) Instituto de Medicina Molecular, Lisboa, Portugal; 3) Instituto Nacional de Saude Dr. Ricardo Jorge, Lisboa, Portugal; 4) Servico de Neurologia, Hospital de Santa Maria, Lisboa, Portugal; 5) Servico de Neurologia, Hospital Geral de Santo António, Porto, Portugal; 6) Servico de Neurologia, Hospital Garcia de Orta, Almada, Portugal; 7) Servico de Neurologia, Hospital Fernando Fonseca, Amadora, Portugal; 8) Servico de Neurologia, Hospital Sao Marcos, Braga, Portugal; 9) Servico de Neurologia, Hospital de Sao Pedro, Vila Real, Portugal; 10) Servico de Neurologia, Hospital Distrital de Mirandela, Mirandela, Portugal.

Cerebrovascular and cardiovascular diseases are the leading cause of death and disability worldwide. They are complex disorders resulting from the interplay of genetic and environmental factors, and may share several susceptibility genes. Several recent studies have implicated variants of the Kalirin (KALRN) gene with susceptibility to cardiovascular and metabolic phenotypes but no studies have yet been performed in stroke patients. KALRN is involved, among others, in the inhibition of inducible nitric oxide synthase, in the regulation of ischemic signal transduction, and in neuronal morphogenesis, plasticity and stability. The goal of the present study was to determine whether SNPs in the KALRN gene region on 3q13, which includes the Ropporin gene (ROPN1), predispose to ischemic stroke (IS) in a cohort of Portuguese patients and controls. We genotyped 34 tagging SNPs in the KALRN and ROPN1 chromosomal region on 565 IS patients and 517 unrelated controls, and performed genotype imputation for 405 markers on chromosome 3. We tested the single-marker association of these SNPs with IS. One SNP (rs4499545) in the ROPN1-KALRN intergenic region and two SNPs in KALRN (rs17286604 and rs11712619) showed significant ($P<0.05$) allelic and genotypic (unadjusted and adjusted for hypertension, diabetes and ever smoking) association with IS risk. A cluster of four imputed SNPs (represented by rs7620580) in complete linkage disequilibrium were the most significantly ($P<0.002$) associated with IS (confirmed by genotyping). This study suggests that variants in the KALRN gene region constitute risk factors for stroke in the Portuguese population and that KALRN may represent a common risk factor for vascular diseases. Currently we are following up our results in the Spanish population.

## 2310/T/Poster Board #859

**Association studies of candidate genes involved in oxidative stress regulation pathways in Lithuanian population.** *V. Kucinskas[1], K. Grigalioniene[1], A. Laucevicius[2], Z.A. Kucinskiene[3].* 1) Department of Human & Medical Genetics, Vilnius University, Vilnius, Lithuania; 2) Clinics of Heart & Vessel Diseases, Vilnius University, Vilnius, Lithuania; 3) Department of Physiology, Biochemistry & Laboratory Medicine, Vilnius University, Vilnius, Lithuania.

A number of biological systems involving proteins encoded by numerous genes are involved in the process of atherogenesis. Unraveling their genetic diversity is important for the understanding its mechanisms and finding new molecular markers for early prediction of the increased risk of future cardiovascular events. Hypothesis of atherosclerosis was formulated and in order to support it with the data the study was planned. The scheme of the study included the bioinformatics, genotyping stages and data analysis. Metabolic / signalling pathways most widely represented in atherosclerosis form a network in which association with inflammation is an important feature. This is consistent with our hypothesis of the role of oxidative stress in the initiation and development of atherosclerosis phenotype. Thus a number of genes participating in the above-stated network can be related to the susceptibility to atherosclerosis via alleles leading to increased vulnerability to oxidative stress. After the large scale analysis of literature and bioinformatic databases 150 single nucleotide polymorphisms (SNPs) of 89 candidate genes, mostly involved in oxidative stress regulation and oxidative homeostasis, were selected to develop a microarray for arrayed primer extension (APEX) resequencing technology. Most of the selected SNPs were in promoter regions or exons that might be expected to cause changes in the function or level of expression of the encoded protein. Out of 150 analyzed SNP's 116 were polymorphic and 34 SNPs were not polymorphic in the studied group. Association analysis using TDT and S-TDT statistics showed statistically significant association of 10 SNP's: rs1376251, rs1800795, rs3811699, rs5882, rs28573147, rs3918242, rs1151640, rs9551963, rs1143627 and rs1126643 in candidate genes: ITGA2, IL1B, ALOX5AP, OR13G1, MMP9, NFKB1, CETP, GPX1, UCP2 and TAS2R50 respectively. The main gene groups are related to: thrombocyte adhesion and vessel damage (ITGA2, MMP9), inflammation response (IL1B, NFKB1), oxidation mechanisms (UCP2, GPX1), cholesterol and lipoxygenase metabolic pathway (ALOX5AP, CETP), and nutrition (TAS2R50, OR13G1). The results of the study support the assumption that different genetic history leads to different spectrum and different frequencies of SNPs across populations.

## 2311/T/Poster Board #860

**Detection of Recurrent Copy Number Variants in Congenital Heart Disease using Multiplex Ligation-dependent Probe Amplification.** *L.A. Larsen[1], K.M. Sørensen[1,2], M. El-Segaier[3], E. Fernlund[3], P. Bouvagnet[4], N. Nehme[4], J. Steensberg[5], A. Errami[6], J. Schouten[6], V. Hjortdal[7], N. Tommerup[1], P.S. Andersen[8].* 1) Wilhelm Johannsen Centre for Functional Genome Research, University of Copenhagen, Copenhagen, Denmark; 2) Department of Clinical Biochemistry, Statens Serum Institut, Copenhagen, Denmark; 3) Department of Paediatric Cardiology, Lund University Hospital, Lund, Sweden; 4) Department of Pediatric Cardiology, Groupe Hospitalier Est, Lyon, France; 5) Department of Paediatric Cardiology, Copenhagen University Hospital, Copenhagen, Denmark; 6) MRC-Holland, Amsterdam, The Netherlands; 7) Department of Cardiothoracic Surgery, Aarhus University Hospital, Skejby, Denmark; 8) Molecular Biology Lab, National Center for Antimicrobials and Infection Control, Statens Serum Institut, Copenhagen, Denmark.

Recent studies have suggested that chromosomal deletions and duplications may be found in a proportion of patients with congenital heart disease (CHD). We have designed an assay for simultaneous analysis of deletions and duplications in 26 genomic regions which have previously been associated with CHD. The assay is based on the Multiplex Ligation-dependent Probe Amplification (MLPA) technique. The assay is performed in a single reaction and targets the following genomic regions: 1p36, 1q21, 2q37, 2p22, 3q22, 4q32, 4p16, 5q35.2, 5q35.3, 6p25.3, 7q22, 7q11.23, 8q12.2, 8p23.2, 8p23.1, 8q34.13, 8q34.11, 10q25.2, 10q25.3, 11q25, 13q14, 15q26, 17p13, 17p11, 20p12, 22q11. At the time of abstract submission we have screened 219 patients with CHD using the MLPA kit. The screening revealed copy number variants (CNVs) in nine patients (4.3%). None of these CNVs were found in 96 controls. Three CNVs were *de novo*: dup(2)(p22.3), dup(5)(q35.-3qter) and del(8)(p23.1). Interestingly, the 2p22.3 duplication was previously detected in another CHD patient as inherited from a healthy parent (Erdogan et al., 2008, J. Med. Genet, 45:704-9). We detected the recurrent dup(22)(q11.21) in four patients. All four 22q11 duplications were inherited from a healthy parent, but the 22q11 duplication was not present in 600 controls. In conclusion the MLPA analysis shows that recurrent CNVs are present in a significant proportion of CHD patients.

## 2312/T/Poster Board #861

**Genetic association analysis of heart rate on chromosome 9p21 in American Indians: The Strong Heart Family Study.** *P.E. Melton[1], S. Rutherford[1], V.S. Voruganti[1], H.H.H. Göring[1], S. Laston[1], K. Haack[1], A.G. Comuzzie[1], J.E. Curran[1], J. Blangero[1], E.T. Lee[2], L.G. Best[3], R.R. Fabsitz[4], R.B. Devereux[5], P.M. Okin[5], J.N. Bella[5], U. Broeckel[6], B.V. Howard[7], J.W. MacCluer[1], S.A. Cole[1], L. Almasy[1].* 1) Genetics, Southwest Foundation for Biomedical Research, San Antonio, TX; 2) Center for American Indian Health Research, College of Public Health, University of Oklahoma Health Sciences Center, Oklahoma City, Oklahoma; 3) Missouri Breaks Industries Research, Inc., Timber Lake, South Dakota; 4) Epidemiology Branch, National Heart, Lung, and Blood Institute, Bethesda, Maryland; 5) Department of Medicine, Weill Cornell Medical College of New York, New York; 6) Medical College of Wisconsin, Milwaukee, Wisconsin; 7) MedStar Research Institute, Washington, DC.

Several studies have identified higher heart rate as an independent risk factor for cardiovascular disease (CVD) and hypertension. However, little is known regarding the genetic architecture of heart rate. The Strong Heart Family Study (SHFS) was designed to identify genetic risk factors for CVD in American Indians (AIs) ascertained without regards to disease status, from large multigenerational families located in Arizona, Oklahoma, and North/South Dakota. Previous genetic linkage research of SHFS participants had identified a significant QTL for heart rate (LOD=3.3; genome wide *p*-value= 0.016) on chromosome 9p21. The greatest support for this signal came from the Oklahoma center (LOD = 4.2). In this study, we examined 2,249 SNP genotypes in the 1 LOD support region of the 9p21 SHFS heart rate QTL from 1,122 AI participants. Heart rate (beats per minute) was measured from echocardiographic Doppler recordings and were inverse normalized and adjusted for effects of age and sex prior to statistical analysis. Fat-free body mass, alcohol use, smoking status, HOMAIR, insulin, HbAIC, antihypertensive medication, systolic, diastolic and mean arterial pressures were assessed but were not significant covariates and were not included in subsequent analysis. We applied a gene-centric joint statistical test that uses the effective number of SNPs within a single gene and is better able to determine significance under multiple testing. Two SNPs (rs7875153 and rs10757082) remained significant after correction among Oklahoma SHFS participants. The SNP rs7875153 ($p$ = 7.95 X 10-5) is located near the gene for KIAA1797 a hypothetical protein that may be involved in mitotic chromosomal condensation. To further investigate this relationship we used RNA expression data available from the San Antonio Family Heart Study (SAFHS), a longitudinal genetic epidemiologic study of CVD in Mexican Americans from San Antonio, TX. Expression levels of the KIAA1797, transcript were significantly associated ($p$ = 0.012) with electrocardiographic heart rate in SAFHS participants. These findings suggest that genetic variation within KIAA1797 is associated with heart rate and may influence risk for heart disease.

## 2313/T/Poster Board #862

**Mutation screening of sarcomere genes MYH7, MYBPC3, LDB3, and TNNT2 in a large cohort of dilated cardiomyopathy families.** *M. Merlo[1], E. Carniel[2], D. Slavov[2], X. Zhu[2], D. Ferguson[2], E. Salcedo[2], J. Cavanaugh[2], G. Sinagra[1], A. Di Lenarda[1], L. Mestroni[2], M. Taylor[2].* 1) Ospedale Maggiore and University of Trieste, Trieste, Tireste, Italy; 2) University of Colorado Denver, Aurora, CO.

**Background:** Idiopathic dilated cardiomyopathy is a severe cause of cardiac ventricular dilation and systolic dysfunction that shows extensive genetic heterogeneity. Mutations in sarcomere proteins have been well-studied in hypertrophic cardiomyopathy but the prevalence of and phenotypic characteristics of sarcomere protein mutations in the dilated phenotype are less understood. **Methods:** We undertook mutation screening of 242 well-phenotyped subjects with dilated cardiomyopathy from 179 families (129 familial and 50 sporadic cases) using denaturing high-performance liquid chromatography and sequence analysis. Four sarcomeric genes (MHY7, MYBPC3, LDB3, and TNNT2) were tested. Putative mutations were evaluated for pathogenicity by testing samples from available relatives and excluding the mutations from healthy controls and available polymorphism databases. **Results:** 2 mutations were detected in 86 subjects tested for MHY7 (2.3%) (M982T, R1434C) and 3 mutations in 209 (1.4%) tested for MYBPC3 (3 missense mutations: S217G, R458H, Ser956Thr) for an overall prevalence of 5/242 (4.1%). No clear mutations were identified in LDB3 or TNNT2. The phenotypes were severe with two mutation carriers having arrhythmias and four mutation carriers have undergone cardiac transplantation. **Conclusions:** Our study, which includes the largest screen of MYBPC3 in dilated cardiomyopathy, found that mutations in MHY7 and MYBPC3 account for approximately 2% of this phenotype. While rare, the mutations found in our study suggest that sarcomeric mutations leading to dilated cardiomyopathy have a severe phenotype.

## 2314/T/Poster Board #863

**Interaction of NPPB genotype on the relationship between left ventricular hypertrophy and plasma BNP levels.** *T. Miki[1,2], Y. Tabara[1,3], M. Igase[2], A. Oghimoto[4], T. Kido[2], E. Uetani[2], N. Ochi[2], K. Kohara[1,2].* 1) Ehime ProteoMedicine Research Center; 2) Department of Geriatric Medicine, Ehime University Graduate School of Medicine; 3) Department of Basic Medical Research and Education, Ehime University Graduate School of Medicine; 4) Department of Integrated Medicine and informatics, Ehime University Graduate School of Medicine.

**Backgrounds:** Recent genome wide association study identified NPPB (natriuretic peptide precursor B) rs632793 as a susceptible polymorphism for plasma brain natriuretic peptide (BNP) levels in Caucasians. Findings from previous GWAS, however, cannot be extrapolated to other populations with different lifestyles and environmental backgrounds. Here we investigated a cross-validation of the relationship between NPPB polymorphism and plasma BNP levels in Japanese. Further we investigated interactions of NPPB genotype in correlation between plasma BNP levels and electrocardiographic left ventricular hypertrophy (LVH).

**Methods:** The study subjects comprised 591 apparently healthy middle-aged to elderly persons (67±8 years old; 37.9% male). All subjects attended the medical check-up program at Ehime University Hospital, and clinical data used in this study, including plasma BNP levels, were obtained through the check-up process. Genomic DNA was extracted from peripheral blood and all SNPs were analyzed by TaqMan probe assay.

**Results:** Plasma BNP levels were significantly different among the genotype (AA (n=457) 28±25, AG (n=119) 32±26, GG (n=15) 56±30 pg/ml, p= $3.0*10^{-5}$). Age (r=0.343, p<0.001), body mass index (r=-0.131, p=0.001), plasma hematocrit levels (r=-0.149, p<0.001) were also correlated with BNP levels. Multiple regression analysis identified the NPPB genotype as an independent determinant for plasma BNP levels (GG genotype: $\beta$=0.156, p<0.001) independent of following confounding factors; age ($\beta$=0.326, p<0.001), BMI($\beta$=-0.123, p=0.002), plasma hematocrit levels ($\beta$=-0.097,p= 0.011), treatment with diuretics ($\beta$=0.094, p=0.013), and electrocardiographic LVH ($\beta$=0.103, p=0.006). Subjects with electrocardiographic LVH showed significantly higher BNP levels (LVH (n=76) 38±32, non-LVH (n= 515) 28±24 pg/ml, p=0.001). However, in subjects without LVH, GG genotype carriers showed predominantly higher BNP levels (51±30 pg/ml) as compared with that of LVH subjects with GA or AA genotype (36±4 pg/ml).

**Conclusion:** Association between NPPB rs932793 polymorphism and plasma BNP levels was replicated in Japanese. The genotype data is essential in order to ensure accurate interpretation of plasma BNP value.

## 2315/T/Poster Board #864

**A functional variation in *BRAP* confers risk of myocardial infarction in Asian populations.** *K. Ozaki[1], H. Sato[2], K. Inoue[3], T. Tsunoda[4], Y. Sakata[2], Y. Onouchi[1], S. Ikegawa[5], S.H. Juo[6], M. Hori[2], Y. Nakamura[7], T. Tanaka[1].* 1) Laboratory for Cardiovascular Diseases, Center for Genomic Medicine, RIKEN, Yokohama, Japan; 2) Department of Cardiovascular Medicine, Osaka University Graduate School of Medicine, Suita, Japan; 3) Department of Cardiology, Kokura Memorial Hospital, Kitakyushu 802-8555, Japan; 4) Laboratory for Medical Informatics, Center for Genomic Medicine, RIKEN, Yokohama, Japan; 5) Laboratory for Bone and Joint Disease, Center for Genomic Medicine, RIKEN, Tokyo, Japan; 6) Graduate Institute of Medical Genetics, Kaohsiung Medical University, Kaohsiung, Taiwan; 7) Center for Genomic Medicine, RIKEN, Yokohama, Japan.

Development and progression of coronary artery diseases including myocardial infarction (MI) depend on complex interactions multiple genetic and environmental factors. We previously showed that a functional variation in *LGALS2* encoding galectin-2 was associated with susceptibility to MI by a case-control association study using a Japanese population. Here we show that galectin-2 binds to BRAP, BRCA1 associated protein, and SNPs in *BRAP* on chromosome 12q24 also confer risk of MI with marked significance in a large Japanese cohort (P = $3.0 \times 10^{-18}$, OR=1.48, 2,475 cases and 2,778 controls). Replication study confirmed this association (P = $4.4 \times 10^{-6}$, 862 cases and 1,113 controls). Furthermore, another Asian population, Taiwanese population, also showed significant association (P = $4.7 \times 10^{-3}$, 349 cases and 994 controls). One SNP, located within intron3 in *BRAP*, enhanced the transcriptional level of this gene. Moreover, suppression of *BRAP* expression level using siRNA in cultured coronary artery endothelial cells suppressed activation of NFkB, a central mediator of inflammation. Smooth muscle cells (SMCs) and macrophages in the human atherosclerotic lesions also expressed BRAP. These findings indicate that *BRAP* is a novel genetic risk factor for MI. Moreover, by combination of this genetic risk factor and five ones (*LTA*, *LGALS2*, *ITIH3*, *MIAT* and *PSMA6*) previously identified by us, the odds ratio increased to about 9. The result indicates that combination of genetic risk factors contributes to the pathogenesis of MI.

**Familial isolated cardiomyopathy caused by a mutation in the flavoprotein subunit of succinate dehydrogenase.** *R. Parvari[1,2], E. Muhammd[1], G. Harel Levy[1], A. Levitas[3], V. Chalifa Caspi[2], E. Manor[4], J.C. Beck[6], A. Saada[5], V.C. Sheffield[6].* 1) Dept Gen & Virology, Ben Gurion Univ, Beer Sheva, Israel; 2) National Institute of Biotechnology Negev, Ben Gurion University of the Negev, Beer Sheva 84105, Israel; 3) Division of Pediatrics, Soroka Medical Center, Beer Sheva 84105 and Faculty of Health Sciences, Ben Gurion University of the Negev, Beer Sheva 84105, Israel; 4) Institute of Genetics, Soroka Medical Center, Beer Sheva 84105 and Faculty of Health Sciences, Ben Gurion University of the Negev, Beer Sheva 84101, Israel; 5) Deparment of Human Genetics and Metabolic Diseases. Hadassah-Hebrew University Medical Center Jerusalem Israel; 6) Dept. of Pediatrics - Division of Medical Genetics; Howard Hughes Medical Institute, University of Iowa, Iowa City, IA 52242, USA.

Cardiomyopaties are the most common disorders resulting in heart failure. Dilated cardiomyopathy (DCM), a disorder characterized by cardiac dilatation and reduced systolic function, is the most frequent cause. However, recessive neonatal isolated dilated cardiomyopathy has scarcely been associated with a mutation. A defect of the human succinate dehydrogenase (SDH) is a rare condition in human, representing 2% of respiratory chain (RC) deficiencies. Its clinical presentation is highly variable, ranging from early onset encephalomyopathies to tumor susceptibility in adults. We present the association of a mutation in the SDHA gene with the clinical manifestation and interfamilial variability of 15 patients diagnosed with dilated and hypertrophic cardiomyopathy. The cardiomyopathy is presumably caused by the significant specific reduction of the SDH enzymatic activity in heart muscle whereas substantial activity is retained in skeletal muscle and lymphoblastoid cells. Identification of the SDHA as the mutated gene was hindered since patients with a similar clinical presentation belonging to the same enlarged family proved to have mutations in another gene and a father homozygous for the mutation is not affected. The same mutation was previously reported to cause a multi-systemic failure leading to neonatal death and to Leigh syndrome. Thus this study highlights the extreme variability that results from homozygosity of the same mutation in a nuclear encoded respiratory complex.

## 2317/T/Poster Board #866

**Large scale candidate gene analysis of lipid traits in the Pakistan Risk of Myocardial Infarction Study and comparison with participants of European descent.** *D. Saleheen[1,3], N. Soranzo[2], M. Zaidi[3], S. Kaptoge[1], E. Angelantonio[1], A. Rasheed[3], M. Alexander[1], P. Haycock[1], N. Sarwar[1], A. Butterworth[1], N. Shah[3], M. Samuel[3], A. Samad[4], M. Ishaq[4], P. Frossard[3], J. Danesh[1], P. Deloukas[2].* 1) Public Health and Primary Care, University of Cambridge, Cambridge, United Kingdom; 2) Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK; 3) Center for Non-Communicable Diseases, Karachi, Pakistan; 4) Karachi Institute of Heart Diseases.

Background: Numerous candidate gene studies and high-throughput genotyping approaches have yielded several loci regulating lipid levels in participants of European descent, with little validation and quantification of these associations in other ethnicities. This is specifically important for 1.5 billion people living in South Asia where cardiovascular disorders are expected to double by 2020. Methods: We tested for associations with lipid traits over 45,000 variants across 2000 candidate genes pertinent to cardiovascular and metabolic syndromes, by using the IBC Illumina 50K array, in 3200 participants of the Pakistan Risk of Myocardial Infarction study (PROMIS). For comparison, we genotyped 2450 participants of European ancestry in the LURIC study by using the same array and performed meta-analyses of previously published studies in Europeans. Associations were tested through an additive genetic model adjusting for age, gender, the first two PCs and disease status. Results: Principal components analyses involving data from PROMIS and HAPMAP3 revealed Pakistani ethnicities to be unique from other worldwide groups. We identified 27 variants, representing five genomic regions, associated with HDL-C, LDL-C or triglycerides with a bonferroni adjusted P-value of < 10-6 and overall validated the associations of 15 genomic regions in South Asians. In particular, we identified CETP to be associated with HDL-C (rs711752; P < 10-14), APOA5, ZNF259 (rs651821; P < 10-14) and GCKR (rs1260326; P < 10-10) to be associated with triglycerides and CELSR2 to be associated with LDL-C (rs646776; P < 10-10). The minor allele frequency and associations observed in South Asians were observed to be consistent with the results obtained in Europeans. The minor allele frequency for APOA5 variants associated with triglycerides, however, was twice as common in PROMIS participants compared to Europeans with stronger associations in the Pakistani population. Conclusions: These findings suggest that several loci associated with lipid traits in Europeans also extend to South Asians, with minor quantitative differences for some loci. South Asians can therefore provide a useful resource for the discovery and validation of QTLs discovered in participants of European descent. More detailed hypothesis-free investigations such as a GWAS in South Asians will enable identification of additional novel loci due to their unique ancestry and differences in allelic architecture.

## 2318/T/Poster Board #867

**Functional Mutation in *ABCG1* Predicts Risk of Ischemic Heart Disease in the General Population.** *J. Schou[1], R. Frikke-Schmidt[1], B.G. Nordestgaard[2, 4], D. Kardassis[3], E. Thymiakou[3], G. Jensen[4], P. Grande[5], A. Tybjærg-Hansen[1, 4].* 1) Dept. of Clinical Biochemistry, Rigshospitalet, Copenhagen University Hospital, Copenhagen, Denmark; 2) Dept. of Clinical Biochemistry,Herlev Hospital, Copenhagen University Hospital, Herlev, Denmark; 3) Dept. Biochemistry, University of Crete Medical School, Heraklion, Greece; 4) The Copenhagen City Heart Study, Bispebjerg Hospital, Copenhagen University Hospital, Copenhagen, Denmark; 5) Dept. of Cardiology, Rigshospitalet, Copenhagen University Hospital, Copenhagen, Denmark.

The ATP-Binding Cassette transporter G1 (ABCG1) has recently been identified as a facilitator of cholesterol and phospholipid efflux from macrophages to HDL. In studies of *ABCG1*-/- versus *ABCG1*+/+ mice, total body expression of *ABCG1* protected against atherosclerosis, without affecting HDL cholesterol (HDL-C) or other lipid or lipoprotein levels. To determine the role of ABCG1 in atherogenesis in humans, we investigated the ability of a functional variant in the *ABCG1* promoter to predict risk of ischemic heart disease (IHD) in the general population. We resequenced the *ABCG1* promoter in 380 individuals with extreme levels of HDL cholesterol, and determined the ability of a new variant, g.-376C>T located in a putative SP1 binding site, to predict risk of IHD in a large prospective study of the general population, The Copenhagen City Heart Study (N=10,313, 31 years follow-up). In the prospective study, the cumulative incidence of IHD was increased in g.-376C>T heterozygotes (frequency: 0.5%) versus non-carriers (P= 0.002). The age and gender adjusted hazard ratio for IHD was 2.4 (95% confidence interval 1.5-3.9). These results for IHD were verified in an independent case-control study (N=10,585; odds ratio: 2.7 (1.4-5.0)). Genotype did not affect HDL-C or any other lipid or lipoprotein levels. Furthermore, in functional studies *in vitro* and *in vivo*, the presence of the -376T mutation completely abolished the binding of Sp1 to the *ABCG1* promoter. **Conclusion:** We have identified a loss of function mutation in the *ABCG1* promoter which reproducibly predicts a 2-3 fold risk of IHD in the general population. This is the first study to demonstrate a role for *ABCG1* in atherogenesis in humans.

## 2319/T/Poster Board #868

**Chromosome 9p21 CAD and Diabetes SNPs Identified through Genomewide Association are Associated with Different Clinical and Molecular Profiles.** *S.H. Shah[1,2], D.R. Crosslin[2], T. Wang[2], J. Johnson[2], C. Haynes[2], S. Nelson[2], D. Seo[3], W.E. Kraus[1], C.B. Granger[1], E.R. Hauser[2].* 1) Dept Medicine, Division Cardiology, Duke Univ Med Ctr, Durham, NC; 2) Center for Human Genetics, Duke University Medical Center, Durham, NC; 3) University of Miami School of Medicine, Miami, FL.

**Background.** Genomewide association studies (GWAS) in CAD and type II diabetes mellitus (DM) have identified two SNPs on chromosome 9p21 near *CDKN2a/b.* We hypothesized that they report on independent genetic effects. **Methods.** We genotyped the CAD SNP rs10757278 and the DM SNP rs10811661 in 1864 subjects ascertained through the cardiac catheterization lab and 78 human aortas. Microarray transcriptome profiling (Affy U95 chip) was performed on aortas. Chi square, linear and logistic regression models were used to compare clinical characteristics by genotype. Mixed models were used to assess correlation between expression tag and genotype. **Results.** SNPs were not in linkage disequilibrium (r2 0.003). Rs10757278 (but not rs10811661) was associated with CAD phenotypes: overall CAD (p=0.0003), 3 vessel CAD (p=0.0004), higher CAD severity as measured by CADindex (<0.0001), left main CAD (0.008), CAD family history (p=0.005), MI (p=0.05), and risk of future MI (p=0.06). Rs10811661 (but not rs10757278) was associated with DM (p=0.03). Both SNPs were associated with lower HDL (p=0.02 for both). In multivariate logistic regression variables independently associated with rs10757278 genotype were race (p<0.0001), cadindex (p=0.001), history of MI (p=0.002) and overall CAD (p=0.04). For rs10811661 race (p=0.003) and DM (p=0.0009) were independently associated with genotype. Each SNP was associated with different expression profiles. Genes most differentially expressed by rs10757278 genotype included *lamin B2* (lipodystrophy gene p=0.001); *PLA2G4C* (phospholipase catalyzing release fatty acid release p=0.006); *KLKB1* (causes prekallikrein deficiency coagulation defect p=0.007); and *BMPR2* (bone morphogenetic protein p=0.007). Transcripts most differentially expressed by rs10811661 genotype included BAIAP2 (insulin receptor tyrosine kinase substrate p= 0.0007); SREBF1 (transcription factor p=0.0007); PTGDS (glutathione independent prostaglandin D synthase p=0.001); and FLNB (filamin member may have role in GPIb$\alpha$function in endothelial cells and platelets p=0.002). **Conclusions.** In conclusion, it appears that the two SNPs identified from GWAS for CAD and DM appear to report on different clinical and molecular phenotypes. Further functional characterization of these SNPs is necessary.

## 2320/T/Poster Board #869

**Massively parallel sequencing in pediatric cardiomyopathy patients.** *S.M Ware, B. Schrand, T. Le, D.C. Jamison, P. Putnam, M. Keddache, J.A. Towbin, S. Kindel.* Cincinnati Children's Hospital and University of Cincinnati College of Medicine, Cincinnati, OH.

Cardiomyopathy is a clinically and genetically heterogeneous disease that affects the cardiomyocyte, leading to decreased ventricular systolic function, diastolic function, or both. Pediatric cardiomyopathy is a particularly malignant subset of this disease with up to 40 percent of symptomatic children progressing to transplant or death within 5 years of diagnosis. The majority of pediatric patients are affected prior to one year of age, complicating diagnosis and treatment. While descriptive measures including physical exam, echocardiogram, cardiac catheterization, and MRI offer data regarding a patient's phenotype, genetic analyses are rarely part of diagnostic protocols. Currently, very limited prevalence data exist to guide design of molecular diagnostics resulting in the majority of pediatric cases being labeled idiopathic. Nevertheless, preliminary evidence suggests that potential treatments for pediatric patients will be etiology specific, reinforcing the need for an understanding of the genetic basis of disease. Here we report the use of massively parallel sequencing to interrogate 30 genes and the mitochondrial genome in 80 patients under age ten with cardiomyopathy. Paired end high depth sequencing was performed using the Illumina Genome Analyzer. Alignment, base pair consensus calling including single nucleotide polymorphism calls, and quality scoring were performed using a novel algorithm. Results of the sequencing screen will be presented including categorization of single nucleotide polymorphism subtype, frequency, and predicted pathogenicity. We assess the relative contribution of amino acid variation in the pediatric cardiomyopathy population and compare rare variant discovery rates to those in the adult cardiomyopathy population. These results provide important information on rare and common variants in candidate genes in the pediatric cardiomyopathy population, establish baseline prevalence data, and serve as an important benchmark for the development of clinically relevant diagnostic testing.

## 2321/T/Poster Board #870

**High-resolution Microarray Analysis in Children with Conotruncal Heart Defects and Hypoplastic Left Heart Syndrome.** *D. Warburton[1], J. Kline[1,3], N. Wong[1], A. Kinney[1], V. Jobanputra[1], C-Y. Yu[1], K. Anyane-Yeboa[1], W. Chung[1], S-H. Lee[2], M. Wigler[2], M. Ronemus[2].* 1) Columbia University, New York, NY; 2) Cold Spring Harbor Laboratory, Cold Spring Harbor, NY; 3) New York State Psychiatric Institute.

We systematically ascertain all babies ≤1 month old with a conotruncal heart lesion (CNT) and all children ≤5 years old with hypoplastic left heart syndrome (HLHS) from the pediatric cardiology service of Morgan Stanley Children's Hospital of New York. Thus far, we have identified 169 patients with CNT, 90 with HLHS and 7 with both. Of completed cases, 51% were identified at birth, 38% during the prenatal period and 11% at outpatient visits. We excluded cases with complete chromosome aneuploidy or where DNA from both biological parents was not available. We included cases with known DiGeorge syndrome both as internal controls and to search for genetic variability that might be correlated with phenotype. We have enrolled 177 (73%) of contacted families. Completion of the study involves microarray analysis of the family trio, genetic and cardiac work-up of the proband, and echocardiograms of the parents. The goal of our project is to analyze a total of 350 families. To date we have performed microarray analysis of 124 trios using the Nimblegen 2.1 million platform and an analytical method developed by the team at Cold Spring Harbor Laboratory. In preliminary analyses only de novo copy number changes (CNCs) were evaluated. All 6 cases of CNT with DiGeorge syndrome were identified on the array as >2Mb deletions in 22q11.2 (8% of CNT cases). Six cases out of 118 trios without DiGeorge syndrome (5.1%) showed de novo CNCs: 1 del(1q) (8.2 Mb); 1 dup(1q) (15Mb); 1 dup(16p) (759kb); 1 del(12q) (356kb) and 2 distinct cases of del(19p) (43kb and 33 kb). All de novo CNCs contain genes with known function, including two small deletions that include only one gene each (ARID3A, GNG7). Both genes encode DNA-binding proteins believed to be important in embryogenesis. There was overlap between the large deleted and duplicated regions of 1q, but not between the two small deletions in 19p. All three patients with >1Mb CNCs had other anomalies such as absence of the corpus callosum, developmental delay and microcephaly. FISH was used to verify the larger lesions, and revealed a tandem duplication (16p) and an unbalanced translocation (1q). The rate of de novo non-DiGeorge CNCs in patients with congenital heart disease is much higher than the rate (≈1%) found in control series using the same array. Thus small CNCs contribute significantly to the etiology of CNT and HLHS. Numbers are as yet too small to determine whether the rates differ for the two anomalies.

## 2322/T/Poster Board #871

**Submicroscopic genomic aberration in fetus with congenital heart defects detected by array comparative genome hybridization.** *Y. Chen[1], W. Wang[1], Y.P. Lei[2], H.B. Cheng[1], J. Ou[1], H.Y. Wang[2], K.W. Choy[3], H. Li[1].* 1) Center for Reproduction and Ge, Nanjing Medical University Affiliated Suzhou Hospi, Suzhou, Jiangsu, China; 2) State Key Laboratory of Genetic Engineering and MOE Key Laboratory of Contemporary Anthropology, School of Life Sciences and Institutes of Biomedical Sciences, Fudan University, Shanghai, 200433, P.R. China; 3) Department of Obstetrics and Gynaecology, and Li Ka Shing Institute of Health Sciences, The Chinese University of Hong Kong, Hong Kong, P.R. China.

Background: Congenital heart defects (CHD) is the most common birth defect and affects nearly 1% of newborns. Environmental factors and genetic factors are involved in the etiology of CHD. Chromosomal imbalances and DNA copy number aberration have been identified in many forms of syndromic CHD and non-syndromic CHD. Method: One million resolution of array comparative genome hybridization (CGH) was applied in the detection of 16 karyotypic normal fetus with non-syndromic CHD. Putative chromosome copy number changes were defined by intervals of three or more adjacent probes with log2 ratios. The Quality-Weighted Interval Score algorithm (ADM2) with a value of 6.0 was used to compute and assist the identification of aberrations for a given sample. We only accept recurrent changes above the set log2 ratio in dye-flip replicates as significant changes in gain or loss of gene copy number. Results: Submicroscopic deletions and duplications, ranging in size from 0.4 to 511Mb, were detected in all the cases with CHD which are normal in G-banding karyotping. The vast majority of these are phenotypically indifferent polymorphisms without pathogenic significant according to the Database of Genomic Variants (http://projects.tcag.ca/variation/) and were not further investigated. 114 imbalances which do not coincide with common DNA copy number variants were listed as undescribed changes. Significant deletion, duplication found across the genome were analyzed further and confirmed by real-time PCR. Conclusions: Our data show that submicroscopic genomic aberration may play an important role in the etiology of these defects, either as direct causes or as genetic risk factors for CHD.

## 2323/T/Poster Board #872

**Investigating the association of Obesity with Ischemic Stroke using the FTO genotype as an Instrumental Variable.** *M.N. Cooper[1], E.J. Jamrozik[1], P.E. Norman[2], G.J. Hankey[3,4], L.J. Palmer[1].* 1) Centre for Genetic Epidemiology and Biostatistics, The University of Western Australia, WA, Australia; 2) School of Surgery, University of Western Australia, Perth, WA, Australia; 3) School of Medicine & Pharmacology, University of Western Australia, Perth, WA, Australia; 4) Stroke Unit, Department of Neurology, Royal Perth Hospital, Perth, WA, Australia.

Obesity is well recognised as a major risk factor for many common diseases including cardiovascular disease, many cancers, type two diabetes and respiratory disorders. The association between obesity and ischemic stroke (IS) remains unclear. Research to date has found both strong, moderate, and no association between obesity and IS. The Western Australian Health in Mens Study (HIMS) is a population based cohort of men aged 65-years and older (n=12,203). Stroke cases were self-reported by questionnaire and confirmed by inspection of hospital records by a stroke neurologist. Using these data, we investigated the association between obesity and IS through the use of a strongly associated instrumental variable, FTO (fat mass and obesity associated) genotype. Multivariate linear regression was used to investigate the association of FTO genotype with BMI. Logistic regression was then used in sensitivity analysis to investigate the association of BMI with self-reported stroke and confirmed IS, using FTO as an instrumental variable for BMI. Multivariate linear regression analysis was completed on data from 3,323 older men (mean age=71.4, SD 4.2). BMI was log transformed to normalise residuals. FTO (MAF=0.38) was associated with BMI (P<0.001) independent of other risk factors (age, HDL, DBP, WHR and hypertension). The F-statistic for FTO on BMI (F=11.1) was above the recommended minimum to ensure validity of use in analysis as an instrumental variable. When adjusting for known risk factors (age, history of diabetes, cholesterol and hypertension) BMI showed no association with stroke (confirmed IS P=0.65, self-reported stroke P=0.34). The association of FTO (modelled additively) as both an interaction term with BMI (P=0.31) and as a main effect term (P=0.77) yielded no significant findings with confirmed IS. Sensitivity analysis to fully investigate the existence of an association of BMI with IS included defining obesity through dichotomising BMI (≤30/>30, P=0.94), as well as categorising BMI according to WHO categories (normal <25; overweight 25-29.9; obese ≥30) as per previous publications, again yielded no significant results. Our findings show no significant association of FTO genotype or obesity with IS within this cohort of older Caucasian men and suggests that obesity is not a causal risk factor for IS. However, a causal association will only be excluded by showing, in randomised trials, that modification of obesity does not lower incidence of IS.

## 2324/T/Poster Board #873

**Association of TCF7L2 with Prospective Risk of Cardiovascular Disease.** *J. Hartiala[1,2], RM. Watanabe[1,3], ML. Brennan[4,5,6], DM. Brennan[5], SL. Hazen[4,5,6], H. Allayee[1,2].* 1) Department of Preventive Medicine, USC Keck School of Medicine, Los Angeles, CA; 2) Institute for Genetic Medicine, USC Keck School of Medicine, Los Angeles, CA; 3) Department of Physiology and Biophysics, USC Keck School of Medicine, Los Angeles, CA; 4) Department of Cell Biology, Cleveland Clinic, Cleveland, OH; 5) Department of Cardiovascular Medicine, Cleveland Clinic, Cleveland, OH; 6) Center for Cardiovascular Diagnostics and Prevention, Cleveland Clinic, Cleveland, OH.

Objective: We sought to evaluate the genetic contribution of the type 2 diabetes (T2D) susceptibility gene, transcription factor 7-like 2 gene (TCF7L2), to cardiovascular disease (CVD) and its complications. Background: CVD is a major complication for T2D patients but the role of TCF7L2, a validated T2D susceptibility gene, in the development of CVD has not been fully explored. Methods: Two TCF7L2 variants, rs12255372 and rs7903146, were genotyped in 1415 individuals ascertained through elective diagnostic coronary angiography. Multiple logistic regression analyses were used to test for association with CVD and T2D traits. Cox proportional models were used for assessing risk of experiencing incident major adverse cardiac events (MACE), including revascularization, myocardial infarction (MI), stroke, or death. Results: In a prospective analysis with the entire sample, the number of MACE in subjects carrying the GT/TT genotypes of TCF7L2 rs12255372 was significantly higher than in GG homozygotes (26% vs.17%; log-rank p=0.0001). This effect was particularly strong in impaired glucose tolerant (IGT) subjects (adjusted HR = 1.4; 95% CI, 1.1-1.7; p=0.01). Both TCF7L2 variants were also associated with T2D with an OR of ~1.5 and ~2.2 in heterozygote and homozygote carriers of the rare alleles, respectively (p < 0.00003). Conclusions: These studies extend the role of TCF7L2 to CVD complications and MACE, even within IGT subjects before the diagnosis of T2D, and add to the growing body of evidence that TCF7L2 is a validated T2D susceptibility gene. These findings may have important implications for preventive clinical management of CVD risk in individuals with IGT.

## 2325/T/Poster Board #874

**Genetic Variation at the *Proprotein Convertase Subtilisin/Kexin Type 5* Gene Modulates HDL Cholesterol Levels.** *I. Iatan[1], Z. Dastani[2], R. Do[2], D. Weissglass-Volkov[3], I. Ruel[1,2], J.C. Lee[3], A. Huertas-Vazquez[3], M.-R. Taskinen[4], A. Prat[5], N.G. Seidah[5], P. Pajukanta[3], J.C. Engert[1,2], J. Genest[1,2].* 1) Department of Biochemistry, Cardiology Division, Cardiovascular Research Laboratories, McGill University, Montreal, Quebec, H3A 1A1, Canada; 2) Department of Human Genetics, Cardiovascular Research Laboratories, Cardiology Division, McGill University, Montreal, Quebec, H3A 1A1, Canada; 3) Department of Human Genetics, David Geffen School of Medicine at UCLA, Los Angeles, CA 90095, USA; 4) Department of Medicine, Helsinki University Central Hospital, HUS-00029, Helsinki, Finland; 5) Laboratory of Biochemical Neuroendocrinology, Clinical Research Institute of Montreal, Montreal, Quebec, H2W 1R7, Canada.

A low level of plasma high-density lipoprotein cholesterol (HDL-C) is a risk factor for cardiovascular disease. HDL particles are modulated by a variety of lipases, including endothelial lipase (EL), a phospholipase present on vascular endothelial cells. The proprotein convertase subtilisin/kexin type 5 (PCSK5) is known to directly inactivate EL, and, indirectly, cleave and activate angiopoetin-like protein 3, a natural inhibitor of EL. We therefore investigated the effect of human *PCSK5* genetic variants on plasma HDL-C levels. Haplotypes at the *PCSK5* locus were examined in nine multi-generational families that included 60 individuals with HDL-C<$10^{th}$ percentile. Segregation with low HDL-C in one family was found. Sequencing of the *PCSK5* gene in 12 probands with HDL-C<$5^{th}$ percentile identified seven novel variants. Using a two-stage design, we first genotyped these single-nucleotide polymorphisms (SNPs) along with 163 tagSNPs and 12 additional SNPs (n=182 total) in 457 individuals with documented coronary artery disease. We identified nine SNPs associated with HDL-C (P<0.05), with the strongest results for rs11144782 and rs11144766 (P=0.002 and P=0.005 respectively). The SNP rs11144782 was also associated with very low-density lipoprotein (P=0.039), triglycerides (P=0.049) and total apolipoprotein B levels (P=0.022). In stage 2, we replicated the association of rs11144766 with HDL-C (P=0.014) in an independent sample of Finnish low HDL-C families. In a combined analysis of both stages (n=883), region-wide significance of rs11144766 and low HDL-C was observed (unadjusted P= $1.86 \times 10^{-4}$ and Bonferroni adjusted P=0.031). We conclude that variability at the *PCSK5* locus influences HDL-C levels, possibly through the inactivation of EL activity and consequently, atherosclerotic cardiovascular disease risk.

**Chromosome 9p21.3 Coronary Artery Disease Risk Allele alters activity of a functional regulatory element.** *O. Jarinova, P. Lau, T. Naing, R. McPherson.* University of Ottawa Heart Institute, Ottawa, Canada.

The 9p21.3 risk locus, identified in several genome-wide association studies for coronary artery disease (CAD) encompasses multiple single nucleotide polymorphisms in tight linkage disequilibrium, lies centromeric to *CDKN2A* and *CDKN2B* genes and overlaps *ANRIL*. We previously reported an upregulation of several cellular proliferation pathways as well as increased expression of short variants of *ANRIL* and reciprocally lower expression of *CDKN2A* and *CDKN2B* in subjects homozygous for the risk allele. These data suggested that the 9p21.3 risk region may contain *cis*-acting regulatory elements responsible for allele-specific gene expression differences. Using phylogenetic footprinting, we have identified four conserved non-coding sequences (CNSs) within the 9p21.3 risk locus for coronary artery disease that may contain such regulatory elements. We demonstrate that one of the CNSs, termed CNS3, has enhancer activity and that the risk variant significantly increases reporter gene expression in human primary aortic smooth muscle cells (AoSMCs). By sequencing the CNS3 regions from the reference and the risk haplotypes, we demonstrated that the observed difference in the CNS3 regulatory activity is attributable to the presence of a single nucleotide polymorphism, rs1333045, which shows strong LD with representative SNPs of the previously defined 9p21.3 risk region (r2=0.85). Moreover, rs1333045 has a similar allele frequency to that of rs1333049 in premature angiographic CAD cases and healthy elderly controls (MAFcases = 0.605 and 0.598; MAFcontrols = 0.445 and 0.441, rs1333045 and rs1333049, respectively) and a virtually identical allele specific odds ratio for CAD (OR = 1.28). Electrophoretic mobility shift assays of AoSMCs nuclear extracts indicated that CNS3 encompasses a specific transcription factor binding site and that the risk allele of rs1333045 has a lower binding affinity compared to its reference counterpart. These findings demonstrate that the 9p21.3 risk allele alters activity of at least one regulatory sequence which in turn may lead to changes in expression levels of *ANRIL* and/or other genes relevant to atherosclerosis.

## 2327/T/Poster Board #876

**Genetic variation affects the correlation patterns between t-PA and PAI-1 concentrations and traditional cardiovascular risk factors in a Ghanaian population.** *N. KODAMAN[1], F.W. ASSELBERGS[2], K.A. POKU[3], D.E. VAUGHAN[4], N.J. BROWN[4], S.M. WILLIAMS[1].* 1) HUMAN GENETICS, VANDERBILT UNIVERSITY, NASHVILLE, TN; 2) DEPARTMENT OF CARDIOLOGY, UNIVERSITY MEDICAL CENTER GRONINGEN, UNIVERSITY OF GRONINGEN, GRONINGEN, THE NETHERLANDS; 3) HUMAN SERVICES MANAGEMENT AND PUBLIC ADMINISTRATION, BUSINESS SCHOOL, UNIVERSITY OF GHANA, LEGON, GHANA; 4) DEPARTMENT OF MEDICINE, VANDERBILT UNIVERSITY, NASHVILLE, TN.

The fibrinolytic system is activated by tissue-type plasminogen activator (t-PA), which is neutralized by plasminogen activator inhibitor type 1 (PAI-1), promoting thrombus formation. The balance between plasma levels of PAI-1 and t-PA has emerged as a risk factor for cardiovascular disease. We analyzed plasma and DNA samples from a Ghanaian population to assess the relationship between t-PA and PAI-1 concentrations and several well-known cardiovascular disease-related traits (blood pressure, BMI, glucose, LDL, HDL, total cholesterol and triglyceride levels). We found significant correlations between PAI-1 and t-PA levels and many of these variables, with significant heterogeneity between sexes. We also looked at 8 loci in 5 candidate genes involved in the fibrinolytic and renin-angiotensin systems, and found that the correlations between PAI-1 and t-PA levels and the cardiovascular disease-related traits varied significantly by genotype, again with significant heterogeneity between sexes. Overall, 59 of 576 within-sex comparisons were significant at the 0.05 level; 25 of 576 tests were significant at the 0.01 level. Importantly, a similar large-scale study of a Dutch cohort found a different pattern of correlations between PAI-1 and t-PA levels and the cardiovascular disease-related traits, and no comparably significant correlations with genotype. Given the predominantly West African ancestry of African-Americans, these findings provide insight into the environmental and genetic factors that contribute to the incidence of cardiovascular disease in African-American populations, and may have clinical implications for predicting cardiovascular disease risk.

## 2328/T/Poster Board #877

**Genome-wide linkage analysis of 23 multiplex Caucasian families identifies a novel susceptibility locus on chromosome 19q13.4 for coronary artery disease.** *G.-Q. Shen[1, 2], S. Rao[1, 2], L. Li[1, 2], Q. Xi[1, 2], E.J. Topol[3], Q.K. Wang[1, 2].* 1) Center for Cardiovascular Genetics, The Cleveland Clinic, Cleveland, OH; 2) Department of Molecular Cardiology, The Cleveland Clinic, Cleveland, OH; 3) Scripps Translational Science Institute, The Scripps Clinic, La Jolla, CA.

**Background:** Coronary artery disease (CAD) is a common complex disease caused by both various genetic and environmental factors as well as their interactions with each other. It is a leading cause of death in developed countries, but the responsible genetic determinants remain unidentified. The aim of this study was to identify novel genetic locus for CAD linked to the disorder using the approach of genome-wide linkage analysis. **Methods:** A total of 281 individuals from 23 multiplex families with familial CAD enriched with well-characterized CAD cases were genotyped. The average family size was 18.5 ± 10.2 members, and the sib-ship was 113 that produced 388 sib-pairs. Genotyping was performed at the National Heart, Lung, and Blood Institute Mammalian Genotyping Facility through the use of 408 polymorphic microsatellite markers that cover the entire human geneome by an average of 10 cM. Model-free linkage analysis was performed with the modified Haseman-Elston regression model through the use of the SIBPAL program of S.A.G.E. Two genomewide scans were conducted: single-point and multipoint analyses. Empirical *P*-value was also calculated using 100,000 Monte Carlo simulations. **Results:** One novel and significant susceptibility locus was identified for CAD on chromosome 19q13.4 region, with a multi-point *pP* value ($-\log_{10}$ *P*-value) of 4.70, *P*-value of $1.53 \times 10^{-5}$ and LOD score of 4.07. These data were further verified by an empirical *P*-value of $0.99 \times 10^{-5}$ (LOD = 4.25) at the same locus, which corresponds to a genome-wide significance of $P < 0.01$. **Conclusions:** These results indicate that our present study identifies a novel genetic-susceptibility locus for CAD and provides a framework to discover novel susceptibility gene(s) for the familial CAD.

## 2329/T/Poster Board #878

**Identification of SNPs in the LDLR and APOB genes linked with premature CAD in heterozygous familial hyperlipidemia.** *N. Dzimiri[1], S. Wakil[1], M. Al-NAjai[1], B. BAz[1], P. Muiya[1], B.F. Meyer[1], M. Alshaid[2], F. Almohanna[3].* 1) Genetics, King Faisal Spec. Hospital & R, Riyadh, Saudi Arabia; 2) King Faisal Heart Institute, King Faisal Spec. Hospital & R, Riyadh, Saudi Arabia; 3) Biological and Medical Research, King Faisal Spec. Hospital & R, Riyadh, Saudi Arabia.

The underlying genetic causes of early onset of coronary artery disease (early CAD) and heterogeneous familial hypercholesterolemia (HFH) are not fully understood. We employed the Affymetrix whole genome scan 250 sty1 array to characterize possible genomic linkage to these disorders and sequencing techniques to identify related mutations in the low density lipoprotein receptor (LDLR), apolipoprotein B (APOB) and protein convertase subtilisin/kexin type 9 (PCSK9), in a Saudi family of 11 individuals with 5 siblings affected with HFH. The propositus had early CAD, very significantly elevated cholesterol (Chol) level of 10.1 mmol/L and LDL-cholesterol (LDL-C) of 7.9 mmol/L as well as low HDL-C level of 0.51 mmol/L. Whole genome scan using the autosomal dominant pattern of inheritance showed high homology for the affected individuals in several regions including chromosomes 1 and 2 which harbour PCSK9 and APOB, respectively. Subsequent sequencing of the coding areas of the APOB and LDLR identified 11 single nucleotide polymorphisms (SNPs) in the LDLR, in which the propositus uniquely carried the homozygous mutant genotypes (haplotype) for all 11 SNPs, in direct contrast to a normolipidemic sibling and a control who carried the homozygous wild type genotypes at these loci. Interestingly, all family members were heterozygous for all except the SNP rs2228671 C>T of this gene, for which the mother shared the C/C genotype with the propositus, two other affected off-springs and a control, all of whom exhibited low HDL-C levels. A confirmatory experiment involving 70 individuals harbouring low HDL-C revealed 74.3% of them as C/C carriers. Also, another set of 7 SNPs in the APOB isolated with HFH. Our study identified a haplotype in the LDLR as a marker for early onset of CAD, and rs2228671 C>T in the LDLR in association with a reduction in HDL-C concentrations in HFH. The results also substantiate the notion of genetic heterogeneity in HFH, underlining the essence of recognizing ethnic-specific gene variability as a potential basis for appropriate management of FH.

## 2330/T/Poster Board #879

**A cluster of SNPs in the apolipoprotein B region is associated with high serum apolipoprotein B levels.** *B.E. Haas[1], T. Tusié-Luna[2,3], C. Aguilar-Salinas[4], L. Riba[2,3], C.L. Plaisier[1], D. Weissglas-Volkov[1], M. Laakso[5], P. Pajukanta[1].* 1) Department of Human Genetics, David Geffen School of Medicine at UCLA, University of California, Los Angeles; 2) Molecular Biology and Genomic Medicine Unit, Instituto Nacional de Ciencias Médicas y Nutrición, Salvador Zubirán, Mexico City, Mexico; 3) Instituto de Investigaciones Biomédics de la UNAM, Mexico City, Mexico; 4) Department of Endocrinology and Metabolism, Instituto Nacional de Ciencias Médicas y Nutrición, Salvador Zubirán, Mexico City, Mexico; 5) The Department of Medicine, University of Kuopio and Kuopio University Hospital, Finland.

Coronary artery disease (CAD) is the leading cause of death worldwide. Lowering low-density lipoprotein cholesterol (LDL-C) levels has been shown to be the most effective way to prevent death due to CAD. In search of novel functional LDL-C variants, we selected SNPs found both in a meta-analysis of genome-wide association studies (GWAS) for LDL-C (Kathiresan et al. 2009) and a human liver cis-eQTL dataset (Schadt et al. 2008). We discovered that rs7575840 was one of the top SNPs identified in this comparison (GWAS rank=52; cis-eQTL rank =24). rs7575840 affects the expression of EST BU630349 in human liver. BU630349 is a predicted, primate-specific noncoding RNA, 872 bp upstream of apolipoprotein B (APOB). rs7575840 is in LD (r2>0.8) with 4 SNPs in the CEU HapMap sample: rs1367117, rs1429974, rs754523, and rs11687710. All SNPs reside in an intergenic region within 105 kb upstream of APOB except rs1367117. rs1367117 is a nonsynonymous SNP (T71I) in exon 4 of APOB with prior evidence of association with serum ApoB levels. To replicate the LDL-C association, we genotyped rs7575840 in METSIM (METabolic Syndrome In Men), a cross-sectional population cohort of 7,710 men from Finland. rs7575840 was significantly associated with LDL-C (p=1.16E-08), ApoB (p=1.80E-10), and ApoB/ApoA (p=7.64E-09) in METSIM. Furthermore, rs7575840 explains a larger ApoB variance in individuals with family history of CAD (1.46%) when compared with individuals without family history of CAD (0.42%). The variance explained in the entire METSIM sample was 0.73%. To determine whether this ApoB association replicates in non-Caucasian populations, we genotyped rs7575840 in a hyperlipidemia case-control study sample of 1376 males and females from Mexico. The same allele of rs7575840 as in Finns was significantly associated with ApoB (p=0.008) in Mexicans. To conclude, a cluster of SNPs in tight LD influences the expression of a non-coding RNA residing in the APOB region and is associated with high serum ApoB levels.

## 2331/T/Poster Board #880

**Haplotype analysis of angiotensinogen (AGT) genetic variation, plasma AGT levels, and essential hypertension.** *W.S. Watkins[1], A. Rohrwasser[1], Y. Zhang[1], W. Tolpinrud[1], A. Peiffer[1], E. Hillas[1], S.C. Hunt[2], G.H. Williams[3], M. Leppert[1], J-M. Lalouel[1], L.B Jorde[1].* 1) Department of Human Genetics, University of Utah, Salt Lake City, UT 84112, USA; 2) Department of Internal Medicine, University of Utah School of Medicine, Salt Lake City, UT 84112, USA; 3) Division of Endocrinology, Diabetes, and Hypertension, Brigham and Women's Hospital and Harvard Medical School, Boston, MA 02115, USA.

Linkage and association between the angiotensinogen (*AGT*) locus, plasma AGT levels, and hypertension have been reported in many studies but have not been replicated in some others. To better characterize the contribution of *AGT* genetic variation to plasma AGT levels and essential hypertension, we have genotyped 25 *AGT* SNPs in 426 individuals from 41 large 2-generation Utah Genomic Reference (UGRP) families. Plasma AGT is highly heritable ($h^2 = 0.68$), and males show higher heritability for plasma AGT than do females ($h^2$: 0.74 vs. 0.48). This may be due to the known interaction between *AGT* and estrogen levels. Blood pressure also shows higher heritability in male offspring than in female offspring (SBP: 0.28 vs. 0.17, DBP: 0.38 vs. 0.14). In these families, *AGT* genetic variation and the quantitative phenotype of plasma AGT are significantly linked, with a maximum LOD score of 4.4 for AGT SNP rs943580. The LOD score increased when haplotypes were used instead of single SNPs (maximum LOD of 5.5 for a haplotype denoted H4). Linkage to the quantitative traits of either systolic or diastolic blood pressure, however, was not significant in these families, which were not selected for disease status. To analyze the relationship between *AGT* and blood pressure in families selected for a hypertensive phenotype, we genotyped these SNPs in 382 individuals from the phenotypically well-characterized HyperPATH/SCOR hypertensive cohort. In hypertensives, significant associations between *AGT* SNPs and plasma AGT are found, but only under condition of sodium depletion ($p < 0.01$). Six common haplotypes (frequencies > 0.05), identical to those identified in the UGRP cohort, were identified. Hypertensives with haplotype H4 -- containing the known functional promoter allele -6A -- have higher plasma AGT levels ($p < 0.003$) and reduced renal plasma flow ($p < 0.0002$). Haplotype H4 is more common in hypertensive cases than in normotensive controls ($p < 0.054$), and haplotype group H1/H2 is more common in controls than hypertensive cases ($p < 0.030$). Thus, in two independent study populations, the same *AGT* haplotypes are linked or associated with plasma AGT levels (and hypertension in one cohort), and they provide more information than do single SNPs alone. Additionally, the association between *AGT* genetic variation and plasma AGT is stronger under conditions of sodium depletion, helping to explain previous conflicting linkage and association results.

**Mutations in Smooth Muscle Myosin Heavy Chain (MYH11) in Coronary Artery Disease, Stroke, and Moyamoya Disease: Evidence for a Common Pathogenesis for Arterial Diseases.** *H. Pannu[1], S.E. Scherer[2], L. Gong[1], E. Regalado[1], N. Avidan[1], D. Guo[1], J. Grotta[1], A.J. Marian[3], E. Boerwinkle[4], J. Grotta[5], S. Shete[6], G. Steinberg[7], D.M. Milewicz[1].* 1) Department of Internal Medicine, University of Texas Health Science Center at Houston, Houston, TX 77030; 2) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX 77030; 3) Center for Cardiovascular Genetic Research, Brown Foundation Institute of Molecular Medicine, Texas Heart Institute at St. Luke's Episcopal Hospital, Houston, TX 77030; 4) Human Genetics Center and Institute for Molecular Medicine, University of Texas Health Science Center at Houston, Houston, TX 77030; 5) Department of Neurology, University of Texas Health Science Center at Houston, Houston, TX 77030; 6) Department of Epidemiology, University of Texas M.D.Anderson Cancer Center, Houston, TX 77030; 7) Department of Neurosurgery and Stanford Stroke Center, Stanford University School of Medicine, Stanford, CA 94305.

Genome-wide association studies (GWAS) have indicated that common variants on chromosome 9p can predispose individuals to a variety of vascular diseases (coronary artery disease, strokes, and abdominal aortic aneurysms), suggesting a common vascular disease pathogenesis. We have previously demonstrated that mutations in the smooth muscle specific isoform of β-myosin heavy chain (MYH11) cause thoracic aortic aneurysms, but we also noted other premature occlusive vascular diseases in MYH11 mutation carriers. MYH11 resequencing was performed in DNA from 669 patients with early onset coronary artery disease (216), early onset stroke (271), and Moyamoya disease (182), along with 188 controls, to determine if novel, non-synonymous variants were more common in DNA from patients with premature occlusive disease than in controls. We identified rare, novel, and non-synonymous MYH11 variants in all three vascular disease cohorts sequenced, but failed to identify these variants in the control group. Analyzing the effects of the rare MYH11 variants on the structure and biochemical function of MYH11 supports causality of these MYH11 mutations for CAD, stroke and MMD. These analyses, along with GWAS studies of vascular diseases, imply a need for a change in the approaches to identifying genetic predisposition and molecular pathways for vascular diseases, viewing the vascular system as a unified disease entity, and not categorizing diseases exclusively on the basis of the vascular bed affected.

## 2333/T/Poster Board #882

**Relationship of rs4420638 in the *APOE/C1/C4/C2* locus to coronary artery disease.** *SS. Bhatia, RW. Davies, R. McPherson.* Ottawa Heart Institute, Ottawa, Ontario, Canada.

**Background:** Genome-wide association studies have reported a significant effect of rs4420638 in the 19q13.2 *APOE/C1/C4* gene cluster to plasma lipid traits and CAD risk. This has been attributed to linkage disequilibrium (LD) with the *APOE* single nucleotide polymorphisms (SNPs) rs7412 and rs429358 which give rise to 3 apoE variants E2, E3 and E4. However in a recent meta-analysis E4 was associated with CAD risk with an odds ratio of 1.06 whereas E2 showed a protective effect (OR 0.8) (JAMA2007;298:1300-11). In contrast rs4420638 lies 3' of *APOC1* and has a reported OR for CAD of 1.17 (NatGen2008;40:161-9) and is in partial LD with rs429358 (r2=0.70). The minor allele frequency of rs4420638 is 0.18 versus 0.14 for rs429358 and 0.07 for rs7412. We tested the hypothesis that the effect of rs4420638 on CAD risk is in part independent of rs429358 and rs7412. **Methods:** The above SNPs were genotyped using standard sequencing methods in 600 CAD patients and 1600 healthy control subjects enrolled in the Ottawa Heart Study (OHS). Additional SNPs in the region lie within enhancer sites (rs483082, rs3513657) the *APOE* gene (rs769449, rs769450) and non-coding regions (rs445925) and were similarly genotyped. Genotypes for rs4420638 were obtained using the Affymetrix 6.0 array. Plasma concentrations of apoE and apoC1 were determined by ELISA. **Results:** In the OHS population rs429358 and rs4420638 (r2=0.71) and rs429358 and an intronic *APOE* SNP rs769449 (r2=0.81) were in moderate LD. The strongest D' values were amongst the *APOE* SNPs and rs4420638 at 1.0. Other SNPs showed weak LD to the *APOE* SNPs and rs4420638. Haplotype analysis demonstrated a stronger association of rs429358 with CAD as compared to rs4420638; the frequency of individuals bearing risk alleles for both SNPs was 0.17 for cases and 0.11 for controls. Carrier status for both rs4420638 risk and rs429358 reference alleles was 0.036 in cases and 0.042 in controls. Thus the minor allele of rs429358 tends to confer a greater CAD risk than does the minor allele of rs4420638. Plasma apoE but not apoC1 concentrations were associated with rs429358; CC: 13ug/ml; CT: 90ug/ml; TT: 149ug/ml (n=20; p=0.0009). Similar results were obtained for rs4420638. **Conclusions:** The relationship of rs4420638 to CAD risk is explained by LD with rs429358 and is not due to linkage with other common SNPs in the same locus. Both rs429358 and rs4420638 are associated with altered plasma concentrations of apoE.

## 2334/T/Poster Board #883

**Searching for a gene on chromosome 18q influencing systolic blood pressure in Mexican Americans.** *S. Rutherford[1], V.S. Voruganti[2], K. Haack[2], J.W. MacCluer[2], L. Griffiths[3], J. Blangero[2], A.G. Comuzzie[2], S.A. Cole[2].* 1) Dept of Anthropology, Penn State University, University Park, PA; 2) Dept of Genetics, Southwest Foundation for Biomedical Research, San Antonio, TX; 3) Griffith Institute for Health and Medical Research, Griffith University, Gold Coast Australia.

Since the etiology of hypertension begins several years before its clinical manifestation, it is important to identify the factors that are likely to have an early influence on blood pressure determination. We conducted genome wide scans on blood pressure phenotypes in Mexican American families from the San Antonio Family Heart Study (SAFHS) and in Australian Caucasian hypertensive sib pairs. Results from both studies identified a single region on chromosome 18q showing involvement with hypertension (LOD = 3.69; p = 0.00002, in Australian sibpairs) and systolic blood pressure (LOD = 2.09; p = 0.00096, in the SAFHS). Eight other studies also report modest evidence for linkage of blood pressure and/or hypertension within 20Mb of this chromosome 18q region. We hypothesize that this chromosome 18q region contains one or more polymorphic variants that account for hypertension in the Australian Caucasians and for the systolic blood pressure variation that we observe in our Mexican American participants. Advances in high-throughput genotyping, single nucleotide polymorphism (SNP) discovery, and haplotype map (HapMap) construction provide an unprecedented opportunity for comprehensive genetic analysis. We searched the 1-LOD score interval (a 19Mb region) and identified SNPs located in a microRNA (miRNA) locus (hsa-mir-122a) and a number of blood pressure and hypertension candidate genes such as *NEDD4L* and *MC4R*. We genotyped 480 SNPs using an Illumina BeadXpress instrument and conducted association analysis to explore the causative role these variants may play in affecting blood pressure related phenotypes. In an analysis of 24 SNPs, suggestive association (p = 0.02-0.046) between 2 SNPs in *NEDD4L* and systolic blood pressure was observed in our Mexican American participants. NEDD4L regulates the amiloride-sensitive epithelial sodium channels (ENaC) and is a key regulator of sodium reabsorption in the distal nephron. A functional SNP located in exon 1 of *NEDD4L* is known to result in premature truncation of a NEDD4L protein leading to a transcript that encodes a nonfunctional protein. Further analysis is needed to determine the role of the *NEDD4L* variants and the chromosome 18q region in systolic blood pressure regulation.

## 2335/T/Poster Board #884

**Transcriptional regulation of *MMAB* at a locus associated with HDL-C level.** *M.P. Fogarty[1], S. Bellendir[2], K.J. Gaulton[1,2], G.E. Crawford[3], T.S. Furey[3], J.D. Lieb[4], K.L. Mohlke[1].* 1) Department of Genetics, University of North Carolina, Chapel Hill, NC; 2) Curriculum in Genetics and Molecular Biology, University of North Carolina, Chapel Hill, NC; 3) Institute for Genome Sciences and Policy, Duke University, Durham, NC; 4) Department of Biology, University of North Carolina, Chapel Hill, NC.

Genome wide association studies have identified a locus associated with HDL-C levels that spans a 175 kb region and contains ≥ 70 strongly associated common SNPs, many of which are located in non-coding regions suggesting a possible regulatory effect on transcription. Using human hepatocytes, we recently observed allelic expression imbalance in only one of four genes at the locus, *MMAB* ($P$=1.4 × $10^{-13}$). We also demonstrated that SNPs associated with decreased HDL-C level were associated with increased *MMAB* mRNA and protein level ($P_{mRNA}$=.0081; $P_{protein}$=.002), suggesting *MMAB* as the most likely target of an HDL-C-associated SNP at this locus. We aim to identify the underlying functional SNP(s) affecting *MMAB* and ultimately to determine how variation in *MMAB* gene expression may affect HDL-C level. Given the evidence of *cis*-acting variation in *MMAB* expression, we hypothesize that the functional variant(s) is likely to have a modest effect on synthesis or stability of the mRNA transcript. For evaluation of transcriptional activity affecting mRNA synthesis, we first prioritized the HDL-C-associated SNPs using datasets that characterize potential regulatory elements including evidence of open chromatin in human hepatocyte-derived cell line HepG2, histone modifications, predicted transcription factor binding and sequence conservation. We identified four highly prioritized SNPs that were also predicted to alter transcription factor binding in an allele-specific manner. Regions of 200 bp surrounding each SNP were cloned into luciferase-reporter vectors and allele-specific transcriptional activity was assessed. Initial results in the HepG2 cell line demonstrated increased transcriptional activity for both alleles of rs1558804 ($P$= 1.0 x $10^{-4}$, ANOVA) compared to a control vector. Additionally, a significant differential allele-specific change in transcriptional activity was observed ($P$ = 8.2 x $10^{-5}$, t-test). These results demonstrate that rs1558804 has enhancer activity and that alleles of rs1558804 may differentially modulate transcription; protein-DNA interactions are currently being assessed. Additional studies will also evaluate HDL-C-associated SNPs in the 3'UTR of *MMAB* that may act to affect mRNA stability. Identification of a functional regulatory SNP would provide insight into the basis of *cis*-acting variation at this locus and may facilitate understanding of how *MMAB* may regulate HDL-C levels.

## 2336/T/Poster Board #885

**Restrictive cardiomyopathy due to multiple mutations in sarcomeric genes usually associated with a hypertrophic phenotype.** *C. Brown[1,2], R. Sakhuja[3], N. Schiller[3], R. Nussbaum[1,2], J.E. Rame[1,3,4].* 1) Program in Cardiovascular Genetics, UCSF, San Francisco, CA; 2) Division of Medical Genetics, UCSF, San Francisco, CA; 3) Division of Cardiology, UCSF, San Francisco, CA; 4) Heart Failure Evaluation and Treatment Center, UCSF, San Francisco, CA.

Mutations in genes that encode components of the sarcomere are well established as the primary cause of hypertrophic cardiomyopathy. It has increasingly been recognized that mutations in sarcomeric genes may present with extensive variable expressivity, causing a range of cardiomyopathy phenotypes. One phenotype recently recognized as a primary sarcomeric disease is restrictive cardiomyopathy, with as many as half of such cases being caused by mutations in sarcomeric genes. We report two cases of restrictive cardiomyopathy caused by multiple mutations in sarcomeric genes.

Case 1 presented with NYHA Class III/IV heart failure at 22 years of age. She was diagnosed with restrictive cardiomyopathy and advanced heart failure requiring heart transplantation. Sequencing of 8 sarcomeric genes revealed homozygous Glu143Lys mutations in *MYL3*, and a novel Gly57Glu mutation in *MYL2*. The patient's mother is a double heterozygote for these two mutations and had a normal echocardiogram and electrocardiogram at 45 years of age. This is the first reported case of three sarcomeric mutations in a primary cardiomyopathy and the first *MYL2* mutation associated with restrictive cardiomyopathy. Case 2 presented at 35 years of age with volume overload while hospitalized for oophorectomy. She was later diagnosed with restrictive cardiomyopathy. She is currently being evaluated for heart transplant. Sarcomeric gene sequencing identified homozygous Asn279His mutations in *TPM1*. The patient's parents are consanguineous and both have echocardiographic evidence of mild cardiomyopathy, suggesting an incomplete dominant pattern of inheritance. While *TPM1* has been reported in cases of hypertrophic and dilated cardiomyopathy, mutations in this gene have not previously been associated with a restrictive phenotype.

The identification of mutations in sarcomeric genes not previously implicated in restrictive cardiomyopathy further supports the notion that sarcomeric mutations can cause different cardiomyopathy phenotypes and challenges the distinction of hypertrophic and restrictive phenotypes as distinct cardiomyopathies. These cases also suggest that restrictive cardiomyopathy may be more severe in patients with multiple mutations as compared to those with only one mutation, as has already been noted in families with hypertrophic cardiomyopathy.

## 2337/T/Poster Board #886

**Concealed Brugada Syndrome in a Long QT Syndrome family with the L1785Q mutation in SCN5A.** *P.L. Hedley[1], M. Christiansen[1], P.E.B Thomsen[2], M. Grunnet[3], T. Jespersen[3], J.K Kanters[2,3].* 1) Statens Serum Institut, Copenhagen, Copenhagen, Denmark; 2) Gentofte Hospital, Gentofte, Denmark; 3) University of Copenhagen, Copenhagen, Denmark.

Mutations in SCN5A, encoding the cardiac sodium channel Nav1.5, can result in several cardiac disorders including long QT syndrome (LQTS) type 3 (LQT3) and Brugada syndrome (BrS). The pivotal criterion for LQTS diagnosis is a prolonged QT interval, as measured by electrocardiogram (ECG). A prerequisite for a BrS diagnosis is ST segment elevation in the right precordial leads of the ECG. Both LQTS and BrS can cause sudden death. However, BrS patients are more often treated with an intracardiac defibrillator (ICD). We describe the genetic cause of disease in a patient with apparent LQTS in whom flecainide administration uncovered a type 1 ST segment elevation pattern. We subsequently characterize the mutant functionally. In a Danish LQTS family, where the proband had presented with an aborted cardiac arrest and a family history of sudden death, a mutation in SCN5A (c.5354T>A; p.L1785Q) was found. The mutation affects the c-terminal region of the protein; one other BrS-involving-complex-phenotype mutation has been identified in this region (p.E1784K). Additionally, two BrS-involving-complex-phenotype mutations (p.1500delK and p.1505_1507delKPQ) have been identified. Electrophysiological analysis was performed using HEK293 cells transiently transfected with Nav1.5-WT or Nav1.5-L1785Q. The mutant revealed a reduced peak current, a negative shift in inactivation properties and a positive shift in activation properties, compatible with BrS. Furthermore, blocking the sodium channel with TTX revealed a drastic increase in the sustained (INa,late), explaining the LQTS phenotype. The ECGs of the three gene carriers in this family indicate a clear QT prolongation with no ST segment elevation; however, flecainide administration revealed a type 1 ST segment elevation. Electrophysiological experiments of the mutant revealed functional characteristics explaining the two different phenotypes. Based on this study we hypothesize that a number of LQT3 patients may be affected by concealed BrS, which may indicate the use of an ICD. As there is no direct link between the location of SCN5A mutations and the clinical phenotype, the presence of a concealed BrS phenotype must always be suspected in SCN5A mutation carriers. However, the clinical prognosis of SCN5A mutation-carriers with combined LQTS and BrS phenotypes needs further investigation.

## 2338/T/Poster Board #887

**Control of VEGF Activity by CRELD1 as a Mechanism in the Cause of Cardiac Atrioventricular Septal Defects.** *C.L. Maslen, J. Redig, D. Babcock, B. Reshey, G.T. Fouad.* Cardiovascular Med, Oregon Hlth & Sci Univ, Portland, OR.

Vascular endothelial growth factor (VEGF) regulates endothelial cell growth and migration and plays a key role in heart development in the formation of endocardial cushions, the precursors to the atrioventricular (AV) valves and septa. Failure of AV cushion development results in the congenital heart defect known as an atrioventricular septal defect (AVSD). Increased expression of VEGF has been shown to interfere with AV endocardial cushion morphogenesis. A functional *VEGF* polymorphism -634G/C is associated with altered VEGF expression suggesting that this variant may modify susceptibility for AVSD. Using a case-control study we demonstrated that individuals with AVSD are more likely to carry the high expressing -634C allele than controls ($p$=0.0012). Missense mutations of *CRELD1* are also associated with AVSD, but are incompletely penetrant. Stratification of our AVSD cohort by *CRELD1* mutation revealed a specific association between *CRELD1* mutations and the *VEGF* -634C allele suggesting a causative interaction. From this we hypothesized that increased VEGF expression in combination with CRELD1-deficiency impairs atrioventricular endocardial cushion formation leading to AVSD. To test this hypothesis AV canals from Creld1$^{+/+}$, Creld1$^{+/-}$ and Creld1$^{-/-}$ mice were explanted, cultured and subjected to increased VEGF (200pg/ml) to mimic the over-expression associated with the -634C allele. Migration of stellate-shaped cells from the canals were tallied 48, 72 and 96 hours after explantation as a measure of epithelial to mesenchymal transformation, a critical step in endocardial cushion formation. We found that under endogenous levels of VEGF the cell counts from Creld1$^{+/-}$, Creld1$^{-/-}$ and Creld1$^{+/+}$ explants were indistinguishable at all time points (n>6); at 96 hours 256±119, 245±193 and 217±122 cells were observed respectively. However, when VEGF was added the Creld1$^{+/-}$ and Creld1$^{-/-}$ explants exhibited significantly higher numbers of cells than the Creld1$^{+/+}$ explants at both 72 hours and 96 hours ($p$<0.05, n>5) with 377± 76, 356± 62 and 221± 113 cells, respectively. This data demonstrates that Creld1-deficient epithelial cells from developing endocardial cushions have an enhanced response to small increases in VEGF. The hyper-reactivity of Creld1-deficient cells to VEGF indicates that CRELD1 is responsible for controlling cell response to VEGF. This interaction between CRELD1 and VEGF may explain the developmental origins of a subset of sporadic AVSD cases.

## 2339/T/Poster Board #888

**Endothelial nitric oxide synthase (eNOS) VNTR polymorphism and premature infants with maternal pregnancy induced hypertension (PIH).** *S. Ursin[1], J.G. Aryama[1], K. Yanamandra[1], H. Chen[1], A. Pramanik[1], J.A. Bocchini Jr.[1], R. Dhanireddy[2].* 1) Pediatrics, Gen Sec, LSUHSC- Shreveport, Shreveport, LA; 2) Dept Pediatrics, UT Health Science Center, Memphis, TN.

Endothelial nitric oxide (eNO) serves as a vasodilator, relaxes smooth muscle, prevents platelet aggregation, and facilitates improved blood flow, leading to vascular homeostasis. Reduced nitric oxide levels result in vasoconstriction and weak tone leading to decreased blood flow and hypoxia. Mutant eNO synthetase (eNOS) genotypes result in reduced nitric oxide levels by decreasing the enzyme activity. Pregnancy induced hypertension (PIH) has a multifactorial etiology. Mutant ENOS genotypes in the mother have been evaluated as risk factors for preeclampsia. However, eNOS genotypes were not studied in the infants with maternal PIH except from our laboratory. The aim of the present investigation was to seek how the fetal genotypes influence maternal circulation during pregnancy. In the present investigation we have studied the association of eNOS variable number of tandem repeats (VNTR) of 27bp in intron 4 region of the gene. We have collected peripheral blood specimens from a total of 173 premature infants consecutively from our NICU facility and genotyped by PCR. Our earlier findings in the study of eNOS genotypes in the promoter region have shown an elevation of -786C mutant alleles resulting in lower nitric oxide levels in infants with maternal PIH as compared to controls. However, in the present study the frequency of rear allele *a* consisting of 4 repeats was not elevated in patients as compared to controls (0.09 vs. 0.14, odds ratio 0.6) contrary to the expectations. Thus we speculate that the mutant genotype in promoter region of eNOS gene has a stronger role in premature infants with maternal PIH compared to the intron 4 VNTR genotype. Clinical data of the infants from NICU with ethnic stratification and distribution of alleles and genotypes and their significance will be presented.

**Distinct hypertrophic and survival pathways for IGF-1 and ANG II.** *A. Zhao, R. Duan, Z. Alvin, G.E. Haddad.* Physiology & Biophysics, Howard University, Washington, DC.

Cardiac hypertrophy is a compensatory mechanism for increased workload on the heart, which progresses into failure if not alleviated. Signaling pathways that regulate apoptosis may play a pivotal role in heart failure. We hypothesize that the signaling pathways related to the hypertrophic effects of IGF-I are distinct from those for its survival benefit. We have examined the role of PI 3-kinase and Akt on primary cardiocytes in in vitro models of cardiocyte apoptosis. Adenoviral vectors were used to express wild-type and mutant-forms of specific signaling molecules in cardiocytes. Performing qRT-PCR, we have found that treatment of cultured cardiomyocytes with IGF-1 had a biphasic response on Akt gene expression, with an increase at 30 min, 24h, 48h but a decrease at 2h. In addition, the gene expression profile with wild-type Akt and Ad-BD110 (constitutively active Akt) transfections translated into higher total Akt content as well as higher Akt activation (phosphorylated Akt to total Akt ratio), as measured by western blot. Incubation and transfection of cultured neonatal cardiomyocytes with IGF-1, wild-type Akt (Ad-Akt) or dominant positive PI 3-kinase (Ad-BD110) induced cellular hypertrophy within 24 hours using fluoroimmunoassay based BrdU incorporation (DELFIA, Perkin Elmer). Ad-BD110 transfection had lesser cellular hypertrophic effect than IGF-1. Wild-type Akt did not produce significant cellular hypertrophy on its own; however, when stimulated with IGF-1 it did. As a positive control, incubation with angiotensin II (ANG II) induced cellular hypertrophy, which seems to be independent from the PI-3K/Akt signaling as well. Addition of IGF-1 or Ad-BD110 in presence of ANG II produced a greater hypertrophic effect than ANG II alone. In addition, ANG II treatment showed a significant increase in ERK1/2 gene expression but a much smaller effect on that of Akt. On the other hand, ANG II and IGF-1 induced ERK1/2 activation, in an additive manner. Our results suggest that the IGF-1/PI3 K/Akt pathway plays an important role in cardiomyocyte survival. Un-stimulated Akt does not convey cardiocyte survival benefits. However, IGF-1 induces Akt-dependent and Akt-independent (ERK1/2) downstream effectors for enhancing cardiocyte survival. ANG II survival benefits are due to its hypertrophic effects and not to anti-apoptotic ones. However, IGF-1 survival benefits are due to the activation of both hypertrophic and anti-apoptotic pathways.

**Genetic Counselling for Inherited Cardiovascular Conditions: A Comparison between Wales (UK), North American Practice and Australia.** *M.C. Nicol[1], D. Kumar[1], A. Clarke[1], M. Care[2], C. Morel[2], I. Macciocca[3].* 1) Institute of Medical Genetics, University Hospital of Wales, CF14 4XW, Wales, United Kingdom; 2) Department of Medicine, The Fred Litwin Family Centre in Genetic Medicine, University Health Network & Mount Sinai Hospital Toronto Canada; 3) Victoria Clinical Genetics Services, Murdoch Children's Research Hospital Melbourne Australia.

Abstract The National Service Framework (NSF) for Coronary Heart Disease in England sets out quality requirements, criteria and systems needed to provide diagnosis, treatment, information and support to families affected by sudden cardiac death (SCD). The chapter 8 of NSF (Standard 5 for Wales NSF) includes recommendations for inherited cardiovascular conditions (ICCs) presenting with SCD. In Wales and other parts of the UK there is evidence of a fragmented approach in meeting the NSF recommendations. Continuing progress in cardiac genetics research and increased awareness among clinicians of the possibilities of genetic testing are leading to rapidly increasing rates of clinical referral and requests for molecular diagnostic testing. Such demands prevent the stabilisation of care pathways, especially in the context of inadequate funding and underdeveloped service infrastructure. In addition to health professionals, Police and Coroners, are often the first people dealing with the bereaved family coping with SCD. This often causes delay in referring families to cardiology and genetic services. A comparison of services in Wales, Melbourne and Toronto has identified aspects of good clinical practice that can guide the development of cardiovascular genetic services. Several of these must be implemented through the coroners' system: * Establishing a cardiac genetics service led by cardiologists and supported by clinical geneticists and genetic counsellors; * Referral of retained organs for specialist cardiac pathology from a coroner's autopsy when no diagnosis has emerged and sudden cardiac death is a possibility; * Information given by the coroner to the bereaved family about the possibility of referral to cardiac genetics; * Information shared by the coroner to the clinical geneticist for autopsy review which can guide differential diagnosis; * Storage of frozen blood by coroner's office to facilitate genetic testing on the proband once the autopsy has been reviewed; * Information given to the family physician of the bereaved, suggesting referral for cardiac genetic assessment; This should enable direct referral of SCD families into a multi-disciplinary cardiovascular genetic network intended to support families and answer their questions, avoid delay in screening 'at-risk' relatives and to coordinate the management of family members in the most effective manner.

## 2342/T/Poster Board #891

**Oligogenic inheritance and clinical variability in long QT syndrome.** *J. Dean[1], D. Walker[1], C. Clark[1], K. Kelly[1], C. Brown[1], W. Lam[2], V. Murday[3], D. Goudie[4], A. Choy[4].* 1) Department of Medical Genetics, Argyll House, Aberdeen, United Kingdom; 2) South East Scotland Regional Genetics Service, Western General Hospital, Edinburgh; 3) West of Scotland Regional Genetics Service, Yorkhill Hospital, Glasgow; 4) University of Dundee, Ninewells Hospital, Dundee.

In Scotland, patients with a personal or family history of familial arrhythmia (e.g. Long QT syndrome (LQTS), Arrhythmogenic Right Ventricular Cardiomyopathy (ARVC)) access clinical risk assessment, genetic counselling and genetic testing through the Familial Arrhythmia Network Scotland, a managed clinical network of cardiologists, pathologists and clinical and laboratory geneticists set up in 2008. In probands with suspected LQTS, KCNQ1, KCNH2, SCN5A, KCNE1 and KCNE2 are screened in Aberdeen. For Brugada syndrome, SCN5A is screened, and in ARVC, PKP2. 123 probands with suspected LQTS, 12 with suspected Brugada syndrome and 24 with ARVC were assessed. Mutations were detected in 43% of LQTS, 16% of Brugada, and 16% of ARVC cases. In LQTS, 24% had KCNQ1, 17% KCNH2 and 2% SCN5A mutations. No mutations in KCNE1 or KCNE2 were detected. Ten LQTS probands had 2 mutations - six had Jervell Lange Neilsen syndrome clinically. The other 4, (3 with 2 mutations in KCNQ1 and 1 with a KCNQ1 and a KCNH2 mutation) had normal hearing. Probands with two mutations had longer QTc's on resting ECG and earlier age of onset than probands with one mutation. Initially, our genetic screening program prioritised the gene to be tested based on clinical features (T wave morphology, precipitants of arrhythmia). The high frequency of multiple mutation detection in apparently autosomal dominant LQTS (4/54, 7%) suggests that parental ECGs do not reliably disclose the parental origin of apparently dominant LQTS, and that all five LQTS genes should be screened in all probands, regardless of clinical presentation. This unexpected oligogenic aetiology of more severely affected probands from apparently dominant LQTS families who have more mildly affected heterozygous relatives may provide one explanation for the well known clinical variability of LQTS.

## 2343/T/Poster Board #892

**Digenic mutations in *FBN1* and *TGFBR2* contribute to Marfan syndrome.** *Y. Fan[1], M. Steinraths[2], B.A. Westerfield[1], J.J. Varela[1], L.S. Pena[1], M. Vatta[1], R.A. Friedman[1].* 1) John Welsh Cardiovascular Diagnostic Laboratory, Section of Cardiology, Department of Pediatrics, Texas Children's Hospital, Baylor College of Medicine, Houston, TX; 2) Vancouver Island Medical Genetics, Victoria General Hospital, 1 Hospital Way, Victoria BC, Canada.

Marfan syndrome (MFS) is an autosomal dominant connective tissue disorder characterized by variable manifestations mainly in three major organ systems including skeletal, ocular, and cardiovascular involvement. Multiple mutations in the genes encoding fibrillin-1 (FBN1) at 15q21.1 and transforming growth factor beta receptor type II (TGFBR2) at 3p22 were found to cause MFS type 1 (MFS1) in 1991 and type 2 (MFS2) in 2004 respectively. FBN1 is an extracellular matrix glycoprotein that is the main component of the calcium-binding microfibrils while TGFBR2 is a transmembrane protein that forms a heterodimeric complex with TGFBR1 and binds TGF-beta. However, digenic MFS has not previously been reported. We report a European Caucasian family in which the 15-year-old female proband presented with tall stature, arachnodactyly, scoliosis, dilatation of the aortic root, mitral valve prolapse and superior lens subluxations. She is developmentally normal with a broad, single uvula and her interpupillary distance measures at the 75th percentile for her age. A previously reported heterozygous missense mutation 4096G>A (E1366K) in exon 33 of the *FBN1* gene and a new heterozygous missense variant of unknown significance 310C>A (P104T) in exon 3 of the *TGFBR2* gene were identified in the proband through direct sequencing. Parental testing demonstrated both sequence variations to be de novo in the proband. Bioinformatics analysis of the TGFBR2 sequence variation using BlastP, ClustalW 1.8, PANTHER and PolyPhen revealed that the proline at amino acid position 104 is highly conserved across species from human to *Xenopus laevis* and the variant P104T is predicted to be pathogenic. Most importantly, this variant was not detected in 188 normal ethnically-matched control chromosomes. Based on the family study, in silico analysis and the control study, we conclude that the *TGFBR2* variant P104T identified in this individual is a disease causing mutation. Identification of digenic mutations in MFS provides direct evidence of the functional association between FBN1 and TGF-beta signaling in extracellular matrix in humans, supporting a synergistic effect of FBN1 and TGFBR2 in the pathogenesis of MFS, and indicating that the presence of mutations in one gene should not exclude screening for further genetic variation. This finding suggests that innovative anti-TGF-beta therapeutic strategies such as losartan might play an important role in the treatment of MFS and related disorders.

## 2344/T/Poster Board #893

**Next-Generation-Diagnostics of heterogeneous monogenic disorders using High-Throughput-Sequencing: the promising example of Hypertrophic Cardiomyopathy.** *S. Fokstuen[1], C. Iseli[2,3], D. Robyr[4], A. Munoz[4], S.E. Antonarakis[1,4], J.L. Blouin[1].* 1) Genetic Medicine, University Hospitals Geneva, Geneva, Switzerland; 2) Ludwig Institute for Cancer Research, Lausanne, Switzerland; 3) Swiss Institute of Bioinformatics, Lausanne, Switzerland; 4) Genetic Medicine and Development, University of Geneva School of Medicine, Geneva, Switzerland.

With a prevalence of 1/500, Hypertrophic Cardiomyopathy (HCM) represents the most common monogenic cardiac disorder (autosomal dominant inheritance), and is also considered the primary cause of sudden cardiac death in young adults. HCM shows a remarkable genetic and allelic heterogeneity (> 550 mutations in at least 22 genes identified so far). Molecular testing for HCM has a growing impact on the medical management of patients/families. To overcome the extensive genetic heterogeneity we have developed a 30 Kbp microarray to resequence all exons (n=160), splice-sites and 5'-UTR of 12 HCM genes (HCM-RA, Fokstuen et al. 2008). This method is now used as a diagnostic tool in our clinical practice. It is very rapid and cost-effective but does not yet detect small indels (~14% of all known HCM mutations). Moreover, HCM-RA lacks flexibility as the addition of new genes requires a new design. In order to solve these shortcomings, we now analyze the 12 HCM array genes (targeted by multi-exonic amplicons) by short single and paired-end reads of High-Throughput-Sequencing (HTS) and a newly developed downstream data analysis pipeline. Mutations/variants are confirmed by classical sequencing. We initially reanalyzed the DNA of 19 patients previously hybridized by the HCM-RA (11 without identified mutations, 8 positive-controls as a composite-pool) in one lane of Illumina Genome-Analyzer flow cell. All 8 known positive control mutations and SNPs previously identified by the HCM-RA were also found by HTS. Furthermore we identified novel variants: two indels and a nonsense mutation in MYBPC3. In order to further explore the practical feasibility of HTS for diagnostic mutation analysis, we tried different options for optimal cost-effectiveness in clinical practice : resequencing of a single patient or pooling of 2-5 patients in one lane. Additional known mutations, like p.Tyr842X in MYBPC3, were found as well as further potentially pathogenic variants, which are still in evaluation. Although improvements are still needed in target enrichment, reduction of false positive variants and data analysis, HTS holds considerable promises for mutation/variant analysis of highly heterogeneous monogenic disorders in clinical practice.

## 2345/T/Poster Board #894

**Akt-dependent regulation of potassium channels by IGF-1 in cardiomyocytes.** *G.E. HADDAD, Z. Alvin, R. Duan, A. Zhao.* Physiology & Biophysics, Howard University, Washington, DC.

Pathological dysregulation of the repolarization of the cardiac action potential is associated with ventricular dysfunction and cardiac arrhythmias. The delayed outward rectifier current (IK), the major ion channel responsible for the ventricular repolarization, can be modulated by inotropic and trophic hormones, such as IGF-1. Due to its known anti-apoptotic effects, IGF-1 can play a critical survival role during heart failure. The aim of this work was to assess the regulation of IK by the cell-survival pathway, IGF-1/PI3 K/Akt, in freshly isolated neonatal rat ventricular myocytes, using patch-clamp technique in whole-cell configuration. Adenoviral vectors were used to express wild-type and mutant-forms of specific signaling molecules in cardiocytes. Cells were stimulated from a holding potential of -40mV, by 500msec, 10-mV step voltages to +40mV. IGF-1 reduced the functional density of IK from 4.1 ± 0.5 pA/pF to 2.6 ± 0.3 pA/pF. IGF-1 effect was eliminated by the PI3 Kinase inhibitor, LY294002 (3μM). Adenoviral transfection of cardiocytes with a constitutively activated PI3 Kinase, Ad.BD110, mimicked the IGF-1 effect on IK (2.5 ± 0.4 pA/pF), which was abrogated by LY 294002. Similar to Ad.BD110, transfection of the cardiac myocytes with wild-type Akt reduced IK (2.4 ± 0.3 pA/pF), which was completely reversed by LY 294002. Inhibition of Akt by dominant-negative Akt (Ad.Akt179M) abrogated IGF-1 effect on IK. In addition, Ad.Akt179M co-transfection with Ad.BD110 showed a yin-yang effect on IK. We conclude that IK is negatively regulated by IGF-1 through downstream activation of PI3 Kinase and Akt. Such a mechanism could play an anti-arrhythmic role during cardiac events that are associated with the activation of the PI3 K/Akt signaling, such as cardiac hypertrophy.

## 2346/T/Poster Board #895

**The ARVD/C variome.** *J.D.H. Jongbloed[1], P.A. van der Zwaag[1], L.G. Boven[1], A. Boesjes[1], A.C.P. Wiesfeld[2], I.C. van Gelder[2], M.P. van den Berg[2], R.M.W. Hofstra[1], E. Buskens[3], J.P. van Tintelen[1], R.J. Sinke[1].* 1) Department of Genetics, University Medical Center Groningen, Groningen, Netherlands; 2) Department of Cardiology, University Medical Center Groningen, Groningen, Netherlands; 3) Department of Epidemiology, University Medical Center Groningen, Groningen, Netherlands.

Arrhythmogenic right ventricular dysplasia/cardiomyopathy (ARVD/C) is a disorder characterized by segmental fibro-fatty replacement of the right ventricular myocardium leading to electrical instability predisposing to ventricular arrhythmias and sudden cardiac death. In 30-50% of cases the disease is familial with an autosomal dominant mode of inheritance with reduced penetrance and variable expression. The discovery of high yields of mutations in the plakophilin-2 (PKP2) gene encoding a desmosomal protein, and mutations, although with lower yields, in other desmosomal genes (DSG2, DSC2, DSP, DES and JUP), showed that ARVD/C can be considered a desmosomal disease. In addition, a mutation in the transmembrane protein 43 encoding gene (TMEM43), not (yet) related to the desmosome, was identified in Canadian families with ARVD/C. Analyzing these genes with current DNA diagnostic techniques is laborious, expensive and time consuming. Moreover, several studies revealed that the presence of compound heterozygous and/or bigenic mutations often occurs in ARVD/C patients, showing that the analyses of all genes related to this disease, irrespective of the fact that a mutation was already identified in one of the genes, is very important. For these reasons, methods to cost-effectively screen all candidate genes at once are required. Recently introduced deep sequencing techniques provide an excellent opportunity for such approach. Therefore, we initiated deep sequencing protocols to identify mutations/variants in the above mentioned ARVD/C genes within a single experiment. To validate the applicability of this technique in a diagnostic setting, the genes were also analyzed using currently used techniques (CSCE, DGGE, direct sequencing). First results underscore the results of previous studies that report the occurrence of multiple mutations/variations within patients/families. These results will be integrated in our recently launched, freely accessible online database, providing updated information on mutations in ARVD/C-associated genes (www.arvcdatabase.info).

## 2347/T/Poster Board #896

**Frequency of Deletions and Duplications in Sarcomere Genes in Hypertrophic Cardiomyopathy.** *T. Lee[1], R. Busin[2], B. Kattman[2], J. Wynn[1], J. Compton[2], S. Aradhya[2], W. Chung[1].* 1) Department of Pediatrics, Columbia University Medical Center, New York, NY; 2) GeneDx, Gaithersburg, MD.

Hypertrophic cardiomyopathy (HCM) is the most common monogenetic cardiovascular disease with a prevalence of 1 in 500 individuals and is the most common cause of sudden cardiac death in adolescents and young adults. The disease is genetically heterogeneous with mutations identified in over 17 genes. Currently available clinical genetic testing panels include sequencing of exons for MYBPC3, MYL2, MYL3, MYH6, MYH7, ACTC, ACTN2, TPM1, TNNC1, TNNT2, TNNI3, CAV3, PRKAG2, LAMP2, GLA, TTR, MTTG, MTTI, and MTTK which identifies disease causing mutations in ~ 60% of patients. It is unclear what accounts for the disease in the remaining 40% of patients, but we hypothesized that large deletions or duplications of these genes could account for a proportion of the HCM cases in which no mutation was identified by sequence analysis. Using a custom designed oligonucleotide exon array containing 810 oligonucleotides for 15 genes for hypertrophic cardiomyopathy we tested 56 sequence negative HCM patients for deletions or duplications. The array was designed containing two or more probes in each exon and the flanking 100 bases and three probes in the intronic regions. Hybridization was performed with sex-matched and differentially labeled reference DNA. Data were analyzed by DNA Analytics software. We identified an intragenic deletion of exons 28-40 in MYH7 that was confirmed by dye reversal and quantitative PCR. The patient is a 14 year old male diagnosed with HCM at age 10 when he presented with chest pain. His echocardiogram demonstrated asymmetric hypertrophy of the mid to apical portion of the ventricular septum. On cardiac MRI, the left ventricular mass was quantitatively mildly increased (Z score +2.2) with normal biventricular systolic function. His family history is significant for a mother and maternal grandfather with documented cardiomyopathy and a maternal great aunt and maternal great uncle who died at the ages of 60 and 38 of unspecified cardiac disease. These data suggest that genomic alterations in genes commonly associated with HCM are an infrequent but important genetic cause of HCM in ~2% of patients without identified mutations by sequence analysis. Therefore, deletion/duplication testing should be considered for HCM cases with normal sequencing results.

**Sequencing Known Genes for Thoracic Aortic Disease in the GENTAC cohort (Genetically Triggered Thoracic Aortic Aneurysms).** *D. Milewicz[1], H. Pannu[1], R. Pyeritz[2], C. Basson[3], H. Dietz[4], C. Maslen[5], K. Eagle[6], B. Kroner[7], the GENTAC consortium.* 1) Dept Internal Med, Univ Texas Med Sch, Houston, TX; 2) Dept Internal Med, Univ of Penn, Phildelphia, PA; 3) Dept Internal Med, Weill Med Col of Cornell Univ, New York, NY; 4) Dept Ped, Johns Hopkins Univ, Baltimore, MD; 5) Dept Mol Med Genet, Oregon HSU, Portland, OR; 6) Dept Internal Med, Univ of Mich. Ann Arbor, MI; 7) RTI International.

Thoracic aortic aneurysms leading to aortic dissections (TAAD) have a significant contribution from single gene mutations with 6 genes identified to date. The NHLBI-supported GenTAC (Genetically-triggered Thoracic Aortic Aneurysms and Related Conditions) registry collects clinical data and DNA/plasma samples on patients at risk for genetically-triggered thoracic aortic disease due to known syndromes (Marfan syndrome (MFS; gene FBN1), Loeys-Dietz syndrome (LDS; TGFBR1 and TGFBR2), vascular Ehlers Danlos syndrome (vEDS, COL3A1), Turner syndrome (TS)) and patients with clinical evidence of genetically triggered aortic disease such as familial TAAD (FTAAD), bicuspid aortic valve and TAAD (BAV/TAAD), and onset of TAAD < 50 years of age. We sought to characterize the gene mutations in the GenTAC cohort. Of the initial 710 GenTAC patients enrolled through December 2008, 103 patients entered with known mutations (56 FBN1 mutations in MFS patients, 4 TGFBR1 and 4 TGFBR2 mutations in LDS, and 4 COL3A1 mutations in vEDS) and 35 patients had TS. 47 patients did not have TAAD. We sequenced the remaining 560 GenTAC patients (35%; MFS, 33%; BAV/TAAD, 16%; FTAAD, 16%; other) for variants in the 6 known genes for TAAD; FBN1 data are pending. Preliminary analysis is presented on variants previously shown to cause disease (19) and possible mutations based on predicted protein truncation or protein structural changes (8). Amongst potential mutations that are in the process of confirmation, there were 1 frameshift and 6 missense variants identified in TGFBR1, and 3 missense changes in TGFBR2. Only one of these patients was diagnosed with LDS at the time of GenTAC enrollment and the others are being reassessed for features of LDS. COL3A1 mutations were identified in 3 vEDS (one patient had 2 mutations) and 4 patients with aortic disease that did not carry an initial diagnosis of vEDS (although diagnoses are being reassessed). Potential mutations also included ACTA2 missense variants in 3 patients with FTAAD and MYH11 variants in 4 patients with FTAAD. The rarity of mutations in the 5 known TAAD genes in the GenTAC patients who do not have MFS indicates further research needs to be done to identify genes predisposing to TAAD. Resequencing services Univ of Washington, Department of Genome Sciences, N01-HV-48194 from NHLBI.

## 2349/T/Poster Board #898

**Nonsense-mediated decay pathway activity modifies disease severity and penetrance among *BMPR2* mutation carriers with Pulmonary Arterial Hypertension.** *J.A. Phillips[1,2,3,4], E.D. Austin[1], J.D. Cogan[1], R. Hamid[1], K.C. Stanton[1], C.A. Phillips[1], L.A. Wheeler[2], I.M. Robbins[2], J.H. Newman[2], J.E. Loyd[2].* 1) Department of Pediatrics, Vanderbilt Univ Sch Med, Nashville, TN; 2) Department of Medicine, Vanderbilt Univ Sch Med, Nashville, TN; 3) Department of Biochemistry, Vanderbilt Univ Sch Med, Nashville, TN; 4) Department of Pathology, Vanderbilt Univ Sch Med, Nashville, TN.

**Background** Autosomal dominant inheritance of germline mutations in the bone morphogenetic protein receptor type 2 (*BMPR2*) gene are a major risk factor for heritable pulmonary arterial hypertension (HPAH). Found in ~80% of HPAH kindreds, *BMPR2* mutations have variable expressivity and reduced penetrance. We hypothesized that: 1) heterogeneity in *BMPR2* mutations contributes to differences in severity and penetrance, 2) *BMPR2* mutation transcripts that are destroyed by nonsense-mediated decay (NMD) (NMDpos) cause haploinsufficiency (HI), and 3) HI mutations are less severe and less penetrant than mutations whose transcripts are not destroyed by NMD (NMDneg) because of the latter's potential to cause dominant negative (DN) effects. **Methods** Testing for *BMPR2* mutations was performed in 169 patients with PAH (125 with HPAH and 44 with sporadic PAH). Of the 106 patients with a detectable *BMPR2* mutation, lymphoblastoid cells were available in 96 to functionally assess their susceptibility to the NMD pathway of RNA surveillance. Phenotypic characteristics were compared between carriers whose *BMPR2* mutations were classified as NMDpos versus NMDneg. **Results** The exonic locations of *BMPR2* mutation carriers did not correlate with differences in age at diagnosis, death, or survival. However, patients with NMDneg mutations had statistically significant younger ages at diagnosis (30.6 vs. 39.9 yrs, p=0.004) and death (32.4 vs. 42.0, p=0.014), as well as shorter survival from diagnosis to death or lung transplantation (5.02 vs. 9.99 yrs, p=0.044) than did the patients who had NMDpos (HI) mutations. Furthermore, 68.3% of NMDneg but only 41.3% of NMDpos mutations were penetrant before age 36 years, p=0.010. As a result, patients with an NMDpos mutation had a 3.0 higher odds of diagnosis after age 35 years than did those with an NMDneg mutation (p=0.010). **Conclusions** First, *BMPR2* mutation carriers with NMDneg mutations have more severe PAH phenotypes than those with NMDpos mutations. This suggests that potentially DN mutations can be more detrimental than mutations that can only cause HI. Second, three fold more NMDneg mutation carriers were diagnosed <35 yrs of age than HI mutation carriers. This suggests that potentially DN mutations are more penetrant that HI mutations. Third, these findings suggest that treatment and prevention strategies for PAH that are directed specifically at *BMPR2* pathway defects may need to vary according to the NMD status of the mutation.

## 2350/T/Poster Board #899

**Prenatal presentation of Jervell and Lange-Nielsen (LQT1) identifies an extended family of syncope and sudden death segregating with four gene mutations in three long QT syndromes: LQT1, LQT2, and LQT3.** *C.S. Rao[1], D.J. Levy[1], U. Birgersdotter-Green[2], M.E. Nunes[1].* 1) Dept Genetics, Kaiser Permanente, San Diego, CA; 2) Division of Cardiology, Cardiac Electrophysiology, UCSD, San Diego, CA.

We report a case of long QT (LQT) syndrome complicated by the inheritance of LQT1, LQT2, and LQT3 syndrome mutations in a single infant. Fetal bradycardia with heart rate of 90-100 was detected in a third trimester gestation in an otherwise uncomplicated pregnancy to a 36yo G3P1 mother of Afghan ancestry. Parents denied consanguinity. Neonatal ECG of the male infant revealed QTc interval of >500 ms, confirmed on repeat at two weeks. The infant failed the newborn hearing screen and was found to have congenital profound bilateral sensorineural hearing loss. A clinical diagnosis of Jervell and Lange-Nielson (LQT1) was made. Parents deny personal histories of syncope or related symptoms but upon ECG both were found to have long QTc intervals. Pedigree analysis revealed an extensive history of syncope, sudden infant death syndrome, and sudden cardiac death in both the maternal and paternal families. Molecular studies on the affected infant detected homozygosity for the known deleterious mutation, R174H, in the KCNQ1 gene confirming the diagnosis of Jervell and Lange-Nielson (LQT1) syndrome. Molecular studies of the affected infant also revealed additional mutations complicating the diagnosis. In the KCNH2 gene associated with Romano-Ward (LQT2) syndrome a novel class II (possible deleterious) variant of unknown significance, K93R, was detected, in addition to a known K897T polymorphism. In the SCN5A gene associated with LQT3/ Brugada syndromes a novel class I (probable deleterious) mutation, R1739Q, was also detected. Molecular and phenotypic studies of both parents and extended sibship to determine the co-segregation patterns for each of these mutations will be described. The KCNQ1 gene encodes the alpha subunit of the voltage-gated IKs cardiac potassium channel, the slowly activating component of the delayed rectifier current largely responsible for repolarization of the cardiac action potential. The KCNH2 gene encodes the IKr potassium channel and is responsible for the termination of the cardiac action potential. The SCN5A gene encodes the alpha subunit of the voltage-gated INa cardiac sodium channel. Mutations disrupt the inactivation of this channel resulting in prolongation of Na+ influx during depolarization. The family is being evaluated to determine compounding effect of multiple inherited LQT gene mutations. This case emphasizes the importance of detailed family history and use of LQT gene panel in determining multiple coexisting diagnoses.

## 2351/T/Poster Board #900

**CHIP-based sequence analysis of 34 cardiomyopathy genes in 250 patients reveals new genes involved in HCM and DCM and multiple pathogenic mutations in single patients.** *H. Smeets[1,2], W. Van Dijk[1], A. Stassen[1], P. Lindsey[1,2], Y. Arens[1], P. Helderman[1], C. Marcelis[3], J. Van der Smagt[4], S. Heymans[2,5], P. Volders[2,5], R. Jongbloed[1,2], A. van den Wijngaard[1].* 1) Dept Clinic Genet, Maastricht UMC, Maastricht, The Netherlands; 2) Research School CARIM, Univ Maastricht, Maastricht, The Netherlands; 3) Dept Clinic Genet, UMC St. Radboud, Nijmegen, The Netherlands; 4) Dept Clinic Genet, Utrecht UMC, Utrecht, The Netherlands; 5) Dept Cardiol, Maastricht UMC, Maastricht, The Netherlands.

Inherited cardiomyopathy is a frequent cardiac disease with a prevalence of 1:500 (HCM) to 1: 2500 (DCM). Due to the large amount of genes involved, the clinical heterogeneity and the laborious screening methods, it is difficult to unravel rapidly the genetic cause in all cases. Current diagnostic screening solves only 60-70% of the families by testing a limited number of genes in an often time-consuming sequential fashion and usually stops when a pathogenic mutation has been identified. However, double pathogenic mutations seem to be present in 5-10% of the familial cases. In order to create a fast, parallel genetic screening pipeline for inherited cardiomyopathy, we designed a resequencing array (CardioCHIP) covering 34 genes in duplicate (300Kb). We included genes known to be involved in DCM, HCM, LVNC and LGMD and candidate genes based on their presence in the sarcomere and Z-disc. All exons and flanking introns (38bp) were included on the CardioCHIP, covering the heart- and muscle-specific RNA-isoforms. The 5'UTR and 3'UTR regions and, for a selection of genes, the promoter regions were included as well. The genes, which were interrogated by the CardioCHIP, were amplified in 152 LR-PCR covering 395 exons, resulting in a sequence of 146.541 nucleotides. So far, 250 patients were sequenced for all 34 cardiomyopathy genes. The mutation detection rate is around 99% and about 98% of the novel exonic variants can be confirmed by conventional sequence analysis. In addition to mutations detected in the 13 genes routinely tested for HCM or DCM, we identified mutations in the 21 additional genes, some of which were the first for those new candidate genes. We identified in several patients up to 4 pathogenic mutations, involved in different pathogenic processes. Our data indicate that parallel analysis of multiple genes is a prerequisite for genetic testing in HCM and DCM to identify rapidly the genetic cause. Due to the potential presence of multiple mutations and to prevent misinterpretation, it is essential to test all genes in all patients and not proceed solely on the first genetic defect identified, as is the current practice. This is also the case for the relatives at risk, which would imply that for proper prognosis and preventive treatment all candidate genes should be tested in parallel for each individual.

## 2352/T/Poster Board #901

**Barth syndrome is not a common cause of dilated cardiomyopathy in adults.** *M. Taylor[1], D. Slavov[1], X. Zhu[1], D. Ferguson[1], J. Jirikowic[1], A. Di Lenarda[2], G. Sinagra[2], L. Mestroni[1].* 1) Adult Med Gen Prog, Univ Colorado Hlth Sci Ctr, Aurora, CO; 2) Ospedale Maggiore and University of Trieste, Trieste, Italy.

**Introduction:** Barth syndrome is a rare, X-linked genetic condition with neutropenia, skeletal myopathy, and dilated cardiomyopathy. Tafazzin (Xq28) mutations cause Barth syndrome, which has been mostly described in boys, although cardiomyopathy has been rarely described in adults. Some data suggest that certain boys with Barth syndrome may experience improvement of their cardiomyopathy in childhood, with recurrence of dilated cardiomyopathy as adults. Since the typical ascertainment of Barth syndrome has been in pediatric patients, whether tafazzin mutations contribute to dilated cardiomyopathy in adult populations, including women is unknown. **Methods:** We screened 295 families with dilated cardiomyopathy (210 male and 84 female probands) for mutations in tafazzin by mutation screening using denaturing high-performance liquid chromatography and sequence analysis. Putative mutations were evaluated for being causative of dilated cardiomyopathy based on standard criteria including screening in available relatives and in healthy controls and for effects on splicing efficiency in the case of one intronic mutation. **Results:** We found minimal variation in the coding sequence of tafazzin in our study. Four novel variants were identified in single individuals from four separate families (IVS2 -27 G/A; Exon 5 F128S, Exon 6 L169L, and exon 11 +114 G/A). Although these mutations were unique among over 700 case and control chromosomes, none of these mutations met all our criteria for pathogenic mutations and most likely represent rare polymorphisms. Furthermore, we showed that the exon 5 mutation (F128S) previously reported as pathogenic in the Barth Syndrome Foundation database is most likely a rare polymorphism restricted to African American populations. The F128F variant, therefore, is the only nonsynonymous change (excluding the initiation codon) that is tolerated in the amino acid sequence of the tafazzin protein. **Conclusion:** Our screening of a large, well-phenotyped cohort suggests that tafazzin mutations are not common causes of dilated cardiomyopathy in adults.

## 2353/T/Poster Board #902

**The burden of living with the risk of inherited arrhythmia for patients coming to genetic counselling.- A study of health status in patients with the risk of Long QT syndrome and Hypertrophic Cardiomyopathy compared to patients with the risk of inherited Breast/Ovarian and Colorectal cancer.** *A. Hamang[1,2], G.E. Eide[1,3], K. Nordin[1,4], B. Rokne[1], C. Bjorvatn[1,2], N. Øyen[1,2].* 1) Department of Public Health and Primary Care, University of Bergen, Trondheim, Norway; 2) Center of Medical Genetics and Molecular Medicine, Haukeland University Hospital, Bergen, Norway; 3) Centre for Clinical Research, Haukeland University Hospital, Bergen, Norway; 4) Department of Public Health and Caring Sciences, Uppsala University, Sweden.

Background: Today it is possible to identify genetic vulnerability for a number of different diseases, including hereditary cancer and serious inherited arrhythmias, through family history and direct mutational testing. Systematic knowledge about how it is to live with the risk of hereditary cancer and how people perceive their health is growing, but the literature is very limited with regards to health status when being at risk of inherited arrhythmias, where the manifestations of symptoms can range from asymptomatic to sudden death. In Norway both patient groups and their family members receive genetic counselling and are followed up with the same routine through predictive genetic testing. Aim: To measure the impact of being at risk of inherited arrhythmia compared to inherited cancer on the functioning and wellbeing of the patients coming to genetic counselling. Patients and methods: The study used a two-group cross-sectional comparative design. Two hundred and fourteen patients with a genetically based risk of cancer, either breastovarian or colorectal cancer, aged 18-80, and 127 patients with an increased risk of inherited arrhythmia, either Long QT syndrome or Hypertrophic cardiomyopathy aged 18-83 and, coming to genetic counselling between 2002-2004 and 2005-2007 were asked to participate in a study. Health status was measured by the Short Form Health Survey [SF-36] on eight domains with values in the range 0 (worst) to 100 (best). The patient SF-36 scores were compared with independent samples t-tests. Results The arrhythmia risk group reported lower SF-36 scores as compared to the cancer risk group on all domains; Significant differences were found in general health (mean difference 6.2 (95% confidence interval 1.6 to 10.8)) and in social functioning (mean difference 6 (95% confidence interval 1.3 to 10.8)), The difference in mental health (3.4 (-0.5 to 7.4)) were borderline significant. Discussion: It may look like the patients with a genetic risk of arrhythmia have a different health profile as compared to patients coming to genetic counseling because of inherited cancer risk. Conclusion: Genetic counselling services must continue to develop and give attention to the differences between patient groups in the further work of development of guidelines and tailored information in the genetic counselling.

## 2354/T/Poster Board #903

**Mutation screening for vascular type of Ehlers-Danlos Syndrome using high resolution melting curve analysis (hrMCA).** *A. Watanabe[1,2], B.T. Naing[1], T. Shimada[1,2].* 1) Dept Biochem & Molec Biol, Nippon Med Sch, Tokyo, Japan; 2) Div Clinical Genetics, Nippon Medical School Hospital, Tokyo, JAPAN.

Vascular type of Ehlers-Danlos syndrome (vEDS), also known as EDS type IV (MIM#130050) is a life-threatening autosomal dominant inherited disorder caused by mutations of type III collagen, *Col3A1*, and clinically characterized by spontaneous rupture of bowel and large arteries. Two-thirds of the mutations in the *Col3A1* gene are a single nucleotide substitutions which cause changes from glycine to other amino acids in the triple helix region composed of (Gly(glycine)-X-Y)$_{343}$ repeats and most of the rest are splicing mutations. The *COL3A1* gene is located at 2q31-q32, contains 52 exons distributed over 44 kb. Since there is no hot spot, mutation detection of *Col3A1* gene is complicated and time consuming, In most cases, mutation search was done using total RNA isolated from patient's fibroblasts. A high resolution melting analysis (hrMCA) is based on monitoring of the fluorescence released during the melting of double-stranded DNA labeled with specifically developed saturation dye, such as LC-Green and has been developed as a promising pre-screening and economical post-PCR mutation scanning method. We applied hcMCA to establish *Col3A1* mutation screening using genomic DNA. PCR primers pairs for *Col3A*1 (52 amplicons in 52 exons) to cover the complete coding region and splice sites were designed. We analyzed genomic DNA samples from patients who have been diagnosed as vEDS. All gene mutations including known three Gly substitution mutations and three splicing mutations of *Col3A1* gene revealed different melting curves in hrMCA. In addition, we found one new nonsense mutation (c.2491C>T; Gln831Ter) in exon 42 which could not be detected by analysis of total RNA because of nonsense mediated mRNA decay. Our results demonstrated that hrMCA of genomic DNA is a powerful and inexpensive scanning method for mutation detection of *Col3A1* gene. Genome scanning by hrMCA should be useful for screening of genetic diseases caused by heterogeneous mutations of the gene composed of many exons like *Col3A1*.

## 2355/T/Poster Board #904

**A multi-stage / multi-design strategy identifies a new QTL for VWF on chromosome 6 - a possible link with VTE?** *G. Antoni[1,2,3], N. Saut[4], Y. Luo[3], G. Burgos[4], C. Biron-Andreani[5], J.F. Schved[5], G. Pernod[6], I. Juhan-Vague[4], M.C. Alessi[4], L. Drouet[1,2], S. Visvikis-Siest[7], P.S. Wells[8], J. Emmerich[9], D.A. Tregouet[1,2], P.E. Morange[4].* 1) INSERM, UMR_S 937, F-75013, Paris, France; 2) UPMC Univ Paris 06, UMR_S 937, F-75013, Paris, France; 3) Dalla Lana School of Public Health, University of Toronto, Ontario, M5T 3M7, Canada; 4) INSERM, UMR_S 626, F-13385, Marseille, France; Université de la Méditerranée, Marseille, F-13385 France; 5) Laboratoire d'Hématologie, CHU Montpellier, France; 6) Service de Médecine Vasculaire, CHU Grenoble, France; 7) Equipe INSERM "Génétique Cardiovasculaire" CIC 9501, Nancy, France; 8) Ottawa Health Research Institute, Ottawa, Ontario, K1Y 4E9, Canada; 9) INSERM U765,Université Paris-Descartes, France.

Factor VIII (FVIII) and von Willebrand Factor (VWF) are two known quantitative risk factors for venous thromboembolism (VTE). In this work, we employed a multi-stage / multi-design strategy to identify new loci that would contribute to VTE susceptibility by modulating FVIII and/or VWF levels. For this purpose, a pedigree linkage analysis was first performed on five extended French-Canadian families including 261 individuals genotyped for 1079 microsatellites and identified four putative regions linked to FVIII and vWF levels. The strongest linkage signal was observed on chromosome 9q34 overlapping the ABO locus, a known susceptibility loci to FVIII and VWF levels. The other three regions, located on chromosomes 2, 6 and 12, were then evaluated by in silico association analysis of a genome-wide association study composed of 419 VTE patients and 1288 controls with the aim of narrowing the linkage signals by focusing on candidate region for VTE. Four SNPs in the chromosome 6 region were in silico associated with VTE at $p<10^{-4}$ and were then investigated for association with FVIII and VWF in a sample of 123 healthy French nuclear families (2 parents and 2 offspring). One SNP was found to explain up to 3% (p=0.0018) of VWF variability in these families and also explained 1% (p=0.009) of VWF variability in an independent cohort of 823 patients with VTE at young age (<50 years). Besides, the allele that has been found associated with decreased VWF levels tended to be associated with a lower risk of VTE (OR=0.70 [0.47-1.04], p=0.081) in an independent French case-control study for VTE of 607 cases and 607 controls. In conclusion, using a multi-stage approach including pedigree linkage analysis, association analysis in nuclear families and case-control data, we obtained some strong arguments about the role of a new locus on chromosome 6 that could be involved in the susceptibility to VTE by controlling plasma VWF levels.

## 2356/T/Poster Board #905

**Genome-wide association study of P-selectin in European ancestry individuals from Cohorts for Heart and Aging Research in Genomic Epidemiology (CHARGE) Consortium.** *M. Barbalic[1], J. Dupuis[2,3], A. Dehghan[4], J.C. Bis[5], R.B. Schnabel[2], W. Koenig[6], N.S. Jenny[7], J.C. Witteman[4], C.M. Ballantyne[8], E.J. Benjamin[2].* 1) Human Genetics Center and Institute of Molecular Medicine, University of Texas Health Science Center at Houston, Houston, TX; 2) National Heart, Lung, and Blood Institute's Framingham Heart Study, Framingham, MA; 3) Department of Biostatistics, Boston University School of Public Health, Boston, MA; 4) Department of Epidemiology, Erasmus Medical Center, Rotterdam, The Netherlands. Member of the Netherlands Consortium on Healthy Aging (NCHA); 5) Cardiovascular Health Resaearch Unit, Department of Medicine, Epidemiology and Health Services, University of Washington, Seattle, WA; 6) Department of Internal Medicine II - Cardiology, University of Ulm Medical Center, Ulm, Germany; 7) Department of Pathology, University of Vermont College of Medicine, Burlington, VT; 8) Department of Medicine, Baylor College of Medicine and Center for Cardiovascular Prevention, Methodist DeBakey Heart and Vascular Center, Houston, TX.

P-selectin participates in the inflammatory process by promoting adhesion of leukocytes to vascular wall endothelium. Its levels have been shown to be highly heritable and, importantly, associated with various cardiovascular disorders. Soluble P-selectin is readily measurable in large cohort studies but the more biologically active molecule is thought to be the membrane bound form. To identify loci affecting soluble levels of P-selectin, we performed a genome-wide association study (GWAS) in a sample of 4,115 individuals of European ancestry in 3 cohorts (Atherosclerosis Risk in Communities (ARIC), Framingham Heart Study (FHS) and Rotterdam Study (RS)) as a part of The Cohorts for Heart and Aging Research in Genome Epidemiology (CHARGE) consortium. We tested the association with ~2 million imputed SNPs using linear regression under an additive genetic assumption. We obtained three genome-wide significant hits nearby the SELP (p=4.05x10-61), ABO (p=1.86 x10-41) and SCAP (p=3.72x10-7) genes. To verify if the same genes are responsible for variation in membrane bound P-selectin levels, we sought to replicate the top findings in a sample of 1,088 individuals from ARIC study with the measures of platelet bound P-selectin. Only the variant in the SELP gene remained significant (p=0.02) when platelet bound P-selectin levels were analyzed. Our results identified genes influencing P-selectin levels and suggested different genetic determinants of soluble and platelet bound P-selectin. They contribute to the knowledge of the adhesion molecules physiology that is necessary to understand the link between the inflammation and atherosclerotic process.

## 2357/T/Poster Board #906

**Molecular genetic analysis of gene expression in tissues from infants with idiopathic conotruncal defects.** *D.C. Bittel[1], N. Kibiryeva[1], J.A. Swihart[2], M.G. Butler[3], G.K. Lofland[2], J.E. O'Brien Jr[2].* 1) Section Medical Geneteics, Children's Mercy Hosps, Kansas City, MO; 2) Section of Cardiovascular and Thoracic Surgery, Children's Mercy Hosps, Kansas City, MO; 3) Departments of Psychiatry & Behavioral Sciences and Pediatrics Kansas University Medical Center.

Children with conotruncal heart defects, decreased pulmonary blood flow from pulmonary artery stenosis or atresia and right ventricular hyperplasia present with a complex set of health problems. Tetralogy of Fallot (TOF) is the most common defect. Treatment of these patients has evolved dramatically in the last few decades, yet investigation into the underlying genetic basis has not provided a molecular mechanism for the failure of proper cardiac development for the majority of children with TOF. A clear delineation of genetic aspects of TOF may allow development of tailored therapeutic approaches to medical and surgical intervention while improving outcomes for these difficult to manage patients. Hence, we have examined cardiovascular tissue from the right ventricle, pulmonary valve and pulmonary artery obtained at the time of reconstructive surgery from 19 children with Tetralogy of Fallot (3 with 22q11.2 chromosomal deletion and 16 nonsyndromic children with normal chromosome studies) and applied whole genome expression microarray technology to characterize gene expression patterns relative to tissues from 5 normally developing comparison subjects. We detected a signal from approximately 20,000 probes (ranging from 39% to 35% of array probes in the three tissues examined). More than 1000 genes had a 2-fold change in expression in the right ventricle (RV) of children with TOF compared to RV from matched control infants. Most of these genes were involved in compensatory functions (e.g., hypertrophy, cardiac fibrosis and cardiac dilation); however, several canonical pathways were implicated as having altered expression patterns. Pattern formation pathways (i.e., WNT, Notch and Hedgehog) were generally suppressed, especially in the RV. This may reflect a general malfunction of these regulatory pathways leading to inaccurate boundary formation and improper structural development in the embryonic heart. Pathway suppression was not ubiquitous but appeared to be confined to these signaling pathways. Routine cytogenetic tests on the majority of these children did not reveal cytogenetic anomalies associated with congenital heart disease. We suggest that small structural or functional disturbances or tissue specific genomic and/or epigenetic fluctuations could lead to gene expression fluctuation causing regulatory network disruption and thus failure of proper cardiac development in the affected individuals requiring more testing.

## 2358/T/Poster Board #907

**A Genome-Wide Study of Common and Rare Variants for Myocardial Infarction and Related Traits in South Asians: The INTERHEART study.** *R. Do[1], C. Xie[2], A. Montpetit[3], G. Pare[4], S. Yusuf[2], J.C. Engert[1], S.S. Anand[2] on behalf of the INTERHEART investigators.* 1) Department of Human Genetics, McGill University, Montréal, QC, Canada; 2) Population Health Research Institute, Hamilton Health Science, McMaster University, Hamilton, ON, Canada; 3) McGill University and Genome Quebec Innovation Center, Montreal, QC, Canada; 4) Center for Cardiovascular Disease Prevention, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA.

Genome-wide association (GWA) studies have been successful at identifying common SNPs with weak effects for myocardial infarction (MI) in Europeans. However, these studies have not been performed in many other ethnicities and the role of rare variants with strong effects is unknown. We investigated both common SNPs and rare variants, with MI in 600 South Asians, a population known to have higher rates of MI, from the INTERHEART study. We genotyped 353,202 SNPs using the Illumina HapCNV370 in 300 early-onset (mean 39.1 years) cases and 300 aged controls (mean 60.6 years). A GWA scan of common SNPs and MI identified a SNP in the 4q35.2 region (p=7.71x10-6) as the strongest result. 38 other associations were observed (p<0.0001). Scans for 10 risk factors of MI were performed and we observed putative associations for each trait (ie. for p<1x10-5, 13 SNPs for LDL-C, 17 for HDL-C, 18 for TG, 20 for BMI, 23 for waist c., 37 for hip c., 2 for waist/hip, 6 for apoB, 2 for apoA1, and 20 for hbA1c). We will follow-up these results in a second stage consisting of an additional 1267 South Asians. In addition, we investigated rare variants using the segmental sharing procedure in PLINK, a method for using whole genome SNP data in population-based samples to identify loci containing multiple rare variants associated with disease. This method scans the genome for extended segments that display excessive identical by descent sharing among case-case pairs. Six linkage peaks (2q36.3, 6p22.2, 8p23.1, 9q31.2, 13q21.2, 15q13.2, p< 0.001) were identified, and the second strongest result (8p23.1, p=0.00028) had been previously identified by our group in a genome-wide linkage study of coronary heart disease in Saguenay Lac St. Jean families. We investigated the role of common SNPs for MI within these regions and observed the strongest association in the 9q31.2 region (p=1.4x10-5). In conclusion, we have completed stage one of a two stage genome-wide study of genetic loci predisposing to MI in South Asians.

## 2359/T/Poster Board #908

**CGH Micro-Array analysis of children with left-side congenital heart defects.** *H. Gill[1], G. Sandor[2], S. Adam[3], M. Thomas[3], T. Tucker[3], J.M. Friedman[3].* 1) Provincial Medical Genetics Program, Children's Hospital, Vancouver, BC, Canada; 2) Paediatric Cardiology Program, Children's Hospital, 4500 Oak St, Vancouver, BC, Canada; 3) University of British Columbia, Vancouver, Canada.

Congenital heart defects (CHD) are the commonest human malformation. In the majority of affected individuals no underlying cause can be clearly identified. Genetic factors are thought to play an important part and recent studies have implicated submicroscopic chromosomal imbalances or pathogenic copy number variants (CNV) in 5- 25% of cases. We sought to investigate the contribution of pathogenic CNV in our population of children with left-sided CHD (LCHD). Since LCHD has been shown to cluster in families, we hypothesized that a genetic etiology would be evident in this group. We recruited children (and their parents) with LCHD from our regional pediatric cardiology service. Cases were excluded if the cause of the LCHD was known, if both parents were not available for testing, if the child was deceased, or if the family lived outside of the province of British Columbia, Canada. Microarray CGH was performed using the Nimblegen 12x135K whole-genome tiling microarrays. The data were analyzed using NimbleScan software, and CNVs were identified using Nexus software (Biodiscovery, Inc.) Of 24 cases of LCHD analysed to date, 20 had aortic coarctation (CoA). In 5 of these cases CoA was the primary lesion of a more complex cardiac defect. 4 cases had aortic stenosis (AS). In 1 of these AS was part of a more complex defect. The male:female ratio was 16:8. The age range was 30 months to 21 years. All were seen by a clinical geneticist and were confirmed as isolated CHD with no other malformations or dysmorphic features. No de novo pathogenic CNVs were found in our cases. 3 published studies have investigated the contibution of CNVs in the pathogenesis of CHD. None focused on isolated LCHD. Erdogan et al 2008 investigated 105 cases of isolated CHD and found 18 pathogenic CNVs (17%). Of 18 cases with isolated LCHD, 1 infant with CoA had a possibly pathogenic de novo CNV. Richards et al (2008) investigated 20 cases of isolated CHD and 20 cases of non-isolated CHD. 5 pathogenic CNVs were identified in the non-isolated group(20%), 1 of which had CoA. However, no de novo CNVs were identified in the isolated group of which 4 had LCHD. Thienpont et al (2007) investigated 60 patients with CHD and other malformations or mental retardation and found 10 (17%) to have a pathogenic CNV. In conclusion, it is likely that de novo pathogenic CNV are not a frequent cause of isolated LCHD.

## 2360/T/Poster Board #909

**Whole genome SNP and CNV analysis of atrioventricular septal defects in the Down syndrome population.** *A.E. Locke[1,6], D.J. Cutler[1], E. Feingold[2], C. Maslen[3], G. Capone[4], R.H. Reeves[5], S.L. Sherman[1], M.E. Zwick[1].* 1) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA; 2) Departments of Human Genetics and Biostatistics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 3) Department of Cardiovascular Medicine, Oregon Health & Science University, Portland, OR; 4) Division of Neurology & Developmental Medicine, Kennedy Krieger Institute, Baltimore, MD; 5) Department of Physiology & McKusick-Nathans Institute for Genomic Medicine, Johns Hopkins University, School of Medicine, Baltimore, MD; 6) Program in Genetics & Molecular Biology, Emory University, Atlanta, GA.

Trisomy 21, the chromosomal abnormality responsible for Down syndrome (DS), is a complex condition associated with a constellation of abnormalities affecting multiple organ systems. The combination of these anomalies is severe, with as few as 20% of conceptuses with trisomy 21 surviving to term. Congenital heart defects (CHD) represent the most common malformation in children born at term. Trisomy 21 is the leading cause of CHD. Nearly half of all DS births are affected by some form of CHD. Complete atrioventricular septal defects (AVSD) occur at a rate of nearly 1/5 and are one of the most common forms of CHD in individuals with DS. When contrasted with the 1/10,000 rate of AVSD in the general population, the 2000-fold greater risk among those with DS strongly suggests that the increased dosage of chromosome 21 (chr21) genes contributes to the occurrence of CHD, and especially AVSD. Through a multi-site recruitment effort, we have ascertained individuals with DS who have complete AVSD (cases) and those who have structurally normal hearts (controls) and their parents. Maternal questionnaires have been completed to obtain demographic information and maternal health history during pregnancy. Medical records on probands have been abstracted to document heart status and other birth defects. Here we present results from the first 120 case-parent trios and the 120 controls based on Affymetrix Genome Wide SNP 6.0 array. In addition to genome wide SNP association, we use common strategies to identify copy number variable regions throughout the genome in this population. We present annotation of the genetic variants we identified and validated, including comprehensive high-resolution aCGH of chromosome 21. Finally, we test all SNPs and CNVs for association with AVSD under both a case/control framework and a case-parent trio (TDT) framework.

## 2361/T/Poster Board #910

**Genome-wide association study on HDL cholesterol level in the Marshfield Personalized Medicine Research Project as part of the eMERGE network.** *S.D. Turner[1], C.A. McCarty[2], Y. Bradford[1], D. Berg[3], P. Peissig[3], J. Linneman[3], J. Starren[3], R.A. Wilke[4], M.D. Ritchie[1].* 1) Center Human Genetics Research, Vanderbilt University, Nashville, TN; 2) The Center for Human Genetics , Marshfield Clinic Research Foundation; 3) Biomedical Informatics Research Center, Marshfield Clinic Research Foundation; 4) Department of Medicine and Department of Pharmacology and Toxicology, Medical College of Wisconsin.

The Electronic Medical Records and Genomics (eMERGE) network is an NHGRI funded initiative with the goal of testing whether electronic medical record (EMR) systems can serve as a resource for collecting phenotypic information for genomic studies. To test this hypothesis, five groups around the United States are using natural language processing algorithms to derive phenotypes in patients who have DNA samples in the institution's biobank. The Marshfield Clinic in Central Wisconsin represents one such institution and our phenotypes are cataracts and high-density lipoprotein (HDL) cholesterol (U01-HG004608). Here we will discuss our genome-wide association study for HDL cholesterol. Individuals having below-normal levels of HDL cholesterol are at increased risk for cardiovascular disease. In order to more thoroughly understand the genetic basis of this complex trait, we have conducted an initial GWAS in 3900 participants in the Marshfield Clinic Personalized Medicine Research Project (PMRP). Self reported race within the PMRP cohort (using U.S. Census classification at the time of study entry) indicates the population is 98.2% white Caucasian of central and northern European descent, making it ideal for a genetic association study since risk of population stratification is minimized. PMRP contains data from >20,000 participants. Participants are ≥ 18 years of age (median 49 years). The database contains HDL levels for >15,000 of these individuals. Clinical lab HDL cholesterol levels were electronically harvested from subject EMRs in 3900 individuals. All samples were genotyped with the Illumina 660-Quad platform. Each SNP passing rigorous quality control measures was tested for association with HDL cholesterol level using linear regression, assuming an additive model. Here we report several highly significant findings, shedding more light on the genetic contribution to a complex lipid phenotype of substantial public health interest. In addition, we compare and contrast these results with the many already published SNPs associated with lipid levels. Finally, we demonstrate the success of using an EMR-derived phenotype to perform genetic analysis of complex disease. This study along with the other eMERGE projects provide evidence supporting the use of biobanks linked to EMRs for genomic studies.

## 2362/T/Poster Board #911

**Genome-wide copy number analysis to identify candidate genes for Thoracic Aortic Aneurysms and Dissections.** *S. Prakash[1], D. Guo[2], M. Bray[1], S. Lemaire[1], D. Milewicz[2], J. Belmont[1].* 1) Baylor College of Medicine, Houston, TX; 2) University of Texas Health Science Center at Houston, Houston, TX.

Thoracic Aortic Aneurysms and Dissections (TAAD) cause 15,000 deaths each year due to acute complications such as aortic rupture, myocardial infarction or stroke. In a genome-wide copy number analysis of 786 sporadic TAAD cases, we identified copy number variants (CNVs) of 29 novel candidate genes that are significantly associated with TAAD. The cohort for this study was derived from the Specialized Center for Clinically Oriented Research (SCCOR) in TAAD and includes patients who underwent surgical repair of thoracic aneurysms at St. Luke's Episcopal Hospital and Baylor College of Medicine (100% Caucasian, 35% female, average age 63, 36% Stanford Type A dissections). Genomic DNA from whole blood was hybridized to Illumina 370 Quad Beadchips. We extracted the intensity and allele frequency data into three copy-calling algorithms (CNVPartition, PennCNV and DNAcopy), and the results were filtered to select CNVs that intersect with known genes. We identified 3189 CNVs in 2289 genes, including 24 patients with large (> one megabase) events. Most of these were copy-neutral events that appear consistent with regions of mosaic uniparental isodisomy. We are currently obtaining additional samples from these patients in order to confirm these events on Illumina 610 Quad Beadchips. We limited our subsequent analysis to CNVs that are statistically associated with TAAD in comparison with control databases representing 3500 unaffected individuals. Each putative CNV was directly confirmed by the first author. Interactome analysis of the candidate genes showed that many participate in cytoskeletal remodeling or TGF-β signaling pathways in vascular smooth muscle cells. Since mutations in smooth muscle contractile proteins and TGF-β receptors cause familial predisposition to TAAD, these novel CNVs are likely to be pathogenic variants that predispose to thoracic aneurysms. To prove a causal relationship of several promising candidate genes with TAAD, we are currently obtaining independent lines of evidence, including replication in other patient cohorts, detection of additional mutant alleles in these genes and functional studies.

## 2363/T/Poster Board #912

**Identification of ZNF366 and PTPRD as Novel Determinants of Plasma Homocysteine in a Family-based Genome-wide Association Study.** *A. Buil[1], A. Mälarsting[2], JC. Souto[3], R. Clarke[4], F. Blanco-Vaca[5], J. Fontcuberta[3], J. Peden[6], M. Andersen[2], A. Silveira[2], S. Barlera[7], U. Seedorf[8], H. Watkins[6], L. Almasy[9], A. Hamsten[2], JM. Soria[1].* 1) Genomics Complex Diseases, Hosp de Sant Pau, Barcelona, Spain; 2) Atherosclerosis Research Unit, Department of Medicine Solna, Karolinska Institutet, Stockholm, Sweden,; 3) Department of Hematology and 5Department of Biochemistry Hospital de la Santa Creu i Sant Pau, Barcelona, Spain,; 4) Clinical Trials Service and Epidemiological Studies Unit (CTSU); 5) Department of Biochemistry Hospital de la Santa Creu i Sant Pau, Barcelona, Spain,; 6) Department of Cardiovascular Medicine, University of Oxford, Oxford, UK,; 7) Department of Cardiovascular Research, 'MarioNegri' Institute for Pharmacological Research, Milano, Italy,; 8) Leibniz-Institut für Arterioskleroseforschung an der Universität Münster, Münster, Germany; 9) Department of Population Genetics, Southwest Foundation for Biomedical Research, San Antonio, Texas, USA.

Total plasma homocysteine concentration (tHcy) is an established biomarker for atherothrombotic diseases and a highly heritable trait. Polymorphisms in genes involved in methionine metabolism only account for a minor proportion of the variation in tHcy in the population. We searched for novel genetic determinants of plasma tHcy using a genome-wide single nucleotide polymorphism (SNP) association study approach. First 283,437 SNPs were tested for association with tHcy in 21 large Spanish families (n=387). Replication analyses of 18 SNPs meeting predefined criteria for association were then performed in patients with premature myocardial infarction (n=1238). Novel associations were found for SNPs near the ZNF366 gene (lead SNP rs7445013, adjusted beta= -0.13, p=0.0004) and the PTPRD gene (rs973117, adjusted beta= -0.10, p=0.005). The genetic contribution to tHcy variation attributable to SNPs at ten loci was estimated to be 10.3% in the family study and 4.0% in the replication study, after adjustment for effects of non-genetic factors. Our findings implicate novel pathways in homocysteine metabolism, and the roles of the associated genes in the etiology of vascular diseases warrant further investigation.

## 2364/T/Poster Board #913

**Multiethnic genetic association study of carotid intima-media thickness using a targeted cardiovascular SNP microarray.** *M.B. Lanktree[1], S. Yusuf[2,3], R.A. Hegele[1], S.S. Anand[2,3], the SHARE investigators.* 1) Departments of Medicine and Biochemistry, Robarts Research Insitute, University of Western Ontario, London, Ontario, Canada; 2) Population Health Research Institute, Hamilton Health Sciences, Hamilton, Ontario, Canada; 3) Departments of Medicine and Clinical Epidemiology, McMaster University, Hamilton, Ontario, Canada.

Identification of subclinical atherosclerosis by ultrasonographic measurement of carotid intima-media thickness (cIMT) is a validated tool, in conjunction with traditional risk factors, for assessment and prediction of cardiovascular disease (CVD) risk. Many previous association studies have, with variable success, identified variants in candidate genes associated cIMT. We evaluated the association between cIMT and ~50,000 SNPs, densely mapping ~2,100 genes, found on the gene-centric Illumina (University of Pennsylvania) CVD beadchip in a multiethnic sample. B-mode ultrasound was performed and DNA was collected from a population-based sample of South Asian (n = 328), Chinese (n = 302), and Caucasian (n = 268) participants. The most robust association with cIMT was observed for rs3791398 in *HDAC4* encoding histone deacetylase 4 (P = 1.8e-5). Given recent associations reported between polymorphisms in natriuretic peptide precursors and hypertension, it is interesting that our third strongest association was with rs10082235 in *NPR1* encoding natriuretic peptide receptor A/guanylate cyclase A (P = 5.4e-5). We also identified marginally significant replication of associations reported in 7 of 15 functional candidate genes ($0.01 \le P \le 0.05$). A model that included SNP genotypes associated with plasma total cholesterol was significantly associated with cIMT (P = 6.0e-4, $r^2 = 0.368$), but did not substantially improve the extent of cIMT variation that could be explained versus traditional risk factors. To our knowledge, this is the first array-based high-density genetic study of associations with cIMT in a multiethnic sample. The results indicate that careful phenotypic evaluation of subclinical atherosclerosis and larger-sized samples, including subjects from multiple ethnicities, will be required to identify variants that are reliably associated with cIMT.

## 2365/T/Poster Board #914

**Genome-wide association study of coronary heart disease and its main risk factors in 8,367 African-Americans from the ARIC, CARDIA, CFS, JHS, and MESA population-based cohorts: The CARe Project.** *G. Lettre[1], K. Ejebe[2], D. Farlow[2], T. Young[2], N. Patterson[2], R. Fabsitz[3], A. Folsom[4], M. Fornage[5], E. Fox[6], E. Larkin[7], G. Papanicolaou[3], M. Reilly[8], J.I. Rotter[9], D. Siscovick[10], H. Taylor[6], R.P. Tracy[11], J.N. Hirschhorn[2], S. Gabriel[2], S. Kathiresan[2], E. Boerwinkle[5], The CARe Project.* 1) Montreal Heart Institute, Montreal, Quebec, Canada; 2) Broad Institute, Cambridge, MA, USA; 3) National Heart, Lung, and Blood Institute, Bethesda, MD, USA; 4) University of Minnesota, Minneapolis, MN, USA; 5) University of Texas, Houston, TX, USA; 6) University of Mississippi, Jackson, MS, USA; 7) Case Western Reserve University, Cleveland, OH, USA; 8) University of Pennsylvania, Philadelphia, PA, USA; 9) University of California in Los Angeles, Los Angeles, CA, USA; 10) University of Washington, Seattle, WA, USA; 11) University of Vermont, Burlington, VT, USA.

In populations of European ancestry, genome-wide association studies (GWAS) have mapped many genetic loci associated with coronary heart disease (CHD) and its main risk factors, including plasma low-density lipoprotein cholesterol (LDL-C), plasma high-density lipoprotein cholesterol (HDL-C), cigarette smoking, type-2 diabetes, and hypertension. To date, however, no large-scale GWAS have focused on CHD in African-Americans. To identify genetic determinants of CHD and its risk factors in this population, the NHLBI-funded Candidate-gene Association Resource (CARe) Project genotyped 8,367 African-Americans from five population-based cohorts (ARIC, CARDIA, CFS, JHS, MESA) using the Affymetrix 6.0 platform.

Appropriate quality-control criteria, including principal component analyses, were applied to remove poorly performing SNPs and samples, as well as population outliers. We tested the association between >800,000 SNPs and circulating HDL-C and LDL-C levels, cigarette smoking, type-2 diabetes status, hypertension status, and prevalent CHD in each cohort. HDL-C, LDL-C, and cigarette smoking were analyzed as quantitative traits using linear regression, whereas type-2 diabetes, hypertension, and CHD were analyzed as dichotomous phenotypes using logistic regression. Association results were combined across studies using meta-analysis. To address the issue of admixture, we developed a new test statistic that combines evidence of association from both genotype and ancestry information. Using this approach, we replicated several associations originally discovered in populations of European descent, for instance SNPs near *CETP*, *LPL*, and *LIPC* with HDL-C levels (P-values $<5x10^{-8}$), SNPs near *APOE*, *CELSR2/PSRC1/SORT1*, and *PCSK9* with LDL-C levels (P-values $<5x10^{-8}$), SNPs near *TCF7L2* with type-2 diabetes (P-values $<5x10^{-6}$), and SNPs in the 9p21 region with CHD (P-values $<5x10^{-4}$). Taking into account local ancestry also allowed us to identify large admixture signals for type-2 diabetes over regions on chromosome 1p32 and 15q21 (P-values $<1x10^{-6}$) and for hypertension over a region on chromosome 1q24 (P-values $<5x10^{-5}$). Importantly, these signals would have been missed using only genotype information. We are currently conducting a replication study in additional African-Americans to test these and other new loci associated with CHD or its main risk factors.

## 2366/T/Poster Board #915

**Longitudinal Genome-wide Association of Cardiovascular Disease Risk Factors in The Bogalusa Heart Study.** *E.N. Smith[1], M. Shaw[2], R. Salem[2], W. Chen[3], S. Srinivasan[3], E.J. Topol[1], N.J. Schork[1], G.S. Berenson[3], S.S. Murray[1].* 1) Scripps Genomic Med, Scripps Translational Sci, La Jolla, CA; 2) University of California, San Diego, CA; 3) Tulane University, New Orleans, LA.

A large benefit of using longitudinal data as opposed to cross-sectional data is that one can discriminate genetically-mediated developmental or aging-related profiles. The study of such profiles can lead to the identification of risk profiles of susceptible individuals before disease onset. For example, cross-sectional data results may only determine variation associated with BMI (i.e., genotype-specific main effect), but may not be able to determine variants associated with the development of obesity over time (i.e., SNP by age interaction effect). The discovery of variants associated with SNP by age effects could be used to screen asymptomatic individuals and provide the opportunity for implementation of preventive measures before disease onset. Previous genome-wide association (GWA) studies have found numerous associations with CVD and its risk factors in cross-sectional data. We are currently performing a GWA study on CVD risk factors using longitudinal data from >1200 individuals in the Bogalusa Heart Study (BHS), a population-based bi-racial cohort with some individuals having as many as 15 CVD risk factor screenings from childhood to adulthood, spanning over 30 years. We have genotyped these individuals using Illumina's Human610 and HumanCVDv2.0 genotyping BeadChips and have used previously associated markers to develop quantitative predictors of risk factor profiles. We show that for many traits, these scores are significant predictors of the traits over time in European-American individuals, with generally consistent effects from childhood through adulthood. In African-American (AA) individuals, scores could be less predictive, indicating a need for more genetic studies in AA individuals. In an effort to find loci that vary in effect over time, we performed longitudinal GWA using mixed models and describe loci associated with traits over time (SNP main effects) and those with effects that vary over time (SNP by age interaction effects). We reproduce a number of previously characterized associations and show that in addition to a SNP main effect on triglyceride levels, we also see a SNP by age interaction at the 11q23.3 locus (rs12280753, $p = 2 \times 10^{-8}$) containing the APOA1/C3/A4/A5 genes, which has previously been associated with triglyceride levels. Overall, our GWA study on longitudinal data provides insight into the genetic basis of how individuals develop disease over time, from childhood into adulthood.

## 2367/T/Poster Board #916

**Pathway-based genome-wide association analysis of coronary heart disease identifies biologically important gene-sets.** *W. Yang[1], L. de las Fuentes[2], V.G. Dávila-Román[2], C.C. Gu[1,3].* 1) Department of Biostatistics, Washington University, St Louis, MO; 2) Department of Medicine, Cardiovascular Division, Washington University, St Louis, MO; 3) Department of Genetics, Washington University, St Louis, MO.

Genome-wide association (GWAS) studies of complex diseases such as coronary heart disease challenge investigators on how to select relevant genetic variants among hundreds of thousands of markers being tested. While a selection strategy purely based on statistical significance of association tests will result in many false positives in GWAS, integrated analysis using information on learnt genetic pathways might help single out biologically important findings. In the present study, we apply a customized gene-set enrichment analysis (GSEA) method to the GWAS data from the Framingham Heart Study (500K SNPs, n=6,421) to evaluate enrichment of genetic association in a collection of 1,395 gene-sets for their contribution to coronary heart disease (CHD). In our method, the most significant SNP within a gene is selected as deputy and its association statistics is normalized to adjust for varying gene size; the gene-sets collection was constructed form known pathways in public-domain databases (KEGG, GO etc.). Among the 1,395 gene-sets, we found 25 with nominal p-values under 0.01, four of which are known for their role in CHD, including vascular genesis (GO:0001570), fatty acid biosynthetic process (GO:0006633), fatty acid metabolic process (GO:0006631) and glycerolipid metabolic process (GO:0046486). Interestingly, the 4 gene-sets involve 170 genes, but only 3 of the genes contain any SNP ranked among the top 100 from 404,467 SNPs in the single-SNP scan. We also detected novel gene-sets less known for their importance to CHD. Particularly, the RAC1 cell motility signaling pathway and the sulfur amino acid metabolic process (GO:0000096) showed most significant enrichment in association with CHD ($p<0.001$). Many genes in the RAC1 signaling pathway are actually important in diabetes and vascular diseases, including myosin and its targets (MYL2, MLCK, PIK3CB and KCNH2), and RAC1 was reported critical for hypertrophic response in the heart. On the other hand, many genes involved in the sulfur amino acid process are related to methylation (e.g., GCLC, GCLM, MTHFR, MTHFD1, MTR and the well-known CVD-associated homocysteine (BHMT)), which may reflect the potential role of epigenetics in the development of CHD. In summary, we showed that the pathway-based analysis can help prioritize association signals in GWAS studies; and the identified gene-sets point out plausible directions for down-stream search of genetic variants important to CHD.

## 2368/T/Poster Board #917

**Follow up genome-wide association study of intracranial aneurysms identifies novel risk loci and confirms previous findings.** *K. Yasuno[1,2], R.P. Lifton[3,4,5], M. Gunel[1,2,3,6], Genetics of Intracranial Aneurysm Trial Investigators.* 1) Neurosurgery, Yale University School of Medicine, New Haven, CT; 2) Program on Neurogenetics, Yale University School of Medicine, New Haven, CT; 3) Genetics, Yale University School of Medicine, New Haven, CT; 4) Howard Hughes Medical Institute, Yale University School of Medicine, New Haven, CT; 5) Internal Medicine, Yale University School of Medicine, New Haven, CT; 6) Neurobiology, Yale University School of Medicine, New Haven, CT.

Intracranial aneurysms (IA) affect approximately 2% of the population and cause 500,000 hemorrhagic strokes annually in relatively young patients (median age 50), resulting in death and severe neurological impairment. The pathogenesis of aneurysm formation and rupture is unknown, and premorbid identification is essential to prevent catastrophic hemorrhage. We have recently completed a genome-wide association (GWA) study using 2,100 IA cases and 8,000 controls from Finland, the Netherlands and Japan, and identified 3 IA risk loci on chromosomes 2, 8 and 9 (Bilguvar et al. Nat Genet 40, 1472-1477, 2008). In order to increase the power to detect modest risk loci, we have conducted additional whole-genome genotyping for 1,000 German and 640 European IA cases using Illumina Human610 BeadChip, and enrolled >12,000 whole-genome genotyped controls from Germany (PopGen and KORA-gen), Finland (Health 2000 and NFBC1966) and iControlDB. As a replication cohort, we also involved an additional Japanese cohort (2,200 cases and 3,300 controls). As a discovery cohort, we analyzed the Finnish cohort and other European cohorts separately because of the clear ancestry difference. We then matched genetic ancestry between cases and controls utilizing the spectral clustering method (Lee et al. Genet Epidemiol, 2009). The association analysis was performed for each SNP genotyped across all the cohorts that passed the QC filters (> 260,000) by applying the conditional logistic regression for ancestry-matched data. Two new loci showed genomic-control corrected p-values < 5x10-7 and were replicated in two Japanese cohorts.

## 2369/T/Poster Board #918

**Genome wide association(GWA) meta-analyses identify loci affecting risk of young onset type 2 diabetes(T2D) and age of onset of the disease.** *M. van Hoek[1], E. Zeggini[2, 3], A.D. Morris[2], R. Welch[4], V. Steinthorsdottir[5], K. Strassburger[6], S. Cauchi[7], V. Lyssenko[8], C. Dina[7], E.J.G. Sijbrands[1], G. Thorleifsson[5], Y.S. Aulchenko[9], L.J. Scott[4], P. Almgren[8], C.M. van Duijn[9], T.M. Frayling[10, 11], M. Boehnke[4], M.I. McCarthy[2, 12] for the DIAGRAM+ consortium.* 1) Department of Internal Medicine, Erasmus University Medical Center, Rotterdam, Netherlands; 2) The Wellcome Trust Centre for Human Genetics, Roosevelt Drive, Oxford, UK; 3) Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, Cambridge, UK; 4) Department of Biostatistics and Center for Statistical Genetics, University of Michigan, Ann Arbor, Michigan, USA; 5) deCODE genetics, 101 Reykjavík, Iceland; 6) Institute of Biometrics and Epidemiology, German Diabetes Center, Leibniz Institute at Heinrich-Heine-University, Düsseldorf, Germany; 7) CNRS-8090-Institute of Biology, Pasteur Institute, Lille, France; 8) Department of Clinical Sciences, Diabetes and Endocrinology, Lund University, University Hospital Malmo, Malmo, Sweden; 9) Department of Epidemiology and Biostatistics, Erasmus University Medical Center, P.O. Box 2040, 3000 CA Rotterdam, The Netherlands; 10) Genetics of Complex Traits, Peninsula Medical School, Exeter EX1 2LU, UK; 11) Diabetes Genetics, Institute of Biomedical and Clinical Science, Peninsula Medical School, Barrack Road, Exeter EX2 5DW, UK; 12) Oxford Centre for Diabetes, Endocrinology and Metabolism, University of Oxford, Churchill Hospital, Oxford OX3 7LJ, UK.

Genome Wide Association (GWA) studies have resulted in a rapid increase of replicated genetic association signals for T2D. However, recognition of disease subtypes provides opportunities towards better prediction and clinical management. A number of studies have shown that strong family history predisposes to earlier age of onset. This may reflect heterogeneity in the genetic background of T2D. We hypothesized that different genetic association patterns operate in early onset T2D. Furthermore, we hypothesized that genetic loci act as modifiers of age of onset. To investigate these associations, we performed meta-analyses on GWA data of the DIAGRAM+ consortium. We analyzed GWA data of 7 studies of European descent(deCODE, DGDG, DGI, FUSION, KORA, the Rotterdam Study and WTCCC). First, we performed a meta-analysis on young onset T2D in 1,317 cases with ages of diagnosis<45 (excluding type 1 diabetes and monogenic forms) and 29,470 controls.(effective sample size 5,088) Secondly, we performed a meta-analysis on age of diagnosis as a continuous trait in 7,773 cases. The strongest meta-analysis signal for young onset T2D was *TCF7L2*(p= $6.3x10^{-27}$) and another 7 of the 17 previously known T2D susceptibility loci had p-values<$10^{-5}$. Excluding previously-proven associations, we identified five novel loci putatively associated with young onset T2D(p-values from $6.0x10^{-7}$ to $2.6x10^{-6}$.) The top finding was located on chromosome 13q33 (near *LOC728215*, p=$6.0x10^{-7}$) and four further loci were found on chromosomes 4q24, 6p12,10q22, and 12q12. For the continuous trait meta-analysis, none of the previously found T2D associated loci had P<$10^{-5}$. The five top continuous trait signals exhibited pvalues ranging from $1.7x10^{-6}$ to $4.9x10^{-6}$. The top result was located on chromosome 1p(near *AMPD1*, p=$1.7x10^{-6}$), and four other loci were found on chromosomes 5q15,11p14, 12q21 and 13q14. BMI adjustment did not change the results. In conclusion, we found 10 new loci associated with young onset T2D and age of onset.(meta-analysis p-value<$10^{-5}$ in at least five studies). Replication must reveal the robustness of the associations. The first replication set will consist of approximately 1,100 young onset cases (age of diagnosis<45) versus 1,100 controls and the second set will consist of approximately 8,000 cases with a wide range of ages of onset. Eventually, our findings are expected to make a valuable contribution to our understanding of the disease and its phenotypic appearances.

## 2370/T/Poster Board #919

**Coronary ARtery DIsease Genome-wide Replication And Meta-Analysis (CARDIoGRAM) - Design of a prospective meta-analysis of 14 genome-wide association studies.** *I.R. König on behalf of CARDIoGRAM.* Institut für Medizinische Biometrie und Statistik, Universität zu Lübeck, Germany.

Coronary artery disease (CAD) is the leading cause of death in U.S. and Europe and is a heritable trait. Classical genome-wide association studies (GWAS) have uncovered at least 13 common alleles associated with CAD. However, each variant confers a modest effect, and together, the variants explain a small fraction of inter-individual variation only. These observations suggest that additional loci harboring CAD-associated variants might be discoverable with larger samples and improved statistical power. To accomplish this, we assembled the CARDIoGRAM Consortium that pools GWAS data from ADVANCE, CADomics, CHARGE, deCode, GerMIFS I-III (KORA), LURIC/AtheroRemo, MedStar/PennCath, MIGen, OHGS, and the WTCCC. In total, the consortium comprises more than 22,000 well-characterized cases with CAD and more than 60,000 controls mostly from population-based studies. In each individual study, genome-wide genotyping was carried out on either Affymetrix or Illumina platforms, and imputation was conducted to generate genotypes for ~2.2 million SNPs in each study. With the aim of conducting a type II meta-analysis using GWAS results from the single studies and consortia, standard operating procedures were generated in order to harmonize the data analyses. Extensive quality control was performed both study-wise and centrally so as to provide standardized data formats of high quality. With the assembled sample size, the estimated power to detect modest effects is substantially increased. For instance, even for genome-wide significance, the power is about 80% for an odds ratio of 1.1, provided that the minor allele frequency is at least 10%. Meta-analyses for the CAD phenotype as well as for important subgroups including myocardial infarction and early-onset CAD will be carried out. Following the initial evaluations, wet lab replication genotyping of top results will be sought in > 15,000 additional cases and 15,000 controls. CARDIoGRAM brings together an enormous wealth of GWAs data on CAD and MI, thus representing the largest study to date to uncover the inherited basis for the leading public health problem in the industrialized world.

## 2371/T/Poster Board #920

**Genome-Wide Association Study of Anatomic Coronary Artery Disease.** *G.W. Beecham[1], D. Seo[2], K. Hamilton[1], I. Konadari[1], J.R. Gilbert[1], P. Goldschmidt-Clermont[2], M.A. Pericak-Vance[1].* 1) Miller School of Medicine, Institute of Human Genomics, University of Miami, Miami, FL; 2) Miller School of Medicine, University of Miami, Miami, FL.

Coronary heart disease is the leading cause of death in the United States, with atherosclerosis of the coronary arteries being the major underlying etiology. Patients with atherosclerotic coronary artery disease (CAD) are more likely to suffer a myocardial infarction or sudden cardiac death. CAD is highly heritable, but there have been few genetic studies of anatomic CAD and the knowledge of CAD genetics is incomplete. To further determine the genetic etiology of anatomic CAD, we have performed the first genome-wide association study of anatomic coronary artery disease, using our dataset of 900 cardiac catheterization patients. Each patient received cardiac catheterization and was assigned a CAD burden index which measures their overall anatomic CAD burden based on size and location of coronary lesions. Data were generating using the Affymetrix SNP array 6.0 platform for 900,000 SNPs. Extensive quality control tests were performed to ensure the integrity of the data, including Eigenstrat methods to correct for population substructure. We tested for association with linear regression using the PLINK software package, and included smoking, cholesterol, blood pressure, age, sex, and two vectors describing the population substructure of the sample. We detected strong association ($p < 0.00001$) on 14 different chromosomes, in 10 different genes. Among these are the largely uncharacterized PRUNE homologue gene on chromosome 1 (p-value = 8 x 10-7) and the citron (rho-interacting, serine/threonin kinase 21) gene on chromosome 12. These signals are being validated in an independent dataset of 1100 CAD patients. These data provide promising results that may lead to further insights into the genetics of anatomic coronary artery disease.

**A Genome-wide association study identifies new loci for ACE activity: potential implications for response to ACE inhibitor.** *C. Chung[1,2], R. Wang[3], J. Chen[4], C. Fann[1], H. Leu[5], H. Ho[6], C. Ting[6], T. Lin[7], S. Sheu[7], W. Tsa[8], J. Chen[8], Y. Jong[9], S. Lin[5], Y. Chen[1], W. Pan[1].* 1) Inst Biomedical Sci, Academia Sinica, Taipei, Taiwan; 2) Division of Molecular Medicine, Institute of Public Health, School of Medicine, National Yang-Ming University, Taipei, Taiwan; 3) Department of Public Health, China Medical University, Taichung, Taiwan; 4) Cardiovascular Research Center, National Yang-Ming University, Taipei, Taiwan; 5) Taipei Veteran General Hospital, Taipei, Taiwan; 6) Taichung Veteran General Hospital, Taichung, Taiwan; 7) Kaohsiung Medical Center, Kaohsiung, Taiwan; 8) College of Medicine, National Cheng Kung University, Tainan, Taiwan; 9) Department of Cardiology, Tao-Yuan General Hospital Department of Health, Taiwan.

Introduction: Angiotensin converting enzyme (ACE) is a key enzyme of the famous renin-angiotensin-aldosterone system and pivotal in blood pressure regulation and other physiological conditions. Because ACE activity is implicated widely in biological systems, we aimed to identify its novel quantitative trait loci for the purposes of understanding ACE activity regulation and pharmacogenetics relating to ACE inhibitor (ACEI). Methods: We performed a two-stage genome-wide association study using Illumina HumanHap550 SNP Chip information from 400 young-onset hypertension (YOH) subjects in the first stage, confirming the findings with an additional 623 YOH subjects in the second stage, and replicating the results in a separate YOH family studies (428 hypertension pedigrees). Results: Eight SNPs of the ACE structural gene were significantly associated with ACE activity (-log p value range, 8.9-19.0). SNP rs4343 in exon17 near the well-known Insertion/deletion polymorphism had the strongest association. The second-stage confirmatory study verified significantly four of these SNPs: rs4343 in ACE gene (-log p =24.52), rs495828 (-log p =7.45) and rs8176746 (-log p =3.42) in ABO gene and rs1015870 in PCDH9 gene (-log p = 2.11). We further replicated the association between ABO blood types and ACE activity in the independent family study, and demonstrated a potential differential blood pressure response to ACEI in subjects with varied numbers of ACE activity-raising alleles. Conclusion: These findings may broaden our understanding of the mechanisms controlling ACE activity and advance our pharmacogenetic knowledge on ACEI.

## 2373/T/Poster Board #922

**A genome-wide association study identifies a potential locus near PKHD1 that might increase aldosterone renin ratio in Taiwanese young-onset hypertension patients.** *TY. Kuo[1], KM. Chiang[1], HY. Ho[2], CT. Ting[2], TH. Lin[3], SH. Sheu[3], WC. Tsai[4], JH. Chen[4], HB. Leu[5], WH. Yin[6], TY. Chiu[7], CI. Chen[7], SJ. Lin[5], JW. Chen[5], WH. Pan[1].* 1) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 2) Taichung Veterans General Hospital, Taichung, Taiwan; 3) Kaohsiung Medical University Chung-Ho Memorial Hospital, Kaohsiung, Taiwan; 4) National Cheng Kung University Hospital, Tainan, Taiwan; 5) National Yang-Ming University School of Medicine and Taipei Veterans General Hospital, Taipei, Taiwan; 6) Cheng Hsin Rehabilitation Medical Center, Taipei, Taiwan; 7) Min Sheng General Hospital, Taoyuan, Taiwan.

Primary aldosteronism is the most common secondary cause of hypertension and has much higher prevalence rate among hypertension patients than previously thought. High plasma aldosterone and low plasma renin concentrations are the main characteristic of primary aldosteronism. Therefore the ratio of plasma aldosterone concentration and plasma renin activity is a widely accepted screening test for primary aldosteronism. We performed a genome-wide association study for identifying genetic variants that might influence Aldosterone-renin ratio (ARR) We genotyped 560,184 SNPs using Illumina 550K SNP Array in 400 hypertensive patients aged between 20 and 50 from Taiwanese population. ARR was calculated for each patient with plasma aldosterone concentration (PAC) as the numerator and plasma renin activity (PRA) as the denominator. Of these patients, individuals with ARR>=40 (ng/dl)/(ng/ml/hr) were considered as cases (n=75) and those with ARR<25 and were considered as controls (n=285). Single SNP tests and haplotype-based tests of association were used for statistical analysis. We identified two SNPs, RS9473992 (P=1.91x10-8) and RS6928877 (P= 2.73x10-7) on 6p12.2 near PKHD1, that were significantly associated with the increase of ARR. A common haplotype that contains the risk alleles of the two SNPs was also identified. Fisher exact probability test for this haplotype shows significant association by haplotype analysis before Bonferroni correction (P=2.61x10-7). However, this association was no longer significant if we considered aldosterone or renin concentrations alone in our study. In addition to PKHD1 gene that is associated with polycystic kidney and hepatic disease, a coding sequence similar to Wilms tumour 1-associating protein was also nearby. For verifying the two SNPs, we are going to use another independent set of samples with 150 cases (high ARR) and 353 controls (low ARR) based on the same criteria. As far as we know, this study is the first genome-wide association study using ARR as a quantitative trait for hypertension.

## 2374/T/Poster Board #923

**Genome-wide association scan identifies multiple loci for plasma levels of protein C in the ARIC cohort.** *W. Tang[1], S. Basu[2], A.R. Folsom[1], X. Kong[2], J.S. Pankow[1], N. Aleksic[3], E. Boerwinkle[4].* 1) Division of Epidemiology and Community Health, University of Minnesota, Minneapolis, MN; 2) Division of Biostatistics, University of Minnesota, Minneapolis, MN; 3) DNA Laboratory, University of Texas Health Science Center at Houston, Houston, Texas; 4) Human Genetics Center, University of Texas Health Science Center at Houston, Houston, Texas.

Protein C is a vitamin K-dependent plasma protein zymogen that, upon activation, functions as an important anticoagulant and also exerts anti-inflammatory, anti-apoptotic, and endothelial barrier stabilization effects. Genetic deficiencies in protein C are associated with increased risk of venous thromboembolism. To map DNA sequence variants influencing plasma levels of protein C, we performed a large-scale, genome-wide association study among 8,048 participants of European ancestry in the Atherosclerosis Risk in Communities (ARIC) Study. A genome-wide scan was conducted with the Affymetrix SNP array 6.0 and imputed to ~2.5 million HapMap SNPs. A linear regression was conducted and adjusted for age, sex, and field center in an additive genetic model. Dosage information for imputed SNPs was incorporated into the regression analysis. The genomic control coefficient was 1.04, suggesting negligible test statistic inflation. A total of 513 SNPs exceeded the genome-wide significance threshold of 5.0E-8 and marked 3 loci on chromosomes 2 and 20: 2p23 (spanning 208K bp, smallest p-value 2.0E-17), 2q13-q14 (spanning 435K bp, 3.8E-36), and 20q11 (spanning 3.3M bp, 2.7E-203). At the 2p23 region, 5 genes were revealed and the SNP with the smallest p-value was from the glucokinase (hexokinase 4) regulator (GCKR) gene, a novel locus for protein C; at the 2q13-q14 region, 6 genes were revealed and the SNP with the smallest p-value was from the protein C structure gene (PROC); at the 20q11 region, 38 genes were revealed and the SNP with the smallest p-value was near the activated protein C receptor gene (PROCR), also called endothelial cell protein C receptor (EPCR); this SNP is in high linkage disequilibrium with a PROCR SNP (missense variant) that showed similar p-value (2.0E-200). The protein C receptor serves as a receptor for activated protein C and further enhances the activation of protein C. After adjustment for the PROCR SNP, 4 genes at the 20q11 region remained genome-wide significant. In summary, our study identified both new and known genetic loci influencing plasma levels of protein C in the general population. These findings may provide important information for prevention and treatment of disorders in which activated protein C is implicated.

## 2375/T/Poster Board #924

**Genome-wide association analysis identifies loci of Sudden Unexplained Death Syndrome (SUDS).** *P. Teekakirikul[1], S. Sangwatanaroj[2], S.R. DePalma[1], J.M. Gorham[1], B. McDonough[1,3], J.G. Seidman[1], C.E. Seidman[1,3,4].* 1) Department of Genetics, Harvard Medical School, Boston, MA; 2) Division of Cardiovascular Medicine, Faculty of Medicine, Chulalongkorn University, Bangkok, Thailand; 3) Cardiovascular Division, Brigham and Women's Hospital, Boston, MA; 4) Howard Hughes Medical Institute, Boston, MA.

Sudden Unexplained Death Syndrome (SUDS), a leading natural cause of death in young Southeast Asian men, has been shown with the significant familial aggregation; however, genetic etiology has not been clarified. This fatal arrhythmic syndrome shares the same ECG pattern as Brugada Syndrome, an inherited heart disorder with autosomal dominant pattern. To date, Brugada syndrome has been related to cardiac sodium channel gene (*SCN5A*) mutation. To identify the genetic variants of SUDS, we used both candidate gene and genome-wide approaches in this study. We sequenced *SCN5A* in 20 Southeast Asian SUDS survivors and detected no genetic variants that account for SUDS. We further performed genome-wide association study using Affymetrix 250K Sty SNP Chip based on these Southeast Asian SUDS cases (n=20) and the Asian population frequency data from the Hapmap (n=90). Of 238,304 SNPs, only two significant SNPs clustered on Chromosome 1 (1p13.3), rs6697697 and rs6686425, demonstrated marked variation in genotype frequency between cases and controls (Bonferroni-corrected *P* value: 0.003 and 0.006, respectively). The risk alleles of two correlated SNPs were strongly associated with SUDS: 1) rs6697697 with odds ratio of 8.06 (3.649-17.78) and 2) rs6686425 with odds ratio 7.82 (3.583-17.06), respectively. These two polymorphisms were then successfully validated using re-sequencing and Sequenom iPLEX Genotyping. We therefore focused on this first putative region. To refine the association, we proceeded to genotype additional 49 SNPs in the 222-kilobase region and detected a single haplotype across this region. Haplotype analysis showed the significant association with SUDS (*P* value = $1.68 \times 10^{-7}$). All SNPs in this genomic region were under Hardy-Weinberg Equilibrium. This linkage disequilibrium block contains two spliced expressed sequence tags (ESTs) that are expressed in human testicular tissues. In summary, we reported a single haplotype in the 1p13.3 region revealed by genome-wide scan that is associated with SUDS and warrants further investigation.

**Replication of Caucasian GWAS lipid signals in Mexicans.** *D. Weissglas[1], A. Huertas-Vazquez[1], L. Riba[2], T. Tusie-Luna[2], C. Aguilar-Salinas[3], P. Pajukanta[1]*. 1) Department of Human Genetics, David Geffen School of Medicine at UCLA, Los Angeles, CA; 2) Molecular Biology and Genomic Medicine Unit, Instituto de Investigaciones Biomédicas de la UNAM, INCMNSZ, Mexico City, Mexico; 3) Department of Endocrinology and Metabolism, INCMNSZ, Mexico City, Mexico.

**Background:** Cardiovascular risk factors such as unfavorable serum lipid levels are highly common among Mexicans and increasing at alarming rates. Previous epidemiological studies have specifically demonstrated an increased predisposition to low high-density lipoprotein cholesterol (HDL-C) and high serum triglyceride (TG) levels in the Mexican population. However, no genome-wide association studies (GWAS) for lipids have been performed in Mexicans. **Methods and Results:** We genotyped 15 SNPs associated with plasma HDL-C and/or TG levels in recent Caucasian GWAS in Mexican familial combined hyperlipidemia families and hypertriglyceridemia case-control study samples. These variants were within or near the genes ANGPTL3, GALNT2, GCKR, APOB, LPL (2), XKR6-AMAC1L2, TRIB1, ABCA1, MTNR1B, NCAN, APOA1/C3/A4/A5, MMAB/MVK, LIPC and LCAT. We performed a combined analysis of the family-based and case-control studies (n = 2,348) using the Fisher's method for combining p-values. We observed significant association with $P < 0.01$ at four of the 15 loci (APOA1/C3/A4/A5, GCKR, GALNT2 and LIPC). These signals were for the same trait and risk allele as in Caucasians. Interestingly, our strongest signal was obtained for TGs with the rare allele of rs964184 ($P = 1.7 \times 10^{-10}$) in the APOA1/C3/A4/A5 cluster that was more common in Mexicans (34%) when compared to Caucasians (14%). Furthermore, the common risk allele of rs10468017, near the LIPC gene, was also more prevalent in Mexicans (85%) than in Caucasians (70%). **Conclusions:** We show replication of four Caucasian GWAS lipid signals in Mexicans. The remaining loci will require a comprehensive investigation to exclude or verify their significance in Mexicans. We also demonstrate that two of these susceptibility variants are more prevalent in the Mexican population and may confer to the increased predisposition to dyslipidemias in Mexicans.

## 2377/T/Poster Board #926

**Genome-wide association study on systolic blood pressure measures in the Framingham Heart Study.** *B. Kerner[1], J. Kong[1], B.O. Muthén[2].* 1) Ctr Neurobehavioral Gen, Univ California, Los Angeles, Los Angeles, CA; 2) Professor Emeritus, University California, Los Angeles, Los Angeles, CA.

The physiology and patho-physiology of blood pressure regulation is highly complex. In order to better understand this regulatory network researchers have undertaking the task to identify genomic variants that might be associated with the variance in blood pressure measures in the general population using genome-wide association studies in ten thousands of individual. Given the complexities of blood pressure regulation it is highly likely, however, that population samples are heterogeneous. Genetic factors that carry risk for blood pressure elevation early in life might be different from those influencing high blood pressure later in life. Physiologic blood pressure variation in normal individuals might have different genetic contributions than those found in high risk individuals. Growth mixture modeling is a less explored method in genetic research to address unobserved heterogeneity in population samples. Here, we applied this technique to longitudinal data of the Framingham Heart Study. We examined systolic blood pressure measures in 1060 males in 692 families and detected three subclasses, which varied significantly in their developmental trajectories over time. The first class consisted of 60 high-risk individuals with elevated blood pressure early in life and a steep increase over time. The second group of 131 individuals displayed first normal blood pressure, but reached high blood pressure values late in their life time. The largest group of 869 individuals could be considered a normative group with normal blood pressure on all exams. In order to identify genetic modulators for this phenotype we tested for genome-wide association between class membership probability and single nucleotide polymorphisms using the Affymetrix 500k array. Class 1 membership probability was significantly associated with SNPs in 23 genes ($p<5 \times 10^{-8}$). Six genes contained multiple significant associations including KANK1 (9p24.3), AGPAT5 (8p23.1), CREB5 (7p15.1), GULP (2q32.3-33), CAPN13 (2p22-p21), and LIPN (10q23.31). Class 2 membership probability was significantly associated with an intronic SNP in SGPL1 (10q21). A limitation of our study is the small sample size of the high risk group. These results await replication; however, they suggest that analyzing genetic data stratified for high-risk subgroups defined by a unique development over time could be useful for the detection of rare mutations in common multi-factorial diseases.

## 2378/T/Poster Board #927

**The Genetics, Exercise and Research(GEAR)Study: A new paradigm for targeting fitness through genetics.** *J. Farmer, D. Tekin, T. Musto, D. Vance, M. Slifer, D. Seo, P. Goldschmidt-Clermont, P. Vance, E. Rampersaud.* University of Miami, Miller School of Medicine, Miami, FL.

Research approaches to better understand the role of individual genetic variation in response to physical activity is a crucial step towards development of personalized clinical medicine. By revealing how genetics and physical activity are associated with health related outcomes, clinicians can develop preventative approaches for the treatment of at-risk asymptomatic individuals. The potential value of physical activity has been demonstrated in prevention of cardiovascular diseases, depression, and dementia. Although some studies have examined the modifying effects of genetics on exercise response in clinical patient populations, very little is known about the relationship between genetics and physical activity among healthy sedentary individuals. To better characterize this relationship we must develop new paradigms for exploring the role of genetics as a component of medical exercise prescriptions. The goal of this project is to define genetic profiles that are associated with varying levels of response to physical activity in the general population. Thus we assembled a multidisciplinary research team consisting of exercise trainers and physiologists, cardiologists, geneticists, molecular biologists, epidemiologists and explored the use of a university wellness center program to answer these questions. Specifically, we have developed the Genetics, Exercise and Research (GEAR) study, a unique, comprehensive approach to understanding the genetics of fitness. GEAR enrolls healthy sedentary individuals to participate in a 12-week exercise training program who undergo a baseline health related fitness (HRF) assessment including (1) cardio-respiratory fitness (CR) measured by the modified Balke treadmill protocol, (2) musculoskeletal fitness (MSK) measured by upper and lower body 1RM testing, and (3) body composition (BC) measured by a skin fold test. Each participant will provide a blood sample (fasting) at baseline and at the end of training for genetic analyses. Lipid and related biomarker profiles of cardiovascular health will also be measured. Questionnaires will be administered to collect information on demographics, family history, medical history, and lifestyle risk factors including dietary information. Physical activity over a 12-week period of time will be documented using a self-report log book with follow-up fitness assessments to evaluate the changes in HRF. Study design and implementation protocol along with baseline data will be presented.

## 2379/T/Poster Board #928

**Epistasis and the Genetic Architecture of Arterial Thrombosis in West Africans.** *N.M. Penrod[1], F.W. Asselbergs[2], K. Poku[3], J.H. Moore[1], S.M. Williams[4].* 1) Department of Genetics, Dartmouth College, Lebanon, NH; 2) University of Groningen, The Netherlends; 3) University of Ghana, Accra; 4) Vanderbilt University, Nashville, TN.

The enzymes, tissue plasminogen activator (t-PA) and plasminogen activator inhibitor 1 (PAI-1) act in concert to counterbalance thrombus formation and degradation in a homeostatic defense against the development of arterial thrombosis and excessive bleeding. PAI-1 production is upregulated by the renin-angiotensin system (RAS), specifically by angiotensin II the product of the angiotensin converting enzyme (ACE). Angiotensinogen (AGT) is the key substrate of this system being cleaved by renin (REN) to initiate these downstream enzymatic reactions. Upon inhibition, ACE indirectly stimulates the release of t-PA which, in turn, activates the corresponding fibrinolytic system. Polymorphisms in these pathways have been shown to significantly impact the plasma levels of t-PA and PAI-1 differentially between males and females in a large-scale population-based sample from urban West Africa. Here we explore the involvement of epistatic interactions between the same polymorphisms in central genes of the RAS and fibrinolytic systems on plasma t-PA and PAI-1 levels within the same population (n=992). Statistical modeling of epistatic interactions between polymorphisms in the ETNK2, REN, ACE, PAI-1, t-PA, and AGT genes was carried out using two-way ANOVA to assess their interaction effects on plasma levels of t-PA and PAI-1. We found the strongest interactions between polymorphisms of REN with the TPA I/D variant (p=0.001) for females and the PAI 4G/5G variant (p=0.009) for males, indicative of PAI-1 levels. Similarly, t-PA levels associated with ETNK2 variations in association with the PAI 4G/5G variant (p=0.029) for females and the REN G/T polymorphism (p=0.024) for males. These results represent only a few of the many significant interactions detected in this analysis. Strikingly, many more interactions were found in this African population than in a previously published study of Caucasians from the Netherlands. The outcome of this analysis confirms the notion that the underlying genetic architecture of cardiovascular disease is complex and, as such, it is necessary to consider the relationship between interacting polymorphisms of the pathway specific genes that predict t-PA and PAI-1 levels.

**Diet Modifies the Myocardial Infarction Risk of Chromosome 9p21 Variants Globally.** *J.C. Engert[1,4], R. Do[1], X. Zhang[2], S. islam[2], S.D. Bailey[2], S. Ragarajan[2], M.J. McQueen[2], X. Wang[3], S. Yusuf[2], S.S. Anand[2] on behalf of the INTERHEART investigators.* 1) Department of Human Genetics, McGill University, Montréal, QC, Canada; 2) Population Health Research Institute, Hamilton Health Sciences and Departments of Medicine and Clinical Epidemiology, McMaster University, Hamilton, ON, Canada; 3) Laboratory of Human Genetics, Beijing Hypertension League Institute, Beijing, China; 4) Department of Medicine, McGill University, Montréal, QC, Canada.

Background: Multiple studies have confirmed that genetic variants in the chromosome 9p21 locus are associated with coronary heart disease (CHD) in several populations. However, interactions of these variants with environmental factors have not been extensively explored. Methods: We genotyped four SNPs at the 9p21 locus in 1,744 Europeans, 1,867 South Asians, 2,292 Chinese, 1,100 Latin Americans and 1,172 Arabs (n=8,175 total) from the INTERHEART study. We assessed the association of 9p21 with myocardial infarction (MI), and tested for interaction with environmental factors including three dietary pattern scores derived from a 19 food item dietary questionnaire. Results: All four chromosome 9p21 variants were in linkage disequilibrium and associated with MI in the combined sample that included all ethnicities (1.18?OR?1.20, 7.42x10-9?P?2.83x10-7). All four SNPs were associated in Europeans (1.17?OR?1.18, 0.016?P?0.024), South Asians (1.22?OR?1.27, 0.0003?P?0.0025), and Chinese (1.18?OR?1.22, 0.0009?P?0.0056) and three were associated in Latin Americans (1.22?OR?1.32, 0.0066?P?0.029)_ while Arabs displayed a non-significant trend for all four SNPs (1.04?OR?1.12). A significant interaction was observed with a prudent diet pattern score for all 4 SNPs, with rs2383206 having the strongest interaction on MI (P=0.0005). A pronounced effect of the G allele of rs2383206 on MI was observed in the group with a low prudent diet score (OR=1.34, P=$7.38x10^{-8}$), while the effect was diminished in a step-wise fashion in the medium (OR=1.17, P=0.0046) and high scoring groups (OR=1.03, P=0.57). The combination of a low prudent diet score and two copies of the risk allele was associated with a two-fold increase in risk for MI (OR=2.04, P=$2.45x10^{-10}$). Similar interactions were found with the level of raw vegetable intake, a major component of the prudent diet score. Conclusions: We demonstrate that diet modifies the risk of 9p21 on acute MI across multiple ethnic groups. These results enhance our understanding of the underlying pathophysiology of chromosome 9p21 variation and highlight the important interplay of genes and environment in the etiology of CHD.

## 2381/T/Poster Board #930

**Synergistic effect of polymorphisms of paraoxonase gene cluster and arsenic exposure on electrocardiogram abnormality.** *Y. Liao[1,2], W. Li[2], C. Chen[1,3], R. Prineas[4], W. Chen[1,5], Z. Zhang[4], C. Sun[2], S. Wang[2,6].* 1) Graduate Institute of Epidemiology, College of Public Health, National Taiwan University, Taiwan; 2) Division of Environmental Health and Occupational Medicine, National Health Research Institutes, Taiwan; 3) Genomics Research Center, Academia Sinica, Taiwan; 4) Epidemiologic Cardiology Research Center, Department of Epidemiology and Prevention, Division of Public Health Sciences, Wake Forest University School of Medicine, NC, USA; 5) Genetic Epidemiology Core Laboratory, National Taiwan University Center for Genomic Medicine, Taiwan; 6) Institute of Environmental Medicine, College of Public Health, China Medical University Hospital, Taichung, Taiwan.

Arsenic has been linked to increased prevalence of cancer and cardiovascular disease (CVD), but the long term impact of arsenic exposure remains unclear. Human paraoxonase (PON1) is a high-density lipoprotein associated antioxidant enzyme which hydrolyzes oxidized lipids and is thought to be protective against atherosclerosis, but evidence remains limited to case-control studies. Only recently have genes encoding enzymes responsible for arsenic metabolism, such as AS3MT and GSTO, been cloned and characterized. This study was designed to evaluate the synergistic interaction of genetic factors and arsenic exposure on electrocardiogram abnormality. A total of 216 residents from three tap water implemented villages of previous arseniasis-hyperendemic regions in Taiwan were prospectively followed for an average of 8 years. For each resident, a 12-lead conventional electrocardiogram (ECG) was recorded and coded by Minnesota Code standard criteria. Eight functional polymorphisms of PON1, PON2, AS3MT, GSTO1, and GSTO2 were examined for genetic susceptibility to ECG abnormality. Among 42 incident cases with ECG deterioration identified among 121 baseline-normal subjects, arsenic exposure was significantly correlated with incidence of ECG abnormality. In addition, polymorphisms in two paraoxonase genes were also found associated with the incidence of ECG abnormality. A haplotype R-C-S constituted by polymorphisms of PON1 Q192R, -108C/T and PON2 C311S was linked to the increased risk. Subjects exposed to high levels of As (cumulative As exposure N14.7 ppm-year or drinking artesian well water N21 years) and carrying the R-C-S haplotype had significantly increased risks for ECG abnormality over those with only one risk factor. Results of this study showed a long term arsenic effect on ECG abnormality and significant gene-gene and gene-environment interactions linked to the incidence of CVD. This finding might have important implications for a novel and potentially useful biomarker of arsenic risk.

## 2382/T/Poster Board #931

**Apolipoproteinn AI and CIII gene polymorphisms among a sample of Healthy Kuwaiti's and CHD patients.** *S. Al-Bustan[1], M. Alnaqeeb[1], B. Annice[1], I. Al-Rashdan[2,3].* 1) Biological Sci, Faculty Sci, Kuwait Univ, Khalidya, Kuwait; 2) Department of Medicine, Faculty of Medicine, Kuwait Univ, Jabriya, Kuwait; 3) Chest Hospital, Al-Sabah Hospital Complex, Shuwaikh, Kuwait.

Apolipoproteins are responsible for the clearance of lipoproteins, failure of which may lead to the development of coronary heart disease (CHD. APOCIII and APOAI genes, components of the APOAI/CIII/IV/V gene cluster on chromosome 11q23-24, encode protein constituent of VLDL and chylomicron remnants, and HDL, respectively. Single nucleotide polymorphisms (SNP's) may alter their function affecting the transport and metabolism of lipoproteins possibly leading to atherosclerosis. In the last few decades CHD has become the leading cause of death in Kuwaitis, with a 33% increase in the mortality rate. Therefore, the objective of this study was to characterize genotypes and minor alleles and their potential association to CHD in the Kuwaiti population. APOCIII 3238C-G and the APOAI -2500C-T SNP's introducing an *Sst*I and *Xmn*I restriction sites, respectively were analyzed in 174 Kuwaiti CHD patients and 234 healthy controls most of which are of Arab ethnicity. Genotyping DNA samples was determined by PCR-RFLP of the *Sst*I and *Xmn*I restriction sites. Genotype and allele frequencies were determined by simple gene counting methods. Hardy-Weinberg Equilibrium and Linkage disequilibrium among the two polymorphisms were estimated for both groups using GENEPOP (Version 3.4). Preliminary analysis of genotype and allele frequencies at both loci in both the CHD (S1:0.834,S2:0.166; X1:0.828, X2:0.172) and healthy controls (S1:0.811,S2:0.189; X1:0.788,X2:0.212) were comparable to those reported in other populations and were found to be in Hardy-Weinberg equilibrium (p>0.05) indicating no direct association to the increased risk of developing CHD in the Kuwaiti population. However, the presence of a strong family history of heart disease in the Kuwaiti patients in addition to the fact that the two polymorphisms were found to be in strong linkage disequilibrium (p=0.006) in the normal controls but not in the patient group (p=0.281) may suggest a genetic component interacting with plasma lipid transport and metabolism in increasing the risk of CHD in the Kuwaiti population. Investigating potential direct or indirect involvement of minor alleles in patients could reflect the interaction of the the highly prevalent dyslipidemia, obesity, sedentary life-style with the diverse ethnicity in Kuwait to promote CHD. Further analysis of other relevant variables such as plasma lipid levels, BMI, ethnicity and a larger sample pool will be required and is currently being analyzed.

## 2383/T/Poster Board #932

**Natural history of the Danon disease phenotype in a large affected population.** *D. Boucek, J. Jirikowic, C. Wells, L. Mestroni, M. Taylor.* University of Colorado Denver, Aurora, CO.

**Background:** Danon disease (OMIM#300257) is a rare X-linked disorder that was originally described in boys affected with cardiomyopathy, skeletal myopathy, and intellectual dysfunction. Subsequent reports of affected females with cardiomyopathy and cardiac conduction problems showed that the disease has X-linked dominant inheritance although males are clearly affected earlier and with greater severity. To date, the majority of reports have focused on the severe nature of the cardiomyopathy in single families or small case series (largest previous case series = 13 families). **Methods:** We developed a Danon disease registry and a patient-information website (www.danondisease.org) under an IRB protocol in order to identify multiple families affected by Danon disease. Family members are evaluated in person or interviewed by telephone. Reported medical data and family history data are collected and reviewed and we ask about cardiac and non-cardiac signs and symptoms of Danon disease. **Results:** To date we have been contacted by 40 families with confirmed or suspected Danon disease with the largest pedigree having 14 affected individuals. Based on our analysis of available clinical data, the average age of first symptom development is 8.2 years and 24.4 years for males and females, respectively. The average age of diagnosis is 11.1 years and 33.7 years for males and females, respectively. Cardiomyopathy in boys is predominantly hypertrophic (75%), but dilated disease does occur (8%); in females 46% and 15% have hypertrophic or dilated cardiomyopathy, respectively. Cardiac conduction abnormalities occur in 75% of males and 61.5% of females. Muscle weakness is reported in 82% of males and, somewhat surprisingly, in 62% of females, suggesting that myopathy in females has been under-recognized previously. Extra-cardiac problems include: retinal pigmentary changes (52%), mild cognitive disability (100% males; 38% females), and abdominal complaints (~25%; including pain, diarrhea/constipation). **Conclusions:** Here we describe the broad phenotype of Danon disease based on data from 40 families, the largest cohort reported to date. Both males and females develop a phenotype with females being diagnosed approximately 2 decades after males. We also noted prevalent skeletal myopathy complaints and mild cognitive concerns in females that have not been reported previously.

## 2384/T/Poster Board #933

**A cardiovascular lifestyle change program for heart disease reversal changes patterns of gene expression in peripheral blood.** *D. Ellsworth[1], J. Weyandt[1], B. Love[2], A. Burke[3], M. Haberkorn[3], H. Patney[1], R. Jordan[1], M. Vernalis[4].* 1) Integrative Cardiac Health, Windber Research Institute, Windber, PA; 2) Invitrogen, Carlsbad, CA; 3) Integrative Cardiac Health, Windber Medical Center, Windber, PA; 4) Integrative Cardiac Health, Walter Reed Army Medical Center, Washington, DC.

Heart disease is a leading cause of death, disability, and healthcare burden. Many cardiac patients receive surgical interventions and lipid-lowering drug therapy as the main component of their treatment, but interventions involving risk factor modification through comprehensive lifestyle changes also are effective in reducing traditional risk factors for cardiovascular disease and in slowing or reversing the progression of coronary atherosclerosis. Although lifestyle change is effective in improving traditional risk profiles, little is known about molecular responses that may form the basis for disease regression. The study population consisted of 74 individuals, 37 Caucasian participants who completed a prospective, nonrandomized intervention designed to stabilize or reverse progression of coronary artery disease through dietary changes, exercise, stress management, and group support and an equal number of nonintervention controls matched to patients based on age, gender, heart disease status, and diabetes status. Risk factors and risk for future coronary events were assessed over the course of one year. Global gene expression profiling was conducted on peripheral blood samples using Affymetrix U133A 2.0 arrays containing ~14,500 genes. Most patients showed significant (P<0.05) improvements in body mass index, lipids, blood pressure, and exercise capacity, as well as long-term cardiovascular risk compared to the control group. Over the course of one year, 1,418 genes showed significant changes in expression (P<0.05 and fold change >1.2) in lifestyle participants compared to only 7 genes among controls. Up-regulated genes outnumbered down-regulated genes by approximately two-fold. Functional ontologies of genes showing the most significant up-regulation included nucleic acid and protein binding, transcription regulation, and cellular assembly. Fundamental molecular changes occur during intensive cardiovascular lifestyle modification. Differentially expressed genes may contribute to improved vascular health through biological processes such as lipid metabolism, plaque stability, and fatty acid transport. Defining molecular responses to lifestyle modification programs may improve our understanding of heart disease and aid in the development of more effective treatments.

## 2385/T/Poster Board #934

**Refining molecular pathways leading to calcific aortic valve stenosis by studying gene expression profile of normal and calcified stenotic human aortic valves.** *Y. Bosse[1,2], D. Fournier[1], A. Pépin[1], P. Pibarot[1], P. Mathieu[1].* 1) Institut universitaire de cardiologie et de pneumologie de Québec, Laval University, Quebec, PQ, Canada; 2) Laval University Hospital Research Center (CRCHUL), Quebec, PQ, Canada.

Calcific aortic valve stenosis (AS) is a major societal and economic burden that is rising following the current shift toward an older population. Understanding the pathobiology of AS is crucial to implement better preventive and therapeutic options. Research conducted during the past decade clearly point to active molecular and cellular processes involved in disease pathogenesis. However, no genomic approaches were used to identify genes and pathways that are differentially regulated in aortic valves of patients with and without AS. A large-scale quantitative measurement of gene expression was performed on five normal and five AS valves using Affymetrix GeneChips. A total of 409 and 306 genes were significantly up- and down-regulated in AS valves, respectively. The two most highly up-regulated genes were matrix metalloproteinase 12 (MMP12) and chitinase 3-like 1 (CHI3L1). The up-regulation of these two biological relevant genes in AS was validated by real-time PCR in 38 aortic valves (12 normal and 26 AS). To provide a global biological validation of the whole-genome gene expression analysis, the microarray experiment was repeated in a second set of aortic valves with (n = 5) or without (n = 5) AS. There was an overrepresentation of small p values among genes claim significant in the first microarray experiment. A total of 223 genes were replicated (p value < 0.05 and fold change > 1.2), including MMP12 and CHI3L1. This study reveals many unrecognized genes potentially implicated in the pathogenesis of AS. These new genes were overlaid on known pathological pathways leading to AS in order to refine our molecular understanding of this disease.

## 2386/T/Poster Board #935

**Apolipoprotein C-III Deficiency Reduces Dyslipidemia in Subjects at Risk for Type 2 Diabetes.** *T.I. Pollin, C.M. Damcott, B.D. Mitchell, M. Miller, A.R. Shuldiner.* University of Maryland School of Medicine, Baltimore, MD.

We recently reported the first known null mutation, R19X, in the human *APOC3* gene, which encodes apolipoprotein C-III (apoC-III). ApoC-III delays triglyceride (TG) hydrolysis and hepatic uptake of TG-rich lipoprotein remnants. The mutation is found in ~5% of the Lancaster Old Order Amish, and carriers have low fasting and postprandial triglyceride (TG) and high HDL cholesterol levels as well as reduced risk of coronary artery disease as measured by coronary artery calcification scores.

A dyslipidemic lipid profile consisting of high TG levels and low HDL-C levels is a frequent complication of diabetes, and apoC-III production is dysregulated in the presence of insulin resistance. Therefore, we sought to determine whether the *APOC3* R19X mutation maintains its favorable effects on lipid levels in the presence of impaired glucose tolerance (IGT) or type 2 diabetes (T2DM) in 886 individuals in the Amish Family Diabetes Study. The frequency of the mutation was similar among individuals with T2DM (10/132, 7.6%), IGT (10/148, 6.8%) and normal glucose tolerance (NGT, 38/606, 6.3%). Although TG levels were higher among those with IGT and T2DM compared to those with NGT, the *APOC3* null mutation was associated with decreased TG levels in all three groups (NGT: median 34 vs. 66 mg/dl in carriers vs. noncarriers, p < 0.0001; IGT: 44 vs. 81 mg/dl, p < 0.0001; and T2DM: 75 vs. 111 mg/dl, p = 0.11). Similarly, HDL-C levels were increased in *APOC3* R19X carriers in all three groups (NGT: mean 63 vs. 51 mg/dl, p < 0.0001; IGT: 61 vs. 49 mg/dl, p = 0.008; and T2DM: 52 vs. 48 mg/dl, p = 0.22). In summary, heterozygous apoC-III deficiency improves dyslipidemia in the presence of an insulin resistant state, raising the possibility that apoC-III lowering might be a potentially useful treatment for reducing CVD risk in patients at risk for T2DM.

## 2387/T/Poster Board #936

**Survival- and age-variant genes in coronary artery disease.** *J. Dungan[1], E. Hauser[2], S. Shah[3], W. Kraus[3].* 1) School of Nursing, Duke University, Durham, NC; 2) Division of Medical Genetics, Deptartment of Medicine, Duke University, Durham, NC; 3) Division of Cardiology, Department of Medicine, Duke University, Durham, NC.

The American Heart Association reports that sudden death is the initial presentation of coronary artery disease (CAD) in 50-60% of people. CAD prevalence and mortality increase with age. We hypothesize that candidate genes for CAD may vary by survival and age, potentially biasing gene associations with CAD. We aimed to characterize survival bias and age effects for selected CAD candidate genes in the Duke CATHeterization GENetics Study and to determine if controlling for survival and age biases clarifies the strength of association between genes and CAD. We analyzed 1,885 subjects in the Duke CATHGEN cohort dataset. Thirty-six single nucleotide polymorphisms (SNPs) from 6 CAD candidate genes were selected to explore survival and age biases in CAD positive cases. To assess survival effects, traditional survival analyses were performed. Survival curves were illustrated using Kaplan-Meier rates with models censored on days to death or last follow up. Log-rank Chi-square tests and Cox proportional hazards were performed for comparison of survival by alleles (dominant model) and genotypes (additive model). To characterize age effects in gene variants, trends for minor allele frequencies (MAFs) by age categories (modified deciles) were evaluated. Logistic regression models were fit for CAD diagnosis (dependent variable) and each gene (independent variables), controlling for age, sex, race, and death (survival). Alpha was set at .05 for two-sided tests. Three SNPs corresponding to the limbic system associated membrane protein gene (LSAMP; RS6788787, RS1915585, and RS1462845) and two kalirin gene SNPS (KALRN; RS7623685 and RS1867647) showed significant differences in allele and/or genotype frequencies by survival. There were trends for lower MAFs in deceased subjects and varying MAF by age categories for the 5 SNPs. Three LSAMP SNPs had significant interactions with survival status: RS6788787 ($p$ = .02), RS1915585 ($p$ = .005) and RS9847048 ($p$ = .02). SNPs in the LSAMP and KALRN genes vary by survival and show trends for varying by age, providing evidence of survival and age effects in gene associations with CAD. Significant SNP by survival status interactions suggest that the effect of genotype on CAD is significantly mediated by survival. Controlling for survival and age in gene associations may be important to refining the genetic contribution to CAD. Our future work includes analyzing data for 5,571 more genotyped subjects from the CATHGEN cohort.

## 2388/T/Poster Board #937

**Altered Body Composition and Elevated Levels of Circulating Plasma Leptin in The Vascular form of Ehlers Danlos syndrome.** *B. Griswold[1], J. Lehman[2], J. Napora[1], L. Sloper[2, 3], O. Carlson[1], N. McDonnell[2].* 1) Laboratory of Clinical Investigation, NIA, Baltimore, MD; 2) Clinical Research Branch, NIA, Baltimore, MD; 3) MedStar Research Institute, NIA, Baltimore, MD.

Vascular Ehlers- Danlos Syndrome (VEDS) is a hereditary disorder of connective tissue caused by mutations in procollagen III. Patients have reduced life expectancy due to arterial or organ rupture. In addition to well-described phenotypic manifestations such as joint laxity, severe scarring and characteristic facial features, we observed that persons with VEDS have an increase in abdominal fat despite normal or low body weight. Since leptin is a marker for increased abdominal fat, we hypothesized that circulating leptin levels in VEDS would be higher than in controls. We also obtained quantitative body composition data utilizing Dual energy X-Ray absorptiometry (DEXA). Plasma samples from 20 subjects with molecularly confirmed VEDS (Age 39 ± 10; 6 males and 14 females) and 20 age, sex and BMI matched controls were assayed for fasting plasma leptin levels utilizing an ELISA platform. Plasma leptin (mean ± SEM) in VEDS was significantly higher than in controls (VEDS: 19 ± 4.3 ng/dL ; controls: 9.1 ± 2.0 ng/dL; p< 0.01). Analysis of body composition data showed that trunk fat was significantly increased in the VEDS subjects as compared to controls (p <0.01) and limb fat/trunk fat ratio was significantly decreased (p < 0.001). Leptin is adipokine with complex interactions in the endocrine system and in the extracellular matrix, and is thought to be involved in the pathogenesis of vascular disease and to promote vascular inflammation in the normal population. Why VEDS subjects have increased truncal fat is not clear but it likely results in exacerbation of vascular damage in this group of patients who have underlying abnormalities of the arterial wall. Targeting the abdominal fat accumulation and increased leptin in VEDS may result in improved outcomes in this disorder for which no effective treatment is yet known.

## 2389/T/Poster Board #938

**Genetic Predisposition for coronary artery disease: A case control study in North Indian population.** *R. Tripathi[1], S. Agarwal[1], S. Tewari[2], P. Singh[3].* 1) Department of Medical Genetics, Sanjay Gandhi Postgraduate Institute of Medical Sc, Lucknow, Uttar Pradesh, India; 2) Department of Cardiology, Sanjay Gandhi Postgraduate Institute of Medical Sciences, Lucknow, Uttar Pradesh, India; 3) Department of Anaesthesiology, Sanjay Gandhi Postgraduate Institute of Medical Sciences, Lucknow, Uttar Pradesh, India.

Background: The coronary artery disease (CAD) is a multifactorial disorder. The manifestation of the disease depends on interactions between environmental and genetic risk factors. Thus, the identification of gene polymorphisms relating to atherosclerosis may contribute towards developing early diagnostic methods and guiding preventive procedures. Objective: Aim of the present study is to find out the association of gene polymorphisms (MTHFR C677T, ACE I/D, LPL N291S, E-selectin S128R, OLR1 501G>C, IVS4-73C>T and 3'UTR 188C>T) with coronary artery disease. Method: 329 angiographically proven CAD patients as cases and 331 individuals with normal treadmill stress test having no history of CAD were included in the study. Genotype analysis was done by polymerase chain reaction restriction fragment length polymorphism (PCR-RFLP). Result: We found MTHFR T allele frequency 7.3% in controls and 11.0% in patients (p=0.004, OR 1.75, 95% CI 1.16-2.55), the D allele is prevalent as 46.6% in control and 54.4% in patients for ACE I/D polymorphism (p=0.003, OR 1.38, 95% CI 1.10-1.72). Whereas, for LPL N291S gene the S allele frequencies were 2.2% and 5.1% in control and patients respectively (p=0.003, OR 2.52, 95% CI 1.29-4.98), the distribution of R allele for E-selectin gene was found 5.6% in controls and 9.6% in patients (p=0.031 OR 1.57 95% CI 1.21-2.91). The OLR1 (501G>C) C allele frequency was 9.8% in controls and 17.8% in patient group (p=0.00 OR 1.99 95%CI 1.42-2.78). Rest of the two polymorphism of OLR1 gene (IVS4-73C>T and 'UTR 188C>T) were insignificantly associated with coronary artery disease (p=0.66 OR 1.05 95% CI 0.84-1.32 and p=0.30 OR 1.13, (0.89-1.43). Interpretation: Our findings suggests that MTHFR C677T, ACE I/D LPL N291S, E-selectin S128R, OLR1 501G>C are significantly associated with CAD however the 3'UTR 188C>T and IVS4-73C>T is insignificant in association.

## 2390/T/Poster Board #939

**Association between Interleukin-10 Gene Polymorphism and Carotid artery Intima-media Thickness, Plaque.** *D. Shin[1,3], GI. Yu[1,3], SY. Lee[1,3], JJ. Lee[1,3], HK. Son[1,3], MY. Lee[1,3], CW. Nam[2,3], IS. Chung[1,3].* 1) PREVENTIVE MEDICINE, KEIMYUNG UIVERSITY SCHOOL OF MEDICINE, TAEGU, TAEGU, KOREA; 2) INTERNAL MEDICINE, KEIMYUNG UNIVERSITY SCHOOL OF MEDICINE, TAEGU, TAEGU, Korea; 3) INSTITUTE FOR MEDICAL GENOME RESEARCH KEIMYUNG UNIVERSITY TAEGU, KOREA.

This study was conducted to examine the association between the carotid artery intima-media thickness (IMT), plaque presence and the interleukin-10(IL-10) gene polymorphism at position -1082, -819, and -592. The data used for this study were obtained from 135 subjects (76 men, 59 women), aged 31-82 years. Ultrasonography was used to measure the carotid artery IMT and plaque. IMT measurement were performed at 4 sites, including both common carotid arteries, and both bulbs. The data were analyzed in two categories: plaque present and plaque absent. Gender, age, uric acid, and homocysteine showed significant differences in plaque present and absent groups(p<0.05). single nucleotide polymorphism(SNP) at position -819 and -592 of IL-10 gene were statistically associated with the right carotid bulb (p>0.005). The association between SNP at position -1082, -819, and -592 of IL-10 gene polymorphism and the IMT (Right and Left Carotid artery and carotid bulb) was studied. SNP at position -819 was significantly correlated with right carotid bulb IMT (p=0.008). SNP at position -592 was also significantly correlated with right carotid bulb IMT(p=0.009). These results should be taken into the consideration that genetic SNP can affect carotid plaque formation and thus, atherosclerosis. Selective approaches of different SNP positions with various genes can be performed to find a closer relationship with carotid plaque formation.

## 2391/T/Poster Board #940

**Maternal Use of a Folate Containing Supplement Protects Against Atrioventricular Septal Defects in Males with Down Syndrome: A Report from the National Down Syndrome Project.** *L.J.H. Bean[1], E.G. Allen[1], S.W. Tinker[1], N. Hollis[1], A.E. Locke[1], K.J. Dooley[2], S.B. Freeman[1], S.L. Sherman[1].* 1) Dept Human Genetics, Emory Univ, Atlanta, GA; 2) Sibley Heart Center, Dept Pediatrics, Emory Univ, Atlanta, GA.

Maternal folate deficiency has been associated with neural tube defects, congenital heart defects, and other birth defects. Individuals with Down syndrome (DS) are at high risk for congenital heart defects and have been shown to have abnormal folate metabolism. Epidemiological data from the National Down Syndrome Project was analyzed to determine the effect of maternal use of a folate containing supplement on the risk of congenital heart defects in probands with Down syndrome (DS). A total of 1012 mothers (511 white, 111 black, and 390 Hispanic) reported race / ethnicity and use of folate containing supplements. Cardiac records on each individual with DS were obtained. The incidence of heart defects in probands was compared between those whose mothers started taking folate before the fourth week of pregnancy (when heart development begins) and those whose mothers took no supplementation before the eighth week of pregnancy (when heart development is complete). Logistic regression was used with the outcome variable being presence/absence of a heart defect in the proband and the predictor variables being maternal folate supplementation use, race/ethnicity and sex of the proband. The most common type of heart defect observed in individuals with DS is atrioventicular septal defect (AVSD); thus, we focused on this specific defect for the analyses presented here. We found a significantly increased risk of AVSD to probands with DS born to mothers who did not take a folate containing supplement (OR = 1.56; 95%CI 1.02-2.40) adjusting for proband sex and race/ethnicity. Because of the nearly two-fold excess of female probands (OR 1.93 (1.40, 2.67)) among DS cases with AVSDs that we previously reported, we stratified our analyses by proband sex. We observed that lack of maternal folate supplementation significantly increased the risk of AVSD in males (OR = 2.22; 95%CI 1.12-4.40), but not females (OR = 1.28; 95%CI 0.73-2.24), with DS. In addition, despite an overall lower incidence of AVSDs in probands with DS born to Hispanic mothers, the effect of folate use was most pronounced in this group. Population-specific effects of folate supplementation may reflect underlying differences in genetic and environmental risk factors between populations. Overall, these results indicate that maternal folate use protects males with DS from AVSDs more so than females. These results possibly explain the higher female risk of AVSD, and suggest an epigenetic mechanism for AVSD.

## 2392/T/Poster Board #941

**Alternative splicing of genes expressed during early embryonic development.** *T. Revil[1], D. Gaffney[1], C. Dias[1,2], L.A. Jerome-Majewska[1,3], J. Majewski[1,2].* 1) Dept. of Human Genetics, McGill University, Montreal, Quebec, Canada; 2) Genome Quebec Innovation Centre, Montreal, Quebec, Canada; 3) Dept. of Pediatrics, Montreal Children's Hospital, Montreal, Quebec, Canada.

A number of genes that are required for normal morphogenesis of developing embryos, including Fgf8, have been shown to have isoform-specific functions. To date, these genes have been identified in isolated experiments and by fortuitous splicing events associated with gene targeting. We predicted that alternative splicing, the process by which a single gene can produce several functionally distinct isoform, is a common event required for establishment of the normal body plan. In this work, we present a whole genome approach, using exon microarrays, to profile the variation in pre-mRNA splicing, transcription initiation, and polyadenylation site choice during early murine development. We show that variation in isoform expression is widespread, and affects many genes with known and predicted function during embryonic development. We use RT-PCR and in-situ hybridization to further validate and investigate spatial and temporal expression patterns of specific isoforms. We propose that alternative isoform expression is a common mechanism controlling the diversity of developmental process, and that techniques such as isoform-specific knockouts, should be utilized to truly dissect the complexity of developmental pathways.

## 2393/T/Poster Board #942

**A Novel Mouse Model Recapitulates Defects Seen in 1p36 Deletion Syndrome.** *B. Kim, H. Zaveri, O. Shchelochkov, SH. Kang, M. Justice, B. Lee, D. Scott.* Human Molec Gen, Baylor College Med, Houston, TX.

Children with monosomy 1p36the most common terminal deletion syndrome with an incidence of 1 in 5,000have a constellation of symptoms that can include by cardiovascular defects, mental retardation, postnatal growth deficiency, hearing loss and CNS abnormalities. Although most features of monosomy 1p36 have been attributed to genes located within 6.2 Mb of the telomere, Kang et al. has reported a cohort of patients with similar findings caused by interstitial deletions of 1p36 located proximal to this region. The smallest deletion in this cohort involved a 2.9Mb region containing Atrophin 2 (ATR2), which encodes a nuclear receptor co-repressor. Mice that are homozygous for the Atr2 null mutation openmind (op) die at E9.5 with open neural tubes and cardiac defects which limit their usefulness as a disease model. However, using a newly identified hypomorphic allele of Atr2 known as eye3, we have generated an allelic series of mice with partial Atr2 function. A portion of $Atr2^{op/eye3}$ mice live into adulthood and have many of the characteristics seen in 1p36 deletion patients. $Atr2^{op/eye3}$ mice have postnatal growth retardation, hearing loss, and a decreased brain size compared to wild type from E17.5 until adulthood. The cerebellums of $Atr2^{op/eye3}$ are abnormal with limited fissure formation at P0 and abnormal foliation of the anterior lobe during the postnatal development. $Atr2^{op/eye3}$ mice also fared poorly in tests requiring normal balance and coordination. At E17.5 the dentate gyri of $Atr2^{op/eye3}$ mice was significantly smaller than controls and a decrease of ganglion cell number was observed in the retina. Since cardiovascular defects, post natal growth deficiency, hearing loss, and CNS abnormalities are found in children with 1p36 deletion syndrome, it is likely that haploinsufficiency of ATR2 contributes to this disorder. We are presently using our Atr2 mouse models to identify the molecular interactions between Arophin 2 and specific nuclear receptors that are responsible for these defects.

## 2394/T/Poster Board #943

**Novel BBsome independent phenotypes in a mouse model of Bardet-Biedl syndrome 3.** *T. Vogel[1], D.Y. Nishimura[2], C.C. Searby[2,6], R.E. Swiderski[2], R.F. Mullins[3], P.R. Pretorius[2,6], S. Seo[2,6], Q. Zhang[2,4], K. Bugge[2,6], D.R. Thedens[3], M.D. Cassell[4], J.A. Wemmie[5], V.C. Sheffield[2,4,6].* 1) Dept Neurosurgery, Univ Iowa, Iowa City, IA 52242, USA; 2) Dept. Pediatrics, Univ Iowa, Iowa City, IA 52242, USA; 3) Dept. Ophthalmology, Univ Iowa, Iowa City, IA 52242, USA; 4) Dept. Anatomy, Univ Iowa, Iowa City, IA 52242, USA; 5) Dept. Psychiatry, Univ Iowa, Iowa City, IA 52242, USA; 6) Howard Hughes Medical Institute, University of Iowa Carver College of Medicine, Iowa, IA 52242, USA.

Bardet-Biedl syndrome (BBS) is a pleiotropic, autosomal recessive, heterogeneous disorder caused by mutations in a group of genes that contribute to ciliary function. As many as fourteen genes are reported to cause BBS. Individuals with BBS have the features of obesity, retinal degeneration, cognitive delay, and congenital anomalies including polydactyly, heart defects and renal abnormalities. Of the genes known to cause BBS, seven encode proteins which form a complex known as the BBsome which is proposed to play a role in vesicular transport to the cilium and plasma membrane. BBS3, a member of the Ras family of small GTP-binding proteins, is also postulated to play a role in vesicular transport, but is not part of the BBsome. To better understand the function of BBS3 and its relationship to components of the BBsome, we created a *BBs3* knockout mouse model. While the *Bbs3* knockout mouse develops retinal degeneration, some features of this model differ from other mutant BBS mice. Notably, *Bbs3* knockout mice do not develop early onset obesity and morphological analysis of the central nervous system reveals an early and severe form of ventriculomegaly when compared to a knockin model of *BBs1* (M390R/M390R) and knockout mouse models of other components of the BBsome developed in our laboratory. Behavioral studies have also identified differences in locomotor function, intracranial pressure, balance and coordination, and memory when compared to wild type mice. Together these results indicate that the *BBs3* mouse model will offer unique insights into the developmental mechanisms underlying BBSsome independent phenotypes.

## 2395/T/Poster Board #944

**Identification of five α-actinin genes in *Danio rerio* and evidence for functional differences between sarcomeric isoforms.** *V. Gupta, R. Darnall, A.H. Beggs.* Genomics Program and Division of Genetics, The Manton Center for Orphan Disease Research, Children's Hospital Boston, Harvard Medical School, Boston, MA.

The α-actinins are an ancient protein family sharing a common evolutionary origin with other members of the spectrin-gene superfamily of actin binding proteins. Structurally and functionally, α-actinins can be divided in to Ca2+-sensitive cytoskeletal isoforms that organize the actin cytoskeleton, and Ca2+-insensitive sarcomeric isoforms that constitutively bind actin filaments at muscle Z-lines. Loss of function of different α-actinins results in distinct phenotypes *in vivo*, related in part to different patterns of expression, however, the isoforms largely show indistinguishable activities in most *in vitro* assays. To determine the structural basis for functional differences between isoforms, we are utilizing zebrafish as a model system to study the different sarcomeric α-actinin isoforms *in vivo*. Although most vertebrates have four α-actinin genes, we find that the zebrafish genome includes five. Three appear to encode for sarcomeric forms, while two are cytoskeletal. Each isoform exhibits a distinct and unique pattern of gene expression as assessed by mRNA in situ hybridization. Morpholino-based knock-down of the sarcomeric isoform, *actn2*, leads to impaired development of zebrafish brain and skeletal muscles. Coinjection of *actn2* mRNA, but not *actn3* mRNA, leads to rescue of the phenotype. These studies, for the first time, show *in vivo* evidence of functional differences among sarcomeric α-actinins. Future studies utilizing the zebrafish model system will lead to a better understanding of α-actinin-dependent pathways in development and function of different organs.

## 2396/T/Poster Board #945

**MicroRNAs as Regulators of Adrenal Cortical Development.** *J.K. Mazilu, Y. Zhao, S. Lin, E.R.B. McCabe.* University of California Los Angeles, Los Angeles, CA.

The molecular mechanisms involved in adrenal gland development remain poorly understood. Though mutations in SF1 and DAX1 have been linked to adrenal hypoplasia congenita (AHC, MIM #300200), approximately 40% of patients with AHC referred to our group and others for testing do not have mutations in either of these genes. While the role of microRNA (miRNA) in development has been established, its role in adrenal development has been largely unexplored. To investigate this role, we choose to study miRNA in adrenal cortical development in the zebrafish, Danio rerio, due to its ease of genetic and molecular manipulation. Dicer1 is a protein essential for miRNA processing. Using a transgenic line of zebrafish expressing GFP in the interrenal organ (adrenal cortex equivalent), we have evidence that dicer1 morphant embryos, which lacked mature, functioning miRNA, have disrupted adrenal development and a greater incidence of adrenal arrest when compared to wild type (WT) and mismatched morpholino (mmMO) embryos. Specifically, ≤10% of WT and mmMO embryos showed two sites of GFP expression, indicating putative adrenal arrest; 30-40% of dicer1 morphants showed this adrenal arrest phenotype, indicated by two or more sites of GFP expression. Moreover, dicer1 morphants retained these multiple sites of GFP expression while WT and mmMO embryos do not. Other features of dicer1 morphants included underdeveloped heads and eyes, absence of a swim bladder, developmental delay, and a "curly tail" phenotype. Co-injection of dicer1-morpholino (MO) and miRNA extracted from embryos at 8 hpf best rescued adrenal development while moderately rescuing other dicer1 morphant features. Since miRNA has been reported to regulate many developmental pathways, we are interested in examining its role in modulating adrenocortical primordial cells' responses to signaling pathways, such as the TGF-β signaling pathway, that participate in adrenal development and function. The medical implications include identifying specific roles and mechanisms of action for miRNA in adrenal development. Such information will have applications in cell-based therapeutics, such as adrenal cortical differentiation of induced pluripotent stem cells (iPS), and will provide insight into a variety of adrenal pathologies, including, not only AHC, but also adrenal aplasia and adrenal tumorigenesis, as well as therapies for these and related disorders, such as congenital adrenal hyperplasia (CAH).

**DAX1: Earliest Marker in Zebrafish Tooth Development is a Marker for Human Tooth and Ameloblastoma Tumors.** *J. Powers[1], Y. Zhaou[2], S. Lin[2], E.R.B. McCabe[2].* 1) Dept Neonatology, Univ California, Los Angeles, Los Angeles, CA; 2) UCLA, Los Angeles, CA.

Background Zebrafish teeth develop on pharyngeal jaws in the fifth branchial arch, but have a pattern of early tooth development remarkably similar to mammals (1). Recently, eve1 has been shown to be involved in initiation of primary tooth (4V1) and early ameloblast development (2). dax1 is initially expressed in the fifth branchial arch in zebrafish at approximately 26 hpf and co-localizes with eve1 expression at ~48hpf. Our previous studies showed embryos injected with dax1 morpholino (MO) exhibit down-regulation of eve1 expression. Based on the zebrafish observation, we hypothesized that DAX1 might be involved in tooth development and ameloblast differentiation in humans. Objective The purpose of this study was to identify whether DAX1 is expressed in normal human dental tissue and ameloblastoma tumors. Design/Methods We obtained samples of previously resected formalin-fixed paraffin embedded normal human dental tissue, and benign and malignant ameloblastoma tumor tissue. We performed in situ hybridization on the de-paraffinized samples using normal adrenal cortex tissue as control. The samples were stained with BCIP/NBT and visualized for DAX1 expression. We also performed western blot analysis on the tissue samples to detect the levels of DAX1 expression in normal dental tissue compared to benign and malignant ameloblastoma tumor tissue. Results Our results showed expression of DAX1 in normal human dental tissue in the regions corresponding to the enamel organ where ameloblasts are housed. DAX1 expression was increased in malignant ameloblastoma tissue compared to normal tissue and benign tumor. Conclusions Prior to our studies, DAX1 has not been shown to be associated with tooth development and ameloblastoma tumors. We were able to use our observations in a zebrafish animal model and translate our findings to humans. Despite ~450 million years since the last common ancestors of zebrafish and humans, identification of orthologous genes and gene functions can lead to novel insights into normal and abnormal developmental processes. 1. ## 2398/T/Poster Board #947

**Expression of Trps1 in Secretory Odontoblasts Results in Dentinogenesis Imperfecta-Like Phenotype in Transgenic Mice.** *D. Napierala[1], I. Maciejewska[2], B. Dawson[1,3], E. Munivez[1], R. D'Souza[2], B. Lee[1,3].* 1) Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX; 2) Baylor College of Dentistry, Texas A&M Health Science Center, Dallas, TX; 3) Howard Hughes Medical Institute.

Odontoblasts are neural crest-derived cells that that differentiate from the dental papilla cells. The terminal differentiation of odontoblasts requires reciprocal cell-matrix interactions and is characterized by withdrawal from the cell cycle, polarization of the cells and secretion of dentin matrix. Hereditary defects in dentin formation in humans are classified as dentinogenesis imperfecta (DGI) or dentin dysplasia (DD). While mutations in the collagen type I (*COL1A1*) and dentin sialophosphoprotein (*DSPP*) genes are responsible for the majority of DGI and DD cases, the etiology of isolated hereditary dentin disorders in many affected families is still unknown. Our recent studies on the role of the Trps1 transcriptional repressor in the mineralization process revealed its novel and important function in odontoblasts. Trps1 is a GATA-type transcription factor involved in craniofacial development and endochondral ossification. During early tooth development *Trps1* is expressed in dental mesenchyme and, after cell differentiation, in preodontoblasts and dental papilla. However, its expression is turned off in differentiated secretory odontoblasts. We generated transgenic mice over-expressing *Trps1* under control of 2.3kb fragment of collagen 1a1 promoter (col1a1-Trps1 mice), which drives expression of a transgene specifically in osteoblasts and odontoblasts. Col1a1-Trps1 mice demonstrate growth retardation after weaning and most die within one week after weaning due to feeding problems. Histological and micro-CT analyses revealed dramatic decrease of dentin mineralization and abnormal dentine structure in transgenic mice. Additionally, expression of major non-collagenous proteins of dentin matrix, dentin sialoprotein (Dsp) and dentin matrix protein 1 (Dmp1), was reduced in *Trps1* transgenic mice. In summary, we have demonstrated that continuous expression of *Trps1* in differentiated odontoblasts results in severe abnormalities in dentin formation and mineralization, which resemble human DGI phenotype. The severity of the dentin abnormalities in col1a1-Trps1 transgenic mice suggests that Trps1 regulates multiple genes involved in dentin formation.

## 2399/T/Poster Board #948

**Identification of X-linked myotubular myopathy in Labrador retrievers.**

*M. Kozlowski[1], J. Bohm[2], E. Snead[3], K. Minor[4], L. Tiret[5], M.K. Childers[6], S.M. Taylor[3], J.R. Mickelson[4], L.T. Guo[7], A.P. Mizisin[7], A.H. Beggs[2], J. Laporte[1], G.D. Shelton[7].* 1) Children`s Hospital Boston and Harvard Medical School, Boston, MA; 2) Institut de Génétique et de Biologie Moléculaire et Cellulaire, Illkirch, France; 3) Western College of Veterinary Medicine, University of Saskatchewan, Canada; 4) School of Veterinary Medicine, University of Minnesota; 5) Alfort School of Veterinary Medicine, France; 6) Wake Forest University, Winston-Salem, NC; 7) School of Medicine, University of California, San Diego, La Jolla, CA.

Mutations in the MTM1 gene, encoding myotubularin, cause X-linked myotubular myopathy, a well-defined subgroup of centronuclear myopathies in humans. Six male Labrador retrievers, from 3 to 4 months of age, from three apparently unrelated litters, presented to the Western College of Veterinary Medicine in Saskatchewan with generalized weakness and muscle atrophy. The first documented clinical signs were recorded during vaccinations around 7 weeks of age, with decreased weight, dropped jaw, generalized weakness, and hind limb muscle atrophy. The clinical course was progressive, leading to comprehensive veterinary assessments around 14 weeks and eventual euthanasia due to severe generalized weakness around 4 months of life (range 3.5 to ~ 6 mo). Laboratory workup was generally noncontributory; serum CK was either normal or only very slightly elevated. Muscle biopsies revealed variability in fiber size, centrally placed nuclei and subsarcolemmal ringed and central dense areas. The subsarcolemmal and central dense areas stained darkly positive with mitochondrial specific reactions for SDH and COX allowing histologic differentiation from Labrador retrievers with CNM. All dogs tested for the known centronuclear myopathy (CNM) mutation in the PTPLA gene were negative. Immunoblot analysis showed that myotubularin was absent in muscle extracts from affected dogs but present in muscle from a control littermate. Ultrastructural studies confirmed the centrally located nuclei, abnormal perinuclear structure and mitochondrial accumulations. Triads were infrequent with an abnormal orientation of T tubules. Immunofluorescence staining of frozen muscle sections using antibodies to label T tubules (DHPRa1) and adjacent sarcoplasmic reticulum (RYR1) confirmed an abnormal distribution of these structures. DNA analysis of the MTM1 gene in all six affected males revealed a unique variant in exon 7 causing the non-conservative missense change N155K in the linker region between the GRAM-PH and phosphatase domains of myotubularin. Three proven carrier dams from two of these kindreds were shown to be heterozygous for the variant and a healthy male littermate was shown not to carry the variant. Analysis of a world-wide panel of 237 unrelated and unaffected Labrador retrievers, and 59 additional control dogs from 25 breeds, failed to identify this variant. Altogether these results suggest that the N155K variant is the pathogenic mutation responsible for the myopathy in these dogs.

## 2400/T/Poster Board #949

**Modification of *C. elegans bbs* mutant phenotypes by guanylate cyclases implicates a perturbation in cGMP levels.**

*C.A. Mok[1,3], M. Healey[4], M. Leroux[4], M. Zhen[3], E. Héon[1,2].* 1) Prog Gen & Genome Biol, Sick Kids Hosp, Toronto, ON, Canada; 2) Dept. of Ophthalmology and Vision Sciences, Sick Kids Hospital, Toronto, ON, Canada; 3) Mount Sinai Hospital Research Institute, Toronto, ON, Canada; 4) Dept. of Mol Biol. and Biochem, Simon Fraser University, Burnaby, BC, Canada.

Bardet-Biedl syndrome (BBS) is an autosomal recessive, genetically heterogeneous, pleiotropic disorder. Cardinal features include photoreceptor degeneration, obesity, digit and cystic renal anomalies, cognitive impairment and hypogonadism. Most BBS genes encode ciliary proteins related to the intraflagellar transport (IFT) system. Consistently, *C. elegans bbs* mutants have defects in ciliary morphology and function (Blacque et al., 2004, Tan et al., 2007). We determined common phenotypes shared by all *bbs* mutants and noticed that all *bbs* mutants share a statistically significant loss of 15-20% in mean body length and a moderate decrease in body width. Neurosensory defects in *C. elegans* have previously been associated with decreased body length (Fujiwara et al., 2002). The transforming growth factor beta (TGF-β) superfamily of proteins encompasses those in a pathway that also controls body size (Patterson and Padgett, 2000). Our genetic analyses between *bbs* and TGF-β mutants (*dbl-1* and *lon-2*) however suggested that these two pathways work in parallel as their body size defects are additive. To understand how BBS proteins modulate body size, we identified a genetic suppressor that restored the body size of *bbs* mutants to normal length. This encodes the guanylate cyclase GCY-35. While capable of suppressing *bbs* body size defects, mutations in *gcy-35* do not rescue the structure and function defects of the amphid sensory neurons in bbs mutants. To regulate body size GCY-35 is required in a subset of the O2 sensory neurons (Cheung et al., 2004, Gray et al., 2004, Chang et al., 2006, Zimmer et al., 2009), and its localisation appears unaffected in *bbs-7* mutants. BBS proteins, on the other hand, are required in the non-overlapping sensory neurons to regulate body size. The body size defects of *bbs* mutants are thus likely due to a defect in cGMP regulation. Consistently, the body size change induced by both loss and gain of function mutants in the cGMP-dependent kinase EGL-4 (Fujiwara et al., 2002) appear genetically epistatic to the body defects in *bbs* mutants, suggesting it as the downstream effector of the BBS complex in sensory cilia. The non-cell autonomous control of body size through guanylate cyclases in a small subset of ciliated neurons identifies an interesting direction for the further dissection of body size defects in *C. elegans* and later study of our human BBS cohorts.

**Ocular defects in *sall3* deficient zebrafish embryos: insights into human disease.**

*K.M. Berry[1], A.M. Innes[2], O.J. Lehmann[3], A.J. Waskiewicz[1].* 1) Department of Biological Sciences, University of Alberta, Edmonton, Alberta, Canada; 2) Department of Medical Genetics, University of Calgary, Calgary, Alberta, Canada; 3) Departments of Ophthalmology and Medical Genetics, University of Alberta, Edmonton, Alberta, Canada.

The study of chromosomal anomalies represents a fruitful means of determining the function of previously uncharacterized genes. We investigated a patient with a telomeric deletion [46, XX, del (18)(q23)] who exhibited unilateral colobomatous microphthalmia, as well as systemic defects that included cleft palate, cardiac septal defects, dysmorphic facial appearance and developmental delay. Customized array CGH was used to accurately define the deletion's extent as a first step in identifying genes contributing to 18q deletion syndrome (a disorder characterized by facial dysmorphism, ocular and neurological defects, and mental retardation). The 2.9Mbp deleted region, the smallest reported 18q deletion syndrome interval, likely defines the critical region for the phenotypes seen in this patient. Bioinformatic analyses of the 10 deleted genes identified three that are ocularly expressed, *ADNP2, CTDP1* and *SALL3*. Morpholino inhibition of *adnp2* in zebrafish revealed no ocular phenotype, and as *CTDP1* had been previously characterized, we concentrated on the uncharacterized gene *SALL3*, a member of the *Spalt-like (Sall)* family of transcription factors. Mutation in paralogs results in Townes-Brocks (*SALL1*), and Okihiro or Duane-radial ray (*SALL4*) syndromes, of which the latter phenotype includes ocular motility defects.

*In situ* hybridization of *sall3* in zebrafish at four early stages (15.5, 18, 20, and 24hpf) showed ubiquitous expression, with particularly high levels in developing motor neurons. Morpholino inhibition of *sall3* function recapitulates the patient's colobomatous microphthalmia with extensive retinal laminar patterning defects evident on histological analysis, consistent with a key role for *sall3* in retinal formation. Furthermore, analysis of gene expression shows a decrease of *epha3* and *epha4b* expression in the *sall3* deficient embryos, indicating improper patterning in the eye. Our ongoing characterization of the broader phenotypes of *sall3* morphants, combined with screening microphthalmia and colobomata patients for mutations, is anticipated to elucidate *SALL3*'s contribution to 18q deletion syndrome and ocular malformations.

**The neural crest basis for craniofacial abnormalities associated with Down syndrome.** *R. Roper[1], M. Stanley[2], N. Duvall[1], S. Stone[1], C. Davis[2], C. Billingsley[1], J. Blazek[1].* 1) Dept Biol, Indiana Univ Purdue Univ, Indianapolis, IN; 2) Department of Pediatrics, Indiana University School of Medicine, Indianapolis, IN.

Trisomy 21 occurs in approximately 1 in 750 live births and results in phenotypes collectively referred to as Down syndrome (DS). Individuals with DS present with a wide range of phenotypes which may include cognitive impairment, facial dysmorphology, congenital heart defects, and gastrointestinal tract abnormalities. Craniofacial anomalies, including a shortened midface, small mandible and small oral cavity, may combine with other clinical traits to affect the breathing, feeding and hearing of individuals with DS. Many of the tissues affected in DS, including craniofacial skeleton, have a neural crest (NC) component and we have demonstrated developmental deficits in generation, migration and mitosis of trisomic NC in a DS mouse model. To understand the molecular origin and comorbidity of NC-related phenotypes, we are using DS mouse models and clinical information from infants with DS evaluated by Developmental Pediatrics at the Riley Hospital for Children in Indianapolis, IN. Morphometric analyses of DS mouse models show that the size of the mandibular precursor is altered throughout development and the macroglossia associated with DS may be relative with a normal tongue and small oral cavity. Our phenotypic evaluation of infants with DS shows that NC-related clinical traits tend to cluster together and may be the result of a generalized NC deficit related to trisomy. Because parts of cardiac, GI, and craniofacial structures are derived from NC and may be affected by trisomy 21, the diagnosis of a heart or GI problem may be indicative of secondary sequelae related to a NC deficit, including feeding and airway issues associated with DS. We hypothesize that an understanding of the cellular and developmental bases of craniofacial tissue in mice as well as the comorbidity of clinical features in infants with DS will suggest preventative measures that can be taken during early development to increase the quality of life for individuals with DS and their families.

## 2403/T/Poster Board #952

**ANALYSIS OF FUNCTION OF BMP SIGNALING INHIBITOR - MAB21L2 IN ENTERIC NERVOUS SYSTEM DEVELOPMENT AND IDENTIFICATION OF MAB21L2 ENHANCERS USING ZEBRAFISH.** *G.M. Burzynski[1], L. Petrova[1], J. Osinga[2], R.M.W. Hofstra[2], I.T. Shepherd[1].* 1) Department of Biology, Emory University, Atlanta, GA; 2) Department of Genetics, University Medical Center Groningen, Groningen, The Netherlands.

The enteric nervous system (ENS) is derived from neural crest cells (NCCs). Reciprocal interactions between the NCCs, gut endoderm and gut mesenchyme regulate the proliferation, migration, and differentiation of ENS NCCs. One important signaling pathway involved in this process is the bone morphogenetic protein (BMP) pathway. Gene expression profiling analysis of the zebrafish ENS mutant lessen revealed that the BMP signaling pathway component, Mab21l2 is down regulated in this mutant. Hirschsprung disease (HSCR) is a pediatric condition characterized by the absence of the enteric ganglia along a variable length of the intestine. A recent genome wide linkage analysis performed on a family with isolated HSCR showed that the 4q31.3-q32.3 region is linked to the disease. Within this region, the human orthologue of zebrafish Mab21l2 is located. We have investigated the expression and function of Mab21l2 during zebrafish development to determine its role in ENS development. Mab21l2 is expressed in the anterior CNS, retina, optic tectum, cranial ganglia, pharyngeal arches, hindbrain, neural tube and in the mesenchyme adjacent to the intestine. Knock down of Mab21l2 causes defects in pharyngeal arches and intestinal smooth muscle development. Critically, morphants also display a significant reduction in the number of enteric neurons. Sequencing of the Mab21l2 locus in patients revealed no mutation in the coding region of the gene. As a result we hypothesized that there is a regulatory mutation that causes the disease phenotype. To identify enhancer regions responsible for driving conserved expression of Mab21l2 in vertebrates, which are potentially perturbed in patients we have utilized Tol2 transposon-mediated transgenesis in zebrafish and sequencing of the regualtory regions in patients. Human and zebrafish genomic fragments of Mab21l2 regulatory region have been cloned into Tol2-gfp reporter constructs. These have been injected into zebrafish embryos and the pattern of GFP expression has been determined. The analysis of polymorphisms detected in patients and evaluation of enhancers' activity in transgenic assay will be presented. Together our data suggests that Mab21l2 is a gene important for ENS development, contributing to HSCR phenotype.

## 2404/T/Poster Board #953

**Variants in the trifunctional MTHFD1 gene as risk factors for spina bifida in the Amish population Khan T, Patel H, Crosby A, Patton MA Medical Genetics, St Georges Hospital, London SW17 0RE, United Kingdom.** *T. Khan, H. Patel, A. Crosby, MA. Patton.* Med Gen, St Georges Hosp, London, United Kingdom.

Neural tube defects are common congenital birth defects, affecting approximately 1 in 1000 pregnancies in American Caucasians. These are extremely complex disorders, and many genetic and environmental factors have been implicated in the aetiology, but as yet no single cause has been identified. Previous work at the Regional Genetics Service at St Georges Hospital, London, has highlighted the trifunctional gene, methylenetetrahydrofolate dehydrogenase 1 (MTHFD1), which resides at the locus 14q24, to be in linkage disequilibrium with spina bifida in the Amish population of the USA. During the current project this gene was sequenced in four affected individuals and three interesting sequence variants were found; R293H, R653Q and R134K. These sequence variants were further investigated in more affected individuals and two control groups (non-affected Amish controls and non-Amish non-affected controls). The R293H variant was found in one affected individual with spina bifida and two of his siblings with spina bifida occulta, and although it was found in three Amish controls, it was not found in one hundred non-Amish control chromosomes. The R653Q variant was present at a frequency of 73% in the affected individuals and at a frequency of 57.6% in the non-Amish controls, although on further analysis, t-test analysis did not confirm this to be statistically significant. Finally, the R134K variant was present in 71.4% of the affected individuals and 60% of the individuals with spina bifida occulta, however due to time constraints this variant was not analysed further. Consequently, although further investigation is required, the results of this study indicate that these variants could act as possible risk factors for spina bifida in the Amish population, either as an accumulative effect, or as an additive effect with other genes.

## 2405/T/Poster Board #954

**The CUB domain protein Neto1 is a molecular switch that modulates Plexin D1 binding specificity for semaphorin axon guidance cues.** *J.R. Gingrich[1], D. Ng[1], B. Gore[2], M. Tessier-Lavigne[2], R.R. McInnes[1].* 1) Research Institute, Hospital For Sick Children, Toronto, Ontario, Canada; 2) Department of Research Drug Discovery, Genentech, Inc., San Francisco, CA, U.S.A.

The CUB domains of the neuronal transmembrane protein Neto1 (Ng *et al.*, PloS Biology **7**: 278-300, 2009) are most similar to the CUB domains of neuropilins (Npns), a family of axon guidance molecules. We have determined that Neto1, like the Npns, is essential for axon guidance of neurons in the developing mouse central nervous system since (i) Neto1 is obligatory for midline crossing of commissural interneurons in the E12.5 embryonic neural tube, and (ii) adult Neto1$^{-/-}$ mice display defects in axon projections in the corticospinal and subiculo-mammillary tracts of the brain. Because secreted semaphorins bind to the extracellular CUB domains of the Npns, we reasoned that a secreted semaphorin may be a ligand for Neto1. We examined the *in vitro* binding of various semaphorins to cells co-expressing Npn-1, Npn-2, or Neto1 and individual plexins. First, we confirmed that Npn-1 and Npn-2 bind semaphorins in the absence of a plexin co-receptor. Neto1, in contrast, bound semaphorin 3F (Sema3F) only in the presence of Plexin D1 and co-immunoprecipitated Plexin D1 only in the presence of Sema3F, indicating that Neto1 and Plexin D1 form a co-receptor for Sema3F. Because Plexin D1 can bind Sema3E in the absence of Neto1, these findings suggest that Neto1 switches the ligand binding specificity of Plexin D1 from Sema3E to Sema3F. Application of Sema3F to Cos7 cells co-expressing Neto1 and Plexin D1 led to cell retraction (mean cell area 1373±93 $\mu m^2$ vs. 1766±44 $\mu m^2$ for controls; n=4 studies, p<0.05), indicating that Sema3F/Neto1/Plexin D1 signalling results in cytoskeletal remodelling, consistent with a role in axon guidance. Moreover, explants of subicular neurons from Neto1$^{-/-}$ embryos fail to respond to Sema3F, and application of the Neto1 ectodomain was sufficient to restore the response of Neto1$^{-/-}$ neurons to Sema3F. We conclude that Neto1 modulates the specificity of Plexin D1 ligand binding, potentially altering and refining the response of neurons to semaphorin guidance cues during forebrain development. Mutations in genes encoding axon guidance receptors that result in human disease are uncommon; but we note that the *NETO1* gene is located on human chromosome 18q22-23, within a mental retardation deletion interval and a bipolar disorder locus.

## 2406/T/Poster Board #955

**Molecular mechanisms of brain malformations in congenital muscular dystrophies.** *H. Hu, Y. Yang, C. Gagen, P. Zhang.* SUNY Upstate Medical University, Syracuse, NY.

Congenital muscular dystrophies with brain malformations are a group of diseases that exhibit overmigration of neurons in the cerebral cortex. At least some are caused by genetic defects of O-mannosyl glycosylation. Earlier studies have demonstrated that disruptions of the pial basement membrane are the underlying causes of overmigration. Hypoglycosylation of $\alpha$-dystroglycan, an extracellular matrix receptor, results in abolished interactions between $\alpha$-dystroglycan and laminin. Using a mouse model of muscle-eye-brain disease, POMGnT1 knockout, mechanisms of basement membrane defect was investigated. While disruptions of the pial basement membrane can theoretically be caused by its reduced strength, increased turnover, or reduced assembly, the results indicated that assembly of the basement membrane was defective due to diminished extracellular matrix-$\alpha$-dystroglycan interactions. For example, laminin assembly at the knockout cell surface is at a much reduced rate. Further, overmigrated neurons disrupted the developing mesenchyme, resulting in ectopic fibroblasts in the cerebral cortex. Evidence suggested that these ectopic fibroblasts induced reactive astrogliosis.

## 2407/T/Poster Board #956

**Chromodomain protein 7 (CHD7) regulates olfactory and inner ear neurogenesis and axonal projections to the vestibular system: implications for sensory impairments in CHARGE Syndrome.** *D.M. Martin[1], W.S. Layman[2], Y. Raphael[3], E.A. Hurd[4].* 1) Pediatrics & Human Gen, Univ Michigan Med Ctr, Ann Arbor, MI; 2) Human Gen, Univ Michigan Med Ctr, Ann Arbor, MI; 3) Otolaryngology, Univ Michigan Med Ctr, Ann Arbor, MI; 4) Pediatrics, Univ Michigan Med Ctr, Ann Arbor, MI.

Neurogenesis and neural innervation of peripheral sensory organs are tightly regulated developmental processes that are critical for normal sensation. CHARGE Syndrome, characterized by multiple sensory impairments, including loss of vision, hearing, balance, and olfaction, is a major cause of deaf-blindness that affects 1 in 10,000 individuals. CHD7, the chromodomain protein mutated in CHARGE, was recently shown in mice to be a positive regulator of neural stem cell proliferation and olfactory sensory neuron formation in the developing olfactory epithelium, but its functions in other sensory tissues and cell types are not well understood. Previous studies also revealed morphological inner ear defects, balance difficulties, and reduced hearing in humans and mice with *Chd7* deficiency, but the cellular and molecular mechanisms leading to these defects have not been explained. Here we tested the hypothesis that CHD7 functions in the inner ear to regulate early neuron formation and axon guidance. We used heterozygous loss of function mice, $Chd7^{Gt/+}$, and a newly generated conditional $Chd7^{flox}$ allele in combination with inner ear specific Cre lines to study *Chd7* global and tissue-specific deficient phenotypes in embryonic and early postnatal ears. Mature $Chd7^{Gt/+}$ mice exhibit selective loss of innervation to the posterior crista, a sensory epithelial structure that regulates angular movement. We also found reduced numbers of delaminating neuroblasts in the *Chd7* heterozygous and homozygous mutant otocyst and cochleovestibular ganglion, and fewer differentiated neurons. There were no measurable defects in embryonic *Chd7* mutant cellular proliferation or survival in the developing *Chd7* deficient otocyst or ganglion, suggesting instead that CHD7 regulates timing of exit from the cell cycle or one or more aspects of neuronal differentiation. Using neuroanatomical tracers, we detected defects in neuronal projections to the posterior cristae in embryonic and postnatal $Chd7^{Gt/+}$ ears. These studies indicate that CHD7 promotes vestibulocochlear neuronal development during early stages of delamination and neurogenesis without major effects on cellular survival. Combined with earlier observations showing that CHD7 promotes neural stem cell proliferation in the olfactory epithelium, these data suggest a general role for CHD7 regulated chromatin remodeling in developing neural progenitors. This work is supported by NICHD.

## 2408/T/Poster Board #957

**Expression of the putative microRNA processing protein, Ars2, in the developing and adult mouse retina.** *R.L. Chow[1], P.E. Nickerson[1], P.L. Howard[1,2].* 1) Biology, University of Victoria, Victoria, BC, Canada; 2) Department of Biochemistry and Microbiology, University of Victoria, Victoria, BC, Canada.

Proper development of the central nervous system depends on the coordinated timing of cell-cell interactions and subsequent cell autonomous responses. These cellular responses function, in part, by regulating downstream transcriptional programs and protein expression that mediate cell cycle exit, cell specification and differentiation. There is growing evidence that microRNAs play an important role in developmental programs by regulating the translation and/or stability of transcripts involved in the maintenance of stem and progenitor cells and their differentiation into tissue-specific lineages. A recently identified gene, *Arsenate resistance gene 2 (Ars2)*, is thought to play a role in microRNA processing and RNA metabolism, and is essential for at least two major processes of embryonic development: cellular differentiation and survival. We sought to determine whether *Ars2* functions during retinal development and first asked whether it is expressed in the developing and/or adult retina. Immunocytochemical analysis was performed using antisera generated against either the N or C terminus of human Ars2. Co-labeling of Ars2 and retinal cell type-specific and cell cycle-related markers was performed on mice ranging from P0-P90 in age. Our immunostaining experiments revealed dynamic patterns of Ars2 expression that include: (i) the upregulation of Ars2 in a subset of putative newly-born retinal neurons, and (ii) cell-class specific changes in Ars2 subcellular localization over time. Ars2 expression appears to be specific to neuronal subtypes, and was not detected in Müller glia. The timing and anatomical distribution of these changes in Ars2 expression is consistent with it playing a role in cell cycle exit and in the initiation of cellular differentiation.

## 2409/T/Poster Board #958

**The role of the Prader-Willi syndrome protein necdin in the development of the autonomic nervous system.** *A.A. Tennese, C.B. Gee, R. Wevrick.* Department of Medical Genetics, University of Alberta, Edmonton, Alberta, Canada.

Individuals with Prader-Willi syndrome (PWS), a rare neurobehavioural disorder, show pain insensitivity, have reduced salivation, and have abnormalities in feeding, drinking, thermoregulation, intestinal motility and reproduction. These functions are partly regulated by the autonomic nervous system (ANS) and may be caused by a defect in the ANS of PWS individuals. Necdin is one of the genes deleted in PWS and is most highly expressed in murine tissues that are relevant to PWS, including the peripheral and central nervous systems. We previously determined that loss of necdin in mice causes axonal extension, bundling, and branching defects in cultured sympathetic chain ganglia neurons. Therefore, we examined the sympathetic nervous system during prenatal development in necdin-null mouse embryos using immunohistochemistry. We identified a defect in the size and location of the superior cervical ganglion (SCG), the most rostral ganglion in the sympathetic chain, in necdin-null embryos. We determined that the initial migration of neural crest cells into the sympathetic chain is normal. The SCG appears normal at midgestation, but does not migrate towards the head at later stages in development as is normally observed in control embryos. In later stage necdin-null embryos, a decrease in innervation of SCG target tissues and an increase in cell death are also observed. As the survival of neurons requires nerve growth factors produced by target tissues, the reduction in axonal outgrowth likely causes the increased apoptosis in the maturing SCG neurons. The adrenal medulla is also formed by the migration of sympathetic neural crest cells into the adrenal gland. We examined the adrenal medulla in prenatal necdin-null embryos but did not identify any differences in size, location, or staining pattern when compared to control embryos. Further dysregulation of the ANS in necdin-null animals may be caused by a defect in the development and function of the hypothalamus, the master regulator of the ANS.

**PIAS1: a protein partner of the microphthalmia-associated homeodomain protein CHX10.** *E.A. Ivakine, L. Ploder, A. Huang, R.R. McInnes.* Program in Developmental and Stem Cell Biology, The Hospital for Sick Children Research Institute, Toronto, ON, Canada.

CHX10 is a highly conserved homeodomain-containing transcription factor essential for the development of vertebrate eye. In both humans and mice, homozygous mutations in the *CHX10* gene result in severe microphthalmia, retinal hypoplasia and absence of the optic nerve, but the molecular mechanisms underlying these developmental defects are incompletely understood. To identify CHX10-interacting proteins potentially involved in eye development, we performed a yeast two hybrid screen using a bovine adult retinal cDNA library and identified PIAS1 as a putative interactor. PIAS1 (Protein Inhibitor of Activated Stat1) belongs to a family of PIAS proteins that are broadly defined as transcriptional co-regulators. PIAS proteins function as E3 ligases in the SUMO conjugation pathway, in which the SUMO polypeptide is covalently linked to substrate proteins, but can also regulate the activity of proteins through sumoylation-independent mechanisms. Using immunofluorescence, we demonstrated that Pias1 is expressed in the inner nuclear and ganglion cell layers of the adult mouse retina and is co-expressed with Chx10 in bipolar cells. Analysis of Chx10 expression during eye development revealed the presence of two isoforms differing by 19 amino acids, resulting from differential splicing in exon 5. Expression of the Chx10 -19 isoform predominates throughout eye development from embryonic stages to adulthood. Both the +19 and -19 CHX10 isoforms interacted with Pias1 in a heterologous cell expression system, and analysis of CHX10 protein deletion mutants revealed that the CHX10 homeodomain is essential for the CHX10:Pias1 interaction. We found that both CHX10 isoforms can be sumoylated, both *in vitro* in a cell-free system, and in heterologous cells. Up to 10 possible sumoylation sites are predicted in the CHX10 protein. However, even when the four major and conserved predicted lysine sites were mutated to arginine (K13R, K184R, K241R, K298R) in a single CHX10 protein, we still observed residual CHX10 sumoylation, likely due to sumoylation at secondary sites. We are presently investigating whether PIAS1 directly regulates CHX10 transcriptional activity and/or its sub-localization within the nucleus, and whether this regulation occurs through a sumoylation-dependent or -independent mechanism. Definition of the role of sumoylation in the biology of CHX10 is likely to provide important insight into the mechanisms through which CHX10 regulates vertebrate eye development.

## 2411/T/Poster Board #960

**Notch function in the skeleton is dependent on both canonical and non-canonical Rbpj signaling.** *J. Tao[1], S. Chen[1], T. Yang[1], B. Dawson[1], T. Bertin[1], B. Lee[1,2].* 1) Human and Molecular Genetics, Baylor College of Medicine, Houston, TX; 2) Howard Hughes Medical Institute, Houston, Texas 77030.

Disruption of evolutionarily conserved Notch signaling causes a wide range of cancers and developmental disorders. Three inherited human diseases result from mutations in genes encoding Notch pathway components: Alagille syndrome, spondylocostal dysostosis, and cerebral autosomal dominant arteriopathy. To understand notch signaling in the skeleton, currently we have developed a series of mouse models for in vivo studies in which tissue specific gain and loss of function mutants were used. We previously generated an osteoblast specific over-expression of the constitutively active Notch 1 Intracellular Domain (NICD) by using collagen type 1 (Col1a1) promoter in committed osteoblasts. These transgenic mice showed a dramatic increase in osteoblast number, proliferation and formation resulting in a severe osteosclerotic phenotype. However, these founder lines exhibited early lethality and variable expression. To gain an insight into potential mechanistic basis for this phenotypic observation, we established a transgenic line with consistent NICD expression and longevity by crossing the $Rosa^{Notch/+}$; with the Col1a1-Cre transgenic mouse. The resulting bigenic mice ($Rosa^{Notch/+}$ ; Col1a1-Cre or Col1-GOF) recapitulated the NICD transgenic mice showing similar phenotypes. Using quantitative RT-PCR, a canonical target of Notch signaling, Hey1, was upregulated more than ten fold in Col1-GOF osteoblasts as would be expected for a NICD gain of function model. To explore the relative contributions of canonical (NICD/Rbpj-dependent) vs. non-canonical (NICD dependent but Rbpj-independent) Notch signaling, we crossed the Col1-GOF mice with a floxed allele of Rbpj. Our analyses showed the addition of the Rbpjf/f allele completely rescued growth retardation and osteosclerosis phenotypes. At the same time, we used a similar approach to study Notch signaling in chondrocytes. The chondrocyte-specific gain-of-Notch-function mice ($Rosa^{Notch/+}$; Col1a2-Cre or Col2-GOF) were stillborn with multiple defects in the skeleton. Significantly, vertebral columns were missing and appendicular long bones were abnormal and short in skeleton preparation. Further, addition of the Rbpjf/f allele to Col2-GOF mice completely rescued long bone phenotypes while vertebral columns were partially rescued. In summary, our data suggest that Notch signaling regulates osteoblasts through the canonical Rbpj-dependent pathway, but for chondrocytes it requires both canonical and non-canonical pathways.

## 2412/T/Poster Board #961

**Sturge-Weber syndrome with CYP1B1 mutations and severe trabecular dysgenesis.** *D. Pathak[1], M. Tanwar[1], T. Dada[2], R. Sihota[2], TK. Das[3], R. Dada[1].* 1) Dept Anatomy, All India Inst Medical Sci, New Delhi, India; 2) Dr. R.P. Centre for Ophthalmic sciences, AIIMS, New Delhi, India; 3) Electron Microscope Facility, AIIMS, New Delhi, India.

Sturge-Weber syndrome (SWS) is a progressive condition of mesodermal phakomatosis. One third cases of SWS have glaucoma. This preliminary study is the first report of CYP1B1 mutation analysis in SWS with congenital glaucoma. Mutations in CYP1B1 gene are major cause of congenital glaucoma.CYP1B1 is involved in metabolism of steroids, melatonin , retinol and other endogenous and exogenous substrates. Mutations in this gene results in diminished or absent metabolism of these key substrates that adversely affect signal transduction pathways and thus impair development and differentiation of anterior segment structures.This results in impaired aqueous outflow and raised intraocular pressure (IOP). CYP1B1 has higher expression in fetal eyes and plays major role in morphogenesis of iris, ciliary body, cornea and anterior chamber angle. Hence we decided to evaluate SWS cases with buphthalmos for CYP1B1 mutations by PCR RFLP followed by sequensing. Three different mutations R390C/H/S were identified at 390 position from earlier studies and all three demolish Hin6 restriction site and DNA sequencing was done to confirm the exact mutation. Trabecular-meshwork (TM) was studied for morphological alterations by scanning electron microscopy (SEM) of trabeculectomy tissue.All patients had normal 46, XY karyotype. PCR-RFLP analyses showed CYP1B1 mutations in 2 of the 5 SWS cases. Case 1 was homozygous for R390H and case 2 was heterozygous for both R390H and E229K mutation. All mutations were confirmed by DNA sequencing. SEM findings were suggestive of severe trabecular-dysgenesis. Mutations in CYP1B1 gene have been reported from different populations in glaucoma patients. No CYP1B1 mutation has been reported in any SWS case till date because syndromic cases were not analysed for mutations in earlier studies. Earlier studies have reported that onset of glaucoma in SWS shows a bimodal pattern. The result from this pilot study show that cases with buphthalmos and early onset glaucoma should be analysed for CYP1B1 mutations. The effect of vascular malformation induced venous engorgement and raised IOP may only be additive and may result in a much more severe phenotype. In conclusion SWS with buphthalmos should undergo CYP1B1 mutations analysis to identify an underlying genetic pathology for glaucoma. This will aid in determining the prognosis and management and will also help to provide comprehensive counseling in such cases.

## 2413/T/Poster Board #962

**Identification of downstream targets for EYA1 in kidney development.** *Y. Fan[1], S. Gisselbrecht[1], B. Busser[4], A.M. Michelson[4], M.L. Bulyk[1,2,3], R.L. Maas[1].* 1) Division of Genetics, Brigham and Women's Hospital and Harvard Medical School, Boston, MA 02115; 2) Department of pathology, Brigham and Women's Hospital and Harvard Medical School, Boston, MA 02115; 3) Harvard-MIT Division of Health Sciences and Technology (HST), Harvard Medical School, Boston, MA 02115; 4) Laboratory of Developmental Systems Biology, National Heart Lung and Blood Institute, National Institutes of Health, Bethesda, MD 20892.

Mutations in human EYA1, a homolog of the Drosophila eyes absent (eya) gene, result in Branchio-Oto-Renal (BOR) syndrome, an autosomal dominant disorder that includes hearing loss, branchial defects and renal abnormalities ranging from mild hypoplasia to agenesis. Eya1 null mice also exhibit renal agenesis, the result of a failure in ureteric bud (UB) outgrowth. Collectively, several studies suggest that the Eya1 protein interacts with the Six1 homeoprotein in intermediate mesoderm to regulate the metanephric mesenchymal (MM) expression of Glial-derived Neurotrophic Factor (GDNF), a morphogen for UB outgrowth. In addition, however, in organ culture, GDNF induces the UB outgrowth in Eya1-/- explants, although outgrowth is attenuated and the bud subsequently fails to branch. Based on these results, we hypothesized that factors other than GDNF might also contribute to UB development, and could be affected in Eya1 mutant mice. To address this question, we used available microarray data from wild type E11.5 mouse embryos to identify genes that are specifically expressed in MM. Next, we compared this gene set with a gene set of Drosophila genes obtained from microarray experiments involving over expression of Drosophila eya in fly mesoderm. We selected, as potential downstream targets of Eya1, MM expressed genes whose fly orthologs were also differentially expressed following eya overexpression. To begin to validate these findings, we examined the expression of these selected genes in Eya1 null mice by in situ hybridization, and by Eya1 knockdown in an E11.5 mouse MM cell line by real-time PCR. In this way, we identified five potential Eya1 targets. In addition, candidate DNA binding sites for the Six1 homeoprotein were identified using the PhylCRM algorithm and data from published protein binding microarrays (PBMs), and similar Six1 binding sites were found in four of the above five genes, consistent with the hypothesis that they might be direct downstream targets of a Eya1/Six1 complex.

## 2414/T/Poster Board #963

**Comparison between Apert Syndrome Fgfr2+/P253R and Fgfr2+/S252W mice reveal phenotypic and MAPK signaling differences.** *Y. Wang[1], V. Uhlhorn[1], J. Friedenthal[1], D.L. Huso[2], M.B. Beasley[1], E.W. Jabs[1].* 1) Mount Sinai School of Medicine, New York, NY, 10029; 2) Johns Hopkins University, Baltimore, MD, 21205.

Apert syndrome has abnormalities in the skull, limb and viscera organs and is caused by FGFR2 +/S252W and +/P253R mutations in humans. Both mutations result in increased affinity and altered specificity of FGF ligand binding, with the S252W mutation causing greater enhancement in FGFR2c binding to most FGF ligands, relative to the P253R mutation. We generated a Fgfr2 +/P253R mouse model and compared it to our reported Fgfr2 +/S252W mouse on the same C57BL/6J genetic background. Fgfr2 +/S252W mice survived for only 1 day and had more abnormalities in the trachea, thymus, heart, and gastrointestinal tract than Fgfr2 +/P253R mice that lived for up to three weeks. Previously we noted that micro-CT scans of both mutants revealed similar abnormal patterns of calvarial suture fusion. Shortening of the skull length and abnormal osteogenesis and proliferation at the developing intramembranous coronal suture and endochondral long bones were not significantly different between the two mutants. Here we studied the visceral organs of these mice. Both mutants had abnormalities of the lung with atelectasis, collapsed lung structure and thickened mesenchyme. Increased cell proliferation was detected in the lungs of both mutants. The amount of Ki-67 positive cells was increased more significantly in Fgfr2 +/S252W compared to +/P253R and WT littermate lungs. MAPK signaling revealed that phosphorylation of ERK1/2 and P38 proteins was significantly increased in Fgfr2 +/S252W relative to +/P253R and/or WT lungs. Phosphorylated PKCalpha was increased in each mutant, also more significantly in Fgfr2 +/S252W lung. Phosphorylated AKT was significantly decreased in both mutant lungs suggesting its negative feedback crosstalk/modulation of the ERK pathway. The greater activation of ERK1/2, P38, and PKCalpha signaling correlates with the increased cell proliferation in Fgfr2 +/S252W compared to +/P253R lungs. The decreased length of survival may be explained by the molecular pathology of the lungs with subsequent respiratory failure in both mutants with Fgfr2 +/S252W being more affected than +/P253R. These data show a lung phenotype-genotype correlation in Apert mice. Our results demonstrate that although both mutations result in similar phenotypes, the FGFR2 +/S252W and +/P253R mutations have differential effects on various organs and their activation of the MAPK signaling pathway.

## 2415/T/Poster Board #964

**Antisense morpholino studies in *Danio rerio* show that *TXNDC10* is involved in the development of the ventral eye.** *R. Chao[1], L. Nevin[2], P. Agarwal[3], J. Riemer[4], X. Bai[5], A. Delaney[6], M. Akana[7], N. LopezJiminez[1], T. Bardakjian[8], A. Schneider[8], D. FitzPatrick[9], P-Y. Kwok[7], L. Ellgaard[4], D. Gould[5], Y. Zhang[10], J. Malicki[10], H. Baier[2], A. Slavotinek[1].* 1) Dept Pediatrics, Univ California, San Francisco, San Francisco, CA; 2) Dept. of Physiology, UCSF, San Francisco; 3) CVRI, UCSF, San Francisco; 4) Dept. of Biology, University of Copenhagen, Copenhagen; 5) Dept. of Ophthalmology, UCSF, San Francisco; 6) Genome Sciences Center, BC Cancer Research Center, Vancouver; 7) Dept. of Dermatology, UCSF, San Francisco; 8) Clinical Genetics Division, Albert Einstein Medical Center, Philadelphia; 9) MRC Human Genetics Unit, Western General Hospital, Edinburgh; 10) Dept. of Ophthalmology, Harvard Medical School, Boston.

Anophthalmia and microphthalmia are important birth defects, but their pathogenesis is incompletely understood. We had previously studied a patient with severe unilateral microphthalmia who had a 2.7 Mb deletion at chromosome 18q22.1 that was inherited from his phenotypically normal mother. In-situ hybridization showed that one of the deleted genes, *Txndc10,* was expressed in the retinal neuroepithelium and lens epithelium of the developing murine eye. We re-sequenced *TXNDC10* in 66 patients with anophthalmia or microphthalmia, and found one missense substitution in an unrelated patient: c.260G>A, predicting p.Arg39Gln, in a male with unilateral microphthalmia and retinal coloboma. In our most recent studies, we sequenced an additional 24 patients with anophthalmia or microphthalmia that had additional eye anomalies, and found c.456G>A, predicting p.Asp108Asn, in a female with unilateral microphthalmia and severe micrognathia. We used two antisense morpholinos, one targeted against the translational start site and one against the exon two donor splice site, to reduce the expression of the *Txndc10* orthologue in *Danio rerio*, *zgc:110025*. The morphant larvae obtained with both morpholinos had significantly smaller eye sizes at 2 and 4 days post fertilization (dpf) and reduced staining with islet-1 antibody directed against retinal ganglion cells at 2 dpf compared to control-injected larvae. Co-injection of human wild type *TXNDC10* mRNA rescued the small eye phenotype obtained with both morpholinos, whereas co-injection of human *TXNDC10*(p.R39Q) mutant mRNA, resembling the mutation in one of the patients with microphthalmia and coloboma, did not rescue the small eye phenotype. In-situ hybridization showed expanded labeling for two genes involved in ventral eye formation, *Pax2* and *Vax2*, in the ventral eye of the morphants compared to controls injected at 2 dpf, suggesting a delay in ventral eye development in the *Txndc10* morphants. Our results suggest that haploinsufficiency for *TXNDC10* perturbs retinal morphogenesis and represents a novel genetic cause of microphthalmia and coloboma. Future experiments to determine if other thioredoxins are important in eye morphogenesis and to clarify the mechanism of function of *Txndc10* in eye development seem warranted.

## 2416/T/Poster Board #965

***Extra-toes spotting (Xs)*: Mutations in Eif3c implicate translation initiation complex proteins in Shh signaling.** *E.S Luetkemeier[1], D.E Gildea[1,2], E.J Spaulding[1], S.K Loftus[1], Y. Yang[1], W.J Pavan[1], L.G Biesecker[1].* 1) Genetic Disease Research Branch, NHGRI, National Institutes Hlth, Bethesda, MD; 2) Graduate Program in Genetics, The George Washington University, Washington DC.

The Sonic hedgehog (SHH) pathway regulates many developmental processes, including limb patterning. Dysregulation of this pathway causes malformations, as seen in Greig cephalopolysyndactyly syndrome (GCPS). One cause for GCPS is mutations of *GLI3*, which encodes a transcription factor in the SHH pathway. However, ~15% of patients with GCPS have no *GLI3* mutation. To find other GCPS genes, we used polydactylous mice as animal models. Extra-toes spotting (*Xs*) was selected since the phenotype is similar to Extra-toes ($Gli3^{Xt}$) (a known GCPS animal model). Both mice have preaxial polydactyly and ventral hypopigmentation, along with shortened forelimbs. Previous mapping excluded *Gli3* as the gene mutated in *Xs*. Linkage mapping was performed to narrow the *Xs* interval, followed by sequencing which showed a heterozygous (c.906C>T, p.R303X) variant in *Eukaryotic translation initiation factor 3-subunit C (Eif3c)*. A second *Eif3c* mutation was identified (c.1761_1817del p.L568_L586del) in Extra-toes spotting-like (*Xsl*). Eif3c is a core subunit of Eif3 as it recruits Met-$tRNAi^{Met}$ and mRNA to the 40S ribosome and scans for the start codon during translation initiation. We conclude that mutations in *Eif3c* cause Xs. As $Gli3^{Xt}$ and *Xs* mice show phenotypic overlap, we hypothesized that mutations of *Eif3c* affect Shh/Gli3 signaling. To test this hypothesis, we used *in situ* hybridization in $Xs^{J}$/+ embryos to evaluate the expression of Shh/Gli3 pathway genes. The *Shh, Ptch1, Fgf8, Gli1*, and *Hoxd13* genes were misexpressed, implying that *Eif3c* causes polydactyly by perturbing the Shh/Gli3 pathway. Therefore, *Eif3c* may be a novel candidate for GCPS human patients who lack *GLI3* mutations. Human *EIF3C* is located on chromosome 16p11.2, in a tandem inverted repeat, with four total copies of the gene. This gene is one of only 134 genes that are known to be human-specific duplications. However, the prevalence and orientation of these four copies are unknown. We performed QPCR, aCGH and FISH analyses to show that there is copy number variation of *EIF3C* among humans. We identified a nonsense mutation in *EIF3C* in one patient who has no GLI3 mutation. In summary, mutations in *Eif3c* cause Xs and the human homolog of this gene is a human-specific gene duplication and the locus has both copy number and structural variation in the population. This gene is a candidate for human malformations that overlap with GCPS.

## 2417/T/Poster Board #966

**Upregulation of the Organic Cation/Carnitine Transporter Family in the Pregnant and Lactating Murine Mammary Gland and Implications for the Suckling Infant.** *A. Lamhonwah[1, 2], I. Tein[1, 2].* 1) Dept Pediatrics, Hosp Sick Children, Toronto, ON, Canada; 2) Dept. Laboratory Medicine and Pathobiology, University of Toronto, Toronto, ON, Canada.

**Background**: Organic cation/carnitine transporters transport carnitine, drugs, and xenobiotics, (e.g. choline, quinidine, verapamil) and are expressed in muscle, heart, blood vessels, brain, placenta, etc. The transport and provision of L-carnitine into breast milk is important for the normal growth and development of the suckling infant, particularly given the very low endogenous L-carnitine biosynthetic capabilities of the infant. Further, organic cationic drugs present in human breast milk may pose a significant exposure risk to the nursing infant. **Methods**: To characterize the expression patterns of mOctn1, -2 and -3 in murine mammary gland, we applied our transporter-specific antibodies to mOctn1,-2 and -3, to murine breast sections of different developmental stages, followed by secondary antibody and the DAB peroxidase detection. Sections were counterstained with hematoxylin. **Results**: We demonstrated the differential expression of mOctn1, -2 and -3 in the epithelial ducts, muscle and lymphoid tissue of murine virginal non-lactating, pregnant, and lactating breast. There was a notable upregulation of expression of all three transporters in both the breast tissue of the pregnant mouse (18 days gestation) and lactating mouse (8 days after giving birth) compared to the virginal 8 week old mouse. There was also very strong expression of peroxisomal Octn3 in the specialized myoepithelial cells of the prelactating breast. **Conclusions**: The upregulation of the Octns is likely related to the increased metabolic energy demand of the actively lactating breast on plasmalemmal Octn2-, mitochondrial Octn1- and peroxisomal Octn3- dependent fatty acid oxidation. This may also be related to an increased nutritional demand by the suckling infant for carnitine and other cationic homologues and xenobiotics from the nursing mother, which would be facilitated by an upregulation of mammary gland ductular epithelial Octn2 transporter.

## 2418/T/Poster Board #967

**TRPS1, a regulator of chondrocyte proliferation and differentiation, interacts with the activator form of GLI3.** *F.J. Kaiser[1], M. Wuelling[2], L.A. Buelens[2], D. Braunholz[1], R. Depping[3], G. Gillessen-Kaesbach[1], A. Vortkamp[2].* 1) Inst. of Human Genetics, University of Luebeck, Germany; 2) Center for Medical Biotechnology (ZMB), Department of Developmental Biology, University Duisburg-Essen, Germany; 3) Department of Physiology, Center for Structural and Cell Biology in Medicine, University of Luebeck, Germany.

The *TRPS1* gene on human chromosome 8q24.1 encodes a multi zinc finger transcription factor protein. Mutations in *TRPS1* cause the tricho-rhino-phalangeal syndrome (TRPS). Besides typical craniofacial anomalies, skeletal malformations are characteristic hallmarks of patients with TRPS. Here we show that TRPS1 interacts with Indian hedgehog (Ihh)/GLI3 signalling and regulates chondrocyte differentiation and proliferation. By immunoprecipitation assays using transiently transfected cells as well as native tissue samples from embryonic mouse limbs, we could demonstrate that TRPS1/Trps1 specifically interacts with the activator form of GLI3/Gli3, whereas a direct binding of the repressor form of GLI3/Gli3 could be excluded. GST pull-down experiments were used to verify the interaction of the isolated GLI3 activator domain with TRPS1. Through the use of different truncated TRPS1 constructs, a domain of 185 aa, containing three predicted zinc fingers, was shown to be sufficient for the interaction with GLI3. Using different mouse models we find that in distal chondrocytes Trps1 and the repressor activity of Gli3 are required to expand distal cells and locate the expression domain of Parathyroid hormone related peptid. In columnar proliferating chondrocytes Trps1 and Ihh/Gli signalling have an activating function. The differentiation of columnar and hypertrophic chondrocytes is supported by Trps1, independent of Gli3. Trps1 seems thus to organize chondrocyte differentiation interacting with different subsets of co-factors in distinct cell types.

## 2419/T/Poster Board #968

**Genetic influences on asthma susceptibility in the developing lung.** *I. Mandeville[1], N. Carpe[1,2], J. Chu[3], L. Ribeiro[1,2], S. Cornejo[1,2], B.A. Raby[3], S.T. Weiss[3], F. Kaplan[1,2,3,4].* 1) McGill Univ-Montreal Child Hosp. Research Inst., Montreal, QC, Canada; 2) Dept. of Human Genetics, McGill University; 3) Channing Laboratory, Brigham and Women's Hospital, Harvard Medical School; 4) Depts of Pediatrics and Biology, McGill University.

Rationale: The prevalence of asthma in children under 4yr has increased dramatically in the last 2 decades. Existing evidence suggests that this increase in prevalence derives from early environmental exposures acting on a pre-existing asthma-susceptible genotype. We are exploring the origins of asthma susceptibility in developing lung in rat strains that model the distinct phenotypes of airway hyperresponsiveness (AHR, Fisher) and atopy (Brown Norway). Methods: We assessed lung function, cell proliferation, epithelial repair, goblet cell number, and BAL cell differentials from postnatal day (PN) 1-14. mRNA (Real-time PCR) and protein (immunohistochemistry [IHC]) were used to assess gene expression in lung tissue and primary lung cell culture. Illumina genome wide profiling was used to compare global gene expression patterns. Results: Initially, we established that BN and Fisher pups modeled early changes in lung structure / function. BN and Fisher pups showed differences in lung resistance at PN14 (the earliest age at which lung function can be reliably assessed) when compared to normoresponsive Lewis pups. At PN7, BN lungs showed increased epithelial proliferation; both BN and Fisher lungs had increased fibroblast proliferation. BN and Fisher lungs also demonstrated altered epithelial repair. Newborn BN rats displayed tracheal goblet cell hyperplasia. Fisher pups had persistent elevation of BAL neutrophils. Having established developmental differences in the respiratory phenotype of these models, we next explored associated changes in gene expression. Principal components analysis confirmed distinct global gene expression differences between strains over time. Linear regression analysis (n=4 per strain per time point) identified developmental variation in expression of 1,376 genes, including several previously implicated in asthma. Biological processes heavily represented were growth and development, ECM and cell adhesion, cell signaling and immune function. Differential mRNA and protein expression was validated for EGFR, PDGFRβ GR, IPO13 and ADAM33. Conclusion: Innate differences in patterns of gene expression in developing lung contribute to individual variation in respiratory phenotype and are likely to contribute to the pathogenesis of asthma.

**Lgl1 deficiency exacerbates the effects of neonatal hyperoxia-induced lung injury.** *K. Nadeau[1,2], I. Mandeville[1], T. Bao[1,3], L. Ribeiro[1,2], N.B. Sweezey[4], F. Kaplan[1,2,3].* 1) Dept Human Genetics, McGill- Univ Montreal Children's Hospital Res Inst, Montreal, PQ, Canada; 2) Dept of Pediatrics, McGill University, Montreal, PQ, Canada; 3) Dept of Biology, McGill University, Montreal, PQ, Canada; 4) Hospital for Sick Children, Toronto, ON, Canada.

Bronchopulmonary dysplasia (BPD) is a leading cause of neonatal morbidity with sequelae that persist into adulthood. Impaired alveolarization in BPD is associated with disruption of elastin fibres and mucus cell hyperplasia. Exposure of the immature lung to hyperoxia is a primary risk factor for BPD. Yet the molecular mechanisms that link oxygen exposure to disrupted alveolarization and postnatal lung inflammation remain unclear. We cloned Lgl1, encoding a developmentally regulated glycoprotein in the lung. Absence of Lgl1 is lethal prior to lung formation. Lgl1+/- mice display a complex phenotype with features of inflammation in the post-natal period and altered lung mechanics at maturity. The present study was designed to explore whether deficiency of Lgl1 in Lgl1+/- mice exacerbates hyperoxia-induced neonatal lung injury. We report that, compared to their Lgl1+/+ littermates, Lgl1+/- mice exposed to hyperoxia for 4 weeks had more profound neutrophilia, increased macrophage influx, more intense fragmentation and disorganization of the elastin scaffold and reduced lung elastance following methacholine provocation. Oxygen exposure was associated with reduced Lgl1 expression in all mouse pups. Lgl1 expression in hyperoxia-exposed Lgl1+/- mice at 4 weeks was ~25% of that observed in Lgl1+/+ littermates. Exposure to hyperoxia for 2 weeks led to profound goblet cell hyperplasia and elevated MUC5AC levels in a subset of Lgl1+/- mice, suggesting that genetic modifiers influence the inflammatory phenotype. Our results suggest that Lgl1 contributes to the complex phenotype of BPD in infancy and that compromised developmental expression of Lgl1 may increase susceptibility to respiratory pathology in adulthood.

## 2421/T/Poster Board #970

**Intracellular function of neuron-specific TAF1 and its isoform in Neuro-2a mouse neuroblastoma cells.** *S. Makino[1], G. Tamiya[2], I. Tooyama[1].* 1) Molecular Neuroscience Research Center, Shiga University of Medical Science; 2) Advanced Molecular Epidemiology Research Institute, Yamagata University School of Medicine.

We previously found a neuron-specific isoform of the *TAF1* (TATA box binding protein-associated factor 1), which is the disease causative gene of X-linked recessive dystonia-parkinsonism showing severe neurodegeneration in striatum (XDP/DYT3; MIM314250). The *TAF1* gene encodes the largest component of the TFIID complex involved in RNA polymerase II-mediated expression of many genes related cell division. The neuron-specific isoform of the *TAF1* gene, named *N-TAF1*, may have an essential role in neuronal survival in the striatum through transcriptional regulation of many neuron-specific genes. To investigate the detailed function of the neuron-specific isoform of the *TAF1* gene, we carried out over-expression of *N-TAF1* in the mouse Neuro-2a (N2a) cell line. The cell lines were prepared by stable transfection of N2a-TetR cells with an inducible mouse N-TAF1/TAF1 expression vector. The doxycycline treatment of N-TAF1/TAF1 inducible cells allowed a substantial expression of its products. We subsequently performed MTS assay, which could easily be interpreted as cellular mitochondria activities, to examine if the over-expression of N-TAF1/TAF1 affect cell proliferation in Neuro-2a. The MTS assay showed that the N-TAF1 induction for 7 days significantly inhibited N2a proliferation whereas the TAF1 induction elevated cell proliferation. In addition, we examined a possible difference in the intracellular trafficking between N-TAF1 and TAF1 using FLAG-tagged protein. Through these in vitro experiments, we demonstrated that *N-TAF1* varies from *TAF1* gene in intracellular transportation, probably reflecting the difference in physiological roles between *N-TAF1* and *TAF1*. These experiments would reveal the essential role of these genes and shed light on the molecular pathogenesis of disease caused by transcriptional dysregulation as well as XDP.

## 2422/T/Poster Board #971

**Biochemical Analysis of NALP1 Inflammasome Variants Associated with Autoimmune Vitiligo.** *C. Mailloux[1], C. Dinarello[2], R. Spritz[1].* 1) Human Med Gen, Univ Colorado Denver, Aurora, CO; 2) Div Infectious Diseases, Dept Medicine, Univ Colorado Denver, Aurora, CO.

Generalized vitiligo is a common autoimmune disease that is often associated with other autoimmune disorders such as autoimmune thyroid disease, Addison's disease, pernicious anemia, lupus, rheumatoid arthritis, psoriasis, and adult onset insulin dependent diabetes. We previously showed that common high-risk genetic variants of the *NALP1* (*NLRP1*) gene are associated with susceptibility to vitiligo-associated multiple autoimmune disease. NALP1, the canonical member of the NLR (NACHT-leucine rich repeat) protein family, forms the backbone of the inflammasome, a complex that regulates apoptotsis and activation of the innate immune system in response to extracellular triggers. Of the vitiligo-associated *NALP1* variants, there is only one non-synonymous SNP, rs12150220, that defines disease susceptibility haplotypes. SNP rs12150220 is located between the N-terminal Pyrin and internal NACHT domains, and corresponds to a low-risk leucine or a high-risk histidine at codon 155. To investigate functional differences between high-risk and low-risk *NALP1* alleles defined by SNP rs12150220, we first developed an antibody that recognizes full-length NALP1 protein, and found that NALP1 expression is highest in B cell lineages. We observed no evident difference in the amount of steady-state NALP1 protein in lymphoblastoid cell lines homozygous for the high-risk 155His and low-risk 155Leu alleles of rs12150220, indicating that expression of these two alleles, and stability of the corresponding 155Leu and 155His NALP1 polypeptides, is similar. This suggests that susceptibility to autoimmune disease may result from differential binding of the NALP1 155Leu versus 155His polypeptides to other components of the inflammasome, thereby differentially activating innate immunity and apoptotic pathways in response to environmental triggers. We are currently investigating binding of NALP1 155Leu versus 155His to known components of the NALP1 inflammasome, as well as to other potential interaction partners that may participate in a complex variety of functionally different novel inflammasomes.

## 2423/T/Poster Board #972

**STRUCTURE-FUNCTION ANALYSIS OF HUMAN HEMATOPOIETIC PBX INTERACTING PROTEIN (HPIP): A NOVEL HUMAN STEM CELL REGULATORY PROTEIN.** *P. Kaur[1], C. Stadler[1], W. Hiddemann[1], K.R. Humpheries[2], S. Bohlander[1], C. Buske[1], M. Feuring-Buske[1].* 1) Helmholtz-zentrum, Med III, Klinikum Groβhadern, Muenchen, Germany; 2) The Terry fox laboratories, Vancouver, BC, Cannada.

Human hematopoietic PBX interacting protein (HPIP) is a 731 amino acid protein, discovered as a novel interacting partner of the PBX homeodomain protein. HPIP inhibits the ability of PBX-HOX heterodimers to bind to target sequences and strongly inhibits the transactivation activity of E2A-PBX1 [t(1;19) translocation, which occurs in 25% of pediatric pre-B cell acute lymphocytic leukaemia] (Abramovich C. et al JBC, 2000; Oncogene, 2002). HPIP cDNA was cloned in pMSCV-IRES-YFP cassette. Umbilical cord blood enriched with CD34+ population of stem cells was obtained to perform in vitro and in vivo experiments. Mutants, with deletions of the microtubule binding region (ΔMBR-HPIP), and NRPID; deletion of LXXLL motif/ PBX interacting domain (ΔNRPID-HPIP) were generated and tested in vitro and in vivo. The constitutive expression of HPIP wt and ΔMBR-HPIP in human cord blood cells (CD34+) enhanced erythroid colony formation in CFC assay ($p=0.008$, $n=6$) while the ΔNRPID-HPIP mutant nullified the effect. Both mutants of HPIP augmented significantly, the formation of primitive colonies (GEMM and GM) in methylcellulose assay ($p \leq 0.01$, $n=6$) as compared to YFP control and HPIP wt. In replating CFC assays ΔNRPID-HPIP showed an increased number of myeloid colonies ($p \leq 0.01$, $n=6$) and GM (p=ns) colonies but a decrease in granulocytic colonies ($p \leq 0.05$, $n=6$) compared to YFP control and HPIP wt. Long-term culture initiating cell assay (LTC-IC) demonstrated that HPIP protein enhanced the frequency of LTC-IC ($p \leq 0.1$, $n=3$) while mutants did not show any significant increase as compared to control YFP. HPIP wt and the mutants did not enhance the yield of LTC-IC derived CFC per million cells (p=ns, n=3). Infected cells were transplanted into NOD/SCID mice. HPIP induced, a significant increase in CD34+CD19+, CD10+ and CD117+ ($p \leq 0.05$ and $p \leq 0.1$) cells. Intriguingly, there was a significant increase in scid repopulating cell frequency introduced by HPIP wt as compared to control YFP in NOD/SCID mice. Interestingly, a decrease in SRC frequency was observed in the case of ΔNRPID-HPIP mutant form as compared to HPIP wt. Affymetrix differential gene expression analysis was performed on CB CD34+ cells transduced with HPIP wt and its mutant forms. A deregulation of genes involved in cytokine-cytokine pathway and MAPK pathway was observed.

## 2424/T/Poster Board #973

**LINE-1 endonuclease-independent retrotransposition.** *H. Kopera[1], J. Garcia-Perez[3], J. Moran[1,2].* 1) Dept Human Genetics, Univ Michigan, Ann Arbor, MI 48109 USA; 2) Howard Hughes Medical Institute; 3) Spanish Stem Cell Bank, Center for Biomedical Research, University of Granada, Avda Conocimiento s/n Armilla, Granada 18100, Spain.

The mobile element Long INterspersed Element-1 (LINE-1 or L1) is a non-LTR retrotransposon that comprises ~17% of the human genome. A full length LINE-1 is 6kb in length and encodes two open reading frames, ORF1 and ORF2. ORF1 encodes for a 40kDa RNA binding protein and ORF2 encodes for a 150kDa protein with endonuclease (EN) and reverse transcriptase (RT) domains. Both ORF1p and ORF2p are required for retrotransposition. Despite its abundance in human DNA, only ~80-100 LINE-1s per human genome remain retrotransposition-competent. Recent evidence shows that LINE-1s are still active in humans and that L1-mediated retrotransposition events are responsible for about 1 in 1000 disease causing mutations. LINE-1 integrates into genomic DNA through a process called target site primed reverse transcription. ORF2p cleaves genomic DNA and the reverse transcriptase activity then uses the exposed 3' hydroxyl as a primer for L1 cDNA synthesis. Our laboratory has recently described retrotransposition of an L1-ORF2p EN mutant in a hamster cell line deficient for the non-homologous end-joining (NHEJ) DNA repair pathway. Analyses of these endonuclease-independent retrotransposition events revealed some LINE-1s integrated at dysfunctional telomeres. Interestingly, when the integration junction was sequenced, the LINE-1 poly(A) sequence was flanked by the complement of perfect telomeric repeats (5'-CCCTAA-3'). Using L1 ribonucleoprotein particles (RNPs), and an oligonucleotide that ends in a series of telomeric repeats as a substrate to mimic a deprotected telomere, we have recapitulated this step of L1 retrotransposition *in vitro*. Interestingly, wild type L1 RNPs contain a putative endonuclease activity that processes the telomeric oligonucleotide before it is used as a substrate for reverse transcription. We currently are examining a cohort of L1-ORF2 endonuclease mutants for their ability to both retrotranspose in a NHEJ-deficient hamster cell line and use oligonucleotides ending in telomeric repeats as substrates for reverse transcription *in vitro*. Thus, these data further our understanding of LINE-1 retrotransposition and integration.

**Impaired responses to sensory stimuli in miR-183 morphant zebrafish.** *P.D. Witmer[1,2], H.A. Burgess[4], S. Xu[3], S. Fisher[1], D. Valle[1].* 1) Human Gen Program, Johns Hopkins Univ, Baltimore, MD; 2) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins Univ, Baltimore, MD; 3) Department of Ophthalmology/Neurological Sciences, Rush Univ Medical Ctr, Chicago, IL.D; 4) Unit on Behavioral Neurogenetics, Laboratory of Molecular Genetics, NICHD, NIH, Bethesda, MD.

The miR-183 miRNA family (miR-183, -96 and -182) is highly enriched in the mammalian retina and other sensory organs. Our own results (Xu et al., JBC 2007) and other recently reported studies including reports implicating miR-96 as a deafness gene in humans and mice (Mencía et al., Lewis et al., Nat Genet 2009) show that these miRNAs play important roles in sensory neural biology. Sequence conservation extends to teleost fish, where expression is detected in the lateral line, a mechanosensory organ. To investigate the functions of the miR-183 family during development, we utilized morpholino-directed knockdown of miR-183, -96 and -182 expression in zebrafish. We produced morphant larvae with abnormal balance, swimming abnormalities and an attenuated response to vibrational stimuli: a phenotype similar to those reported for zebrafish circler mutants. To examine sensory function further in these triple-morphant fish, we tested auditory responses to acoustic startle and visual responses using dark flash. Our results indicate a significantly reduced response to startle and a significantly increased latency in response to dark flash stimuli. Taken together these results strongly suggest that these fish hear and see less well than their sibling controls. Interestingly, knockdown of a single miRNA in the cluster, miR-183, results in bilateral loss of the anterior otolith, a structure necessary for auditory function. Even so, in miR-183 morphant fish that retain their otoliths, we observe the same abnormal response to dark flash seen in the triple-morphant group. In contrast, no changes in morphology or response to sensory stimuli were observed for miR-96 or miR-182 single morphants. Thus, it appears that loss of miR-183 alone accounts for the sensory impairments observed in morphant fish. We conclude that members of the miR-183 family are important for sensory neuron development and/or function. Additional studies are underway to characterize the nature of the sensory deficits in these fish and relate these observations to human phenotypes.

**Human lysyl oxidase-like protein 2 (LOXL2) functions as an amine oxidase toward collagen and elastin.** *Y. Kim, Y.M. kim.* Department of Biochemistry, Wonkwang University School of Medicine, Iksan, Jeollabuk-Do, Korea.

The lysyl oxidase-like protein 2 (LOXL2) is a member of the emerging family of lysyl oxidase (LOX), several of which have been shown to function as copper-dependent amine oxidases catalyzing lysine-derived cross-links in extracellular matrix proteins, such as collagen and elastin. LOXL2 contains four scavenger receptor cysteine-rich domains in addition to the characteristic domains of the LOX family, including a copper-binding domain, a cytokine receptor-like domain, and residues of the lysyl-tyrosyl quinine cofactor. Recently, LOXL2 was also reported to mediate the induction of epithelial-mesenchymal transition for tumor progression. In an effort to assess its amine oxidase activity, we expressed LOXL2 as recombinant forms attached with hexa-histidine residues at the carboxy terminus. The purified LOXL2 proteins showed an amine oxidase activity toward different types of collagens and elastin. These results indicate that LOXL2, with the four copies of SRCR domains, also function as an active amine oxidase. Availability of the pure and active forms of LOXL2 will be significantly helpful for functional studies related to substrate specificity and crystal structure of this amine oxidase, which should provide significant insights into functional differences within the LOX family members.

### 2427/T/Poster Board #976

**Investigating the Mechanism of APOBEC3-Mediated Inhibition of LINE-1 Retrotransposition.** *S.R. Richardson[1], I. Narvaiza[4], A.E. Hulme[1,5], A.J. Doucet[1], J.L. Garcia-Perez[1,6], M.D. Weitzman[4], J.V. Moran[1,2,3].* 1) Department of Human Genetics, University of Michigan Medical School, Ann Arbor, MI, USA; 2) Department of Internal Medicine, University of Michigan Medical School, Ann Arbor, MI, USA; 3) Howard Hughes Medical Institute; 4) The Salk Institute for Biological Studies, La Jolla, CA, USA; 5) Department of Cell and Molecular Biology, Feinberg School of Medicine, Northwestern University, Chicago, IL, USA; 6) Spanish Stem Cell Bank, Center for Biomedical Research, University of Granada, Spain.

Long INterspersed Element 1 (LINE-1 or L1) is an endogenous retrotransposon whose sequences comprise about 17% of human DNA. Although most L1 sequences are nonfunctional molecular “fossils”, an estimated 80-100 L1 elements per human genome are able to mobilize by a mechanism termed retrotransposition. Retrotransposition involves cleavage of genomic DNA by the L1-encoded endonuclease, and the use of the liberated 3’OH as a primer by the L1-encoded reverse transcriptase to generate a cDNA using the L1 mRNA as a template. L1 retrotransposition frequently is associated with alterations to genomic DNA, and about 65 cases of human disease have been attributed to L1-mediated retrotransposition events. L1 therefore poses a substantial threat to genomic integrity, and it follows that host genomes may have evolved mechanisms to curtail L1 mobility. One such defense appears to be the APOBEC3 (A3) family of cytidine deaminases. Specifically, APOBEC3A (A3A) and APOBEC3B (A3B) have been demonstrated to inhibit L1 retrotransposition in a cultured-cell assay; however, the mechanism of inhibition is not known. Here, we describe our efforts to determine how A3A and A3B inhibit L1 retrotransposition. Our results suggest that A3-mediated inhibition may occur independently of the sequence of the LINE element, as both A3A and A3B are able to restrict retrotransposition of LINE-1 elements from mouse and a LINE-2 element from zebrafish, which bear little identity to human L1 sequences. Our data also suggest that A3-mediated inhibition of L1 retrotransposition is not exerted during the first step of integration, as we have found that endonuclease-independent L1 retrotransposition is inhibited by both A3A and A3B. We currently are employing in vitro assays to determine the impact of A3A and A3B on other L1-encoded activities. Our ultimate goal is to achieve a mechanistic understanding of A3-mediated inhibition of L1 retrotransposition.

### 2428/T/Poster Board #977

**Mutation profile of CYP1B1 Gene in North Indian Congenital Glaucoma Population.** *M. Tanwar[1], T. Dada[2], R. Sihota[2], TK. Das[3], R. Dada[1].* 1) Dept Anatomy, AIIMS, New Delhi, India; 2) Dr. R.P.Centre for Ophthalmic Sciences, AIIMS, New Delhi, India; 3) Electron Microscope Facility, AIIMS.

Mutations in CYP1B1 gene are a predominant cause of congenital glaucoma. This study was planned with the aim to identify the mutation profile of CYP1B1 gene in north-Indian PCG patients. After ethical clearance, fifty congenital glaucoma patients and 50 ethnically matched controlled were recruited. Genomic DNA was isolated from blood and trabecular meshwork and CYP1B1 gene was screened for six most prevalent mutations (Termination at 223, Gly61Glu, Pro193Leu, Glu229Lys, Arg368His and Arg390Cys) by PCR-RFLP. DNA sequencing was done to identify other mutations and for confirmation of RFLP positive samples. On PCR-RFLP, 21/50 (42%) cases were found positive for one/more of these mutation.However on sequencing we found that 23/50(46%) harbored CYPIBI mutation. Ter@223 was found in 18%,p.R390H in 16% and p.R368H in 8% cases. Three novel mutations p.L24R, p.F190L, p.G329D were identified by DNA sequencing. Leucine, phenylalanine and glycine are conserved at 24,190 and 329 positions in CYP1B1 protein in different species suggestive of important functions at these loci. Ter@223 was found to be most prevalent mutation in our patients while p.R368H was most prevalent in southern India. Difference in frequency and mutation profile may be due to heterogeneous Indian population. CYP1B1 mutation impairs anterior chamber development and differentiation with block in aqueous outflow and raised intraocular pressure (IOP). In conclusion three novel mutations have been identified. Studies of pathogenic sequence variants in CYP1B1gene in different populations may contribute to a better understanding of disease pathogenesis. This may lead to the development of novel therapeutic approaches in near future.

## 2429/T/Poster Board #978

**Collection, Classification, and Assessment of Variants of the Wilson Disease Copper Transporter ATP7B.** *D.A. Bugbee, L. Prat Davies, S.M. Kenney, G. Macintyre, D.W. Cox.* Medical Genetics, University of Alberta, Edmonton, Alberta, Canada, T6G 2H7.

Wilson Disease (WND) is an autosomal recessive disease caused by impaired or abolished capacity to remove copper from the body. Patients with WND accumulate copper in multiple organs. This excess copper produces various clinical symptoms (hepatic and/or neurological) presenting anywhere from 3 to 70 years of age. Several biochemical tests aid in diagnosis of WND, however none is abnormal in all patients. Thus, diagnosis proves challenging. In 1993 the gene responsible for causing WND was identified as encoding a P-type ATPase, ATP7B. This protein traffics and transports copper within, and out of, the cell. Numerous variants of *ATP7B* have been identified in both affected and non-affected individuals. To better understand the implications of variation in *ATP7B*, we have curated variant information in a searchable Wilson Disease Database (http://www.wilsondisease.med.ualberta.ca/database.asp) that adheres to HGVS nomenclature guidelines. Over 1600 submissions have been entered into the database from: our data, the literature, and direct submission. In total, these entries include 644 variants, of which 54 are suspected to be non-disease-causing (NDV), 57 are silent changes (Sil), and 510 are possible disease-causing variants (DV). Of this 510 DV category there are: 150 deletion/insertions/duplications, and 360 substitutions. The remaining 23 variants have been submitted as both DV and NDV from various sources. The classification for each variant is supported by several criteria, including functional data. In our laboratory, variants are functionally assessed by a combination of a Chinese Hamster Ovary (CHO) cell viability assay, an ATP7B trafficking assay, and a yeast growth assay. The CHO viability assay examines the ability of each variant to protect cells from toxic amounts of copper. This result indirectly indicates a variant's capacity to perform its *in vivo* roles, both in transport and trafficking. These cells can then be directly observed for trafficking using immunofluorescence microscopy. The yeast assay examines copper transport function, as trafficking is thought to be absent in yeast. Many variants still require functional assessment and classification support as indicated in the Wilson Disease Database.

## 2430/T/Poster Board #979

**FOXD3 in the genetic syndrome of Carney triad, [paragangliomas associated with gastrointestinal stromal tumors (GISTs) and pulmonary chondromas] and in sporadic GISTs.** *A. Horvath[1], F. Faucz[1], G. Assie[2,3], S. Kim[4], M. Lodish[1], M. Raygada[1], E. Bimpaki[1], M. Nesterova[1], K. Tsang[1], E. Remmers[5], M. Almeida[1], J.A. Carney[6], J. Bertherat[3], C. Antonescu[7], L. Helman[4], C. Eng[2], C. Stratakis[1].* 1) Section on Endocrinology & Genetics, PDEGEN, NICHD, NIH, Bethesda, MD 20892, USA; 2) Genomic Medicine Institute and Lerner Research Institute, Cleveland Clinic Foundation, Cleveland, OH 44195, USA; 3) Department of Endocrinology, CHU Cochin & Institut Cochin, INSERM U567, CNRS UMR8104, IFR 116, Université Paris V-René Descartes, 75014 Paris, France; 4) Pediatric Oncology Branch, National Cancer Institute, NIH, Bethesda, MD 20892; 5) Genetics and Genomics Branch, National Institute of Arthritis, Musculoskeletal and Skin Diseases, NIH, Bethesda, MD 20892; 6) Department of Laboratory Medicine and Pathology (Emeritus member), Mayo Clinic and Foundation, Rochester, MN 55905, USA; 7) Department of Pathology, Memorial Sloan-Kettering Cancer Center, New York, New York 10021, USA.

The discovery of constitutive KIT and PDGFRA activation in the majority of gastrointestinal stromal tumors (GIST) led to the identification of a distinct group of GISTs that do not harbor KIT and PDGFRA mutations (non-KIT/PDGFRA-GISTs). These tumors respond poorly to imatinib mesylate or other kinase activity inhibitors and affect mostly pediatric and young adult patients that: (1) do not have other associated lesions or a family history of GIST ("sporadic"); or, (2) exhibit the Carney-Stratakis syndrome [CSS; OMIM#606864], an autosomal dominant syndrome characterized by paraganglioma (PGL) and GIST and caused by mutations in the SDHB, SDHC, and SDHD genes, or the nonfamilial Carney Triad [CT; OMIM#604287], a condition that associates PGLs and GISTs with pulmonary chondromas and other tumors. We analyzed patients with CT and their tumors using a genome-wide approach (Assie G, et al. Am J Hum Genet. 2008;82:903, Matyakhina L, et al. J Clin Endocrinol Metab 2007;92:2938). In 5 tumors from 4 (of 22) patients with CT and non-KIT/PDGFRA-GISTs, we identified somatic deletions on the region 1p31 harboring the FOXD3 gene. FOXD3 encodes the factor "Genesis" that is expressed during early embryogenesis and is a main determinant of embryonic stem cell fate. Western blot analysis and immunohistochemistry confirmed FOXD3 protein downregulation in tumors from CT patients with deletions. FOXD3 sequencing in 22 CT patients showed no additional germline or somatic mutations. However, we found 3 FOXD3 coding variants in 3 unrelated patients with sporadic non-KIT/PDGFRA-GISTs among 24 patients with such tumors: c.161G>A/p.R54H, c.286G>T/p.V96L, and c.255_266del12. The R54H and Del12 were also studied in a total of 930 unrelated control individuals and the V96L in 296 unrelated controls. Analyzed together, R54H and Del12 are more frequent among GIST patients ($p=0.089$). V96L is also more frequent in non-KIT/PDGFRA-GISTs (without reaching statistical significance). R54H and Del12 affect the evolutionarily preserved forkhead box of the FOXD3 protein; R54 is present in all forkhead box-containing proteins in both humans and mice. Electro-mobility shift assays with constructs containing the three FOXD3 mutants suggested impaired interaction between each of the mutants and DNA target sequences. We conclude that FOXD3 defects may be involved in non-KIT/PDGFRA-GIST pathogenesis. Ongoing studies aim at further elucidating the role of FOXD3 in the formation of this tumor.

## 2431/T/Poster Board #980

**Molecular investigation of an autism risk region on chromosome 12.**
*H.N. Cukier[1], I. Konidari[1], M.Y. Rayner[1], D.Q. Ma[1], H.H. Wright[2], R.K. Abramson[2], J.L. Haines[3], M.L. Cuccaro[1], J.R. Gilbert[1], M.A. Pericak-Vance[1].* 1) Miami Institute for Human Genomics, University of Miami, Miami, FL; 2) University of South Carolina School of Medicine, Columbia, SC; 3) Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

There is a strong genetic component to autism, but studies to date have demonstrated that the underlying genetic architecture is complex, with numerous genes potentially involved. One strategy for uncovering these genes is the use of large, extended families with multiple, distantly related, affected individuals. Our previous genome-wide linkage study identified a 4 centimorgan region (75-79 cM) on chromosome 12 that demonstrated significant linkage (HLOD = 4.51) across eleven extended multiplex families with only male affected individuals. Our goal is to comprehensively evaluate the chromosome 12 candidate region in order to identify the genetic abnormalities that underlie the strong autism linkage peak. We anticipate that this genetic abnormality will confer a relatively moderate autism risk due to its presence in these large, extended families. We are currently using a three-pronged approach to identify potential causative variants; 1) analysis of copy number variations (CNVs) across the region using comparative genomic hybridization (CGH) arrays, 2) traditional Sanger sequencing to identify variants in known and well annotated genes, and 3) deep re-sequencing of the entire candidate region using the Illumina Genome Analyzer II to identify all potential variants in the region. In order to identify copy number alterations, an Agilent custom CGH array was designed across a broad region containing the linkage peak (51,309,829-66,881,321 bp). Twenty-three affected individuals from 10 distinct extended families were evaluated. Thirteen CNVs were present in at least two affected individuals within a family. However, we were unable to confirm that these CNVs were causative of autism. Sanger sequencing was performed on 12 autistic individuals in 8 distinct families that define the region, as well as 10 control Caucasian individuals for 20 of the annotated genes in the minimal shared region (60,710,030-64,239,801 bp). Preliminary sequencing results failed to show variations of interest in 8 genes; the remaining 12 genes demonstrate one or more alterations that warrant further investigation. Deep re-sequencing using the Illumina GA II next-generation sequencing system of the minimal candidate region to completely catalogue variation in these families is currently underway and studies are ongoing to determine if any identified single nucleotide or copy number variations play a role in the etiology of ASD.

## 2432/T/Poster Board #981

**The alternative glucocerebrosidase promoter is located within a 1000-bp region 2.6 kb upstream of the usual promoter.**
*M. Hrebicek[1], E. Svobodova[1], O. Luksan[2], L. Mrazova[1], F. Majer[1], J. Minks[1], J. Eberova[2], M. Jirsa[2], L. Dvorakova[1].* 1) Institute of Inherited Metabolic Disorders, Charles Univ., Prague 2, Czech Republic; 2) Laboratory of Experimental Hepatology, Institute of Clinical and Experimental Medicine, Prague.

Gaucher disease is a lysosomal glycolipid storage disorder caused by an inherited deficiency of glucocerebrosidase. The patients carry mutations in the glucocerebrosidase gene (GBA, 1q21). The gene has a promoter (“downstream promoter”) immediately upstream of exon 1. A database search identified ESTs and other partial glucocerebrosidase transcripts that apparently originated at an alternative promoter located 2.6 kb upstream of the downstream promoter. The alternative transcripts from the putative upstream promoter contained one or two extra exons (exon -2 or exons -2, -1, respectively), but the first ATG codon and predicted protein sequence were the same as in transcripts from the downstream promoter. Our main goal was to confirm that the predicted alternative promoter initiates transcription of GBA. A 1000 bp PCR product containing the sequence of the predicted upstream promoter was cloned in both sense and antisense orientations into pGL4 plasmid vector (Promega) into the polylinker site upstream of the firefly luciferase reporter gene. The constructs were transfected to HepG2 (human hepatoblastoma) cells. The pRL-TK vector (Promega) harboring the Renilla luciferase gene was co-transfected as an internal control enabling normalization of the transfection efficiency. A luminescent signal was measured for both upstream and downstream promoters, however, the highest promoter activity (17. 82 ± 1.1 relative units) was observed in the construct containing the sequence of downstream promoter, while the luminescent signal from alternative promoter construct was 3, 01 ± 0.43 relative units. Furthermore, no luminescent signal was measured in constructs with inserts in the opposite orientation used as negative controls. A CPG island overlapping with the putative promoter was completely unmethylated when analyzed by bisulfite sequencing. 5’-RACE (RNA ligase mediated RACE) suggested 3 possible transcription initiation sites. Transcripts from upper promoter were found by RT/PCR in four different human tissues and the ratio between the transcripts from both promoters appeared to be similar in different tissues, the assay, however, was not quantitative. Alternative promoters often play role in tissue-specific proteins with different amino-acid termini - which is not the case in the glucocerebrosidase promoters. Conclusion: We have confirmed that the alternative upper promoter initiates transcription of GBA. Supported by GAUK 121407, VZ MÅM ÄŒR 0021620806.

## 2433/T/Poster Board #982

**Comprehensive targeted re-sequencing of a 150kb contiguous genomic region of chromosome 5p14.1 associated with autism.**
*A.J. Griswold[1], D.Q. Ma[1], H. Cukier[1], I. Konidari[1], W. Hulme[1], P. Whitehead[1], J. Jaworski[1], H.H. Wright[2], R.K. Abramson[2], M. Cuccaro[1], J.L. Haines[3], J.R. Gilbert[1], M.A. Pericak-Vance[1].* 1) Institute for Human Genomics, University of Miami, Miami, FL; 2) University of South Carolina, Columbia, SC; 3) Vanderbilt University, Nashville, TN.

Recent genome-wide association studies (GWAS) have identified and validated in multiple independent datasets a novel region with significant association to autism on chromosome 5p14.1. The approximately 200kb peak region of association (25.9-26.1Mb) is flanked by the Cadherin 9 (CDH9) and Cadherin 10 (CDH10) genes located approximately 1Mb proximal and 1.5 Mb distal, respectively. CDH10 and CDH are excellent autism candidate genes as they are involved in the regulation of cell-cell junctions in the developing brain. Potential abnormalities in CDH10 expression in autism have been reported. The peak region itself, however, lacks well annotated genes or regulatory sequences though the clustering of significant association signals suggests that a common variant(s) there is responsible for the association. To identify the associated variant(s) and potential rare variants within the candidate genes, we sequenced evolutionarily conserved regions in the peak area, as well as the annotated exons of CDH9 and CDH10 in 100 autism cases and 100 control individuals. We identified 50 known SNPs and 37 novel variants within the conserved regions near the association peak. We also identified 9 known and 26 novel variants in CDH10, including 2 non-synonymous amino acid changes, and 12 known and 9 novel variants in CDH9, including 5 non-synonymous amino acid changes. Analysis of these variations in a larger dataset demonstrated no common or rare variant(s) that by themselves can be shown to contribute to autism. Advances in next-generation sequencing technologies have enhanced our ability to rapidly sequence large targeted genomic regions quickly and in multiple samples. We are in the process of sequencing the entire peak region of association. To facilitate our re-sequencing of this autism association region, we have PCR amplified approximately 150kb of genomic DNA from the peak region, using tiled long-range PCR amplicons ranging from 5 to 11kb, in 48 allele specific autism cases and 48 control individuals. These fragments are being pooled in equimolar amounts to generate libraries of DNA for each individual to be analyzed using multiplexed paired-end sequencing on the Illumina Genome Analyzer II platform. We will identify the complete catalog of genetic variation in this region of association in these individuals in an effort to identify the causative mechanism contributing to autism risk.

**New rare variants in *MAFF* antioxidant gene in Mexican population.**
*A. Martinez-H[1], E. Cordóva[1], H. Gutierrez[2], K. Carrillo[1], F. Centeno[1], A. Rojas[3], L. Orozco[1,4].* 1) Investigación, Instituto Nacional de Médicina Genómica, Mexico DF; 2) Posgrado de Ciencias Biológicas, UNAM, México DF; 3) Instituto Nacional de Pediatría. México DF; 4) Posgrado en Ciencias Genómicas, Universidad Autónoma de la Ciudad de México. México DF.

Eukaryotic organisms have cellular mechanisms to protection against oxidative and electrophiles damage, which are responsible of several chronic diseases such as cancer and degenerative processes of aging. One of the most important mechanisms is the Nrf2-Keap1 pathway and, for switch on it and to prevent cellular damage is necessary the heterodimerization of Nrf2 with small Maf proteins (MafF, MafG, MafK). Studies in mouse knockout *nrf2* have demonstrated an increased in the sensibility to cancer and degenerative diseases development. Despite of the importance of this mechanism, there are few studies only in Caucasian and Asiatic populations about the SNPs in *NRF2* and small *MAFF* genes. The aim of this study was to determine the structure of *MAFF* gene in 120 Mexican healthy individuals. Genotyping was performed by direct sequencing of 1,000 pb upstream of the transcription start site and the entire coding region. The allelic frequencies of each SNPs were compared with other populations. We identified 20 SNPs: 7 rare novel variants, and 13 polymorphisms previously reported. Fourth of these SNPs were in the promoter, two in introns and seven in the 3’UTR on the exon 3. Furthermore, five SNPs, previously reported in other populations, were not found in Mexicans. The absence of SNPs in the coding regions of small *MAFF* gene suggests that this gene is highly conserved, so rare variants could alter the structure of the MafF protein and therefore, its interaction with Nrf2 protein. By the other way, we observed that allelic frequencies of SNPs located in the 3’UTR region were different to those reported in other studies, pointing out the importance to perform this type of analysis in populations from different ethnic origin. These results could constitute an useful tool for the further analysis of the role of the small-MafF proteins in disease development.

**Using Drosophila and mammalian model systems to study the effect of MeCP2 on signaling pathways.** *A. Gamliel[1], T.R. Grossman[3], E. Bier[3], M.G. Rosenfeld[1,2].* 1) Deptartment of Medicine, University of California, San Diego, La Jolla, CA; 2) Howard Hughes Medical Institute; 3) Section of Cell and Developmental Biology, University of California, San Diego, La Jolla, CA.

RETT syndrome and some progressive neurological disorders result from mutations as well as increased expression levels of MeCP2. We hypothesize that deregulation of specific target genes by themselves or in particular combinations may affect specific signaling pathways that could play a major role in the progression of the disease. As many of the genetic pathways that guide basic developmental processes in vertebrates and invertebrates have remained largely conserved during evolution, we took advantage of the Drosophila melanogaster wing as an assay system to test for genetic interactions between MeCP2 known signaling pathways. To identify signaling pathways that may be perturbed by altered MeCP2 levels, we generated transgenic Drosophila lines using the UAS-GAL4 system. We found that wing specific over-expression of human MeCP2 led to disorganization that was reminiscent to the changes that occur in specific signaling pathway mutants. We showed by a series of genetic interactions that indeed MeCP2 affected the suspected pathways. We confirmed that the results observed in the fly model were also applicable to the mammalian system by showing that changes in MeCP2 levels affect the same signaling pathway using reporter gene constructs, and quantitative RT-PCR of endogenous proteins in transfected neuroblastoma cells, as well as in mouse brain tissue. In order to identify which genes are direct targets of MeCP2 we performed a genome-wide Solexa ChIP sequencing in neuroblastoma cells that identified many of the previously known MeCP2 target genes, for example, BDNF, DLX5-6, FKBP5, SGK1, ID1-4, as well as many novel target genes that were components of the signaling pathway identified in our fly screen. We are now testing whether the modulation of specific signaling pathways can affect the function of MeCP2. We hypothesize that MeCP2 -dependent neurological defects may be caused by modulation of the specific pathways postnataly, consequently inhibiting neuronal maturation. Taken together our findings may facilitate therapeutic applications targeting the specific pathways, which may enable the reversal of the neurological defects.

## 2436/T/Poster Board #985

**A newly identified Bardet-Biedl Syndrome 3 (ARL6) long isoform has a vision specific function.** *P.R. Pretorius[1,2,3], L.M. Baye[3], R.F. Mullins[4], C.C. Searby[2], D.Y. Nishimura[1], K. Bugge[2], B. Yang[5], E.M. Stone[2,4], D.C. Slusarski[3], V.C. Sheffield[1,2].* 1) Dept Pediatrics, Univ Iowa, Iowa City, IA; 2) Howard Hughes Medical Institute; 3) Dept. Biology, University of Iowa, Iowa City, IA; 4) Dept. Ophthalmology and Visual Sciences, University of Iowa, Iowa City, IA; 5) Dept. Obstetrics and Gynecology, University of Iowa, Iowa City, IA.

Hundreds of individually rare, but collectively common Mendelian disorders result in visual impairment. One of these disorders is a heterogeneous syndromic form of retinal degeneration, Bardet-Biedl Syndrome (BBS). At least twelve genes are reported to individually cause BBS. Typically, individuals with BBS experience vision loss during childhood leading to blindness by the third decade of life. To gain insight into the mechanism underlying retinal degeneration associated with BBS, we have established mouse and zebrafish models of *BBS3*. A member of the Ras family of small GTP-binding proteins, *BBS3*, is postulated to play a role in vesicular transport. We have identified a second longer transcript of *BBS3* in humans, *BBS3L*, which is enriched in the eye. This transcript is highly conserved in mouse and zebrafish. The eye-specific expression of the BBS3L isoform will facilitate the dissection of BBS function in the retina, independent of alterations to other tissues. To this end, a *Bbs3L* knockout mouse has been generated and histological analysis at 9 months reveals disorganization of the inner segments, indicative of retinal degeneration. To further evaluate the functional effects of *BBS3* deficiency in the eye, an antisense morpholino approach was utilized to knockdown *bbs3* gene expression in zebrafish. Consistent with an eye specific role, knockdown of *bbs3L* results in reduced visual function as assessed by the visual startle response. Moreover, immunohistochemical analysis of *bbs3L* morphant embryos reveals that green opsin expression was not restricted to the outer segments of the photoreceptors but was also detected in the cell bodies of the outer nuclear layer. To dissect the individual functions of *BBS3* and *BBS3L*, rescue experiments using human BBS3 or BBS3L RNA were performed. Co-injection of each RNA with the *bbs3* morpholinos demonstrated that *BBS3L*, but not *BBS3*, is sufficient to rescue the vision defect. Additionally, *BBS3L* RNA restored green opsin localization. These data demonstrate that *BBS3L* is required for proper vision function and retinal organization, and that *BBS3L* has a unique eye-specific role compared to BBS3.

## 2437/T/Poster Board #986

**Functional analysis of EFHC1, a gene involved in Juvenile Myoclonic Epilepsy, in Drosophila.** *M.G. Rossetto[1], E. Zanarella[1], G. Orso[1], A. Daga[1], A. Delgado-Escueta[2].* 1) Scientific Institute E. Medea , Padova, Italy; 2) David Geffen School of Medicine at UCLA and VA GLAHS Epilepsy Center of Excellence, Epilepsy Genetics/Genomics Laboratories, Comprehensive Epilepsy Program.

Juvenile Myoclonic Epilepsy (JME), a common and lifelong epilepsy, is the most common cause of primary grand mal seizures and accounts for 10 to 12% of all epilepsies. Mutations in myoclonin/EFHC1 cause JME in 20% of JME families. We are using Drosophila melanogaster to unravel the cellular role of EFHC1 and generate a model for JME. We identified two Drosophila homologues of myoclonin/EFHC1 which display a similar degree of homology with their human counterpart. We are currently focusing on the study of one of these two fly genes named CG8959. We have generated CG8959 knockout mutants and transgenic Drosophila lines for targeted overexpression of the CG8959 encoded protein. CG8959 knockout mutant flies appear phenotypically normal. However, quantitative analysis reveals increased number of boutons in the neuromuscular junction synapse. CG8959 overexpression reduces the complexity of the NMJ arbor and dendrite arborization in peripheral sensory neurons. Moreover, CG8959 overexpression in the posterior compartment of the fly wing causes loss of posterior margin and wing veins. Modification of this phenotype by mutations in the Notch gene suggests a functional interaction between myoclonin/EFHC1 proteins and the Notch pathway. Modulation of myoclonin/EFHC1 expression in Drosophila affects neuromuscular junction and dendrite arborization. Maintenance of a population of dynamic microtubules is important for axonal extension, synaptic bouton formation and dendritic arborization. Thus changes in microtubule organization could be the common theme underlying the NMJ synapse and dendritic arbor phenotypes produced by loss and overexpression of CG8959.

## 2438/T/Poster Board #987

**The Dynamin-like GTPase atlastin is required for homotypic fusion of endoplasmic reticulum membranes.** *A. Daga[1,4], D. Pendin[1], G. Orso[1], J. Tosetto[1], A. Martinuzzi[2], S. Liu[3], T. Moss[3], J. McNew[3].* 1) DTI at the Scientific Institute E. Medea Padova, Italy; 2) Scientific Institute E. Medea, Conegliano, Italy; 3) Department of Biochemistry and Cell Biology, Rice University, Houston, Texas USA; 4) Department of Neurology, The David Geffen School of Medicine, University of California, Los Angeles, California, USA.

Establishment and maintenance of proper architecture is essential for endoplasmic reticulum (ER) function. Homotypic membrane fusion is required for both the biogenesis and maintenance of the ER and has been shown to depend on GTP hydrolysis. Here we demonstrate that Datlastin, the fly homolog of the GTPase atlastin-1 whose mutation causes Hereditary Spastic Paraplegia (HSP), localizes on ER membranes and that loss of Datlastin causes ER fragmentation. Datlastin embedded in distinct membranes has the ability to form trans-oligomeric complexes and its overexpression induces enlargement of ER profiles, consistent with excessive fusion of ER membranes. In vitro fusion experiments confirm that Datlastin autonomously drives membrane fusion in a GTP dependent fashion. In contrast, GTPase-deficient Datlastin is inactive, unable to form trans-oligomeric complexes due to failure to self-associate, and incapable of promoting fusion in vitro. These results demonstrate that Datlastin mediates membrane tethering and fusion and strongly suggest that it is the GTPase activity required for ER homotypic fusion.

## 2439/T/Poster Board #988

**Study of the intracellular dynamics of C111Y and C111S mutations identified in Factor IX from Mexican patients with severe hemophilia B.** *J. Mantilla[1,2], N. Enjolrras[3], C. Negrier[3], A. Jaloma-Cruz[1,2].* 1) Dept CIBO, Jalisco, IMSS, Guadalajara, Guadalajara, Mexico; 2) Doctorado en Genética Humana, CUCS, Universidad de Guadalajara, Guadalajara, Jalisco, México; 3) Laboratoire d'Hémobiologie, Faculté de Médecine RTH Laennec, Lyon, France.

ANTECEDENTS. We identified a group of punctual recurrent mutations in non-CpG sites of factor IX gene (FIX) causing severe hemophilia B, relevant in terms of the involved non-random mutagenesis in Latin-American populations and the functional significance of mutations at cysteine (C) which forms disulfide bond in a FIX domain with high structural and functional commitment. We studied two mutations at 17,747 nucleotide in the second-like epidermal growth factor (EGF2) corresponding to the Exon E to identify their effect in the structure-function relationship of the protein by the study of their intracellular trafficking. MATERIALS AND METHODS. C111 wild-type and the mutations C111S and C111Y were inserted by directed-site mutagenesis into an expression vector (pcDNA 3.1®) containing the FIX wild-type (wt) gene. The correct insertion of FIX wt and the two mutations was verified by restriction analysis and sequencing. Transfection on Cos-7 cells by Fugene6® after 48hrs was tested with a control plasmid containing the green fluorescence protein (pGFP) with a good efficiency (64.5%) evaluated by a flux-cytometry. The intracellular FIX amounts and secretion were quantified by ELISA assay. Transfected cells were incubated in presence of inhibitors like Brefeldin A, which blocks protein transport from endoplasmic reticulum (ER) to the Golgi complex; N-Acetyl-Leu-Leu-Norleucinal (ALLN) and Clasto-lactacystin beta-lactone, proteasomal inhibitors, and NH4Cl and Leupeptin, lysosomal inhibitors. RESULTS. Respect to FIX wt, the mutations showed a decreased FIX secretion (28%) and intracellular accumulation of 145% (C111Y) and 157% (C111S). The effects of the inhibitors caused a higher intracellular accumulation of the mutants which led a degradation mainly in lysosomes (NH4Cl) and secondly in proteasomes (ALLN). By the effect of Brefeldin A on C111S we can assume an adequate transport from ER to Golgi complex, opposite to C111Y which seems to be blocked at ER and to have elevated degradation in proteasomes (ALLN effect). The experiment was repeated 5 times (final results). CONCLUSIONS. The disruption of the disulfide bond in the mutants have an important effect on the native folding of FIX protein, evident by the effects on its transport through ER and the degradation mechanisms, with a predominant degradation at proteasomes when the ER transport is blocked and a higher degradation at lysosomes when the transport from ER to Golgi complex is adequate.

## 2440/T/Poster Board #989

**The oligomeric structure of the y+LAT-1/4F2hc amino acid transporter analysed using FRET microscopy.** *M. Tringham[1], M. Toivonen[1], J. Salmi[1], O. Simell[2], J. Mykkänen[2].* 1) Department of Medical Biochemistry and Genetics, University of Turku, Finland; 2) Department of Paediatrics, University of Turku, Finland.

y+LAT-1 and 4F2hc are protein subunits that form a transporter complex for cationic amino acids in the basolateral membrane of epithelial cells, mainly in the small intestine and proximal kidney tubules. Mutations of y+LAT-1, 51 of which are currently known, cause lysinuric protein intolerance (LPI, OMIM #222700), a rare metabolic disorder characterised by diminished intestinal absorption of the cationic amino acids lysine, arginine and ornithine and by severe loss of these amino acids into the urine. The more detailed structure of this transport complex has so far been unclear - it has remained unelucidated whether the complex is formed as a dimer or a tetramer of the subunits. What has been known, however, is that the y+LAT-1 subunits cannot reach the plasma membrane without forming a complex with 4F2hc. We previously established fluorescence resonance energy transfer (FRET) microscopy as a tool in studying the interactions of y+LAT-1 and 4F2hc. We have now applied the acceptor photobleaching application of the FRET technique to the exploration of the heteromerisation status of the y+LAT-1/4F2hc transporter complex. Based on our results, when fused into fluorescent vectors and transfected into the HEK293 cells, the y+LAT-1 proteins interact together in different cellular compartments in the presence as well as absence of 4F2hc. Our findings therefore suggest that the holotransporter is a tetramer of y+LAT-1 and 4F2hc subunits.

## 2441/T/Poster Board #990

**Src kinase modification of human UDP-glucuronosyltransferase-2B7 required for inactivation of genotoxic estrogen metabolites associated with breast cancer.** *I.S. Owens, P.S. Mitra, N.K. Basu, K. Chakraborty.* PDEGEN, NIH, NICHD, Bethesda , MD.

Whereas ER-bound UDP-glucuronosyltransferase (UGT)-2B7 avidly conjugates genotoxic catechol-estrogens (CEs), 2B7 presence in mammary gland suggests it prevents CE-based depurination associated with breast-cancer initiation. As UGTs have been shown to require phosphorylation, 2B7 has PKC and tyrosine kinase (TK) phopshorylation sites, it incorporates immunoprecipitable [33P]orthophosphate and undergoes inhibition by TK inhibitors. 2B7 mutants demonstrate that Y236- and Y438-phosphorylation is required, and Src-specific PP2 inhibition that depleted anti-phospho-Y438-2B7 content supports this claim. Also, PP2 disruption of 2B7 and active-Src co-localization and their cross-linking confirms their in-cellulo interaction. Furthermore, Src incorporated 6.5-fold more [$\gamma$33P]ATP-dependent label into microsomes isolated from 2B7His-transfected SYF-/-cells and solubilized than [$\gamma$33P]ATP alone; parallel Src-modified microsomes using unlabeled ATP generated 6-fold greater activity with 4-OH-estrone. Western blot of the in-vitro modified 2B7His-containing microsomes showed corresponding increases in purified phospho-Y438 kDa-2B7His at 55 kDa that was immuno-confirmed with anti-phospho-Y438-2B7. Moreover, evidence indicates Src-specific scaffold protein, AKAP12, supports Src-dependent ER-signaling associated with 2B7 activity. The results indicate Src and UGT2B7 are closely engaged allowing Src support of regulated 2B7-phosphorylation enabling it to protect against catechol estrogen depurination linked to breast-cancer initiation. This research was supported by the Intramural Research Program of the NIH, NICHD.

## 2442/T/Poster Board #991

**SNP variation in IVS 10 of CFTR gene cause aberrant mRNA splicing in CF patients.** *D.A. Coviello[1], L. Costantino[1], C. Colombo[2], L. Claut[2], V. Paracchini[1], L. Porcaro[1], M. Zanardelli[2], G. Pizzamiglio[2], P. Capasso[1], D. Degiorgio[1], M. Seia[1].* 1) Laboratory of Medical Genetics Ospedale Maggiore Policlinico, Mangiagalli e Regina Elena, Milan, Italy; 2) Regional CF Unit; Ospedale Maggiore Policlinico, Mangiagalli e Regina Elena, Milan, Italy.

Genomic variations in intronic regions affecting mRNA splicing are increasingly reported. Incorrect splicing can generate aberrant transcripts and also modulate the level of normal transcript. CFTR (Cystic Fibrosis Transmembrane Conductance Regulator) gene mutations are usually screened in newborns and in patients, and although diagnostic protocols have a good sensitivity and specificity, a significant percentage (6%) of CF alleles remain unidentified even after extensive studied of the gene by DNA analysis. In the present study we investigate the molecular defect, by CFTR mRNA analysis, of 11 cystic fibrosis (CF) patients, in which only one or no allele were identified by DNA analysis of the whole CFTR gene. CFTR gene is tightly regulated and differentially expressed transcript in many mucosal epithelial cell types, we decided to collect biological material from nasal epithelial cells using cyto-brush, from 11 CF patients and 5 non-CF controls. RNA was extracted with TRIzol reagent, first strand cDNA was synthesized using hexanucleotide primers and high capacity cDNA Archive kit. The cDNA was amplified in six overlapping fragments spanning the entire gene and then visualized on agarose gel for identifying large deletion/insertion and the product of possible alternatives splicing; each fragment was next sequenced and cloned into plasmid vectors. The mRNA analysis has allowed us to detect an extra band of higher molecular weight than the normal cDNA fragment. Sequencing the specific mutated allele a cryptic exon in two patients (18%) was identified: the new exon is a 101 bp insertion located between exons 10 and 11 . Further sequencing of the genomic region of IVS 10 allow us to identify a new SNP. We believe that this sequence variation cause a new donor splice site. The molecular characterization of nine remaining patients is still ongoing. Our results confirm the usefulness of RNA analysis to look for DNA mutations that can affect the normal splicing processes.

## 2443/T/Poster Board #992

**Fine-scale variation and genetic determinants of alternative splicing across individuals.** *J. Majewski[1, 2], K.L.C. Lam[2], C. Dias[2], J. Coulombe-Huntington[1,2].* 1) Dept Human Genetics, McGill Univ, Montreal, PQ, Canada; 2) McGill University and Genome Quebec Innovation Centre, Montreal, PQ, Canada.

It is only recently, thanks to the increasing throughput of new technologies, that we have been able to explore the full extent of alternative pre-mRNA splicing (AS) in the human transcriptome. This is unveiling a vast layer of complexity in isoform-level expression differences between individuals. In this work, we use splicing sensitive microarray data from lymphoblastoid cell lines to conduct an in-depth analysis on splicing efficiency of known and predicted AS exons. By combining publicly available AS annotation with a novel algorithm specifically designed to search for AS events, we demonstrate that the extent of differential splicing among individuals is far greater than has previously been reported. Specifically, many genes show subtle but significant genetically controlled differences in exon inclusion. PCR validation shows that 43 out of 59 (73 %) of a sample from our new AS candidate gene regions undergo detectable AS. Through sequencing, we were able to identify the most likely causative SNP in most of the validated cases. In 17 of the cases we were able to show, using a splice-site strength prediction tool, that the expected effect of a SNP invariably agreed in directionality with the micro-array results, perfectly explaining the differences in isoform levels between individuals. In 14 of the remaining cases, we show that the splicing changes could be explained by a SNP disrupting predicted splicing enhancer elements. We verified the effects of six candidate SNPs using in vivo transient transfection minigene assays. This study shows that splicing differences between individuals, including quantitative differences in isoform ratios, are frequent in human populations and that causative SNPs can be identified using in silico predictions. Several of these differences were found in disease-relevant genes such as IL6 and MMAB. It is highly likely that such differences are involved in phenotypic diversity and susceptibility to complex diseases.

## 2444/T/Poster Board #993

**Lamin A and telomerase collaborate to trigger cellular senescence.** *K. Cao, C. Blair, D. Faddah, M. Olive, M. Erdos, E. Nabel, F. Collins.* Genome Technology Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD.

Hutchinson-Gilford progeria syndrome (HGPS), a devastating premature aging disease, is caused by a point mutation in the lamin A gene (LMNA, Accession number: NM_170707). This mutation constitutively activates a cryptic splice donor site, resulting in a mutant lamin A protein termed "progerin". Recent studies have demonstrated that progerin is also produced in normal human cells and tissues at low levels. To probe the causative role that progerin might play in senescence of normal cells, we studied early and late passage fibroblasts from the same individual, and found that progerin transcription was activated in senescent cells. Screening various primary and transformed cell lines revealed an interesting inverse correlation between telomere length and progerin transcription. Moreover, shRNA knockdown of telomerase in cancer cell lines resulted in increased progerin production. Exon array analysis further demonstrated that extensive changes in alternative splicing of multiple genes, including LMNA, occur as telomeres shorten and cells approach senescence. Our findings suggest a novel synergism between telomere erosion and progerin production in induction of cellular aging, and provide the first genome-wide analysis of the changes in alternative splicing during cell senescence.

## 2445/T/Poster Board #994

**Intronic c.592-4_C.592-3delTT in *DGUOK* Gene Abolishes mRNA Splicing.** *Q. Ji[1], D. Dimmock[2], L. Tang[1], M. Descartes[3], R. Gomez[3], L. Rutledge[3], E. Schmitt[1], L. Wong[1].* 1) Baylor College of Medicine, Houston, TX; 2) Medical College of Wisconsin, Milwaukee, WI; 3) University of Alabama at Birmingham, Birmingham, AL.

Deoxyguanosine kinase (DGUOK) catalyzes the first step of the mitochondrial deoxypurine salvage pathway, the phosphorylation of purine deoxyribonucleosides. Mutations in the *DGUOK* gene have been linked to inherited mtDNA depletion syndromes, neonatal liver failure, nystagmus, and hypotonia. Previously, we reported the first case of heterozygous intronic c.592-4_C.592-3delTT in *DGUOK* in one patient with DGUOK deficiency (Hum Mutat, 2008. 29(2): pp. 330-1). This alteration was predicted to cause aberrant splicing based upon two computer algorithms. We now report a homozygous c.592-4_c.592-3delTT alteration found in two affected siblings of asymptomatic consanguineous parents. The proband presented with symptoms of idiopathic hepatitis, liver dysfunction, nystagmus, and retinal blindness. This individual died at 6 months of age due to liver failure. This individual's affected sibling presented similarly and has remarkable elevations of tyrosine, methionine, and alanine. Many organic acids were elevated in urine including lactic acid, Krebs cycle intermediates, and para-hydroxy compounds; ketone bodies were also present. RNA studies support aberrant splicing. Total RNA was isolated from whole blood. Sequencing of cDNA clones detected exon 5 skipping in the two affected siblings, but not in the normal control. These results indicate that the homozygous c.592-4_C.592-3delTT is deleterious and responsible for the DGUOK deficiency. The parents were subsequently confirmed to be carriers of this mutation. In summary, we have demonstrated that c.592-4_C.592-3delTT is a pathogenic splice receptor site mutation leading to DGUOK deficiency.

## 2446/T/Poster Board #995

**Prediction and functional validation of expressed SNPs altering mRNA splicing.** *E.J. Mucaki, P.K. Rogan.* Biochemistry, University of Western Ontario, London, ON, Canada.

mRNA splicing changes induced by common, polymorphic SNPs were predicted with information theory-based models of constitutive splice sites and confirmed by expression studies. SNP-related, allele-specific splicing effects, were predicted from differences in the strengths of allelic natural and/or cryptic splice sites. We qualified selected SNPs for quantitative RT-PCR studies using published Affymetrix exon expression microarray data from Hapmap individuals. This study reports splicing effects for SNPs with low coefficients of variation in expression (CVE) among individuals with the same genotype. Predicted SNPs within *XRCC4*, *IL19*, *C21orf2*, *UBASH3A*, *TTC3*, *PRAME*, *ARFGAP3*, *Fλ8*, *BCR*, *BACE2*, *CLDN14*, *TMPRSS3* and *DERL3* were tested for allele-specific splicing effects. For each, multiple, distinct splice forms were quantified using HapMap cell lines heterozygous and homozygous for the relevant SNPs, including allele-specific changes in exon skipping, cryptic splicing, and partial intron retention. Results for minor allele SNPs in each individual were compared with distinct, constitutively spliced, non-polymorphic exons from the same genes and were normalized against external reference genes expressed at similar levels. Nine of 15 SNPs showed significant changes in the use of the splice site affected by the SNP. Homozygotes (n=4) for the allele producing a stronger constitutive splice site (1.3-2.2 bit; 2.5-4.6 fold increase) exhibited higher levels of transcription of the associated gene (45-300% increased expression). Exon skipping (and intron inclusion) was increased 3-9 fold in homozygotes for a SNP adjacent to the skipped exon (due to a 4-fold reduction acceptor strength). Exon skipping was decreased in an allele that improved exon definition due to a SNP that abolished one of a pair of tandem, overlapping acceptors. Increased exon skipping was detected for as little as a 40% reduction (0.5 bits) in splice site strength, however, large CVEs were seen in individuals for 4 SNPs that exhibited small changes in splice site strength. Five SNPs were predicted to activate cryptic splice sites (for 4 acceptors and 1 donor), 4 of which were confirmed in heterozygotes and minor allele homozygotes. Some SNPs appear to contribute to disease by affecting constitutive mRNA structure and abundance. A mutant SNP in *XRCC4* is linked to renal cell carcinoma and bladder cancer, and SNPs in type-1 diabetes and bipolar disorder are in LD with *TTC3* and *BCR*, respectively.

## 2447/T/Poster Board #996

**Mutation-negative FAP patients with mRNA defects of APC.** *M.W. Condie[1], T.M. Tuohy[1], P. Shires[2], R.W. Burt[1], D.W. Neklason[1].* 1) Huntsman Cancer Inst, Univ Utah, Salt Lake City, UT; 2) Saint Luke's Hospital, Kansas City, MO.

Background: Familial adenomatous polyposis (FAP) is a colon cancer syndrome with a prevalence of 1:10:000, hallmarked by 100s to 1000s of precancerous colonic polyps and nearly 100% risk of developing colon cancer at an average age of 39 years in the absence of colon surveillance and surgery. Mutations in the APC gene lead to FAP and an attenuated form called AFAP with reduced polyp numbers and cancer risk. Mutation detection fails using DNA-based technology in 20% of FAP and 50% of AFAP patients due to testing limitations, inability to determine significance of DNA change, or other responsible genes. A subset of disease causing APC mutations may be due to non-coding or even coding variants that result in RNA splice defects. Methods: A RNA-based assay has been developed to screen APC mRNA for splice defects in mutation-negative FAP and AFAP patients. Primers and PCR conditions were developed for five overlapping amplicons that cover exons 1 - 14 and the beginning of exon 15 in the APC mRNA. PCR products from the cDNA of patients are run on agarose gels and examined for atypical products. These products are then sequenced and results verified by genomic analysis. Results: To date, cDNA from 14 mutation-negative families has been tested, and two mutations resulting in splice defects have been identified when other standard techniques failed to demonstrate loss-of-function mutations. One is a single nucleotide change, deep in intron 4 that generates a splice acceptor site, an additional exon (exon 4A), and a stop codon. The second is a 1.5-kb deletion in intron 14 which causes deletion of exon 14 in the mRNA transcript; exon 13 is spliced to exon 15 resulting in an out-of-frame stop codon. Both families present as AFAP. This is a useful assay to compliment DNA-based testing in APC mutation-negative patients or patients with a variant of uncertain significance. Additionally, to address cases where undetected mutations affect the stability of the resultant transcript, allelic imbalance can be examined in amplicons containing one of the common APC single nucleotide polymorphisms (SNPs) using real time PCR.

## 2448/T/Poster Board #997

**A Comparative Study of The Biology of Two Dominant Retinal Degenerative Disorders on Chromosome 17.** *R. Ramesar[1], A-B. Pandor[1], L. Roberts[1], S. Prince[2], C. Seoighe[3], J. Greenberg[1].* 1) MRC Human Genetics Research Unit, Division of Human Genetics, Institute for Infectious Diseases and Molecular Medicine,; 2) Department of Human Biology, University of Cape Town, Cape Town, Western Cape, South Africa; 3) School of Mathematics, Statistics and Applied Mathematics National University of Ireland, Galway, Ireland.

Retinitis pigmentosa is the major cause of inherited forms of retinal blindness. In the past 20 years, with the use of genetic technologies, the biology of this large group of heterogeneous conditions has begun to unravel, leading to logical therapeutic interventions. Here we report on the biology at two distinct loci, originally identified by ourselves, on chromosome 17, underlying dominant RP. We also report on our current research aimed at therapeutics. Objective: To identify the biological basis of disease in two clinically indistinguishable autosomal dominant forms of retinitis pigmentosa (adRP). Methods and Materials: The RP17 form of adRP is caused by a R14W mutation in the Carbonic Anhydrase IV (CA4) gene on chromosome 17q. Constructs of mutant (R14W) and wildtype versions of the CAIV gene were made and various tagged forms of these constructs were investigated in COS7 and HEK293 cells. The RP13 form of adRP, on the other hand, is caused by a mutation in the universal spliceosomal component, PRP8. We have used several techniques to investigate the possible retinal target genes which may be secondarily compromised as a result of the primary PRP8 mutation, including a genome-wide expression survey of splicing. Results: The CA4 gene (RP17) is expressed in the endothelial cells of the choriocapilaris; whereas the PRP8 protein is universally expressed. Our cell biological work shows mis-folding, mis-trafficking of mutant CA4, and raised markers of misfolding and apoptosis in mutant cell lines. The genome-wide expression data on the RP13 gene has shown that a large number of genes are misspliced as a result of a defective PRP8 gene; it would seem that there is a global downstream effect resulting in biological compromise. Discussion: Although clinically indistinguishable, these two forms of adRP, are the result of totally disparate pathological mechanisms. The mutant CA4, results in apoptosis of endothelial cells, and deterioration of the choriocapillary vascular supply, resulting in ischemia-related photoreceptor death. Preliminary work with synthetic chaperones has shown that it is possible to relieve protein misfolding in cell culture, leading to rescue, of mutant CA4-carrying cells, from apoptosis. RP13 reflects only a retinal phenotype. The most significantly affected genes (from the expression data) are currently being investigated for their possible contribution to the retinal phenotype.

**Validity and Repeatability of Two PCR Methods for Determining CGG Size and X Inactivation Skewing Percent of the FMR1 Gene.** *A. Hadd[1], J. Kline[2], K. Oppenheimer[3], S. Brown[3], B. Levin[2], A. Kinney[2], S. Sah[1], S. Filipovic-Sadic[1], T. Stenzel[1], G. Latham[1].* 1) Asuragen, Inc, Austin, TX; 2) Columbia University, Mailman School of Public Health, New York, NY; 3) University of Vermont College of Medicine, Burlington, VT.

INTRODUCTION. Fragile X Syndrome is caused predominantly by the expansion of CGG sequences in the FMR1 gene. The specific number of CGG repeats is associated with many disorders, including Fragile X Primary Ovarian Insufficiency, the leading genetic cause of premature menopause. As a precursor to a study to test whether repeat lengths of intermediate size are related to ovarian aging, two PCR methods were evaluated for determining CGG repeat length and X-chromosome inactivation (XCI) skewing percent. METHODS. The validation and repeatability studies compared prototype reagents from Asuragen and a laboratory developed test (LDT) based on published methods (Tassone et al, JMD, 2008). PCR amplicons were sized using capillary electrophoresis. Validity was determined for 25 female samples comparing predicted CGG repeats with DNA sequencing. The reliability of measuring the XCI skewing percent was determined in another sample of 25 women by splitting gDNA into two reactions; one digested with HpaII and amplified with a HEX-labeled primer, and the other undigested and amplified with a FAM-labeled primer. Ratios of HEX to FAM peak heights were used to calculate the XCI skewing percent. RESULTS. The validation set comprised 49 alleles of size 20-80 repeats (one allele >200 repeats was omitted because it was outside the quantifiable range of DNA sequencing). Sample pass rates were 47 and 49 for the two Asuragen assays, and 49 and 46 for the two LDT assays. Rounded (i.e., integer) predicted CGG repeat values were within ±1 CGG from the true value for all alleles and equal to the true value in 90% to 98% of alleles, depending on the assay and run. Comparing unrounded predicted values with true values, the Asuragen method showed a slightly higher negative bias and a slightly lower standard deviation than the LDT method. The reliability set comprised 50 alleles sized between 20-43 CGG repeats; the XCI skewing percents ranged from 50.9%-89.6%. The Asuragen method yielded XCI skewing percents that were, on average, about 2% lower and less dispersed than percents yielded by the LDT assay. CONCLUSIONS. Both methods showed excellent validity for sizing and excellent repeatability for the XCI skewing percent. The Asuragen method is preferred because it has slightly better validity for sizing and is less time intensive. These results, which demonstrate a simple two-color methylation workflow, form the basis for using the Asuragen assay in epidemiologic studies.

**New Paradigms in Fragile X Testing by PCR.** *F. Tassone[1,2], W. Zhang[1], S. Filipovic-Sadic[3], L. Chen[3], S. Sah[3], J. Kempannien[3], A. Hadd[3], T. Stenzel[3], G. Latham[3], P. Hagerman[1,2].* 1) Dept Biochemistry & Molec Med, Univ California, Davis, Davis, CA; 2) M.I.N.D. Institute, University of California Davis Medical Center, Sacramento, CA; 3) Asuragen, Inc. Austin, TX.

INTRODUCTION: Expansion of CGG repeats in the fragile X mental retardation (FMR1) gene is associated with a constellation of clinical involvements. There is a growing and acute need for larger-scale screening efforts for expanded FMR1 alleles, and a major push for screening of all newborns (~500,000/yr in California alone). PCR methods are generally limited to fewer than ~100-200 CGG repeats, and all samples detected with premutation or full mutation alleles are still analyzed by Southern blot (SB). Sensitive and accurate detection of full mutation alleles, with the ability to reconcile zygosity and methylation statuswithout the need for SBhas the potential to ultimately sidestep current technological hurdles for broader testing. METHODS: De-identified clinical samples from the the M.I.N.D. Institute at UC Davis were tested by three novel Asuragen PCR methods: gene-specific PCR, CGG Repeat Primed PCR and methylation PCR. Amplicons were resolved by agarose gel and/or capillary electrophoresis. CGG repeats were calculated by comparing size to sequenced FMR1 standards or by counting distinct CGG peaks. Methylation status was assessed by comparing a sample aliquot treated with HpaII and amplified with a HEX-labeled primer to an undigested aliquot amplified with a FAM-labeled primer. Specificity was confirmed by CGG probe blotting. PCR results from blinded samples were submitted prior to comparison with SB results. Blood spot card punches were washed, dried and suspended directly in PCR reagents prior to thermal cycling. RESULTS: Over 200 clinical samples comprising the full-spectrum of clinical genotypes were correctly sized by PCR. Results were concordant with SB for all samples; 2 premutation samples were detected with full mutations not detected by SB results. All female homozygous samples were correctly identified. Alleles were accurately sized for 27/27 blood spot samples with 7/7 full mutation alleles directly determined by PCR. Methylation status of full- and premutation alleles was quantified and concordant with Southern blot. CONCLUSIONS: The ability of these novel PCR research reagents to detect large full mutations, reliably interpret female homozygous samples and assign methylation status was demonstrated. PCR-based sizing was also demonstrated using direct analysis of blood spot card DNA. Together, these results suggest a PCR-only workflow that may shift the current fragile X diagnostic paradigm.

## 2451/T/Poster Board #1000

**Androgen Receptor VNTRs and SNP as Clinical Biomarkers in Humans.** *A. Freeman, H. Qian, L. O'Brien, P. Haslett, K. Landschulz.* Eli Lilly and Company, Indianapolis, IN. 46285.

The Androgen Receptor gene (AR, Chr X) encodes a transcription factor that is activated by androgens, such as testosterone, to regulate downstream gene and protein expression. The activating domain in AR exon 1, contains two variable number of tandem repeats (VNTRs), CAG and GGC, and a synonymous, E211 single nucleotide polymorphism (SNP). While the VNTRs, resulting in glutamine (CAG) or glycine (GGC) stretches in the receptor, are known to be inversely associated with androgen activity, sensitivity and disease, the E211 SNP, a possible surrogate marker for the VNTRs, has not been extensively studied. We sought to better understand these genetic variants; their ethnic distribution, heritable relationship and potential as clinical biomarkers for disease and drug response. We used fragment analysis and allelic discrimination to genotype the two AR VNTRs and E211 SNP in the HapMap DNAs from 90 African, 88 European (CEPH) and 90 Asian subjects. A chi-square test was performed to determine the difference and significance of variant allele frequencies and Linkage Disequilibrium (LD), which was estimated using the method described by Weir and Cockerham (1979). On average, ethnic distribution of the AR variant alleles was observed. For the CAG VNTR, Africans had 17-18 repeats, Asians had 22-25 repeats and the CEPH population had a bimodal distribution ranging from 20-21 and 23-25 repeats. Conversely, the GGC VNTR in the African population showed a bimodal distribution around 14-16 and 18-19 repeats, while the CEPH and Asian populations had 17-18 repeats. In the African, CEPH and Asian populations, the "G" allele of the E211 SNP had 24.4%, 83.3% and 100% frequency, respectively. We confirmed that both VNTRs were in LD in all three ethnic populations ($p<0.05$), although the LD between the E211 SNP and each VNTR was population dependent. In the CEPH population, the E211 SNP was not in LD with either VNTR. However, in the African population, we found the E211 SNP was in LD with the GGC VNTR only ($p<0.01$), despite reports of partial LD with both VNTRs in African-American men (Ross et al, 1998). Our data show an inherent ethnic variability and linkage between the AR VNTRs that is not fully represented by the SNP in the human population. Future in vitro and in vivo studies will be required to elucidate how these genetic markers are associated with androgen sensitivity and to assess their potential as clinical predictors of androgenic drug response.

## 2452/T/Poster Board #1001

**Identification of CUGBP1 mRNA targets by CUGBP1/RNA immunocapture.** *L.L. Bachinski[1], C. Huichalaf[2], K.A. Baggerly[1], B. Schoser[3], B. Udd[4], L.T. Timchenko[2], R. Krahe[1].* 1) Univ Texas MD Anderson CA Ctr, Houston, TX; 2) Baylor College of Medicine, Houston, TX; 3) Friedrich-Baur Institute, Ludwig-Maximillians-University, Munich, Germany; 4) Tampere University Hospital and Medical School, Tampere, Finland.

In myotonic dystrophy (DM) CUGBP1 is hyper-phosphorylated and steady-state protein levels are up. In both phosphorylated and unphosphorylated isoforms, CUGBP1 is a key protein in regulation of alternative splicing and protein translation. To identify CUGBP1 mRNA targets and to determine whether these targets are dysregulated in DM, we extracted RNA from CUGBP1 immunoprecipitates of ribonuclear protein fractions from normal and DM cells and hybridized these to Affymetrix exon arrays. To determine the normal targets of CUGBP1, we compared immunoprecipitated results to those from whole transcriptome. Captured probes were differentially enriched for targets from 5' ends, 3' ends, and alternative exons (overall p value =0.024 for top 50 probes). Of the 26 known CUGBP1 targets, we identified 14, most of which had enriched probes in the expected regions of the target genes. Known targets identified included *CLCN1, MAPT, MEF2A, MELK, MTMR1, SRF, WEE1, AURKA, AURKB, CDC2, CEBPB, CSKN2B, MOS*, and *RBM9*. Focusing on genes known to be important in muscle differentiation and maintenance, we identified novel candidate CUGBP1 mRNA targets from all three predicted target classes. Interesting novel candidates included *CRYBB3* (lens crystalline), *PPEF1* (Ca+2 binding), *KCNN2* (Ca+2-activated K+ channel) and *RBM6* (RNA binding motif protein). Identification of CUGBP1 target mRNAs is an important step in the elucidation of pathways which are affected in DM by elevation of CUGBP1.

## 2453/T/Poster Board #1002

**The digenic hypothesis unraveled: Epigenetic effects of GJB6 deletion del(GJB6-D13S1330) cause allele-specific loss of GJB2 expression in cis.** *J.M. Rodriguez-Paris[1], I. Schrijver[2].* 1) Department of Pathology, Stanford University School of Medicine, Palo Alto, CA; 2) Department of Pathology and Pediatrics, Stanford University School of Medicine, Stanford, CA.

Connexin 26 and connexin 30 are the major connexins expressed in the cochlea, where they are co-localized and form heteromeric gap junctions. Mutations in the GJB2 gene, which encodes connexin 26, are the most common cause of prelingual non-syndromic sensorineural hearing loss. The large ~309 kb deletion del(GJB6-D13S1830) which involves GJB6 (connexin 30), causes hearing loss in homozygous individuals, or when compound heterozygous with a GJB2 mutation. We demonstrate that mutations in these two genes do not cause hearing loss through a digenic mechanism of inheritance as was postulated previously, but that, instead, GJB2 expression is abolished through an epigenetic effect in cis. Allele-specific expression of GJB2 was investigated in three unrelated individuals compound heterozygous for a GJB2 mutation and del(GJB6-D13S1830). The mutated GJB2 allele in trans with del(GJB6-D13S1830) was expressed in all three individuals whereas the GJB2 allele located in cis with the deletion was not expressed at all. Thus, the GJB6 deletion results in allele-specific loss of GJB2 expression. Our data support the hypothesis that del(GJB6-D13S1830) disrupts a putative cis-regulatory element probably located within the deleted region, which leads to complete loss of expression of the GJB2 allele in cis with the GJB6 deletion.

## 2454/T/Poster Board #1003

**MicroRNA expression profile in fragile X syndrome.** *L.P. Capelli[1,2], Z. Kutalik[2], J.J. Médard[2], P. Descombes[3], S. Jacquemont[4], G. Tanackovic[2].* 1) Department of Genetics and Evolutionary Biology, Institute of Biosciences, University of São Paulo, SP, Brazil; 2) Department of Medical Genetics, University of Lausanne, Lausanne, Switzerland; 3) Genomics Platform - NCCR, Frontiers in Genetics, University of Geneva, Geneva, Switzerland; 4) Service of Medical Genetics, CHUV-UNIL, Lausanne, Switzerland.

Fragile X syndrome (FXS) is the most common form of inherited intellectual disability (1:2500). It is caused by an expansion of CGG repeats in the 5' untranslated region of the *FMR1* gene. Affected individuals carry a full mutation (>200 CGG) that leads to hypermethylation of the expanded sequence and upstream CpG islands, causing transcriptional silencing of the gene. Normal individuals (6 to 54 CGG repeats) and premutated carriers (55 to 200 CGGs) produce the protein. The precise function of the *FMR1* product, FMRP, is unknown. It is involved in transport of mRNAs along synapses and regulation of their translation, as well as in neuronal maturation. More recently, a role of FMRP in the microRNA (miRNA) pathway was proposed. MiRNAs are small non-coding RNAs which, as part of the miRISC (RNA-interference induced silencing complex), regulate gene expression at the level of mRNA translation or stability, by virtue of imperfect base-pairing with mRNAs. At present, there is no clear understanding of the role that FMRP plays in the miRNA pathway, how it regulates protein synthesis at synapses and weather the two functions are somehow linked. FMRP is part of the protein complex responsible for the miRNA processing, as well as of the miRISC. Therefore, the absence of FMRP could affect miRNA processing or function, and consequently this could cause a global miRNA/mRNA imbalance and contribute to FXS. To address this question, we performed a comparative analysis of miRNA profiles in six *Fmr1* KO mice and six controls using mice miRNA microarrays. In a total of 380 miRNAs, we observed 26 miRNAs that were over or under expressed (20% fold change with $p<0.05$) in the KO animals. Further, using quantitative PCR, we quantified the amounts of 17 transcripts known to be translationally regulated by FMRP and involved in neuronal maturation, neuronal functioning and synaptic plasticity in both the KO and control animals. Thirteen out of 17 transcripts studied were differentially expressed in KO animals and, interestingly, six of them were predicted as target of a subset of miRNAs that we showed to be misregulated in the KO animals. Our results point to a role of FMRP in miRNA processing/stability and indicate that this might be a link between the miRNA pathway and deregulation of mRNA translation in FXS. (First author sponsored by CAPES).

## 2455/T/Poster Board #1004

**Evidence for protein-coding transcript connectivity networks composed of chimeric RNAs in human cells.** *S.E. Antonarakis[1], R. Guigo[2], S. Djebali[2], P. Kapranov[3], A. Reymond[4], K. Salehi-Ashtiani[5], J. Lagarde[2], V. Lacroix[2], S. Foissac[2], P. Ribera[2], D. Martin[2], C. Ucla[1], J. Drenkow[6], T. Gingeras[6].* 1) Gen Med & Dev, CMU9180, Univ Geneva, Geneva, Switzerland; 2) CRG, Barcelona, Spain; 3) Helicos, Boston, MA, USA; 4) Univ Lausanne, Switzerland; 5) Harvard Univ, Boston, MA, USA; 6) CSHL, New York, USA.

The organization of gene structures have followed the Jacob and Monod bacterial gene model proposed more than 50 years ago. Since then, the unraveling of the complexity of the transcriptomes found in cells from yeast to human has blurred the boundaries of genes. Using rapid amplification of cDNA ends (RACE), tiling arrays, RT-PCR, cloning and sequencing we have sought to characterize the extent upon which individual gene boundaries are defined on two human chromosomes (21 and 22). Analyses of the locations of the 5'and 3' transcriptional termini of 492 protein coding genes revealed that for 85% of these genes the boundaries of these genes extend well beyond the annotated termini. In these cases, the average distance from the distal 5' end to the index site in a gene is about 1 Mbp. The transcripts encoding these extended genes are chimeras composed of exonic and intronic sequences found comprising other intervening genic regions. The biological importance of these chimeric transcripts is underscored by the non-random interconnections of genes involved and the increase likelihood of the genes involved in many chimeric interactions being evolutionarily older. The characterization of these RNA networks made up of chimeric transcripts further highlights the non-linearity of information stored in the genome and expressed in the transcriptomes as well as the possible way cells have to monitor the complex and distal transcriptional activities ongoing in cells.

## 2456/T/Poster Board #1005

**Characterization and functional analysis of *OTC* gene regulatory regions.** *O. Luksan[1], J. Eberova[1], M. Bouckova[2], M. Jirsa[1], M. Hrebicek[2], L. Dvorakova[2].* 1) Laboratory of Experimental Hepatology, Institute for Clinical and Experimental Medicine, Prague, Czech Republic; 2) Institite of Inherited Metabolic Disorders, 1st Faculty of Medicine, Charles University in Prague and General University Hospital in Prague, Czech Republic.

Ornithine carbamoyltransferase (OTC, EC 2.1.3.3) is an enzyme of the mitochondrial matrix catalyzing the synthesis of citrulline from ornithine and carbamoyl phosphate. The *OTC* gene is located on Xp21.1. OTC deficiency is the most common inherited urea cycle disorder manifesting in a spectrum of severity ranging from neonatal hyperammonemic coma followed by death to later onset of milder symptoms or asymptomatic course. The published data bring evidence that mutation analysis of the protein coding regions fails in 20-25% of cases. The disease may be caused by gross gene rerrangements or defects in regulatory regions of the gene in such cases. In our study we identified and functionally characterized regulatory regions of *OTC*. We determined 3 alternative transcription start sites of the *OTC* gene at positions c.-95, c.-119 and c.-169 upstream of the translation origin. Based on analogy with model organisms we predicted and examined a promoter (linked directly to the 5'UTR) and enhancer (located 9 kb upstream the transcription origin) region of *OTC*. Using the dual luciferase reporter assay we found a significant increase in transcriptional activity of the promoter when compared with the control plasmid. Moreover, three times higher expression of the reporter gene was observed when enhancer was subcloned into the plasmid containing the promoter. In one male patient with mild phenotype of OTC deficiency, we evaluated the influence of single nucleotide substitution c.-366A>G in the promoter. No statistically significant difference in the transcriptional activity was observed when comparing normal and mutated promoter, however, a 50% difference in the reporter gene expression was found when promoter interacted with the subcloned enhancer. This finding indicates pathogenicity of the c.-366A>G variation. Bisulfite sequencing revealed that the methylation pattern of the *OTC* promoter is tissue specific and the degree of methylation inversely correlated with *OTC* expression. These tissue differences were more prominent in male samples in which X-inactivation did not interfere with methylation. In conclusion our results show that expression of *OTC* is controlled by a weak promoter and a strong enhancer. Single nucleotide substitutions in the regulatory regions such as the c.-366A>G variation may cause OTC deficiency. Tissue specific expression of *OTC* may be partially affected by differential methylation. Support: IGA MZ CR NR/9364 and IKEM MZO 00023001.

## 2457/T/Poster Board #1006

**miR-204 is required for vertebrate eye development.** *S. Banfi[1], S. Carrella[1], R. Avellino[1], M. Karali[1], R. Marco-Ferreres[2], P. Bovolenta[2], I. Conte[1,3].* 1) TIGEM, Fondazione Telethon, Naples, Italy; 2) Departamento de Neurobiología Molecular Celular y del Desarrollo, Instituto Cajal, CSIC, and CIBER de Enfermedades Raras (CIBERER), Madrid, Spain; 3) Institute of Genetics and Biophysics Adriano Buzzati Traverso CNR, Naples, Italy.

The functional role of specific microRNAs in controlling the morphogenetic and cell differentiation events involved in normal eye development in vertebrates is still largely unknown. Here we show that a single microRNA, miR-204, is capable to regulate multiple aspects of eye development in medaka fish. Targeted ablation of miR-204 function by morpholino injections in medaka determined a severe eye phenotype characterized by microphthalmia, aberrant lens formation, incorrect retinal cell differentiation and coloboma. Through a variety of in vitro and in vivo approaches, we found that Meis2 is a key target of miR-204 and plays a pivotal role in the generation of this phenotype via the regulation of the Pax6 pathway. These data demonstrate for the first time that a specific microRNA is involved in the regulation of basic processes underlying eye development and open new avenues on a better comprehension of the pathogenetic mechanisms underlying eye developmental disorders.

## 2458/T/Poster Board #1007

***Dube3a* regulates monoamine synthesis by increasing Punch (GTPCH1) activity in the Drosophila brain.** *K. Summers[1], F. Ferdousy[3], J. O'Donnell[3], N. Elsisi[2], G. Hilliard[2], L.T. Reiter[1].* 1) Department of Neurology, University of Tennessee Health Science Center, Memphis, TN; 2) Department of Molecular Sciences, University of Tennessee Health Science Center, Memphis, TN; 3) Department of Biology, University of Alabama, Tuscaloosa, AL.

The subtle regulation of proteins and transcripts at the synapse may explain the changes in synaptic plasticity and function that lead to autism spectrum disorders (ASD). The human *UBE3A* gene has clearly been implicated in ASD pathogenesis when duplicated and, in some cases in conjunction with Angelman syndrome. Our lab has been using the genetic model organism *Drosophila melanogaster* to screen for proteins regulated by UBE3A and we recently identified Punch (GTP cyclohydrolase I), a key regulator of dopamine/serotonin synthesis as a potential UBE3A target. Individuals with ASD often respond well to serotonin reuptake inhibitors, which increase free pools of serotonin at the synapse and can ameliorate some ASD symptoms. Here we show that *Dube3a* is able to regulate Punch levels in the nervous system. We detected elevated levels of both tetrahydrobiopterin (BH4), the rate-limiting co-factor in dopamine/serotonin synthesis, and dopamine in fly heads over-expressing *Dube3a*. As expected, expression of *Dube3a*-RNAi decreased both BH4 and dopamine levels in flies. These changes in neurochemistry were also associated with pronounced activity changes dependent on dopamine levels.

*Punch* mutants display profound neuronal pathfinding defects as embryos and reduced survival rates to adulthood. We expressed *Punch*-RNAi in a subset of PNS neurons and found abnormal dendritic branching phenotypes that were similar to the phenotype in *Dube3a* loss of function animals. These data suggest that Punch functions in synaptic stability and growth during neuronal development. These results provide a connection between dopamine/serotonin and *Dube3a* expression that may be directly applicable to the treatment of individuals with 15q duplication autism and may also explain why some idiopathic ASD patients respond to selective serotonin reuptake inhibitors better than others.

## 2459/T/Poster Board #1008

**Auditory electrophysiology of the *mdxCv3* mouse shows abnormal latencies which may provide evidence for the role of dystrophin and the dystrophin-associated protein complex in proper auditory function.**

*DM. Pillers[1], S. Tokarz[1], J. Pang[2], B. Kempton[3], B. Malmin[3], D. Trune[3].* 1) Dept Pediatrics-Neonatology, University Wisconsin, Madison, WI; 2) Division of Biomedical Engineering, Oregon Health and Sci Univ, Portland, OR; 3) Dept Otolaryngology - Head and Neck Surgery, Oregon Health and Sci Univ, Portland, OR.

Dystrophin is a cytostructural protein in muscle that links the actin cytoskeleton to extracellular laminin via the dystrophin-associated protein complex (DAPC). The Dystrophin gene encodes several different sized isoforms, and their defective production in Duchenne muscular dystrophy (DMD) underlies the many muscle, eye, brain, and heart pathologies of that disease. There is evidence to implicate the DAPC in auditory function. The laminin-deficient *dy* mouse has an abnormal ABR audiometry threshold response (Pillers, 2002). We have also shown that dystrophin mutations in the *mdx$^{Cv3}$* mouse result in altered ABR latency responses (Pillers et al., ASHG 2004). To better characterize the role of dystrophin and the DAPC in hearing, ABR was used to evaluate auditory function in the *mdx*, *mdx$^{Cv3}$*, and in age-matched C57BL/6J controls. Cochlear dystrophin gene and protein expression was evaluated to identify which isoforms are normally present and thus potentially defective in muscular dystrophy mouse models. Both the wild-type C57BL/6J and mdx mice(which lack full-length dystrophin, Dp427m) demonstrated normal ABR threshold and latency responses. However, the *mdx$^{Cv3}$* mouse that lacks all forms of dystrophin displayed shorter ABR latency responses. Western blot analysis of C57 cochlea showed expression of Dp427m and the isoforms Dp116, and Dp71. None of these dystrophin proteins were detected in the cochlea of the *mdx$^{Cv3}$*. Immunohistochemistry showed multiple areas of dystrophin expression in C57 and *mdx* inner ear tissues, including the organ of Corti, and the stria vascularis. No dystrophin labeling was seen in the cochlea in the *mdx$^{Cv3}$*. RT-PCR analysis using primers sets and probes for full-length dystrophin Dp427m, four commonly detected isoforms, and two alternate forms of Dp427m (Dp427c (cortex) and Dp427p (Purkinje)), showed that all isoforms were expressed in the cochlea of C57 mice with the exception of Dp260. The sum of the expression of Dp427m, Dp427c, Dp427p, Dp140, Dp116, and Dp71 appeared to account for all cochlear isoforms. Proper integration between the intracellular cytoskeleton and the extracellular matrix (ECM) appears to play a role in normal hearing. Disrupting the ECM (laminin) has been shown to alter threshold audiometry responses. Here we show that disrupting the intracellular component by removing all dystrophin isoforms alters latency thresholds, providing more evidence that the DAPC plays a role in normal auditory function.

## 2460/T/Poster Board #1009

**Charactereization of the transcription complex regulating Surival Motor Neuron (SMN) gene expression.**

*L. Simard[1], F. Boli[2], J. Dionne[3], M. Fedjaev[3], R. Jayachandran[1], A. Pchejetski[3].* 1) Biochemistry & Medical Genetics Dept., University of Manitoba, Winnipeg, MB, Canada; 2) Montreal Neurological Institute, McGill University, Mtl., QC, Canada; 3) University of Montreal, Sainte-Justine Research Centre, Mtl., QC, Canada.

Spinal muscular atrophy (SMA), a lower motor neuron disorder, is a leading cause of early infant death. Mutations in the *SMN1* gene are responsible for SMA. Because there are two nearly identical *SMN* genes in humans, *SMN2* is an attractive therapeutic target even though it predominantly produces transcripts lacking exon 7. Two HDAC inhibitors are currently being tested in SMA clinical trials; however, these drugs can target up to 40% of genes. We hypothesized that understanding the mechanisms regulating *SMN* gene expression, especially with regards to observed post-natal down-regulation, could help identify more specific therapeutic targets. Our published studies indicated that the core transcription complex was different in undifferentiated and neuronal-like P19 cells and involved numerous transcription factors. In this study, linker-scanning mutagenesis of Smn promoter-luciferase gene constructs and competitor-electrophoresis mobility shift assay (EMSA) strategies allowed us to exclude C/EBPβ, NF1 and Sp1 from the two major protein-binding domains of the core Smn promoter. Competitor-EMSA allowed us to demonstrate Ets binding; but, excluded the Pea3, Ets1, Ets2, and Elk1 family members. Consequently, we used a proteomics approach to identify the specific Ets transcription factor regulating Smn promoter activity in P19 cells. Step-wise purification was monitored by EMSA and the final step relied upon DNA-affinity chromatography. Fractions containing our protein of interest were pooled, subjected to in-gel trypsinization and LC-MS/MS separation. Spectra were interpreted using Spectrum Mill software. This allowed us to identify GABPα as the Ets family member binding to the Smn promoter. GABPα is a unique Ets transcription factor as it binds as a heterotetramer comprised of two GABPα and two GABPβ molecules. Site-directed mutagenesis of the Smn promoter confirmed the need for 2 functional Ets cis-elements and GABPα binding was confirmed by supershift-EMSA and chromatin immunoprecipitation. Taken together, we now have a working model of the Smn transcription complex and have initiated chromatin immunoprecipitation studies to investigate Ets and CREB (a previously reported transcription factor binding to the SMN promoter) for their involvement in Smn gene expression in neuronal an non-neuronal tissues during the critical period of Smn down-regualtion post-natally. *Funded by CIHR, ALS Society, Muscular Dystrophy Canada, and Families of SMA..*

## 2461/T/Poster Board #1010

**Small RNA associated with transcriptional start sites and repetitive elements in postnatally derived mouse neural stem cells.**

*KE. Szulwach[1], X. Li[1], A. Shetty[1], ME. Zwick[1], X. Zhao[2], P. Jin[1].* 1) Dept Human Gen, Emory Univ, Atlanta, GA; 2) Dept of Neurosciences, Univ of New Mexico, Albuquerque, NM.

Increasingly complex networks of small RNAs act through RNA interference (RNAi) pathways to regulate gene expression, which could shape diverse cellular pathways. Neurogenesis is regulated at many levels by both extrinsic and intrinsic factors. Recent studies have revealed the important roles of small regulatory RNAs in neurogenesis. To further explore the role of small regulatory RNAs in neurogenesis, we examined expression of small RNA 14-30 nucleotides in length in a homogenous population a postnatally derived neural stem cells. ~43 million small RNA derived cDNA molecules were sequenced. After identification of sequences overlapping currently annotated miRNA, snoRNA, tRNA, rRNA, we identified >100,000 previously unannotated small RNA. These RNA were dominated by a particular class of low abundance 17-19nt RNA that associate with divergent transcription at protein coding transcriptional start sites (TSSa-RNA). We also observed an additional ≈30,000 sequences that overlapped repetitive elements, including many LINE, SINE, and LTR associated small RNA. By comparing the genomic locations from which small RNA were derived we found that relative to RefSeq TSSs there was an overabundance of small RNA within a ≈500bp region in both the sense and antisense orientation directly surrounding TSSs, while there was not significant enrichment of small RNA sequences beyond 750bp of TSSs. These data provide a unique assessment of transcriptional output in postnatally derived neural stem cells and will be generally useful for comparison with genetically defined human neurodevelopmental disease models in mice.

**Identification of Deregulated Direct Target Genes of the Hepatitis B Viral (HBV) protein, HBx using chromatin immunoprecipitation and expression microarray profiling.** 
*C.G.L Lee[1,2,3], Y. Lu[2], W.K. Sung[4,5], C.W.H. Lee[4,5], D.W. Zhang[1,2], M. Ronaghi[6].* 1) Biochemistry, Yong Loo Lin School of Medicine, National University of Singapore, Singapore; 2) Division of Medical Sciences, Humphrey Oei Institute of Cancer Research, National Cancer Centre, Singapore, Singapore; 3) Duke-NUS Graduate Medical School, SINGAPORE; 4) Department of Computer Science, National University of Singapore, Singapore; 5) Genome Institute of Singapore, SINGAPORE; 6) Stanford Genome Technology Center, Department of Biochemistry, Stanford University, USA.

The hepatitis B X (HBx) protein is strongly implicated in hepatocarcinogenesis (HCC). Although HBx does not bind DNA directly, it interacts with transcriptional regulators resulting in aberrant gene expression and deregulated cellular pathways. We integrated chip-based chromatin-immunoprecipitation(ChIP-chip) and expression microarray profiling and identified 184 gene targets directly deregulated by HBx. We also computationally infer 144 transcription factors that interact with HBx. Interaction of HBx and some of the predicted transcription factors (pTF) as well as the promoters of the deregulated target genes of these pTFs were experimentally validated. Significantly, we also demonstrated that the pTFs interact with the promoters of the deregulated HBx target genes and that deregulation by HBx of these HBx target-genes carrying the pTF consensus sequences can be reversed using pTF siRNAs. The roles of these deregulated direct HBx target genes and their relevance in cancer was inferred via querying against biogroup/cancer-related microarray databases using the web-based NextBioTM software. Integrating ChIP-chip and expression microarray data, 6 pathways, including the Jak-Stat pathway, were predicted to be significantly deregulated when HBx binds indirectly to direct target gene promoters. In summary, this is the first demonstration of the utilization of ChIP-chip to identify deregulated direct gene targets from indirect protein-DNA binding and of the feasibility of identifying TFs that interact with HBx to deregulate target gene expression. Increased knowledge of the gene/transcriptional factor targets of HBx will enhance our understanding of the role HBx in hepatocarcinogenesis and facilitate design of better strategies in combating Hepatitis-B virus associated hepatocellular-carcinoma.

## 2463/T/Poster Board #1012

**Activation of human delta globin gene in transgenic mice.** 
*M.F. Manchinu, S. Porcu, M.F. Marongiu, D. Poddie, F. Crobu, C. Casu, M.S. Ristaldi.* Istituto di Neurogenetica e Neurofarmacologia, CNR, Cagliari, Italy.

The δ globin gene, located between the γ and β genes on human chromosome 11, produces a small amount of δ globin in children and adults, participating to the HbA2 synthesis. Our previous work showed in vitro that creation of the CACCC box consensus sequence on the δ globin gene promoter is sufficient to enhance its expression to a considerable extent. The δ globin chain could be a valid substitute of the β globin chain in thalassemia disorder and an antisickling agent in sickle cell anemia. Here we show that: 1) the δ globin gene promoter can be activated in vivo in a transgenic mouse model; 2) the activated δ globin gene promoter is able to drive the expression of δ globin gene to a high level. We have produced transgenic mice lines with a DNA construct in which the wild type (wt) β globin gene promoter and the proximal CACCC box containing δ globin gene promoter are linked in cis to a single erythroid specific enhancer. The order of the different elements in our construct mimics the spatial organization of the β globin cluster were the δ globin gene is situated 5' to the β gene and relatively closer to the LCR. We have also produced transgenic control lines, bearing the wt δ globin gene promoter on place of the CACCC containing δ. The δ and β globin gene promoters are respectively linked to two different (firefly and renilla) luciferase reporter genes. We have analyzed 3 independent transgenic lines bearing the CACCC containing δ globin gene promoter construct, and 3 independent lines bearing the control construct (wt δ globin gene promoter). While the expression level of the wt δ globin gene promoter remains around 20% compared to the β globin gene promoter in each time point observed (12.5, 14.5 and 16.5 days post coitum), the expression level of CACCC containing δ globin gene promoter reached high expression levels in fetal liver at 12.5 p.c. (82% ± 17), 14.5 pc (75% ± 23) and 16.5 pc (97% ± 29). We also have produced two transgenic lines carrying the mini LCR and the δ gene driven by the CACCC containing δ promoter (CACCCδ-LCR). Our preliminary results on a single copy transgenic line show an expression level of the δ gene of 30% compared to the endogenous β major. This level of expression could be considered curative both for β thalassemia and sickle cell disease. We plan to obtain the final validation of the δ globin gene as a therapeutic gene by the rescue of a thalassemic mouse model (th3/th3).

## 2464/T/Poster Board #1013

**Vitamin D receptor associated with late-onset Alzheimer disease promotes amyloid precursor transcription.** 
*K. Hara[1], G.W. Beecham[1], P.J. Gallins[1], P.L. Whitehead[1], G. Wang[1], C. Lu[1], M.A. Slifer[1], L. Wang[1], S. Züchner[1], E.R. Martin[1], D. Mash[2], J.L. Haines[3], M.A. Pericak-Vance[1], J.R. Gilbert[1].* 1) Miami Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, Florida 33136, USA; 2) Department of Neurology, Brain Endowment Bank, University of Miami Miller School of Medicine, Miami, Florida 33136, USA; 3) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, Tennessee 37232, USA.

Late-onset Alzheimer disease (LOAD) has a strong genetic component. The vitamin D receptor (VDR) is one potential genetic risk factor for LOAD. Genetic association of VDR with LOAD has been described in a Turkish population and we have previously identified the strongest association with LOAD at rs11568820 (p=7.76x10-6, Odds ratio =1.69), which is known to be a promoter SNP that has functional effects on VDR transcription. It has been shown that vitamin D deficiency is associated with cognitive impairment and LOAD. However, a molecular role of VDR in AD pathogenesis remains to be elucidated. VDR is a known transcription factor that interacts with SMAD3, which affects amyloid precursor protein (APP) transcription by promoting TGF beta signaling. Previously, we tested the hypothesis that VDR affects APP promoter activity and demonstrated, using the luciferase reporter assay, that APP promoter activity was significantly up-regulated by VDR over-expression independently from vitamin D. Vitamin D, in fact, inhibited APP over-transcription in neuro2A cells. Additionally, the relative expression levels of endogenous APP mRNA is increased significantly by transient VDR over-expression in both human astrocytes and neurons, confirming the VDR effect on APP transcription and expression in the nervous system. Here we extend these results to human brain by showing that VDR mRNA is significantly over-expressed in 10 LOAD brains compared to 10 age-matched controls. Immunohistochemical assay also revealed stronger staining for VDR in neurons in the LOAD frontal cortices compared to those of controls. These results suggest that VDR over-expression may be involved in LOAD pathogenesis, APP may be a target gene for VDR signaling and that Vitamin D, in at least some cases, may inhibit as well as activate the effects of VDR.

## 2465/T/Poster Board #1014

**mRNA-Seq Whole Transcriptome Analysis of a Single Cell.** 
*K. Lao[1], F. Tang[2], C. Barbacioru[1], Y. Wang[1], E. Nordman[1], C. Lee[1], N. Xu[1], X. Wang[1], J. Bodeau[1], A. Surani[2].* 1) Molec Cell Biol, Applied Biosystems, Foster City, CA; 2) Wellcome Trust/Cancer Research UK Gurdon Institute of Cancer and Developmental Biology, University of Cambridge, Tennis Court Road, Cambridge, CB2 1QN, UK.

We developed a digital gene expression profiling assay at single cell resolution by combining a modified single cell whole transcriptome amplification method with the next generation sequencing technique, SOLiD System. Using only a single mouse blastomere, our mRNA-Seq assay can detect the expression of 74% (5,270) more genes than microarray techniques. Moreover, 8 - 19 % of the genes with multiple known transcript isoforms We developed a digital gene expression profiling assay at single cell resolution by combining a modified single cell whole transcriptome amplification method with the next generation sequencing technique, SOLiD System. Using only a single mouse blastomere, our mRNA-Seq assay can detect the expression of 74% (5,270) more genes than microarray techniques. Moreover, 8 - 19 % of the genes with multiple known transcript isoforms express at least two isoforms in the same blastomere or mature oocyte, which unambiguously demonstrated the complexity of the transcript variants at whole genome scale. With conventional transcriptome assays it was not possible to ascertain if the multiple transcript isoforms found in a tissue or organ coexist in the same cell, or if they are just expressed in different cell types or at different cell cycle stages of the same cell type. This knowledge is crucial to provide a real understanding of the transcriptome complexity within individual cells. Finally, for Dicer and Ago2 knockout oocytes, we also showed that in Dicer knockout and Ago2 knockout mature oocytes, 1,924 and 1,687 genes respectively were abnormally upregulated, and 1,343 and 987 transcripts respectively were downregulated compared to wildtype controls, which proves the global importance of small RNAs (including microRNAs and endogenous siRNAs) for oogenesis. The main technical novelty of this work is the combination of an improved unbiased amplification of cDNAs from single cells with well over a 100 million reads, or a few gigabases of cDNAs on SOLIDTM. This not only allowed us to discover many novel transcripts that have been overlooked but also to get a quantitative estimate of their abundance in the cell by the frequency with which the sequence occurs in the mRNA-Seq reads. This single cell mRNA-Seq assay will greatly enhance our ability to analyze transcriptome complexity during mammalian development, especially for early embryonic development and for stem cells, which are usually rare cell population in vivo.

## 2466/T/Poster Board #1015

**Arsenic induces differential expression of Nrf2-dependent enzymes HO-1 and NQO1.** *F. Centeno[1], E. Córdova[1], J.L. Cruz-Colín[1], M.E. Morales-Marín[2], L. Orozco[1,2].* 1) Investigacion, Inst Natl de Medicina Genomica, Mexico D.F., Mexico; 2) Posgrado en Ciencias Genómicas, Universidad Autónoma de la Cd. de México.

Ground water arsenic is the main source of human exposure worldwide and it represents an important health issue. Arsenic exposure has been associated with different kinds of cancer, vascular diseases and skin lesions. It has been reported that arsenic induces oxidative stress in liver, brain and erythrocytes, being the oxidative damage the major mechanism of arsenic-mediated cellular toxicity. Nrf2 transcription factor (Nuclear Factor Erythroid 2-related Factor 2 ) activation has been proposed as an important mechanism against arsenic exposure in different cell types, by means of the regulation of a battery of genes encoding antioxidant and phase II detoxification enzymes. The aim of this study was to evaluate the Nrf2 response to arsenic exposition in two different cell lines. In this context, we analyzed the expression of two Nrf2-responsive enzymes: HO-1 (Heme-Oxygenase 1) and NQO1 (NAD(P)H dehydrogenase quinone 1), in a liver-derived cell line (HepG2) and in a lymphoblastoid cell line treated with 2.5, 5 and 10μM sodium arsenite. Transcriptional activation of Nrf2, HO-1 and NQO1 genes was evaluated by Real-Time RT-PCR and protein levels were determined by Western blot. A high transcription induction of HO-1 by arsenic treatment was observed in both HepG2 and lymphoblastoid cells. Interestingly, a higher activation of HO-1 was observed in lymphoblastoid cells after 10μM arsenite treatment, this cell line reached above 200 fold HO-1 transcription induction compared with those with out treatment, while the HO-1 induction in HepG2 was around 20 fold. An increase in the HO-1 protein levels was documented in both cell lines after arsenic exposure. In contrast to the high NQO1 induction previously reported by other well-characterized Nrf2-inducers, like sulphoraphan, NQO1 showed a slight induction by arsenic. Nrf2 mRNA levels remained constant in HepG2 but it showed and slight increase in lymphoblastoid cell line. Our results suggest that there is a difference in the induction mediated by arsenic of Nrf2-dependent enzymes HO-1 and NQO1 and that HO-1 expression is the main Nrf2-induced mechanism against arsenic-mediated cell toxicity, mainly in lymphoblastoid cells.

**Identification of decreased expression of transcripts with alternative 3'UTRs in the brains of *Gtf2ird1*$^{-/-}$ mice.** *J. O'Leary, E.J. Young, L.R. Osborne.* Departments of Molecular Genetics and Medicine, University of Toronto, Toronto, Ontario.

Williams-Beuren Syndrome (WBS) is an autosomal dominant neurodevelopmental disorder caused by the hemizygous deletion of a 1.5 Mb region from chromosome 7q11.23. The clinical symptoms of WBS are numerous and include behavioural and cognitive components. WBS patients usually have overly friendly personalities and suffer from generalized anxiety, simple phobias, ADHD, and mild mental retardation with relative preservation of language skills. Two of the genes deleted in WBS, *GTF2I* and *GTF2IRD1*, are transcription factors which show widespread but distinct expression patterns during development. Genotype-phenotype studies in patients with atypical deletions of the WBS region have implicated these genes in the neurological features of WBS and *Gtf2ird1*-targeted mice have features consistent with the WBS phenotype, namely impairments in fear response, increased sociability and decreased aggression. In order to identify neural targets of GTF2IRD1, microarray analysis was performed comparing gene expression in the brain of *Gtf2ird1*$^{-/-}$ and WT mice, both at embryonic day 15.5 and at birth. Overall, the changes in gene expression in the mutant mice were not striking with most changes falling in the range of 0.3 to 2 fold. Real-Time PCR was used to verify the expression levels of candidate genes identified in the arrays using primer pairs within the microarray probe region in the 3'UTR, as well as within the coding region of each gene. Interestingly, the majority of genes whose transcript level alteration was verified by PCR showed decreased expression only with assays targeting the 3' UTR, but not with assays targeting the coding region. These include *Stx3*, *Actl6b*, *Taf6* and *Zfp68*. Analysis of these genes using 3' RACE identified transcripts using alternative polyadenylation sites that could result in probe-specific alterations in transcript level. Although the significance of these alternate transcripts is not yet known, the 3' UTR plays a pivotal role in transcript localization, stability and translation. Micro-RNA binding sites have been associated with longer 3'UTRs and in the brain, alternate 3'UTR sequences have been shown to influence spine morphology and synaptic plasticity. Given the emerging roles of alternative 3'UTRs it is feasible that the changes in gene expression we have identified could contribute to the behavioural phenotype of the *Gtf2ird1*$^{-/-}$ mice.

## 2468/T/Poster Board #1017

**Comparative Analysis of Transcriptional Activity of PERV LTR Subtypes in Human, Monkey, and Pig Cell Lines.** *H. Kim[1], Y. Jung[1], J. Huh[2], D. Kim[3], B. Cho[4], H. Ha[1], K. Ahn[1].* 1) Department of Biological Science, Pusan National University, Busan, Korea; 2) National Primate Research Center, KRIBB, Ochang, Chungbuk, Korea; 3) Korea Bioinformation Center, KRIBB, Daejeon, Korea; 4) Department of Animal Science, College of Life Sciences, Pusan National University, Miryang, Korea.

Porcine endogenous retroviruses (PERV) in the pig genome have the potential to act as harmful factors in xenotransplantation (pig-to-human). Long terminal repeats (LTRs) of the PERV elements have showed promoter activity that could affect neighboring functional genes. Transcription activities of 11 long terminal repeat subtypes were analyzed using kidney cell line of various species (HEK293, Cos7, PK15). They showed different transcription regulation activity in different cell lines. The E4 type (H2-2) derived from pig kidney showed distinct promoter activity in the human kidney HEK293 cell line. Deletion mutants based on the boundary of U3, R and U5 region of the H2-2 clone were constructed and examined transient transfection assay, indicating that U3 region containing binding sites for transcription factors (MAZR, HIF-1, STAT5A, and GATA-4) was crucial for transcription regulation.

## 2469/T/Poster Board #1018

**Complex regulatory network of transcription factors and interacting proteins involved in Axenfeld-Reiger syndrome.** *M. Acharya, L. Huang, M. Walter.* Department of Medical Genetics, University of Alberta, Edmonton, AB, Canada.

Axenfeld-Rieger (AR) malformation is an autosomal dominant disorder of the anterior segment of the eye associated with glaucoma. Mutations in the PITX2 "homeobox" transcription factor and FOXC1 "forkhead box" transcription factor have been reported to cause AR malformation linked to chromosome 4q25 and 6p25 respectively. Interaction between these two transcription factors has been established previously from our lab, where PITX2 has been shown to have a repressor effect on FOXC1 transcription activation. To understand the complex regulatory network of PITX2, we performed yeast two-hybrid (Y2H) screening of the human trabecular meshwork (HTM) cDNA library using PITX2 as "bait". The trabecular meshwork is a region reportedly associated with anterior segment dysgenesis of the eye and glaucoma. We identified PRKC apoptosis WT1 regulator (PAWR) as a novel PITX2-interacting protein that downregulates PITX2 transactivation in HTM cells. PAWR has already been established as an inducer of apoptosis in cancer and transcription repressor to WT1 thereby blocking expression of the anti-apoptotic protein Bcl2. We further identified FOXC2 as an interacting partner of PAWR from our Y2H screening. Mutations in FOXC2 cause Lymphedema-distichiasis, which includes developmental defect in anterior segment of the eye. FOXC2 has also been found to have structural and functional similarity with FOXC1. We, therefore, confirmed the binary interaction between PAWR and FOXC2 in vitro by Ni-pulldown assay and in vivo by co-immunoprecipitation assays. We also observed FOXC1-PAWR and FOXC1-FOXC2 interactions when tested in vitro by Ni-pulldown assays. We further confirmed that the same C-terminal leucine-zipper (LZ) domain in PAWR interacts with PITX2, FOXC1 and FOXC2. Interestingly, we found an upregulation effect on transcription activity of FOXC2 in presence of PAWR. Based on these results, we think there is a complex regulatory network operating in the eye involving PITX2, PAWR, FOXC1, and FOXC2. Therefore, we are looking forward to do more in-depth study of the assembly and functional significance of the protein-complexes involving PITX2, PAWR, FOXC1, FOXC2 for better understanding of the pathogenesis underlying the AR malformation, glaucoma and associated anterior segment diseases in the eye.

**Analysis of the 3'UTR insertion/deletion polymorphism of ARMS2 gene in age-related macular degeneration.** *G. Wang[1], KL. Spencer[2], WK. Scott[1], P. Whitehead[1], BL. Court[1], J. Ayala-Haedo[1], SG. Schwartz[3], JL. Kovach[3], P. Gallins[1], M. Polk[1], A. Agarwal[4], EA. Postel[5], JL. Haines[2], MA. Pericak-Vance[1].* 1) Miami Institute for Human Genomics, Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami, Miami, FL 33136; 2) Center for Human Genetics Research, Vanderbilt University, Nashville, TN 37232; 3) Bascom Palmer Eye Institute, University of Miami, Miami, FL 33136; 4) Department of Ophthalmology, Vanderbilt University, Nashville, TN 37232; 5) Duke Eye Center, Duke University Medical Center, Durham, NC 27710.

Controversy remains concerning which gene at the chromosome 10q26 locus confers risk for AMD and resolution of statistical genetic analysis is limited by strong linkage disequilibrium across the region. Functional analysis of the related genetic variations and biological studies on the genes ARMS2 and HTRA1 can be helpful to solve this puzzle. Recently Fritsche et al reported that AMD is associated with unstable ARMS2 transcripts caused mainly by a complex insertion/deletion (indel; consisting of a 443bp deletion and an adjacent 54bp insertion) in its 3'UTR. To validate this indel, we analyzed our samples by sequencing and quantitative PCR. We found that the indel is more complex than originally reported (443 bp deletion and 54 bp insertion) and composed of two side-by-side indels separated by 17 bp: (1) 9 bp deletion with 10bp insertion; (2) 417 bp deletion with 27 bp insertion. ARMS2 is ubiquitously expressed in human tissues. Comparatively, ARMS2 is preferentially expressed in the occipital cortex while HTRA1 is expressed in a much lower level in both retina and occipital cortex suggesting a possibly more important role for ARMS2 in the physiology of vision than HTRA1. No association between the genotype of the indel and ARMS2 mRNA level was found in human blood samples, suggesting due to the reported strong linkage disequilibrium between the A69S variant and the indel, that it could be A69S variant, not the indel, that confers risk of AMD.

## 2471/T/Poster Board #1020

**Study on fgf9 and fgfr3 gene expression profiling in mice.** *M.M. GU[1], X.Y. CHEN[1], X.L. WU[1], S.Y. LU[2], Z.G. WANG[1,2].* 1) Department of Medical Genetics, Shanghai Jiao Tong University School of Medicine, Shanghai, China; 2) Ruijin Hospital Affiliated to Shanghai Jiao Tong University School of Medicine, Shanghai, China.

The fibroblast growth factor 9 (FGF9) belongs to the FGF superfamily, which consists of 22 members involved in various developmental processes including development of various tissues such as limb, nervous and skeletal systems in vertebrates. FGF9 is widely distributed in brain, kidney, motor neurons and bone tissue at embryonic period. By binding with its receptor (e.g. FGFR3), FGF9 can promote the proliferation of glial cells, dental mesenchymal cells, prostate epithelial cells and stem cell. FGF9 also can promote development of lung and the reproductive system during the embryonic period. However, it was not identified that the expression profiling of fgf9 and fgfr3 in adult mice. We analyzed cDNA from twelve tissues (heart, liver, spleen, cerebellum, kidney, lung, brain, thymus, muscle, stomach, joint and marrow) using RT-PCR. The results showed that fgf9 was strongly expressed in heart, cerebellum, kidney and muscle, with somewhat lower expression in brain and joint. We could not be detect in any other tissues. Whereas the fgfr3 was widely expressed in all twelve tissues, especially higher expression in lung and brain. Using immunohistochemistry method, we also evaluated the expression of fgf9 and fgfr3 proteins. The fgf9 was widely expressed in brain. Whereas the fgfr3 protein was widely expressed in liver and brain. In different cells of other tissues, fgf9 and fgfr3 were both expressed in muscle fiber of heart and muscle, in tubular cells of kidney and in proliferating and hypertrophic chondrocytes of joint. In the joints of different age mice, the fgf9 and fgfr3 were both detected strongly in the growth plate of newborn and 1 week old mice, with somewhat lower expression in the joints of 4 week mice. But both of them were not expressed in the growth plate of 8 week old mice. These results led us to study how FGF9 played important roles in human bone and joint development and diseases such as multiple synostoses syndrome.

## 2472/T/Poster Board #1021

**A functional approach to understand the role of the Kinesin Binding Protein (KBP) in Goldberg-Shprintzen syndrome.** *M.M.M. Alves[1,5], G. Burzynski[2], A. Brooks[3], C.C. Hoogenraad[4], I. Shepherd[2], B.J.L. Eggen[5], R.M.W. Hofstra[1].* 1) Department of Genetics, University Medical Center Groningen, Groningen, Netherlands; 2) Department of Biology, Emory University, Atlanta, USA; 3) Department of Clinical Genetics, Erasmus Medical Center, Rotterdam, Netherlands; 4) Department of Neuroscience, Erasmus Medical Center, Rotterdam, Netherlands; 5) Department of Developmental Genetics, Faculty of Mathematics and Natural Sciences, University of Groningen, Haren, Netherlands.

Goldberg-Shprintzen syndrome is a rare autosomal recessive disorder characterized by polymicrogyria, mental retardation and Hirschsprung disease. Recently, we showed that patients suffering from this disease have inactivating mutations in the *KBP/KIAA1279* gene. However, the function of its encoded protein is largely unknown. Considering that mutations in KBP are associated with both enteric and central nervous system defects, clarifying its function will lead to new insights about the protein network associated with neuronal development. Based on its primary sequence, KBP is predicted to have two tetratricopeptide repeats (TPRs). Since the basic function of TPR motifs is to mediate protein-protein interactions, a yeast two-hybrid screen was performed to identify possible KBP interacting proteins. We obtained various possible interactors, of which the two major categories were kinesin like proteins involved in the transport of vesicles and organelles towards the plus end of the microtubules, and microtubule destabilizing proteins implicated in axonal growth. These interactions were further confirmed by co-localization studies, co-immunoprecipitation assays and expression studies in mice primary cortical neurons. Moreover, an epistatitc interaction between KBP and SCG10 was also found in our zebrafish model supporting these findings. As several kinesins were identified, a probable interaction with microtubules was explored, both by co-localization and in vitro binding assays. Moreover, an implication in cell differentiation and neurite development was analysed by KBP knock down in PC12 cells.

Based on the results obtained, we postulate that KBP plays an important role in neuronal development and it is likely involved in microtubule organization/stability by direct interaction with SCG10 but it is not directly associated to microtubules.

In conclusion, our results bring new insights about Hirschsprung disease and polymicrogyria development pointing towards a microtubule associated problem and present KBP as a new/major player involved in neuronal development.

## 2473/T/Poster Board #1022

**A dual role for hMSH5 in DNA damage response and DSB repair.** *C. Her.* Sch Molec Bioscience, Washington State Univ, Pullman, WA.

Increasing evidence has suggested that the human MutS homolog hMSH5 may possess diverse functions in several biological processes which include meiotic recombination, class switch recombination, and mitotic DNA double-strand break (DSB) repair. In order to establish a foundation for delineating the precise functions of hMSH5 in these processes, we have investigated the roles of hMSH5-c-Abl interaction in both DNA damage response and DSB repair. The results of these recent studies have demonstrated that the hMSH5 protein can be subjected to induction by DNA damage, in which the elevated levels of hMSH5 promote ionizing radiation (IR)-induced caspase-3-dependent apoptotic response. This role of hMSH5 is entirely dependent on the interaction with c-Abl, resulting in enhanced c-Abl activation and the subsequent p73 activation. The significance of this observation can be mirrored by the effects of the peculiar interaction between hMSH5P29S and c-Abl on sensitizing cells to IR, indicating that mutations impairing this process could significantly affect normal cellular responses to anti-cancer treatments. On the other hand, our most recent data have also demonstrated a functional requirement for c-Abl-mediated hMSH5 phosphorylation in DSB repair. Using a chromosomally integrated recombination reporter, we have demonstrated that DSB-triggered tyrosine phosphorylation of hMSH5 is an essential early event for non-crossover HR repair of DSBs. In fact, cells expressing a phosphorylation deficient hMSH5 mutant are more sensitive to DSB-inducing agent cisplatin. Collectively, our studies tend to suggest that a significant induction of hMSH5 protein in cells could promote DNA damage-triggered apoptotic response, conversely a moderate increase in the level of hMSH5 might facilitate DSB repair.

## 2474/T/Poster Board #1023

**The tumour suppressor CYLD and the ubiquitin ligase MID1 associate at the microtubules and have counteracting effects on microtubule stability.** *J. So[1, 2], A. Wilde[3], M. Huber[4], S. Krauβ[2], A. Köhler[5], R. Schneider[5], S. Schweiger[2, 6].* 1) Division of Clinical and Metabolic Genetics, The Hospital for Sick Children, Toronto, Canada; 2) Max Planck Institute for Molecular Genetics, Berlin, Germany; 3) Department of Molecular Genetics, University of Toronto, Toronto, Canada; 4) Department of Dermatology, University Hospital Center and University of Lausanne, Lausanne, Switzerland; 5) Institute for Biochemistry, Center for Molecular Biosciences, University Innsbruck, Innsbruck, Austria; 6) Division of Medical Sciences, University of Dundee, Dundee, UK.

Mutations in the CYLD tumour suppressor have been identified in patients with familial cylindromatosis and familial trichoepithelioma, which are both autosomal dominant genetic predispositions to multiple tumours of the skin appendages. CYLD has been shown to deubiquitinate TRAF proteins and Bcl-3, both leading to inhibition of NF-κB activation. Recent studies have demonstrated the localization of CYLD at the microtubules, and its putative role in the cell cycle. We have now found that CYLD is a microtubule-associated protein that accelerates microtubule destruction in cells treated with the microtubule depolymerizing agent nocodazole. CYLD protein carrying a point mutation that truncates the protein at a.a. 485 and thereby deletes the C-terminus, including the majority of the third predicted CAP-GLY domain and the ubiquitin hydrolase domain, still associates to microtubules, but has no influence on microtubule stability. Accordingly, specific knockdown of CYLD results in an increase of microtubule stability and faster recovery after nocodazole withdrawal. In addition, we demonstrate that the association of CYLD to microtubules may be effected by its interaction with a known microtubule stabilizer, the ubiquitin ligase MID1. MID1 mutations result in X-linked Opitz G/BBB syndrome, a ventral midline malformation syndrome characterized by hypertelorism, hypospadias in males, heart defects, laryngotracheoesophageal anomalies, structural brain anomalies, and developmental delay. We show by immunofluorescence, yeast two-hybrid assay and co-immunoprecipitation that MID1 and CYLD interact and co-localize to the microtubules. We further demonstrate that they have counteracting effects on microtubule de- and re-polymerization in nocodazole challenge and withdrawal experiments in in vivo settings. Our data strongly suggest that, in addition to upregulation of NF-κB signaling, CYLD plays an important role in microtubule dynamics by acting as a destabilizer and as an antagonist to the microtubule-stabilizing ubiquitin ligase MID1. This interaction has implications for the pathogenetic mechanisms involved in tumour formation and development of ventral midline malformations.

## 2475/T/Poster Board #1024

***C15orf2* is imprinted in brain and encodes a nuclear protein that is present in cortex and hypothalamus.** *M. Wawrzik[1], R. Herrmann[2], J. van de Nes[3], K. Buiting[1], B. Horsthemke[1].* 1) Institut für Humangenetik, Universitätsklinikum Essen, Essen, Germany; 2) Department of Pediatrics and Pediatric Neurology, University Hospital Essen, Essen, Germany; 3) Department of Pathology and Neuropathology, University Hospital Essen, Essen, Germany.

The Prader-Willi syndrome (PWS) is a neurogenetic disorder which results from the loss of paternal contribution for a 1.5 Mb imprinted region on the proximal long arm of chromosome 15. In 2000, we identified an intronless gene in this region (*C15orf2*), which maps between *NDN* and *SNURF-SNRPN* and encodes an 1156-amino-acid protein of unknown function. By Northern-Blot analysis we detected expression only in adult testis. Based on these findings we had suggested that *C15orf2* might play a role in spermatogenesis. Nielsen at al. (2005) have suggested that *C15orf2* is under strong positive selection in primates. Interestingly, there is no orthologuous gene in the mouse. Using RT-PCR, we have now detected expression of *C15orf2* in a number of different tissues including fetal brain. By analysing expressed fragment-length polymorphisms in *C15orf2*, we found biallelic expression in adult testis but paternal only expression in fetal brain. The latter finding is compatible with a role of this gene in PWS. By Western-Blot analysis of protein extracts from human brain with an anti-C15orf2 antibody we could detect C15orf2 in cortex and hypothalamus. Analysis of the amino acid sequence by PSORTII, a software for the prediction of eukaryotic protein subcellular localization, revealed a possible localization of C15orf2 in the nucleus. We could confirm this prediction by transient overexpression of *C15orf2* in Hela and HEK293 cells. The nuclear localization of C15orf2 suggests that the protein may have a direct or indirect function in the regulation of gene expression.

## 2476/T/Poster Board #1025

**A simple denaturing HPLC method to determine phase in amplicons with double heterozygosity.** *B.Y.L. Wong[1], D.E.C. Cole[1,2,3,4].* 1) Clinical Pathology, Sunnybrook Health Sciences Centre, Toronto, ON, Canada; 2) Laboratory Medicine and Pathobiology, University of Toronto, Toronto, ON, Canada; 3) Pediatrics (Genetics), University of Toronto, Toronto, ON, Canada; 4) Medicine, University of Toronto, Toronto, ON, Canada.

INTRODUCTION: The calcium-sensing receptor (CASR) helps regulate extracellular calcium homeostasis. In the human *CASR* gene, three common SNPs (A986S, R990G and Q1011E) have been studied for their impact on protein function, but results are not conclusive. Considering their opposing individual effects and variable allele frequency in different populations, a tri-locus haplotype could potentially provide unique information on overall function. Here, we describe a procedure to determine the *cis/trans* configuration in *CASR* double heterozygotes by denaturing HPLC. MATERIALS AND METHODS: The sequence containing codons 960 to 1030 was amplified by standard PCR. Doubly heterozygous control samples in *trans* configuration were obtained by mixing the PCR amplicons from samples homozygous at one of the polymorphic sites. Controls in *cis* configuration were constructed by amplifying DNA homozygous at one site with a long mutagenic primer containing the mutant base at the other site. To exclude any artifact from amplification with mutagenic long primer, the same long primers were also used to amplify normal samples to generate amplicons singly homozygous which were then mixed to produce the *trans* double heterozygous controls. Chromatograms of amplicons from both short and long primers were compared. All PCR products were sequenced to confirm their expected genotypes. DHPLC analysis was carried out in the Transgenomic WAVE® system equipped with a DNASep column. Seventy-seven double heterozygotes (39 A986S+R990G, 23 A986S+Q1011E, 15 R990G+Q1011E) previously identified among 2107 samples were analyzed by this method. RESULTS AND DISCUSSION: The sequencing results showed that doubly homozygous amplicons constructed with the long mutagenic primers produced only the expected haplotypes. The DHPLC chromatograms of the *trans* double heterozygotes produced by both short and long primers were identical. The chromatograms of mixtures with *cis* configuration were readily distinguishable from their trans counterparts. All 77 double heterozygotes were found to be in *trans* configuration. In some cases, evidently, the partial denaturation of doubly heterozygous amplicons at the optimum melting temperature depends on the configuration of the mismatches and their flanking sequences. Our results with the three *CASR* variants suggest that DHPLC may be a simple and easy method to determine phase when double heterozygosity involves closely clustered SNPs.

## 2477/T/Poster Board #1026

**PANArray cancer related miRNAs profiling with direct labeling on chip.** *H. Kim, JJ. Choi, M. Cho, H. Park.* PANAGENE Inc., Institute of Bioscience, Yuseong-gu, Daejeon, Korea.

MicroRNAs(miRNAs) are short non-coding RNAs that play a critical role in many important biological processes. MiRNA expression profiling is important to understand the biological mechanisms, develop drugs, and diagnose. However, analyzed method of expression profiling is limited for short base of miRNA. Microarray which is hybridization based technique is the best for detection tool on miRNA characteristic. So, we have developed a PNA-based microarray that is highly sensitive, specific and reproducible to analyze miRNA expression profiles with direct miRNA labeling on chip after hybridization. PNA probes are well known to have stronger binding affinity, specificity to its complementary DNA or RNA strand and stability to biological enzymes. Unlabeled total RNA is hybridized to the PNA-based microarray and then only hybridized miRNA labeling is performed by using enzymatic ligation with pCp-Cy3. Labeling method of only hybridized miRNAs is an important technique for reproducibility and reliable results of microarray. Our data showed very low cross hybridization for miRNAs differing by single nucleotide such as human let7(a-i) family. Also, this PNA-based microarray platform can detect small amounts of individual miRNAs from <400ng of total RNA with above 99% correlation between independent replicates in 6hrs. Therefore, PANArray™ miRNA can be a powerful tool to analyze miRNA expression profiling in cancer diagnosis and prognosis for high throughput screening with high accuracy.

## 2478/T/Poster Board #1027

**Microarray gene expression profiling of limiting biological samples.** *M. Watt[1], R. Alexandridis[1], C. Skalitzky[1], N. Burns[1], J.D. Heath[2], B. Kwong[2], R. James[1], R. Selzer[1].* 1) Roche NimbleGen, Inc., Madison, WI; 2) NuGEN Technologies Inc., San Carlos, CA.

In microarray-based gene expression profiling experiments, the expression levels of thousands of genes in individual samples are simultaneously monitored to study the effects of certain treatments, diseases, or developmental stages on gene expression. Standard microarray hybridization and detection protocols require microgram amounts of sample RNA. Also, the highest quality of purified RNA is essential for a successful and reproducible gene expression profiling experiment. Often, samples (for example, clinical needle biopsies and micro-dissected tissues) are extremely small and typically result in nanogram amounts of RNA as starting materials for analysis. For expression profiling analysis of such limited RNA samples, a global RNA amplification scheme is required. Optimally, the RNA amplification procedure will generate microgram amounts of RNA (or cDNA) and maintain the relative transcript abundance present in the initial mRNA sample. Here, we present our findings on the microarray hybridization performance of a range of amplified eukaryotic RNA samples (2 to 20 ng total RNA input). Reproducibility and reliability of linear amplification methods (mRNA-based and whole transcriptome), compared to standard (non-amplified) sample preparation, were assessed using both qRT-PCR and high-density oligonucleotide microarray platforms. The correlation between the results of microarray experiments derived from non-amplified and amplified samples is presented. This study indicates that high quality microarray data can be generated from small amounts of RNA; RNA amplification allows the detection of a large number of genes expressed in the starting RNA population without significantly altering their relative signals. The continued validation of RNA amplification technologies is recommended, particularly as sample limits are further expanded. Robust RNA amplification methods, partnered with expression profiling platforms, have fostered advancements in the understanding of important pathophysiological scenarios and their transition into clinical settings.

## 2479/T/Poster Board #1028

**Overexpression of modified cyclophilin A ragulated endoplasmic reticulum stress.** *H. Kim, W. Choe.* Kyung Hee Univ Department of Biochemistry and Molecular Biology, Medical Science and Engineering Research Center for Bioreaction to Reactive Oxygen Species, Biomedical Science Institute, School of Medicine, Kyunghee University, Seoul 130-701, Korea.,.

The protein is guided to the ER by a signal sequence. signal sequence of preprolactin, after translocation into microsomes and cleavage by signal peptidase, is converted to an intermediate form. The KDEL sequence(lys-asp-glu-leu) is a signal for permanent retention of proteins in the endoplasmicreticulum(ER). Cyclophilin A(CypA) is a relatively abundant small immunophilin exist in the cytoplasm of all mammalian cells. These immunophilins link to cytoplasmic dynein indirectly through the association of the immunophilin peptidylprolyl isomerase (PPIase) domain with dynamitin, a component of the dynein-associated dynactin complex. our study showed that the localization of cyclophilin A(cypA) is regulated by prolactin signal sequence and the KDEL sequence. The ER stress can be induced not only by alterations in physiological conditions such asproteins undergo post-translational modifications in the ER, which requires high levels of luminal Ca2+ and oxidative components. Exposure of cells to glucose starvation, inhibition of protein glycosylation, disturbance of Ca2+ homeostasis, or oxygen deprivation devastates ER environments and causes unfolded proteins to accumulate in the ER (ER stress). we identified ER existence of a modified cyclophilin A expressed in the Endoplasmic reticulum directed by the prolactin signal sequence and the KDEL sequence that resisted ER-stress in chang cell.

## 2480/T/Poster Board #1029

**Characterization and multimerization of recombinant cyclophilin A mutant.** *I. Oh, W. Choe.* Department of Biochemistry and Molecular Biology, Medical Science and Engineering Research Center for Bioreaction to Reactive Oxygen Species, Biomedical Science Institute, School of Medicine, Kyunghee University, Seoul 130-701, Korea.

Cyclophilins belong to a group of proteins that have peptidyl-prolyl cis-trans isomerase activity. The first member of the cyclophilins to be identified in mammals, cyclophilin A (CypA), is the major cellular target for, and thus mediates the actions of, the immunosuppressive drug cyclosporin A. To determine the multimerization of CypA and mutant, Substitution of CypA serine 16 (Ser16) into proline (Pro) and alanine (Ala55) into arginine (Arg) were conducted by PCR in two steps, we investigated the induction of CypA-GST fusion protein. Fusion protein could be purified from crude lysate by affinity chromatography on immobilized glutathione. Bound fusion proteins can be eluted with reduced glutathione under non-denaturing conditions. Eluted fusion protein cleavaged using thrombin agarose and remove GST from CypA. Purified CypA was analyzed by Native-PAGE and immunoblot analysis. Native-PAGE revealed that wild type CypA formed monomer but P16S mutant formed dimmers. Peptidyl-prolyl cis-trans isomerase activity was assayed for the mutants using peptide substrate N-succinyl-Ala-Ala-Pro-Phe-p-nitroanilide, which was lower than wild-type CypA. The antioxidant activity of the CypA and mutants have been examined by total antioxidant capacity assay using cu++ reagent. These assay reveal that CypA mutant lost antioxidant activity.

## 2481/T/Poster Board #1030

**Discovery And Profiling Of Human Short RNAs Using Single Molecule Sequencing (tSMS).** *P. Kapranov[1], F. Ozsolak[1], S. Foissac[2], E. Giladi[1], D. Lipson[1], J. Reifenberger[1], C. Hart[1], J. Thompson[1], P. Milos[1].* 1) Helicos BioSciences Corporation, 1 Kendall Sq Ste B7301 Cambridge, MA 02139-1671; 2) Integromics, S.L., Grisolía, 2 - 28760 Tres Cantos Madrid, Spain.

The repertoires of RNA molecules produced by eukaryotic cells have proven to be exceptionally complex. A large fraction of these molecules are produced from the regions of the genome not considered to be protein coding. Furthermore, as shown by the ENCODE Consortium, structures of RNA molecules can be complex, bringing together distal regions of the genome and portions of different genes, thus challenging our very definition of what we have described as a gene.

The population of short RNAs (sRNAs, <200nt) has also seen a dramatic increase in complexity with the discovery of whole new classes of RNAs such as promoter-associated and termini-associated short RNAs (PASRs & TASRs) and others along with the realization that the sRNA population of a human cell line can comprise 100's of thousands of different un-annotated species. Profiling of sRNAs using next-generation sequencing confirmed the complexity of the un-annotated sRNAs as well as presence of at least one new functional class of novel sRNAs, the class of PASRs.

True Single Molecule Sequencing (tSMS) which requires minimal sample manipulation and no amplification or ligation, could provide better estimate of the complexity of an RNA population and abundances of individual RNA species. We show the feasibility of analysis of human sRNA population via tSMS approach using both no-amplification and amplification-bases methods. As expected, the ligation/amplification-based approach while correlative with the no-amplification method, resulted in skewing abundancies of known sRNAs by up to 1-2 orders of magnitude. Overall, profiling of human sRNAs using tSMS has detected large numbers of un-annotated RNA species, including the class PASRs. In addition, we report a novel class of sRNAs that contain a stretch of non-genomically encoded polyU residues at their 5' ends and are sense to the 5' ends and antisense to the very 3' ends of genes thus strongly suggesting that they are produced by copying polyadenylated RNA species using RNA-dependent RNA-polymerase like activity.

This data suggests that a portion of the vast complexity of sRNA populations can only be partially revealed by any single technology. In depth analysis of these results will be presented.

**Length of ORF, position of the first AUG and Kozak motif are important factors for possible dual-coding transcripts.** *X. Kong, H. Xu, P. Wang, Y. Fu, Y. Zheng, L. Hu.* Molec Gen, Inst Hlth Sci, Shanghai, China.

A single mammalian transcript normally encodes one protein. But the transcript of GNAS (G-protein alpha subunit)contains two reading frames and produces two structurally unrelated proteins, XLαs and ALEX. However, no other confirmed GNAS-like dual-coding transcript was reported up to now, even though several candidate genes were predicted by bioinformatics analysis. In this study, we constructed a series of vectors to test how two protein products could be translated with a single transcript in vitro. The length of ORF (open reading frame), position of first AUG and Kozak motif were found to be important factors. These factors as well as 55-bp NMD (nonsense-mediated mRNA decay) rule were used in our bioinformatics search for candidate dual-coding transcripts. 1307, 750 and 474 two-ORF containing transcripts were found in human, mouse and rat, respectively, of which 170, 89 and 70 were potential dual-coding according to our study. Most transcripts showed low conservation between those species. Additionally, the dual-coding transcripts were found to be significantly rich in transcripts of zinc finger protein family which are usually DNA-binding proteins involved in transcription process and regulation.

## 2483/T/Poster Board #1032

**Identification of human sphingomyelin synthase 1 (*SMS1*) gene splice variants.** *S.A. Limborska[1], A.V. Rozhkova[1], V.G. Dmitrieva[1], O.N. Zhapparova[2], E.S. Nadezhdina[2], L.V. Dergunova[1].* 1) Institute of Molecular Genetics RAS, Moscow, Russian Federation; 2) Institute of Protein Research RAS, Pushchino, Moscow Region, Russian Federation.

Recently sphingomyelin synthase 1 (SMS1) gene has been identified. The enzyme SMS1 occupies a central position in sphingolipid metabolism: it catalyses the conversion of ceramide and phosphatidylcholine to sphingomyelin and diacylglycerol (DAG). Since SMS1 was assumed to be involved in both cell death and survival by regulating pro-apoptic mediator ceramide and pro-survival mediator DAG it is of a great importance to investigate the regulation of SMS1 in the cell. To date we have found 12 new alternative transcripts of SMS1 gene using in silico and in vitro methods. Most of them differ from SMS1 mRNA in 5'-untranslated regions (5'-UTR). New-revealed 5'-UTRs are located in front of exon I and also between exons I and II, II and III, VI and VII. These exons were identified in SMS1 gene earlier. We also found alternative transcripts of this gene that include not-known before exons, situated between exons VII and VIII. Analysis with GENOMATIX software revealed several putative promoter regions adjacent to four new exons. Variations in levels of different transcripts between tissues were obtained by semi-quantitative RT-PCR. We presume that regulation of SMS1 gene functional activity is provided by using alternative promoters and synthesis of alternative mRNAs. It was shown that some of predicted open reading frames (ORFs) of new transcripts encode full-length SMS1 protein while others encode C- or N-terminal truncated forms of the protein. In particular circumstances the presence of different alternative transcripts of SMS1 gene may give rise to at least three different proteins. The cDNA containing ORF for C-truncated SMS1 isoform was cloned into the eukaryotic expression vector pEGFP-C2 and the resulting plasmid was used to transfect HeLa and Vero cells. It was demonstrated that C-truncated isoform localized to the Golgi complex like the full-length SMS1 isoform. We suggest that regulation of SMS1 gene function is provided at the level of transcription as well as at the level of translation.

## 2484/T/Poster Board #1033

**Recovery of Alu SINE *de novo* inserts in tissue culture.** *B. Wagstaff, A. Engel.* Tulane Cancer Ctr and Department of Epidemiology, Tulane Univ, New Orleans, LA.

A tissue culture assay for tagged Alu SINE retrotransposition has been in use for several years. However, recovery of *de novo* Alu integrants from this assay is extremely time consuming and data is very limited. A method for easy recover of L1 insertions has previously been developed. This approach relies on the introduction of a plasmid origin of replication that later is used in conjunction with a selectable marker to rescue circularized L1-containing genomic DNA in bacteria. However, the L1-construct could not be directly applied for the recovery of tagged Alu inserts. We developed an alternate construct that utilizes a similar approach to rescue inserts from a tagged Alu vector. This new Alu Rescue vector can be recovered from transfected HeLa cells following retrotransposition. We currently have recovered and analyzed multiple *de novo* integrants and report our findings here. Sequencing data revealed that recovered inserts faithfully mimic many aspects of Alu sequences present in the primate genomes, such as the presence of direct repeats and of 3' polyA tails. Alu insertions occurred randomly dispersed throughout the chromosomes. However several Alu inserts were localized in the A-tail of an existing Alu or L1 element. Overall this is a powerful technique with useful applications to analyze Alu insertion in cells with different genetic backgrounds.

## 2485/F/Poster Board #1

**Further delination of a 46,XX Disorder of Sexual Development in a syndromic presentation.** *P. Hurtado[1], H. Pachajoa[2].* 1) Genetist, Universidad del Valle, Cali, Colombia; 2) PhD student, Universidad del Valle, Cali, Colombia.

Case report We described a patient with multiple malformations, born of non consanguineous parents. No inconvenient is register in her pregnancy. Born by C section at 38 weeks of gestation. Length: 45 cms Weight: 2130 grs. At physical examination at birth it was noticed: unilateral cleft lip and palate and bilateral microphthalmia. He stayed at the NICU for 5 days because of this. In further examination it was found a congenital heart disease, bilateral inguinal hernia and bilateral cryptorchidism. He has had a global retardation and has not achieved the goals for his age. At the actual physical examination we found: short stature, low weight microcephaly, anteverted narins, bilateral hernia, "clenched-like" hand, left clef lip and palate, bilateral microphthalmia. Hypoplasic scrotum with no testicles in it. Bilateral inguinal hernia. He is hypertonic in arms and legs and has a speech delay. Paraclinics karyotype report 46, XX. Total testosterone: less than 10.00 ng/dl (241-827 normal range for men). Dehidroepiandrostenidione: less than 0.044 ug/ml. 17-Hydroxiprogesterone: 7.01 ng/ml. Echocardiogram: permeable oval foramen. At the pelvic magnetic resonance: there is no uterus, ovaries neither vagina. None prostate or seminal glands. There are penis, corpora cavernosa, and small scrotum. In the inguinal canal there are images suggestive of testicles. SRY pending. Discussion 46,XX testicular disorder of sex development (46,XX testicular DSD) is characterized by the presence of a 46,XX karyotype; male external genitalia ranging from normal to ambiguous; two testicles; azoospermia; and absence of Müllerian structures. Approximately 20% of individuals with 46,XX testicular DSD present at birth with ambiguous genitalia. We reported a patient with a syndromic 46,XX DSD due by the microphtalmia, but also with the cleft lip and palate and congenital heart disease. We didn't found a similar report in the literature. We consider this case of special interest.

## 2486/F/Poster Board #2

**CLINICAL AND CYTOGENETIC EVALUATION OF TWO CASES WITH WILLIAMS SYNDROME.** *L. Bobadilla-Morales[1,2], R. Silva-Cruz[1], C.E. Monterrubio-Ledezma[1], H.J. Pimentel-Gutierrez[1], A. Corona-Rivera[1,2].* 1) Lab. Citogenet G y B, Inst de GH DrECR, Dpto. Biol Molecular Genomica, Univ Guadalajara, CUCS, Guadalajara, Guadalajara, Jalisco, Mexico; 2) Unidad de Citogenética, Servicio de Hematología Oncología Pediátrica, División de Pediatría, Nuevo Hospital Civil "Dr. Juan I. Menchaca", Guadalajara, Jalisco, México.

Williams syndrome (WS) is caused by a hemizygous submicroscopic deletion in 7q11.23 including the elastin gene. WS shows dysmorphic facies, cardiovascular disease, mental retardation, a characteristic cognitive profile and idiopathic hypercalcemia. Case 1. Male, 7 years old. Both parents were healthy. Healthy pregnancy. Weigh birth 3500g. He shows developmental and speech delay. At examitation, height 112cm, cefalic perimeter 50cm, mouth 5.5cm. Triangular facies, stellate iris pattern, strabismus, anteverted nares, flat nasal bridge, oligodontia, hoarse voice, hypoplastic nails, attention deficit disorder and extroverted personality. Normal serum calcium (9.8mg/dl), IgE 149 UI/ml, normal hematic and thyroid function. He presents stenosis in pulmonary valve. Clinical evaluation from the American Academy of Pediatrics (AAP) score was 11 points. Karyotype, 46,XY,9qh-,21s+. FISH study was positive to WS microdeletion (LSI WSR Dc 7q11.2 and 7q31). Case 2. Female, 2 years old from healthy parents. The mother presented gestational diabetes. Caesarean delivery, APGAR 7/8, weight 4150gr, 50cm height. Physical examination at 5 months old: weight 4680 (-3.9 DE), height 58cm (-2.8 DE), cephalic perimeter 38.5cm (-2.46 DE), triangular facies, stellate iris pattern, depressed nasal bridge and wide, café au lait spots. Laboratory: serum creatinine 0.6mg/dl. serum calcium 10mg/dl, T3 1.75ng/ml, T4 2.6mcg/dl, TSH 3.3mU/ml. Subaortic interventricular communication with moderate pulmonary hypertension and persistent ductus arteriosus was observed by echocardiography at 2 months old. Kidney showed loss of differentiation corticomedular, multicystic renal dysplasia, bilateral hypotrophy renal. Cardiovascular surgery was performed at one year old. AAP score was 7. Karyotype, 46,XX,9qh+. FISH study was negative to WS deletion. WS represent a diagnostic challenge. Evolution, detailed clinical signs such as cardiological findings and AAP score helps to the WS diagnosis. Clearly positive score of 11 obtained from patient 1 is compatible with FISH positive WS deletion result. However in patient 2, who showed a positive score of 7, the FISH result was negative. In this patient cardiological alterations do not represent the most frequent cardiopathy but renal abnormalities and most of the clinical findings support WS diagnosis and the heterogeneity postulated to this patients.

## 2487/F/Poster Board #3

**Confirmation of a Distinct Phenotype Associated with Interstitial Long Arm Deletion of Chromosome 16q22.2→q24.1.** *M. Golabi[1], B. Hall[2], P. Cotter[3], S. Chan[1].* 1) Pediatrics Genetics, California Pacific Medical Center, San Francisco, CA; 2) Division of Clinical/Biochemical Genetics and Dysmorphology, Department of Pediatrics, University of Kentucky, Lexington, KY; 3) Children's Hospital and Research Center at Oakland, Oakland, CA.

Deletions of 16q are rare with few cases reported. We report a new case of interstitial deletion of chromosome 16; involving 16q22.2→q24.1, describe the clinical findings of the proband, review literature with similar deletion, and document a distinct and recognizable phenotype associated with this deletion. The proband was a full term female infant with birth weight 1950 grams, length 44 cm, and head circumference 30 cm. She had intrauterine growth retardation. She had high, broad forehead with recessed hairline, wide split metopic and sagittal sutures with large fontanelles, flat occiput, hypertelorism with epicanthal and lower canthal folds, upslanted palpebral fissures, significant lipoatropy of infraorbital regions, broad nasal bridge, anteverted nostrils, simple long philtrum, small mouth, one natal tooth, asymmetric cry, and micrognathia. Ears were dysplastic, triangular shaped, low set, and posteriorly rotated. She had a short neck with redundant tissue, small chest, wide set hypoplastic nipples, and atrial septal defect. There was significant cutis aplasia around the umbilical ring and diastasis recti. The infant had long, tapered digits with small nails, adducted thumbs, and fingers passively flexed with no camptodactyly. Her toes were long and held in flexion. There was an abnormal hair pattern with frontal and parietal hypotrichosis and body hypertrichosis. Skin was thin and hands were wrinkled. Neurological exam was noted for jitteriness, truncal hypotonia and appendicular hypertonia. The brain MRI and ophthalmological evaluations were normal. High resolution karyotype revealed a de novo interstitial deletion of 16q with breakpoints at 16q22.2 and 16q24.1. The oligonucleotide array CGH analysis showed a single copy number loss of 13.4 Mb of the region 16q22.2→q24.1. Follow-up at one month revealed poor feeding and poor growth. Review of literature revealed 2 cases with overlapping deletions involving 16q22.1→q24.1 and 16q22.3→q24.2. These 2 cases had identical clinical features to the proband including high forehead, large anterior fontanelle, diastasis of cranial sutures, broad and flat nasal bridge, hypertelorism, short and up slanted palpebral fissures, high arched eyebrows, dysmorphic and low set ears, natal teeth, micrognathia, flexed fingers, and abnormal position of toes. We confirm that there is a distinct phenotype associated with monosomy of 16q22.2→q24.1. Lipoatrophy and cutis aplasia should be sought for in future cases.

## 2488/F/Poster Board #4

**Interstitial microdeletion of 4p16.3: Contribution of *WHSC1* haploinsufficiency to the pathogenesis of developmental delay in Wolf-Hirschhorn syndrome.** *K. Kosaki[1], K. Izumi[1,2], H. Okuno[1,3], K. Maeyama[3], S. Sato[3], T. Yamamoto[4], C. Torii[1], R. Kosaki[1,5], T. Takahashi[1].* 1) Department of Pediatrics, Division of Medical Genetics, Keio University, Tokyo, Japan; 2) Center for Human Genetics, University Hospitals Case Medical Center, Cleveland, OH; 3) Department of Pediatrics, Saitama City Hospital, Saitama, Japan; 4) International Research and Educational Institute for Integrated Medical Sciences (IREIIMS), Tokyo Women's Medical University, Tokyo, Japan; 5) Department of Clinical Genetics and Molecular Medicine, National Center for Child Health and Development, Tokyo, Japan.

The critical interval for Wolf-Hirshhorn syndrome pheotype has been assigned to a region called WHSCR2 at chromosome 4p16.3. The pathological significance of the haploinsufficiency of the *WHSC1* gene, which is at the centromeric end of WHSCR2, remains unclear. Recently, a patient with the classical facial features of WHS who exhibited only a mild developmental delay and deletion involving WHSCR2 but with an intact *WHSC1* gene was reported in the journal. We here report a patient with WHS who had a comparable but distinctive deletion that disrupted the *WHSC1* gene and a severer degree of developmental delay. The documentation of a much severer developmental delay in the present patient, compared with the patient with intact *WHSC1* alleles, does not prove but does support the notion that *WHSC1* contribute to the severe developmental delays typically observed in patients with WHS. The recently elucidated biological role of a transcript of the *WHSC1* gene (*RE-IIBP*) as a histone H3 lysine 27 methyltransferase is compatible with this notion in that the histone modification of H3-K27 is an essential process in neuronal cell lineage specification. Fine-mapping of the extents of the deletions in more Wolf-Hirschhorn syndrome cases would be helpful to determine whether the disruption/retention of the *WHSC1* locus is predictive of the developmental outcome in patients with Wolf-Hirschhorn syndrome.

## 2489/F/Poster Board #5

**Postnatal diagnosis of trisomy 8 mosaicism after normal amniocentesis.** *S. Ramanathan[1], K. Kessler[2], P. Koduru[3], L. Mehta[4].* 1) Peds Genetics, Loma Linda Univ. Health Care, Loma Linda, CA; 2) Medical Genetics, Schneider Children's Hospital, Manhasset, NY; 3) Dept. Pathology, Schneider Children's Hospital, Manhasset, NY; 4) Dept. of Genetics and Genomic Sci, Mt Sinai SOM, New York, NY.

Constitutional trisomy 8 mosaicism (CT8M) is rare but known to be associated with a widely variable phenotype ranging from dysmorphic features and mental retardation to normal intelligence. Renal and cardiac defects are well documented. We report on two patients with normal amniocentesis karyotypes, diagnosed postnatally with CT8M. Patient 1 was evaluated at age 5 for global delays, hypotonia and prematurely gray hair. He had bushy eyebrows, high forehead and long, mildly upslanted palpebral fissures. Digits were unusual and tapered with prominent pads at the base, index finger clinodactyly and single transverse crease on the left hand. There was increased first-second toe gap on the left foot; right foot showed overlapping toes. Prior amniotic fluid chromosome analysis, done for maternal age, was normal. Blood chromosome analysis showed trisomy 8 in 4/30 cells. Patient 2 had abnormal prenatal ultrasound findings of bilateral hydronephrosis, ventricular septal defect (VSD), enlarged cisterna magna and questionable hemivertebrae. The pregnancy was complicated by maternal diabetes which was well controlled. Amniotic fluid chromosome analysis was normal. At birth, evaluation showed short upturned nose, full mouth, overfolded right ear and deep, single to bridged, palmar creases. Bilateral hydronephrosis and VSD were confirmed. X-rays of the spine were normal. Blood chromosome analysis showed trisomy 8 in 12/20 cells. Chromosome analysis on circumcised foreskin showed trisomy 8 in 9/20 cells. Both patients had deep plantar creases. Trisomy 8 mosaicism is caused by mitotic non-disjunction. Prenatal diagnosis is complicated by the higher distribution of abnormal cells in extra-embryonic mesoderm rather than in cytotrophoblasts and amniocytes. Therefore, fetal blood karyotyping may be necessary to evaluate for CT8M (van Haelst, 2001). Alternately array CGH may detect low-level mosaicism on amniocytes that may be missed by conventional cytogenetics (Wood, 2008). Our patients further illustrate the pitfalls of prenatal diagnosis. With regard to postnatal diagnosis, both our patients had minor dysmorphisms, but CT8 mosaicism was suspected by the deep plantar creases, which are highly suggestive of this diagnosis and prompted further evaluation even after a normal prenatal karyotype.

## 2490/F/Poster Board #6

**Survival of Down syndrome patients in Lithuania.** *A. Sinkus, L. Jurkeniene, I. Andriuskeviciute, L. Salomskiene, G. Sinkute.* Inst Biology, Lab Cytogenetics, Kaunas University of Medicine, Kaunas, Lithuania.

Every year the medical boards in Lithuania (with the population 3.4 million people)ascribe about 800 sixteen-year-olds to disablement groups, which makes 1.6% of the population. Half of these individuals, about 400 people, are disabled because of severe mental retardation. Each year in Lithuania 70 babies suffering from Down syndrome (DS) are born but at the age of 16 DS is diagnosed only for 12-16 individuals (1.8% of disabled patients, or 3.5% of mentally retarded patients). The specified reasons of death are usually non-informative in medical histories ("Down syndrome", "chromosomal disease"). In informative 100 certificates the following reasons of death were enumerated: bronchopneumony in 60 patients, acute respirative infection - in 4, staphylococcous infection -1, tuberculosis -2, congenital vitium cordis -20, other congenital malformations -4, leukemy -4, accidents -5. In our country we have registered 641 alive DS patients: 374 children under 16 years of age and 267 adults (two oldest patients were 48 years of age). We have made karyotype analysis in lymphocyte culture for 393 of them (61.3%). The chromosomal investigation has confirmed the diagnosis of DS in 372 (94,6%) patients. Normal karyotype was found in 19 (4.8%) patients.In two patients chromosome anomalies other than trisomy-21 were found. The karyotype in one 3-year-old boy was 49,XXXXY.The deeply mentally retarded boy had many malformations typical of DS patients. The other chromosome patient without trisomy-21 was 29-year-old mild mentally retarded woman in whose karyotype ring chromosome 9 was found. For both latter patients the physicians suspected DS. In two patients nearby trisomy-21 an additionally reciprocal translocations of other chromosomes were present. Therefore, in Lithuanian population false-positive diagnosis of Down syndrome was found in 5.3% of patients, i.e. markedly rarely as compared with analogical investigations in other countries. One of the reasons of such situation is the racial homogeneity of Lithuanian population presented almost exclusively by Caucasians. But in newborn Lithuanian babies the freguency of false-positive diagnoses arises up to 32.1%: among 134 patients with clinical diagnosis of DS the normal karyotype was found in 43. The main clinical feature - mental retardation - cannot be recognized in infants, and the neonatologists send the patients for karyotype analysys due to isolated microanomalies.

## 2491/F/Poster Board #7

**Proximal Deletion 1p36 syndrome identified by CGH array: A small (~2 MB) deletion extends the phenotype to include pupillary colobomas and preauricular pits.** *C. Bay, A. Rutherford, T. Bonilla.* Clinical Pediatric Genetics J415, Univ Kentucky, 740 S. Limestone Dr. Lexington, KY 40536.

Among our 4 patients with 1p36 deletions is a patient recently identified to have an apparently de novo 2 MB interstitial deletion of proximal 1p36, identified by CGH array (oligoV7.4 Baylor) with loss of 1p36.12p36.11. The clinical phenotype was not consistent with the classic 1p36 monosomy syndrome (Battaglia, 2008). This patient has features more consistent with the phenotype recently outlined by Kang et al (2007) and Rudnik-Schoneborn et al (2008), which is now called Proximal monosomy 1p36 syndrome. This patient, however, has a smaller, more proximal deletion than the few previously reported patients. Clinical features: 2 week old white male, born at term to a 20 year old G2P1 white female. Paternal age was 27 years. Pregnancy remarkable only for decreased fetal movements. No known teratogenic exposures. Birth length and weight both ~25-50 centile. Bilateral pupillary colobomas were appreciated immediately and were the indication for referral. PE at 2 weeks included: length 50th centile; weight 10th centile; OFC 50-75 centile. Features: hypertelorism, downslanting palpebral fissures, normally arched eyebrows, prominent nasal bone, unilateral preauricular pit, posteriorly angulated ears with overfolded superior helices, mild micrognathia with mildly pointed chin, increased skin of posterior neck, widely spaced nipples and mild 5th finger clinodactyly. Pertinent negatives: normal sized anterior fontanelle, normal arch to eyebrows, eyes not deep set; no brachy/camptodactyly. Echo: small VSD; Renal US: normal; CXR: normal; Parental FISH studies: normal. This patient extends the phenotype of Proximal interstitial 1p36 deletion syndrome to include pupillary colobomas and preauricular pits. He has a deletion which appears to be proximal to all previously reported cases known to us, and provides support for CGH array testing in neonates with colobomata and preauricular pits.

## 2492/F/Poster Board #8

**Cytogenetic and molecular study in patients with 22q11.2 deletion syndrome phenotype.** *S.I.N. Belangero[1], A.N.X. Pacanaro[1], D.M. Christofolini[1], F.T.S. Bellucco[1], L.D. Kulikowski[1], M.C. Cernach[2], C.M. Lourenço[3], C.A. Kim[4], A.M. Hacker[5], B.S. Emanuel[5,6], M.I. Melaragno[1].* 1) Genetics, Universidade Federal de São Paulo, São Paulo, São Paulo, Brazil; 2) Development Biology, Universidade Federal de São Paulo, São Paulo, Brazil; 3) Neurogenetics, Universidade de São Paulo, Ribeirão Preto, Brazil; 4) Children's Institute, Faculdade de Medicina da Universidade de São Paulo, São Paulo, Brazil; 5) Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, USA; 6) Department of Pediatrics, The University of Pennsylvania School of Medicine, Philadelphia, USA.

The 22q11.2 deletion syndrome (22qDS) is characterized by facial dysmorphism, cleft palate and heart defect. Its main etiology is a hemizygous deletion in chromosome 22 which occurs in about 1:4000 livebirths, making it the most common microdeletion syndrome. Most deletions (80-90%) are de novo alterations and the vast majority of patients (~90%) have the same 3Mb deletion. Although smaller deletions occur, they do not necessarily result in milder symptoms, making genotype-phenotype correlations difficult. We present a molecular and cytogenetic study of 74 patients with 22qDS phenotype, using classical cytogenetics, FISH-BAC (fluorescent in situ hybridization with bacterial artificial chromosome probes) using a TBX1 region probe, and MLPA (multiplex ligation-dependent probe amplification). The karyotypes appeared to be normal, while FISH analysis showed 17 deletions. The MLPA study, performed in 51 patients, revealed 16 deletions, of which 14 had the 3Mb deletion and one a 1.5Mb deletion. One patient presented two non-continuous deletions, a proximal one of 1.5Mb, and a distal one of 1.7Mb, separated by about 1.5Mb. Other regions associated with the 22qDS phenotype, such as 10p, 4q, 8p, and 17p, were also studied by MLPA and showed normal results for all patients, reinforcing that the 22q11.2 region is the main locus causing this phenotype. Forty-nine patients were studied by both approaches, MLPA and FISH, and all results were concordant. The overall deletion frequency (26%) was lower than reported in the literature, probably due to less strict clinical diagnosis criteria in our sample. One of the 17 deletions was inherited from the mother, revealing a 94% de novo deletion rate, which is similar to previous reports. We determined the size in 16 deletions, of which 87.5% were typical 3Mb deletions and 1.3% atypical deletions, in line with the literature that indicates 87% and 2%, respectively, although the 1.5Mb deletion frequency (1.3%) was lower than in the literature (7%). This kind of genetic investigation is important for an appropriate genetic counseling to the patients and their families. Further 22qDS clinical studies, using different approaches, can help in the diagnosis and in the establishment of genotype-phenotype correlations. Moreover, a better understanding of the disease pathogenesis can improve the prognosis and treatment of the symptoms, for a better quality of life and a longer life span of patients.(Financial support:FAPESP;CNPq).

## 2493/F/Poster Board #9

**Partial deletion of the BRAF gene is associated with a unique phenotype.** *W. Graf, s. Yu.* children's mercy hospital, kansas city, MO.

Background: The human BRAF gene contains 18 exons encoding a Braf protein with 766 amino acids. BRAF is a serine/threonine kinase involved in the RAS/RAF/MEK/ERK/MAPK pathway and the transduction of mitogenic signals from the cell membrane to the nucleus. BRAF is expressed in most tissues with high expression in neuronal tissue. Clinically, BRAF gene mutations cause a typical cardiofaciocutaneous (CFC) syndrome characterized by congenital heart defects, recognizable facial features, ectodermal abnormalities, and intellectual disability. Phenotype variants of CFC syndrome overlap with Noonan and Costello syndromes, which collectively include a heterogeneous spectrum of KRAS, BRAF, MAP2K1(MEK1) and MAP2K2(-MEK2)gene mutations. Methods: We screened the genome of a male infant with severe postnatal recurrent emesis, growth failure, mild non-specific facial dysmorphism, scoliosis, and severe diffuse developmental encephalopathy by microarray-based comparative genomic hybridization (aCGH). Results: We identified a novel 93 Kb genomic deletion of chromosome 7q34 (chr 7:140080282-140271033) involving the BRAF gene. The deleted region in our patient spans 3' part of first intron, exons 2-7, and 5' part of the seventh intron of BRAF gene. Clinically, the child shared some of the major features of CFC, Noonan, and Costello syndromes. However, the child in this report had sparse straight hair, normal cardiac function, and normal neuroimaging with postnatally acquired microcephaly. Conclusion: This is the first reported BRAF gene deletion. The partial BRAF deletion in this patient could represent a alternative genetic mechanism to point mutation leading to a unique phenotype with features overlapping CFC, Noonan, and Costello syndromes. This predicted truncated protein would not form heterodimers with its partner, RAF1, and would not bind to either upstream or downstream molecules as it does not contain any of the functional CR domains which are encoded by the missing exons. This suggests that the partially deleted BRAF gene may lead to the uunique clinical phenotype via loss-of-function of the BRAF gene. Other individuals with CFC syndrome without identified gene mutation by sequencing may have deletions of BRAF gene detectable by aCGH techniques.

## 2494/F/Poster Board #10

**The 22q13 Deletion Syndrome: An Under-Diagnosed Cause Of Severe Speech And Language Delay in Singaporean Children.** *A. Lai[1], E. Lim[2], M.H. Yong[3], L. Knight[3], E.C. Tan[2].* 1) Genetics Service, Dept of Ped Med, KK Women's and Children's Hospital; 2) KK Research Centre, KK Women's and Children's Hospital; 3) Cytogenetics Laboratory, KK Women's and Children's Hospital.

The 22q13 deletion syndrome is characterised by neonatal hypotonia, global developmental delay, delayed or absent speech, normal to accelerated growth and minor dysmorphism. Due to lack of clinical awareness, it is under-diagnosed and its prevalence unknown. The deletion can result from a simple chromosome deletion, an unbalanced translocation, or a ring chromosome. The critical region has been identified as the region containing the SHANK3 gene. Although the deletion can occasionally be detected by high resolution chromosome analysis, most cases require fluorescent in-situ hybridisation (FISH) analysis, multiplex ligation-dependent probe amplification (MLPA) or array comparative genomic hybridisation (aCGH) for diagnosis. We present two patients with this condition. Patient 1 is a 6-year-old girl who presented with the VACTERL association of congenital anomalies at birth, including cleft lip and palate, congenital heart defect, unilateral arm deformity and multicystic dysplastic kidneys. The 22q13 deletion was detected on FISH analysis that showed deletion of the ARSA (control) probe when performing a FISH analysis for the velocardiofacial syndrome (deletion 22q11.2). Patient 2 is a 5-year-old girl who presented at 2 years old with hypotonia and global developmental delay. The 22q13 deletion was detected by MLPA and confirmed by FISH analysis and aCGH. Both patients have mild dysmorphism, normal growth and marked speech delay. With increased awareness, we now consider this condition in the differential diagnosis of children with hypotonia, developmental delay, speech and language disability, autistic-like features, minor dysmorphism, and normal or accelerated growth. FISH analysis for confirmation of the diagnosis is available locally.

## 2495/F/Poster Board #11

**Silver-Russell Syndrome caused by a deletion encompassing *H19*.** *K. Gronskov[1], S.E. Boonen[1], J. Ek[1], B. Dolmer[2], K. Brondum-Nielsen[1].* 1) Kennedy Center, Glostrup, Denmark; 2) Pediatric dept., Naestved Hospital, Naestved, Denmark.

Silver-Russell syndrome (SRS) is characterized by pre- and postnatal growth retardation, facial dysmorphism and growth asymmetry. Recently, it has been discovered that approximately 35% of SRS patients show abnormalities in 11p15. Abnormalities at 11p15 can also cause the overgrowth syndrome Beckwith-Wiedemann syndrome (BWS) in 50-60% of cases. SRS and BWS thus seem to be opposite syndromes. 11p15 harbours two imprinting control regions, ICR1 and ICR2, which regulate the expression of 14 imprinted genes predominantly involved in growth. The H19DMR region in ICR1 contains 7 CTCF binding sites. This region is methylated on the paternal chromosome, which abolishes CTCF binding. This enables expression of the growth factor IGF2 and prevents expression of H19. From the maternal allele H19 is expressed whereas IGF2 is repressed. Several mechanisms can lead to BWS and SRS; BWS can thus be due to maternal microdeletion, paternal duplication or paternal uniparental disomy of 11p15, or isolated loss of methylation of KvDMR1 or isolated hypermethylation of H19. These defects lead to either loss of methylation of KvDMR1 or hypermethylation of H19 or both. Molecular mechanisms leading to SRS revealed so far are isolated loss of methylation of H19 and a single case of maternal duplication of 11p15 leading to loss of methylation of H19 and hypermethylation of LIT1. We present here a patient referred to us for SRS. Methylation sensitive MLPA analysis showed loss of methylation of H19DMR. Conventional MLPA analysis showed a deletion of H19DMR leaving CTCF binding sites 1-5 intact whereas the analysis showed deletion of CTCF binding site 7. It was not possible to determine whether CTCF binding site 6 was deleted. MLPA analysis using subtelomeric probes showed a normal result. Microsatellite analysis indicated that the deletion was paternally inherited. This is the first case to our knowledge of a deletion in 11p15 causing SRS.

## 2496/F/Poster Board #12

**New case of the recurrent 15q24 microdeletion presenting with hypotonia, tethered cord, and seizures.** *K. Herman[1], S.L. Davis[2], A.M. Hata[1].* 1) Genetics, UC Davis, Sacramento, CA; 2) Pediatric Neurology, Children's Hospital Oakland, Oakland, CA.

We present a 7-year-old Hispanic male with a history of hypotonia, developmental delay, seizures, and tethered cord. The patient is reported to have had hypotonia, muscle weakness, and poor balance since infancy. At age 5, he was noted to have increased urinary frequency and a decrease in balance and was found to have a tethered cord. In addition, this patient had onset of seizures at the age of 4 and is currently well controlled on medication. He is also noted to have sleep apnea and developmental delays. Based on these features, testing for a mitochondrial disorder was initiated at an outside institution and deletion studies were negative. Array CGH was also ordered and revealed a 15q24.1-q24.3 deletion. Parental studies have not yet been completed. Several reports in the literature have described this deletion and defined this region of chromosome 15q24 as a site of a recurrent microdeletion syndrome. Features reported include unusual facial features, developmental delay, microcephaly, digital abnormalities, genital abnormalities, and joint laxity. Our patient presented with tethered cord which has not previously been reported in individuals with this microdeletion. In addition, seizures have only been reported in one previous patient and hypotonia in our patient appears more significant that suggested in other cases. Finally, unusual facial features (high anterior hair line, broad medial eyebrows, hypertelorism, downslanted palpebral fissures, broad nasal base, long smooth philtrum and full lower lip) have been reported. This patient, however, presented with such mild facial dysmorphisms that a clinical diagnosis was not apparent. We suggest that this case further characterizes the phenotype of the recurrent 15q24 microdeletion syndrome.

## 2497/F/Poster Board #13

**Detection of uniparental disomy using linkage mapping set markers.** *A. Felton, J. Lee, A. Chhibber, B. Johnson, C. Davidson, D. Rodriguez, A. Pradhan, R. Padilla, R. Fish, S. Berosik, S. Hung, R. Petraroli, L. Joe.* Life Technologies, Foster City, CA.

According to Mendel's Law, a child inherits one set of alleles from each parent. However, there are some exceptions, as a few imprinted genes are expressed from alleles inherited from only one parent, either maternal or paternal. Uniparental disomy (UPD) occurs when an individual inherits both copies of a chromosome pair from only one parent and no copies from the other parent. Children with UPD 15, deficiency in the expression of imprinted genes from both parents on Chromosome 15, are subject to two genetic disorders, Prader-Willi syndrome (PWS) and Angelman syndrome (AS). DNA from potential candidates for PWS or AS can be screened using PCR and capillary electrophoresis (CE). DNA from the both parents and the child are evaluated using microsatellites, or STRs (Short Tandem Repeats) with fluorescently labeled primers. We demonstrate new CE and software methods for the comparison of the set of three DNA samples. Such methods could help in providing the researcher with automated results, consistent across a wide range of laboratory environments.

## 2498/F/Poster Board #14

**Phenotypic Spectrum in Waardenburg Syndrome Types I and II: Associations of Clinical Manifestations.** *D. Lin, S. Lin, H. Lin, H. Lee, H. Huang, M. Shu, C. Hsu, C. Chuang.* Dept Pediatrics, Mackay Memorial Hosp, Taipei, Taipei, Taiwan.

Waardenburg syndrome (WS), an inherited disorder, is characterized by a pigmentation anomaly, hearing impairment and various defects of neural crest derived tissues. Based upon the diagnostic criteria, eighty-six individuals from forty four families affected with WS are classified into WS type-1 (WS-1), and type-2 (WS-2) in about equal incidence. There are no evidences of statistically difference between the two groups with respect to hearing loss, iris pigmentary disorder, white forelock, skin hypopigmentation and other associated anomalies. However, WS-2 individuals are significantly more likely to having pigmentation disorders compared to WS-1 individuals in taking account of iris, hair and skin pigmentary disturbances as a whole. Among the clinical traits, iris pigmentary disorder is the most predominant manifestation with nearly a half composed of hypoplastic blue irides. Hearing loss, affecting a half of the WS individuals, is significantly associated with iris pigmentary disorder. Furthermore, the severity of hearing loss is significantly correlated with the extent of forms of iris pigmentary disorder. These results may suggest same mechanism in controlling both severity of deafness and extent of iris pigmentary disorder. The close relationship of hearing loss with iris pigmentary disorder may warrant further studies on molecular basis, as well as embryogenesis regarding mechanism in controlling melanoblasts formation and differentiation.

## 2499/F/Poster Board #15

**Moyamoya Syndrome with Concomitant Renovascular Disease in a Young Girl with Neurofibromatosis Type 1 (NF1). Should Patients with NF1 and Renal Artery Stenosis be Screened for Moyamoya?** *A. McGregor, D. Jones, S. Einhaus, E. Pivnick.* Pediatrics, University of Tennesse Health Science Center, Memphis, TN.

A young girl presented to the emergency room with a tick bite and was found to have severe hypertension. She was started on amlodipine and referred to Nephrology, where she complained of dizziness that began after starting amlodipine. She was noted to have cafe au lait spots. Renovascular hypertension and Neurofibromatosis Type 1 (NF1) were suspected. Her renal ultrasound appeared normal, but her plasma renin level was elevated. She underwent a renal angiogram, which revealed moderate to severe right renal artery stenosis. An angioplasty was successfully performed; subsequently, no anti-hypertensive medications have been required. She was referred to Genetics. Prenatal, birth, and family history was unremarkable. The physical examination revealed many cafe au lait spots and axillary freckling, but no other physical stigmata of NF1. Due to complaints of headaches, a MRI of the brain was performed. This showed increased vascular flow-voids in the perimesencephalic and medial sylvian regions concerning for early changes of distal carotid occlusive disease. Due to concerns about moyamoya syndrome, she was referred to Neurology. During the visit, she reported episodes of hand numbness and tingling with dropping of objects. This was concerning for possible transient ischemic attacks. Neurology ordered a magnetic resonance angiogram (MRA), which was consistent with possible moyamoya. She was referred to a neurosurgeon who recommended a cerebral angiogram. It showed severe stenoses of portions of the right anterior cerebral and middle cerebral arteries, occlusion of portion of the left anterior cerebral artery, and a moyamoya pattern of dilated collateral perforating vessels. Surgical intervention is planned. Moyamoya and renal artery stenosis are well-described complications of NF1 but the prevalence of co-occurrence is not known. We suspect that the patient became dizzy on amlodipine due to decreased cerebral perfusion. This case raises the question of whether screening for moyamoya is justified in patients with NF1 and renal artery stenosis, particularly if they have been having headaches and/or sensory symptoms. If moyamoya is present, a sudden decrease in blood pressure may result in stroke. We propose that the prevalence of the co-existence of renal artery stenosis and moyamoya in NF1 warrants further investigation as it impacts treatment of hypertension.

## 2500/F/Poster Board #16

**POLYMORPHISM ILE587VAL IN THE EIF2B5 GENE AS SUSCEPTIBILITY FACTOR IN MULTIPLE SCLEROSIS.** *C. Ungaro[1], F.L. Conforti[1], T. Sprovieri[1], M. Muglia[1], L. Citrigno[1], A.L. Gabriele[1], A. Gambardella[1,2], R. Mazzei[1].* 1) ISN-CNR, Mangone (CS), Cosenza, Italy; 2) Institute of Neurology, University "Magna Graecia", Catanzaro, Italy.

Multiple Sclerosis (MS) is a demyelinating disease of the Central Nervous System (CNS) due to genetic and environmental factors. It is a chronic progressive pathology characterized by a gradual destruction of myelin and neuron axons in the brain and spinal cord. The risk among the general population to develop MS is about 1/800. MS primarily affects adults, with an age of onset typically between 20 and 40 years, and is more common in women than in men (3:2, respectively). Mutations in EIF2B1-5 genes, encoding for the five subunits of eIF2B, cause the Vanishing White Matter Disease (VWMD) also known as Childhood Ataxia with Central Nervous System Hypomyelination (CACH) syndrome, an autosomal recessive leukoencephalopaty. The onset is usually between ages 2-6 with a rapid progression towards death during the early childhood; however, an adult onset form was been reported with slow progression and mild symptoms, mostly linked to mutations in EIF2B5 gene. Genetic and biochemical data of MS patients, just described, and MRI data showing VWM images similar to MS lesions, have encouraged the present study in which we performed the EIF2B5 gene mutational screening in 130 Italian MS patients and in 215 healthy subjects. The polymorphism Ile587Val in exon 13 resulted very common in the MS patients ($\chi 2$=14.439; p=0.0007). Therefore, the current data suggest that polymorphism Ile587Val in exon 13 of the EIF2B5 gene should be considered as susceptibility factor in the development of MS.

## 2501/F/Poster Board #17

**Polysplenia and cardiovascular defect heterotaxy in a tunisian girl born after a five years history of infertility related to non-syndromic asthenozoospermia.** *N. Abdelmoula, I. Trabelsi, R. Louati, S. Kammoun, T. Rebai.* Lab Histology, Univ Medicine, Sfax, Tunisia.

Heterotaxy is a clinically and genetically heterogeneous disorder characterized by disturbed body symmetry and malposition of internal organs. It is a developmental condition caused by the disturbance of the left/right axis, in the early embryonic period. Such development of left-right asymmetry requires ciliary motion at the embryonic node. Heterotaxy comprises a broad spectrum of abnormalities and typical manifestations include abnormal symmetry and malposition of the thoraco-abdominal organs and vessels, complex congenital heart disease and extracardiac defects involving midline-associated structures. Here, we describe a Tunisian female newborn with typical findings of heterotaxy syndrome. Cardiovascular defects include dextrocardia and abnormal pulmonary and systemic venous return like abnormal pulmonary venous connection into the coronary sinus, and interruption of the inferior vena cava, with azygos vein continua. Extracardiac defects involve polysplenia and a midline liver. There is no history of consanguineous marriage but record of male infertility for the newborn's father, related to non-syndromic asthenozoospermia. Ciliary structural abnormalities have been recently linked to heterotaxy with identification of mutations in 2 ciliary genes, DNAI1 and DNAH5. Screening for these two genes mutations will be made for our patient and results will be presented and discussed.

## 2502/F/Poster Board #18

**Hemochromatosis: a multigenic and multifactorial disease.** *G. Le Gac, C. Férec.* Inserm U613, EFS-Bretagne, Centre Hospitalier Universitaire; Brest, France.

With the recognition of five causative genes (HFE, HJV, HAMP, TFR2 and SLC40A1) and the presentation of the historic HFE p.C282Y/p.C282Y genotype as a necessary but not sufficient condition to explain an iron overload, position of hemochromatosis (HC) in the complex category of multigenic and multifactorial disorders is now indisputable. Different grades of severity can be attributed to the genetic heterogeneity of the disease, in particular when considering the respective roles of HC proteins in iron homeostasis. These grades range from the HJV and HAMP-related juvenile conditions to the typical adult-onset HFE-related condition, which is usually diagnosed in the fourth decade for men and the fifth for women. The iron overload course in TFR2-related patients is distinct from that of the juvenile conditions, but it can be more rapid and impressive than usually observed in HFE-related patients. Position of the SLC40A1 gene is more ambiguous. Indeed, depending of their impact on the ferroportin iron exporter (loss-of-function vs gain-of-function), mutations of this gene are responsible of different clinical syndromes (ferroportin disease vs HC type 4). Although definition of the p.C282Y/p.C282Y genotype penetrance is still a matter of debates, the expressivity of this predominant genotype clearly depends on a balance between accentuating and reducing factors. The influence of gender, age and lifestyle components, such as alcohol abuse, has been well documented. Involvement of modifier genes or epigenetic mechanisms is less obvious. It is clearly supported by several studies in Hfe knockout mice, but few data are currently available in humans. Overall, pointing that the ferroportin disease refers to a different iron overload syndrome, the large phenotypic heterogeneity observed in hemochromatosis can be viewed as a continuum. Based on certain of our works, and of a review of the literature, we aim to underline the elementary elements that must be considered in a diagnosis process for hemochromatosis. We also aim to justify the use of in vitro and in vivo assays for the characterization of rare mutants and the establishment of new structure/function relationships. Finally, we propose to discuss about the search for the p.C282Y mutation, supporting the idea that, in future, this test could be viewed as not sufficient for a genetic counseling and the organization of a familial screening.

## 2503/F/Poster Board #19

**Genetic and clinical profile of patients registered in the Brazilian Database on Orofacial Clefts.** *I.L. Monlleo[1], T.M. Felix[2], A. Fett-Conte[3], G.F. Leal[4], E.M. Ribeiro[5], J. Souza[6], F.M.P. Vicente[7], P.A. Mossey[8], V.L. Gil-da-Silva-Lopes[7].* 1) Department of Paediatrics, State University of Alagoas, Maceio, AL, Brazil; 2) Servico de Genetica Medica, HCPA, Porto Alegre, RS, BRAZIL; 3) Servico de Genetica da Faculdade de Medicina de Sao Jose do Rio Preto, SP, BRAZIL; 4) Centro de Atencao aos Defeitos da Face, Recife, PE, BRAZIL; 5) Servico de Genetica do HGCC, Fortaleza, CE, BRAZIL; 6) Centro de Atendimento Integral ao Fissurado labiopalatal, Curitiba, PR, BRAZIL; 7) Servico de Genetica Medica do Hospital de Clinicas, Unicamp, Campinas, SP, BRAZIL; 8) University of Dundee, Dental Hospital & School, Dundee, SCOTLAND, UK.

Introduction: Databases are useful tools to gather information not only for prevalence monitoring, but also for investigation of causes, prevention, evaluation of outcomes, and provision of expertise, education and training. On this basis, our team designed the Brazilian database on orofacial clefts (BDOC). The strategy was to start as a nation-wide, prospective, hospital-based, and multi-disciplinary database. Aim: To profile clinical and genetic aspects of persons with orofacial clefts recorded in the first phase of the BDOC. Methods: Seven clinical geneticists collected information using a structured case record form. Eligibility criteria were (a) patients with isolated clefts (CL, CLP and CP), (b) Pierre Robin sequence, (c) X-linked cleft, (d) multiple malformed subjects including orofacial clefts and (e) syndromes with orofacial clefts. Results: Data from 126 patients were recorded from November 2008 to May 2009. The ratio of male to female was 1.93:1. Age ranged from 30 days to 17 years. Clinical presentation was: 71 CLP (47 unilateral and 24 bilateral), 31 CP, and 23 CL (18 unilateral and 5 bilateral). Additional CFA was described in 34 patients whereas other birth defects in 21. Recurrence of clefts in relatives was verified in 33 cases. Conclusion: Clinical and familial characteristics seem to be similar to other populations described. Participation of clinical geneticists possibly improved accuracy of clinical and familial data recorded. The BDOC has the potential to become a clinical network suitable for studies on phenotype-genotype correlation, prevention and quality of healthcare. Support: CAPES, CNPq, Fapeal, Fapesp.

**Clinical variability associated with the chromosome 1q21.1 microdeletion: an additional case with previously unreported skeletal abnormalities.** *N. Dolzhanskaya[1], S. Reddy[2], N. Zellers[1], M. Velinov[1].* 1) Institute for Basic Research in Dev. Disabilities, Staten Island, NY; 2) Richmond University Medical Center, Staten Island, NY.

A 3 months old male infant was evaluated because of large anterior fontanelle, poor feeding and bilateral clavicular pseudoarthrosis. He was born at 36 weeks gestation. The birth weight was 6 lbs 8 oz. The pregnancy was complicated with polyhydramnios. Radiology exam showed bilateral clavicular pseudoarthrosis and 11 ribs. His mother had polycystic ovary syndrome. The child had relative microcephaly with very wide front fontanelle. He had dysmorphic facial appearance with hypertelorism, scarce eyebrows, micrognatia and high arched palate. His nipples were hypoplastic. Array CGH analysis was done using a commercial BAC based array and revealed a microdeletion at the chromosomal band 1q21.1. 244K oligonucleotide array analysis was done and the deleted region was further characterized to span about 2.7 Mb in the region chr1: 144,122,609-146,800,272 (NCBI build 36) and to include at least 40 coding genes. 25 patients with similar sub-microscopic deletion were recently reported. Our patient's deletion includes the 1.35 Mb minimal deleted region noted in the previously reported patients (chr1: 145,000,000-146,350,000 ,NCBI build 36). 1q21.1 microdeletion in the previously reported patients was variably associated with mental retardation, heart defects, joint laxity or cataracts. There was a significant proportion of asymptomatic patients. No skeletal abnormalities as in our patient were reported. However, no radiology evaluations were mentioned in the previously reported patients. Since the skeletal abnormalities in our patient may be asymptomatic later in life, they could be missed on clinical evaluations. Our report further underscores the great clinical variability of the phenotype associated with 1q21.1 microdeletion and may provide skeletal markers for prenatal diagnosis or suspicion for this recently described and apparently common chromosomal abnormality.

## 2505/F/Poster Board #21

**Impact of environmental factors during pregnancy on minor physical variants in nonsyndromic cleft lip with or without cleft palate (CL/P) families and controls.** *C. Brandon[1], K. Neiswanger[1], R.S. DeSensi[1], M.E. Cooper[1], A.E Czeizel[2], J.T. Hecht[3], M.L. Marazita[1].* 1) Dept Craniofacial & Dental Gen, Univ Pittsburgh, Pittsburgh, PA; 2) F Comm Ctl Hered Dis, Budapest, Hungary; 3) Univ Texas-Houston Med School, Houston, TX.

Exposure to environmental factors during the first trimester of pregnancy impacts the development of the fetus and is associated with birth defects, such as cleft lip and palate. Minor physical variants (MPVs) are congenital anomalies which may have a genetic basis, and also may result from environmental exposures during pregnancy. MPVs are morphological features of the body that are generally clinically insignificant. However, an increased number of MPVs may indicate a more serious condition. The goal of this study was to examine whether environmental exposures during the first trimester of pregnancy result in an increased number of MPVs in offspring. Additionally, we explored whether families with a history of a genetic condition (CL/P) and exposure to environmental insults during pregnancy have an increased number of MPVs compared to controls. Fifty-nine MPVs were assessed in 110 children from 64 mothers. Mothers were asked about their habits of smoking, alcohol consumption, and prenatal vitamin use during the first trimester of each pregnancy. Women who consumed alcohol during the first trimester had a significant increase of MPVs in their children ($p=0.02$). Smoking, as well as alcohol and smoking combined, were not significantly associated with increased number of MPVs in offspring. Vitamin intake was not related to a significant decrease in number of MPVs. The sample was further divided in to 3 groups: CL/P cases (n=56), non-cleft family members (n=40) and controls (n=14). The mean counts of MPVs in the 3 groups were not significantly different. Exposure to alcohol, smoking and vitamin use did not show significant impact on the number of MPVs between CL/P cases, non-cleft family members and controls. However, a non-significant trend was observed showing that non-cleft family members with an exposure to alcohol or smoking had the greatest number of MPVs; whereas controls with no exposures had the lowest number of MPVs. Our results support that exposure to alcohol during pregnancy may increase the number of MPVs in offspring. Our results suggest that increased MPVs are seen in non-cleft family members when also exposed to alcohol and smoking, even with a small sample size. Supported by NIH Grants R01-DE016148, P50-DE016215.

## 2506/F/Poster Board #22

**Developing a clinical genetics diagnostic approach to cleft lip and/or palate.** *E. Goh[1], R. Klatt[1], C. Forrest[2], D. Fisher[2], S. Bowdin[1].* 1) Division of Clinical & Metabolic Genetics, Hospital for Sick Children, Toronto, ON, Canada; 2) Division of Plastic Surgery, Hospital for Sick Children, Toronto, ON, Canada.

Cleft lip, with and without cleft palate, has an incidence of approximately 1 in 700 births worldwide, with a higher incidence depending on the ethnic population. Cleft palate alone has an incidence of approximately 1 in 2000 births. Multiple publications have been produced looking at the optimal way to address the various medical, social, emotional and counseling issues surrounding clefting. Many papers stress the importance of a multidisciplinary approach including the interaction of surgeons, speech pathologists, otolaryngologists, audiologists, geneticists, genetic counselors, and allied health professionals. From the perspective of clinical genetics, the main goal is to assess for other congenital abnormalities, as well as to determine an etiology if possible, in order to counsel the families about recurrence risk. However, with over 500 genetic syndromes associated with clefting of the lip, palate or uvula, not to mention the environmental exposures and chromosomal abnormalities that have been reported, the search for an etiology may be challenging. To this end, we have developed an algorithmic approach to cleft lip and/or palate with a focus on both syndromic and non-syndromic genetic causes. We have also developed clinic material to standardize the questions and examination in order to increase the efficiency and accuracy of genetic diagnosis in the clinic environment. We present a pilot study of 50 index patients seen over an intensive one month period at the Hospital for Sick Children using this algorithm to streamline the clinical experience. Our results support the literature indicating the majority of cases are non-syndromic and isolated, however the range of syndromic diagnoses made emphasizes the utility of genetic evaluation and genetic counseling in seemingly isolated cases. The use of a systemic algorithm as an approach to cleft lip and/or palate has beneficial effects in the clinical environment as well as potentially as an educational aid for patients, trainees and educators alike.

## 2507/F/Poster Board #23

***Fgfrl1* null mice have reduced expression of *Tpm3* and other sarcomere genes in the diaphragm.** *N. LopezJimenez[1], S. Gerber[2], B. Trueb[2], A. Slavotinek[1].* 1) Pediatrics, Univ California, San Francisco, San Francisco, CA; 2) Dept. of Clinical Research, University of Bern, Switzerland.

*Fgfrl1* (also known as *Fgfr5*) homozygous null (-/-) mice have thin, amuscular diaphragms and die at birth because of an inability to inflate their lungs. The myofibers of the diaphragm are normal, suggesting that reduced muscle cell migration or proliferation in the diaphragm causes the diaphragm hypoplasia. Fgfrl1 forms constitutive homodimers and is thought to promote cell adhesion mediated by heparan sulphate. Fgfrl1 also binds Fgf2, a potent stimulator of muscle cell proliferation. We hypothesized that patients with diaphragm defects (DD) would have sequence variants in *FGFRL1* that reduced gene expression and altered diaphragm thickness. We sequenced the coding exons and exon-intron boundaries of *FGFRL1* in 100 patients with DD, confirming six known, coding SNPs: c.209G>A (p.P20P), c.977G>A (p.P276P), c.1040C>T (p.D297D), c.1120C>A (p.P362Q), c.1306G>T (p.R424L), and c.1426C>T (p.P464L). We found no novel sequence alterations. The allele frequency for the 6 coding SNPs did not differ significantly between patients with DD and patients with craniosynostosis or normal controls ($p>0.05$). However, one patient with a DD and a 4p16.3 deletion including *FGFRL1* was hemizygous for the minor allele for 3 of the 6 SNPs on the remaining 4p16.3 allele, raising the possibility that the DD was related to the 4p16.3 deletion, with the minor alleles of the SNPs further reducing *FGFRL1* expression. We then hypothesized that genes involved in muscle formation would be differentially expressed between *Fgfrl1* wildtype mice and -/- mice. We used RNA from the diaphragms of *Fgfrl1* wildtype and -/- mice and Affymetrix Genechip Mouse Gene 1.0 ST arrays, and found 8 genes with significantly reduced expression levels ($p<0.05$) in -/- mice compared to wildtype mice - *Tpm3*, *Fgfrl1* (as expected; $p = 0.004$), *Myl2*, *Lrtm1*, *Myh4*, *Myl3*, *Myh7* and *Hephl1*. Interestingly, *Tpm3* is mutated in patients with nemaline myopathy, in which diaphragm hypoplasia is recognized. *Myl2*, *Myh7* and *Myl3* encode sarcomeric proteins and are mutated in hypertrophic and dilated cardiomyopathy. We consider that the diaphragm hypoplasia is likely to be caused by reduced Fgfrl1 levels, either associated with decreased heparan sulphate and Fgf2 binding with reduced muscle cell proliferation, or associated with reduced myoblast adhesion and diaphragm thinning. Alternatively, the decreased levels of the muscle-related genes seen in our expression arrays could reflect the diaphragm hypoplasia seen in the -/- mice.

## 2508/F/Poster Board #24

**Minor physical variants in nonsyndromic cleft lip with or without cleft palate (CL/P) families and controls.** *K. Neiswanger[1], C.A. Brandon[1], R.S. DeSensi[1], K. T.Cuenco[1], A.E. Czeizel[2], J.T. Hecht[3], M.L. Marazita[1].* 1) Dept Oral Biol, Univ Pittsburgh Sch Dent Med, Pittsburgh, PA; 2) F Comm Ctl Hered Dis, Budapest, Hungary; 3) Univ Texas-Houston Med School, Houston,TX.

Minor physical variants (MPVs) are physical traits such as strabismus or single palmar creases that occur as part of the normal variation in a population. However, they may also be increased in individuals with clinically significant birth defects or in disorders like schizophrenia. Furthermore, individuals with multiple MPVs are at increased risk for a major anomaly. The Pittsburgh Oral Facial Cleft study assesses MPVs in multiplex CL/P families and controls, to determine if the overall rate of MPVs is increased in cleft families, compared to controls. We analyzed two sets of MPVs: 1) MPVs that occurred with a frequency of less than 20% of our sample (N= 59 MPVs), and 2) MPVs occurring in less than 5% of our sample (N=32 MPVs). The sample included 279 individuals (126 male, 153 female) from Pittsburgh, PA, Budapest, Hungary, and Houston, TX. More than 98% of the sample were Caucasians; <2% were African-Americans or biracial. There were 82 individuals with nonsyndromic CL/P, 150 non-cleft family members, and 47 controls with no family history of clefting. When MPVs that occurred at a frequency of <20% were considered, the entire sample had an average of 3.48 MPVs (CL/P cases: 3.37; non-cleft relatives: 3.65; controls: 3.15; NS). For the less common set of MPVs that occurred at a frequency under 5%, the average number of MPVs in the sample was 0.85 (CL/P cases: 0.80; non-cleft relatives: 0.95; controls: 0.62, NS). The number of subjects without any MPVs did not differ significantly between CL/P families and controls [for MPVs < 20%: CL/P cases 10/82 (12%), non-cleft relatives 22/150 (15%), controls: 6/47 (13%); for MPVs < 5%: CL/P cases 43/82 (52%), non-cleft relatives 79/150 (53%), controls: 29/47 (62%)]. When sub-groups of MPVs were examined using two-tailed t tests, there were no significant differences in the mean number of hand/arm, foot/leg, or limb MPVs between CL/P subjects, family controls, and pure controls for either the common or the rarer set of MPVs. There was a trend toward more head MPVs in family controls than in unrelated controls (MPVs <20%: $P = 0.10$; MPVs <5%: $P=0.08$), although this was not maintained for the MPVs <5% when the data were log transformed due to non-normality in the data. In general, we did not find an increase in MPVs in either individuals with CL/P or their non-cleft relatives. Larger samples are needed to verify these results. NIH grants R01-DE016148, P50-DE016215.

## 2509/F/Poster Board #25

**Stormorken syndrome: Confirmatory report in a French family.** *G. Morin[1], A. Hazard[1], B. Roméo[2], B. Demeer[1], A.G. Le Moing[1], J.C. Capiod[3], E. Bourges-Petit[4], H. Sevestre[5].* 1) Clinical Genetics, Amiens University Hospital, France; 2) Pediatric Pneumology, Amiens University Hospital, France; 3) Hematology, Amiens University Hospital, France; 4) Pediatric Cardiology, Amiens University Hospital, France; 5) Pathology, Amiens University Hospital, France.

In 1985, Helge Stormorken reported a new syndrome associating thrombocytopathia, muscle fatigue, asplenia, miosis, migraine, dyslexia and ichthyosis. This affection segregated in a Norvegian family with an apparent autosomal dominant transmission on 4 generations. The physical characteristics were documented in a teen-aged boy and his mother: small stature, deep set eyes, high and arched forehead, permanent miosis without efficiency of mydriatic drugs and decreased darkness vision. A bleeding tendency was demonstrated, including hematomas, frequent nose bleedings but no major hemorrhagic accident. Hematologic investigations exhibited consistently prolonged bleeding time, normal coagulation, presence of giant platelets and various abnormal forms of red cells with Howell-Jolly bodies in the peripheral blood. The spleen was absent in both patients explaining the post-splenectomy aspect of the red cells. The muscular defect consisted in limitation during physical exercise and an abnormally increased duration of muscle response. Ichthyosis was mainly located in the extremities. Both patients suffered from headaches with photophobia. Dyslexia was early diagnosed for the affected son, responsible of learning disability, but less severe for his mother. From that time, this disease was only reported in a Japanese mother and daughter, who both presented muscle weakness, moderate increasing of creatine kinase rates and thrombocytopenia. Muscle biopsy showed fibre necrosis and regeneration, variation in fibre size, and tubular aggregates in approximately 5% of the fibres. We report the observation of a young boy and his father. At 17 days of life the baby presented an urticaria-like eruption on the face and the lower limbs. Blood count revealed thrombopenia (48000/mm3) but the myelogram was normal. During the hospitalization, he presented an episode of supraventricular tachycardia requiring a treatment with acebutolol and amiodarone. The father had small stature (157cm), high pitched voice, chronic eruption of the arms and shoulders partially regressive after anti-mycosic treatment, and a severe but reactive miosis responsible of impairment of darkness vision. He also presented asplenia and moderate thrombocytopenia (97000/mm3). At the age of 2 years and half, a less severe miosis became more apparent in the son. Peripheral blood examination revealed anisocytosis, the presence of macrothrombocytes, Howell-Jolly bodies and prolonged bleeding time.

## 2510/F/Poster Board #26

**Genitopatellar syndrome: A further delineation or a new association?** *L.E. Becerra[1,2], R. Valenciano[3], D. Morales[2], L. Chacón[2], E. Monroy[2], M. Díaz[1], J.J. Toscano[1], J.E. García[1], M.L. Ramirez[1].* 1) Division de Genética, CIBO-IMSS, Guadalajara, Jalisco, Mexico; 2) Centro de Rehabilitación Infantil Teletón (CRIT), Chihuahua, Chihuahua, Mexico; 3) Escuela de Medicina, CUCS-U de G, Guadalajara, Jalisco, Mexico.

Introduction. Genitopatellar syndrome (OMIM 606170) is clinically featured by the association of absent/hypoplastic patellae, genital anomalies, mental retardation, agenesis of the corpus callosum, flexion deformities of the knees and hips, club feet, and hypogonadism. Clinical report. A male, 6 years-old was sent to the Clinical Genetics due to MCA. He was product of the second pregnancy (G2, P2) of healthy non-consanguineous parents. At birth: weight 2400 g, height 44 cm, and Apgar score 9-10. The following malformations were recorded: umbilical hernia, ventricular septal defect, right cryptorchidism, hypospadias and poor swallowing. Psychomotor development was notoriously delayed. Physical examination: OFC 38.2 cm, height 116 cm, weight 21 kg. Microcephaly, turricephaly, prominent metopic, bitemporal narrowing, round face, down-slanting palpebral fissures, blepharophimosis, telecanthus, low nasal bridge, bulbous tip of the nose, submucous cleft palate, prominent upper lip, prognathism, posteriorly rotated and easily foldable ears, left preauricular pit, bilateral retroauricular notches, short neck with redundant skin back, slim thorax, holosystolic murmur of low intensity, increasing inter-nipple distance, left microorchidism, limitation to extension in upper limbs, bilateral digitalized thumbs, hyperconvexed nails, lower limbs with small and dislocated patella, popliteal folds and limitation to extension, and bilateral club foot. Karyotype was normal (46,XY). X-ray, showed in thorax a fusion costal on 6-7th, and bilateral tibia vara. MRI demonstrated pachygiria, and hypoplasia of corpus callosum. Discussion. Among differential diagnosis the following syndromes were discharged: Goldblatt syndrome (OMIM 241760), which has not coarse face, limbs contractures, and neurological migration alterations. Fryns-Aftimos syndrome (OMIM 606155) was ruled out due to the absence of polydactyly, notoriously affected nose and webbed defects on limbs and neck. Multiple pterigium syndrome (OMIM 265000) was no considered because of the lacking of cranio-neurological affectation, and distinctive expressionless face. Bibliography. Online Mendelian Inheritance in Man, OMIM. Goldblatt J; Wallis C; Zieff S. A syndrome of hypoplastic patellae, mental retardation, skeletal and genitourinary anomalies with normal chromosomes. Dysmorph. Clin. Genet 1988: 2:91-93.

**MELAS syndrome: Mexican Case Report.** *R. E'Vega[1, 2], L. Sandoval[3], A. Franco[4], C. Galván[4], M. González[5], M. Islas[6], A. Rincon[7], N. Dávalos[2,7, 8, 9].* 1) Instituto de Genética Humana, UdeG, Guadalajara, Mexico; 2) Doctorado en Genetica Humana, Centro Universitario de Ciencias de la Salud, Universidad de Guadalajara, Mexico; 3) Genetica, Centro de Investigacion Biomedica de Occidente, Guadalajara, Mexico; 4) Carrera de Medicina, Centro Universitario de Ciencias de la Salud, Universidad de Guadalajara, Mexico; 5) Neuropediatria Hospital Regional "Dr. Valentin Gomez Farias" ISSSTE, Guadalajara, México; 6) Departamento de Fisiología, UdeG, Guadalajara, Mexico; 7) Instituto de Enfermedades Crónico Degenerativas, UdeG, Guadalajara, Mexico; 8) Instituto de Genetica Humana, Departamento de Biologia Molecular y Genomica CUCS UdeG; 9) Unidad de Medicina Genomica y Genetica, Hospital Regional "Dr. Valentin Gomez Farias" ISSSTE, Guadalajara, México.

**INTRODUCTION** MELAS (mitochondrial myopathy, encephalopathy, lactic acidosis and stroke-like episodes) syndrome, described by Pavlakis in 1984, is a genetically heterogeneous mitochondrial disorder. It can be caused by mutation in several genes: MTTL1, MTTQ, MTTH, MTTK, MTTS1, MTND1, MTND5, MTND6 and MTTS2 It can be accompanied by central nervous system disorders such as seizures, hemiparesis, hemianopsia, cortical blindness and episodic vomiting. Phenotype is variable. Presentation occurs with the first stroke-like episode, usually at aged 4-15 years. **CASE REPORT** 15 year-old Mexican male, born in Tepic, Nayarit from non consanguineous parents. Onset at age 8 with grand mal seizures accompanied by continuous vomiting, without sphincter relaxation. Phenitoine prescription until now, presenting approximately 4 seizures each month despite the treatment. Physical exploration at age 13 reveals CP 51 cm (P 10), height 137 cm (< 3 P), weight 34kg (P 10), SS 146 cm, IS 67 cm, brachycephaly, normal auricular pavelions, wide nasal base, long philtrum, asymmetric thorax, apparent left hypoplasia, general muscular hypoplasia, lumbar hyperthricosis, and genu valgum. The rest of the physical exploration is normal. Radiography shows bilateral degeneration of femoral heads. Electromyography does not show evidence of polyneuropathy, however the diagnosis of a myopathy is not left aside due to the presence of increased polyfacetic potentials and diminished insertion potentials. Laboratorial studies reveal lactic acidosis. **DISSCUSION** Differential diagnosis with other mitochondrial encephalopyopathies such as Leigh syndrome, Kearns- Sayre syndrome, MERF syndrome and Leber optic atrophy should be considered.

## 2512/F/Poster Board #28

**DNA Resequencing and Variant Identification Using a Non-syndromic X-linked Mental Retardation (MRX) Panel.** *C. Davidson[1], F. Bartel[2], R. Santhanam[1], E. Nordman[1], B. Johnson[1], R. Padilla[1], R. Fish[1], L. Joe[1], S-C. Hung[1], A. Pradhan[1], A. Felton[1], M. Friez[2].* 1) Applied Biosystems, 850 Lincoln Centre Dr, Foster City, CA 94404; 2) Diagnostic Laboratories, Greenwood Genetic Center, One Gregor Mendel Circle, Greenwood, SC, 29646.

The prevalence of X-linked mental retardation (XLMR) is estimated to afflict approximately 1/1000 males. To date, there have been approximately 90 X-linked genes implicated in causing XLMR with the majority of these genes being associated with syndromal MR (MRXS). A smaller set of genes on the X chromosome have been associated with nonsyndromal MR (MRX) where the only discernible feature is mental retardation/intellectual disability. Significant overlap between these two sets of genes indicates that syndromal and nonsyndromal can both be caused by alterations in many of the XLMR genes. From a clinical perspective, proper diagnosis of males with nonsyndromal XLMR is more straightforward when a positive family history exists. Unfortunately, many undiagnosed males with MRX exist, and the absence of an X-linked pedigree makes the identification of their underlying etiology much more difficult. Indicative of this difficulty is that MRX accounts for roughly 2/3 of the total number of XLMR cases. To test for MRX, the Molecular Diagnostic Laboratory at the Greenwood Genetic Center has designed a resequencing panel consisting of 95 amplicons encoding the exons and intron junctions of nine X-linked genes (*ACSL4*, *ARX*, *FTSJ1*, *GDI1*, *IL1RAPL1*, *JARID1C*, *OPHN1*, *PQBP1*, and *ZNF41*) based on their precedent for being the most common MRX genes in the literature at the time of selection. To demonstrate the advantages of a new capillary electrophoresis (CE) instrument, nineteen blinded probands suspected of having MRX were directly sequenced using the Greenwood MRX resequencing panel. Variant detection in the nine genes across the nineteen samples was performed and no truncating mutations were identified. The gene with the most frequent non-synonymous SNPs was *ZNF41*; two non-recurrent (I125R and D397E) missense variants and one recurrent (D315E) missense variant were identified in *ZNF41*. A non-recurrent missense variant (R1546Q) was identified in *JARID1C* and a recurrent missense variant (V39I) in *OPHN1*. Bioinformatic analysis predicted all identified non-synonymous SNPs to be benign changes with minimal impact on respective protein's function. Further, a single non-recurrent in-frame indel was identified in the gene *ARX* (A111del)-.The MRX Resequencing Panel coupled to the new Fast Resequencing Workflow highlights the advantages of using CE for DNA resequencing and variant identification across a large number of samples and genes.

## 2513/F/Poster Board #29

**Novel FLNB mutation in a child with complex congenital heart disease and skeletal features of atelosteogenesis, type III.** *G.A. Bellus[1], B. Kahn[2], R.S. Lachnan[3], D. Krakow[4], S. Gulley[1].* 1) Genetic & Metabolic Services, Dep. Pediatrics University of Colorado, Aurora, CO; 2) Fetal Maternal Medicine, Dept. Obstetrics & Gynecology University of Colorado, Aurora CO; 3) Ahmanson Dept Pediatrics, Cedars-Sinai Research Instittute, Dept Radiology, David Geffen Sch Medicine, UCLA, Los Angeles, CA; 4) Ahmanson Dept Pediatrics, Cedars-Sinai Research Instittute, Depts of Orthopedic Surgery, Huamn Genetics Obstetrics & Gynecology, David Geffen School of Medicine, UCLA, Los Angeles, CA.

Mutations in FLNB are known to cause at least five clinically distinct disorders: autosomal dominant Larsen syndrome (LS), Atelosteogenesis, type I (AOI), Atelosteogenesis, type III (AOIII), Boomerang dysplasia (BD) and Spondylocarpotarsal synostosis syndrome (SCTSS). LS, AOI, AOIII and BD have overlapping skeletal features, vary in clinical severity ranging from LS (least severe) to AOI and BD (most severe) and are caused by FLNB missense mutations that occur in highly conserved regions of the FLNB protein. The majority of FLNB mutations that cause AOI, AOIII and BD are localized to exons 2 and 3 that comprise the CH2 domain of the N-terminal actin binding region. Mutations causing LS occur predominantly within the filamin B beta sheet repeats 14 and 15 (exons 28 and 29). However, this association is not exclusive and there is overlap between phenotypes and regional localization of FLNB mutations. Congenital heart disease is not considered to be a feature of AOI, AOIII or BD but some cardiac features (mitral valve prolapse, aortic dilation, and atrial and ventricular septal defects) have been reported in LS patients. We present a case of a new-born male who presented with cleft palate, facial dysmorphism, complex congenital heart disease (pulmonary atresia with hypoplastic R heart physiology) and skeletal findings consistent with AOIII. Sequencing of FLNB revealed a novel mutation (4912G>T / Val1638Phe) within exon 29. FLNB Val1638 is highly conserved among species and this mutation is highly likely to be pathologic. This patient represents the first report of complex congenital heart disease in a patient with an AOIII phenotype and suggests that FLNB beta sheet repeat domains play some role in cardiac embryogenesis.

## 2514/F/Poster Board #30

**Frontometaphyseal dysplasia: severe phenotype in two sisters.** *I. Furquim[1], M. Passos-Bueno[2], S. Robertson[3], C. Kim[1], D. Bertola[1].* 1) Unidade de Genética, Instituto da Crianca, Sao Paulo, Brazil; 2) Instituto de Biociências, USP, São Paulo, Brazil; 3) Departament of Paediatrics and Child Health, Dunedin School of Medicine, Dunedin, New Zealand.

Frontometaphyseal dysplasia (FMD) belongs to a group of overlapping dysplasias called the otopalatodigital syndrome (OPD) spectrum disorders, that comprises besides FMD, otopalatodigital (OPD) syndromes type 1 and 2, and Melnick-Needles syndrome (MNS). The skeletal dysplasia observed in these conditions consists of varying degrees of undertubulation of the long bones, cortical irregularities and campomelia. Extra skeletal malformations observed are CNS abnormalities, cleft palate, cardiac defects, omphalocele, mixed deafness and obstructive uropathy. The common molecular basis is mutations in FLNA , the gene encoding filamin A. Mutations reported to date are missense or small in-frame deletions, that are exert a gain-of-function effect. Most pedigrees are consistent with X-linked inheritance. In males, severity ranges from mild to more severe presentations and females exhibit variable expressivity. Here we report on two sisters affected with FMD presenting with prominent supraorbital ridges, hypodontia, mild joint contractures of the fingers and normal intelligence. Radiological studies showed undermodeled long bones and pronounced supraorbital hyperostosis. The father had cutaneous syndactyly of the third and the fourth fingers of the left hand and the second and the third toes of his left foot. X-ray revealed mildly undermodeled long bones. A daughter from a previous relationship had similar facial appearance. The molecular analysis of the FLNA gene in both affected sisters disclosed a novel heterozygous c.6611C>T mutation which leads to p.P2204L. Nevertheless, this gene alteration was not found in blood leukocytes from the father. The residue is conserved in all three filamins, which suggests that this mutation is responsible for the phenotype observed in the sisters. Contrary to what is frequently observed in FMD, in which females are usually less severely affected than related affected males, in the family here reported the father had a very mild phenotype. This presentation is consistent with mosaicism for the causative mutation in the father, which has been described in the overlapping OPD and Melnick-Needles syndromes. Examination of other tissues, besides blood, in the father will be performed to confirm this hypothesis.

## 2515/F/Poster Board #31

**Geleophysic dysplasia is a clinically and genetically heterogenous disease.** *P. Piccolo[1], J. Hicks[2], V. Fano[3], S.A. Caino[3], M.G. Obregon[3], M. García-Barcina[4], J. Tolmie[5], S.K. Brunetti-Pierri[1].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, USA; 2) Department of Pathology, Baylor College of Medicine, Houston, TX, USA; 3) Hospital J. P. Garrahan, Buenos Aires, Argentina; 4) Unidad de Genética, Hospital de Basurto Avda, Bilbao, Spain; 5) Institute of Medical Genetics, Yorkhill Hospital, Glasgow, UK; 6) Jules Stein Eye Institute, University of California, LA; 7) Howard Hughes Medical Institute, Houston, TX, USA.

Geleophysic dysplasia (MIM 231050) is a rare autosomal recessive disorder characterized by short-limb dwarfism, brachydactyly, and a 'happy-looking' facial appearance. It is frequently associated with cardiac valvular disease although the incidence and natural history of the heart complications remain unclear. Mutations in the *ADAMTSL2* gene resulting in a dysregulation of TGF-β signaling have been recently recognized as responsible for this condition. We have screened for *ADAMTSL2* mutations ten cases of geleophysic dysplasia diagnosed on the basis of clinical and radiological findings. Pathogenic mutations were found in only two cases suggesting that additional and yet unknown gene(s) are involved in the pathogenesis of the disease. Short stature and brachydactyly were present in most of the cases while laryngeal stenosis, cardiac disease, and Perthes disease were variably present. Taken together, these findings show a significant clinical variability and are consistent with a broad disease spectrum. In 3 of 4 cases in which skin fibroblasts were available, we detected by electron microscopy cytoplasmic lysosome-like inclusions which have been previously reported as a characteristic finding of the disease. In summary, the clinical and molecular findings in our patients show that geleophysic dysplasia is a clinically and genetically heterogenous condition.

## 2516/F/Poster Board #32

**Absence of choroidal neurofibromas, a suggestive sign for multiple café-au-lait spots unrelated to NF1?** *K. Fukai[1], T. Oshimo[1], Y. Imai[2], K. Shiraki[3], M. Ishii[1].* 1) Dept Dermatology, Osaka City Univ, Osaka, Japan; 2) Dept Orthopaedic Surgery, Osaka City Univ. Osaka, Japan; 3) Dept Ophthalmology, Osaka City Univ. Osaka, Japan.

The presence of multiple café-au-lait spots is most often associated with neurofibromatosis type 1 (NF1), but can be also part of the manifestation of McCune Albright syndrome, ring chromosome syndrome and Watson syndrome. However, some of the patients with multiple café-au-lait spots lack any of the associated anomalies of the above and thus are called familial multiple café-au-lait spots (MCAL). The etiology of MCAL is still unknown, but three linkage analyses of MCAL excluded the locus of NF1. Here, we describe a patient with multiple café-au-lait spots without choroidal abnormalities. A 28-year-old woman with café-au-lait spots was referred for evaluation as NF1. She had more than six large café-au-lait macules on her chest, abdomen, back, and extremities. Small pigmented freckles were also present on the trunk and the extremities, sparing on the axillaes. No skin tumors were found. X-ray and MRI examination showed no abnormalities of the skull, the spine, and long bones of the extremities, the spinal code, and the central nervous system. Ophthalmological examination revealed no Lisch nodules, and no choroidal abnormalities. She had no family history of pigmentary disorders or neurofibromatosis. The patient is an intelligent and attractive lady, and has no associated signs for systemic disorders. We concluded that the spots are highly probably not related to NF1. The frequency of choroidal neurofibromas in NF1 was once thought to be rare. However, the development of infrared light examination with a scanning laser ophthalmoscope allowed ophthalmologists to examine choroid non-invasively, and Yasunari et al studied 17 cases with NF1 and reported that the frequency was as high as 100%. Furthermore, Nakakura et al. examined 14 NF1 patients and found that the choroidal abnormalities were detected in all of the 14 case, 28 eyes. Inversely, choroidal abnormalities suggestive for neurofibromas were not observed in non-NF1 patients so far. Considering the extremely high specificity and sensitivity of the choroid neurofibroms for NF1, choroidal neurofibroma may be included in the future diagnostic criteria for NF1. The test is non-invasive and rapid, and thus the patients with multiple café-au-lait spots should be tested for possible choroidal neurofibromas.

## 2517/F/Poster Board #33

**NOTCH3 GENE MUTATIONS IN TWINS WITH CADASIL.** *R. Mazzei[1], C. Ungaro[1], F.L. Conforti[1], D. Guidetti[2], A. Magariello[1], A. Patitucci[1], G. Di Palma[1], A. Gambardella[1,3].* 1) ISN-CNR, C.da Burga, Mangone (CS), Cosenza, Italy; 2) UOC di Neurologia, Ospedale Guglielmo da Saliceto, Piacenza, Italy; 3) Institute of Neurology, University "Magna Graecia", Catanzaro, Italy.

Background: CADASIL is an autosomal dominant disorder leading to cognitive decline and dementia. Mutations in the NOTCH3 gene, encoding a transmembrane protein involved in cellular signalling and cell differentiation, are responsible. These highly stereotyped mutations are located within the 22 exons, encoding for the 34 Epidermal Growth Factor (EGF)-like repeats of the extracellular domain of the Notch3 receptor, all mutations resulting either in a gain or loss of a cysteine residue. Therefore it has been suggested that the unpaired cysteine residues, generated by these mutations may cause aberrant interaction of the Notch3 receptor with its ligand. Objective: In the present study we examined the NOTCH3 gene exons in two couples of twins from two different families with clinical and radiological findings consistent with CADASIL. Patients and method: After clinical examination the patients underwent MRI investigation, and then they were analyzed for mutations in the NOTCH3 gene using the DHPLC analysis and direct sequence. Conclusion and discussion: In the first couple of dizygotic twins, DHPLC analysis revealed a variant profile in exon 11. Sequencing of the exon 11 showed a nucleotide change that lead an amino acid substitution at position 578 (R578C), resulting in a gain of a cysteine residue. In the second couple of monozygotic twins a variant DHPLC profile was found in the exon 10. Subsequently, the sequencing analysis showed a nucleotide change leading a gain of a cysteine residue in position 528 (G528C). Despite carrying the same mutations, the two couples of twins showed a variable clinical phenotype. The remarkable discrepancies in the clinical manifestation of the disease, also noticed in twins, suggests a strong influence of other inheritability and environmental factors.

## 2518/F/Poster Board #34

**SOS1 gene mutation in a patient with a Costello-like phenotype.** *D. Bertola[1], A. Brasil[1,3], A. Jorge[2], A. Malaquias[2], L. Wanderley[3], L. Albano[1], I. Furquim[1], A. Pereira[3].* 1) Pediatrics, Instituto da Crianca, Sao Paulo, Brazil; 2) Endocrinology, HCFMUSP, Sao Paulo, Brazil; 3) Molecular Biology Laboratory, InCor, HCFMUSP, São Paulo, Brazil.

Costello syndrome (CS) is a developmental syndrome of RAS/MAPK pathway desregulation, encompassing failure to thrive, dysmorphic craniofacial features, cardiac and neurological abnormalities and a predisposition to papillomata and malignant tumors. It has been suggested that CS should be a diagnostic label that applies only to those patients with a HRAS gene mutation, which is responsible for the great majority (<80%) of the cases. Nevertheless, a Costello-like phenotype was described in patients presenting KRAS gene mutations. So far, mutations in SOS1 gene are responsible for Noonan syndrome (NS) and, possibly, for some cases of cardiofaciocutaneous syndrome. In the former, the patients commonly show ocular ptosis, curly hair and hyperkeratotic skin and lower frequency of mental retardation, when compared to the ones with PTPN11 mutation. We report on a 24 year-old patient with a clinical diagnosis of CS. He presented with severe developmental delay/mental retardation, behavioral problems, failure to thrive, relative macrocephaly, ventriculomegaly, coarse facial features, short neck, pectus exacavatum, congenital heart disease, cryptorchidism, repaired inguinal hernia, darker skin compared to other family members, keratosis pilaris and markedly loose skin, with deep palmar and plantar creases and important hyperextensibility. Molecular studies of the RAS/MAPK pathway genes disclosed a c.806T-C (p.M269T) in the SOS1 gene. Analysis of the HRAS and KRAS genes were normal. This SOS1 gene mutation was previously described in two typical NS patients. Contrary to what is currently recognized that SOS1 gene is involved primarily in typical NS patients, our report emphasizes that some atypical findings, such as, striking loose skin and an unusual cardiac involvement, could be part of the spectrum of SOS1 gene mutations. Moreover, although is common sense that HRAS is the main gene in CS, in the absence of mutations in this particular gene, KRAS gene and, now, SOS1 gene should be analyzed in these patients. The underlining genetic mechanism has implications in the follow-up of these individuals, once those presenting HRAS gene mutations has a higher risk of tumor development. Supported by FAPESP grants - 08/50184-2.

## 2519/F/Poster Board #35

**Severe facial deformity in an adolescent girl with a novel variant in POLH gene causing Xeroderma Pigmentosum.** *A. RAAMS[2], N. LEBOEUF[1], H. SHUHAIBER, HANS H.[3], E. GUZMAN[3], M. GARZON[1], N. JASPERS[2], K. ANYANE-YEBOA[3].* 1) DEPARTMENT OF DERMATOLOGY, COLUMBIA UNIVERSITY MEDICAL CENTRE, NEW YORK, NY; 2) DEPARTMENT OF GENETICS ERASMUS MEDICAL CENTRE,ROTTERDAM, NETHERLANDS; 3) DEPARTMENT OF PEDIATRICS, COLUMBIA UNIVERSITY MEDICAL CENTRE, NEW YORK,NY.

Xeroderma pigmentosum (XP) is an autosomal recessive disease characterized by sun sensitivity, early onset of freckling and subsequent neoplastic changes on sun-exposed skin. We describe an 18 -year -old El Salvadorian female with a reported history of XP complaining of progressive severe facial pain and difficulty swallowing. She reported a history of progressive vision loss with complete blindness for one year. She lost her ability to eat over the days because of progressive destruction of her maxilla and mandible.The patient was diagnosed clinically with XP at the age of seven, when she developed a skin cancer on the right cheek which was treated with an unknown non-surgical method. The patient's family history was remarkable for an affected 12 -year -old brother, two cousins alive with symptoms of disease and one who died at the age of 13 with presumed disease. Her entire central face was destroyed by tumor, with displacement of the right globe and consumption of the left. CT scan confirmed the presence of a massive deformity of the facial anatomy, encompassing the ocular structures with associated osseous and sinus destruction. Genetic studies revealed a normal nucleotide excision repair capability and moderate cellular UV-sensitivity compatible with a diagnosis of XP variant. In the POLH (polymerase eta) gene and cDNA, we found an insertion in exon 6 at codon 225: a C is changed into TT causing a frameshift. Apparent homozygosity in both cDNA and genomic sequences and absence of heterozygote polymorphisms in introns 4-7 are compatible with parental consanguinity.The POLH gene is located on chromosome 6p21.1- 6p12 spanning 40 kb of DNA; it comprises 11exons covering the entire coding sequence .The corresponding mRNA, 2432 bp in size, has an open reading frame of 2139 bp. Since the discovery of POLH, a considerable number of mutations of this gene have been described to be associated with the XPV ( Xeroderma Pigmentosum phenotype). Our case underscores the severity of symptoms associated with this newly designated variant XP21NY causing a frameshift mutation at codon 225. Further studies are currently underway to genetically test other family members being affected. More studies are needed to correlate this genotypic variant with the severity of thE phenotypic presentation, affecting several family members at the same time.

## 2520/F/Poster Board #36

**Correlation of a novel FBN1 mutation (c.5225 -2 A>C) with isolated ectopia lentis in a Chinese patient.** *J. Du, S.F. Li, L.Y. Li, G.X. Lu.* Reprod & Stem Cell Eng, Central South University, Changsha, HN., China.

Mutations in FBN1 gene causes Marfan syndrome (MFS;OMIM 154700) as well as other fibrillinopathies such as isolated ectopia lentis(EL; OMIM 129600), MASS syndrome(OMIM 604308), Weill- Marchesani syndrome(OMIM 608328) and Shprintzen-Goldberg syndrome(OMIM 182212). In this study, we aimed to analyze the correlation between FBN1 mutation and isolated EL in a Chinese patient with isolated EL. The 10-year-old boy suffered from myopia since he was 5. His naked visual acuity in the left and right eye were 0.2 and 0.1, respectively, and best corrected visual acuity,0.5 and 0.2, respectively. The slit lamp examination showed that his left lens dislocated to nasal side and right lens to upper nasal side. The ultrasonographical diagnosis showed that the axial length of the left eye was 22.66mm, and that of the right eye was 22.59mm with bilateral vitreous and retina appearing normal. The ratio of the patient's arm span to height was 147/146(<1.05). The patient was not found other skeletal features or cardiovascular disorders. His parents were nonconsanguineous and in good health. Five microliter peripheral blood was collected in EDTA from the patient and his parents, and the genomic DNA was extracted from the leukocytes by the standard method. The 65 exons and flanking intronic sequence of FBN1 gene were amplified by PCR. Mutation screening of the PCR products was performed using denaturing high-performance liquid chromatography (dHPLC) and those PCR products with heteroduplex chromatogram were followed by further DNA sequencing. The dHPLC result showed a heteroduplex chromatogram of the 42th exon PCR product in the patient but not in his parents. The subsequent sequencing analysis showed that the patient carried a heterozygous mutation, c.5225 -2 A>C in the splice 3' acceptor site of the 41 th intron in FBN1 gene, while his parents didn't have this mutation. As we know, the mutation c.5225 -2 A>C has not been reported in the previous studies. The alteration of AG to CG in the splice site between the 41 th intron and the 42th exon would lead to frameshift mutation and form a truncated fibrillin-1 protein, which causes abnormal suspensory ligament development and imbalant tensile strength, and finally results in displacement of lens. In summery, our data indicated that the novel mutation, c.5225 -2 A>C in FBN1 gene might be an etiological cause of isolated EL. The study also provided a basis of genetic counseling and the further prenatal diagnosis.

**Characterization of disease phenotypes in a multi-generational family segregating a MECP2 A140V mutation.** *J. Gorski, R.M. Troxell, J.L. Kussmann.* Div. Medical Genetics, Dept Child Health, Univ Missouri School of Medicne, Columbia, MO.

Mutations in the gene encoding methyl-CpG-binding protein 2 (MECP2) result in Rett syndrome, a severe neurodevelopmental disorder predominantly affecting females. In males, MECP2 mutations cause a variety of disease phenotypes including severe neonatal encephalopathy, severe hypotonia and mental retardation. MECP2 A140V mutations are somewhat unique in not causing Rett syndrome in females but causing neurodevelopmental disease in hemizygous males. Several reports have documented the association of A140V MECP2 mutations in males with neurodevelopmental abnormalities; however, the reported number of affected individuals is small and the phenotype remains poorly defined. Here, we report a four generation family that segregates the A140V MECP2 mutation in six affected males and four female carriers. Each affected individual carries a MECP2 C>T transition at nucleotide 419 resulting in an A140V missense mutation in the MECP2 methylated DNA-binding domain. Affected males ranged from 3 to 43 years of age. Younger affected males display hypotonia, seizures, tremors, developmental delays, and aggressive and mild autistic-like behavior. Older males display mental retardation, a progressive parkinson-like disorder, spastic quadriparesis, and macro-orchidism. Carrier females were not mentally retarded. However, they did display a variety of neurological and psychiatric problems including depression, obsessive-compulsive disorder, attention-deficit hyperactivity disorder, learning difficulties, and memory loss. To our knowledge, this is the largest kindred to be described segregating the MECP2 A140V mutation. We believe that these cases confirm the previous observation that MECP2 A140V mutations adversely affect hemizygous males, and expand our understanding of the disease phenotype in both hemizygous males and heterozygous females.

## 2522/F/Poster Board #38

**Recurrent erythema nodosum in a patient carrying a mutation in the Mediterranean fever gene (MEFV).** *M. Michelson-Kerman[1,2], C. Vinkler[1,2], I. Nezer[1], D. Lev[1,2].* 1) Inst Med Genetics, Wolfson Medical Ctr, Holon, Israel; 2) Maccabi Health Sevice, Wolfson Medical Ctr, Holon, Israel.

Erythema nodosum (EN)is a painful disorder of the subcutaneous fat, and it is the common type of panniculitis. The disorder is characterized by tender, nodular lesions located on the anterior aspects of the lower extremities. The process is considered to be an immunologic response and may serve as a marker for systemic diseases such as inflammatory bowel disease, tuberculosis, sarcoidosis, bacterial or deep fungal infection and cancer. Certain antibiotics, oral contraceptives and pregnancy may also be associated. The condition is usually self-limiting and specific treatment is seldom needed in uncomplicated cases. We present an unusual recurrent course of erythema nodosum in a 35 year old woman who is a carrier of a mutation in the MEFV gene. A 35 year old, generally healthy, non-pregnant, woman from Sephardic Jewish ancestry, had suddenly developed moderately painful palpable nodules on the anterior aspects of the lower extremities. Diagnostic evaluation included normal blood count, erythrocyte sedimentation rate and normal liver functions. C-reactive protein, antistreptolysin O-titer, blood cultures and tuberculosis test were negative. Chest radiography was normal. The symptoms exacerbated despite treatment with nonsteroidal anti-inflammatory drugs. Clinical improvement appeared after two courses of corticosteroid therapy,which is unusual for common EN course. Mutational analysis of the MEFV gene revealed a heterozygous E148Q mutation. Familial Mediterranean fever (FMF) is an autosomal recessive disease characterized by recurrent attacks of fever with serosal inflammation. The MEFV gene encodes the protein pyrin that plays an important role in modulating the innate immune response. MEFV mutations have been identified primarily in patients from Mediterranean populations and in Israel the carrier state is as high as 1 in 5. Although the clinical spectrum and genetic alteration in FMF is variable,erythema nodosum has never been described as a presenting sign of FMF especially in patients with a heterozygous mutation. Heterozygous mutations in the MEFV gene have been described in association with certain diseases such as Henoch-Schonlein purpura, rheumatoid arthritis and other autoinflammatory disorders and are are considered to be modifying factors. We suggest that MEFV, and particularly the E148Q mutation, is an important susceptibility factor and an independent modifier for the clinical manifestation of erythema nodosum in our case.

## 2523/F/Poster Board #39

**Lipomatosis familial benign cervical (BCFL). A familial case report.** *EJ. Ramirez[1,2,3], SE. Totsuka-Sutto[1,3], TA. García-Cobían[1], L. García-Benavides[1], D. Román-Rojas[4], EG. Cardona-Muñoz[1].* 1) Unidad de Investigación Cardiovascular, CUCS, Departamento de Fisiología, Univ Guadalajara; 2) Dpto de Genética, Instituto Jalisciense de Cirugía Reconstructiva, Secretaria de Salud Jalisco; 3) Instituto de Genética "Dr. Enrique Corona Rivera", CUCS; 4) Doctorado en Farmacología, CUCS, Univ. de Guadalajara. Gudalajara, Jalisco, México.

Lipomatosis familial benign cervical (BCFL) (151800 OMIM) is a rare disease characterized by the presence of multiple, symmetric, non encapsulated lipomas in the face, neck, shoulders, supraclavicular and deltoid region, abdomen, groin, and buttocks. There are multiple synonyms for this disorder such as Lipodystrophy cephalothoracic, Multiple symmetrical lipomatosis, Madelung's disease and Launois-Bensaude syndrome because they described this nosologic entity in 1888 and 1889. It seems more frequent in countries around the Mediterranean Sea. Is usually described in adults from 30 to 60 years old, with 1 in 25,0000 incidence and a male-to-female ration of 15-30:1. Most cases have no hereditary pattern, familial occurrence has been reported and autosomal dominant mode of inheritance has been postulated. The ethiology remains unknown but more of 90% have associated alcoholism and they have features of metabolic syndromes such as diabetes mellitus, hyperlipidemia and hyperuricemia. We describe a 48-years old male, who was referred to plastic surgery by multiple symmetric lipomas in face and neck. At physical examination showed normal weight and height, neck collar of fat, lipomatosis on face and shoulders, muscle cramps and extensor plantar reflexes. Eight relatives were found with variable affectation. Our patient and his relatives presented a typical fatty tissue accumulation. The present case show a family with BCFL supported on the clinical data (lipomas in the face, neck and shoulders) and nuclear magnetic resonance in the patient and different grade of severity of affectation in all eight family members. Male-to-male transmission wasn't observed but the autosomal dominant inheritance cannot be discarded.

## 2524/F/Poster Board #40

**A Recurring Mutation G12S in HRAS causes Variable Ocular Phenotype in Costello Syndrome.** *S. Shankar, K. Rauen.* Medical Genetics, Dept of Pediatrics, Univ California San Francisco, San Francisco, CA.

Costello syndrome is a rare developmental disorder characterized by failure to thrive, neurocognitive delay, distinctive facial features, cardiac involvement, musculoskeletal and cutaneous features. These patients have about 15% lifetime risk for developing malignant tumors. Costello syndrome is caused by missense mutations in the gene *HRAS*, with the Gly12Ser substitution accounting for >80% of all individuals with a known mutation. *HRAS* belongs to the Ras oncogene family encoding products of the Ras/MAPK signal transduction pathway. Dysregulation of the Ras/MAPK pathway results in a number of syndromes (referred to as RASopathies) with significant phenotypic overlap. A number of ocular features have been described in RASopathies. We sought to analyze the ocular features in a cohort of 35 mutation positive Costello individuals, 32 harboring the G12S mutation, two with the G12A mutation and one with the G13C mutation. We analyzed available medical information and parental reports for these patients. The age group of the patients ranged from 2 to 37 years. Ocular involvement was reported in 33/34 (97%) patients; 1 patient had not yet had an eye exam and another had no reported eye issues. Significant ocular features included strabismus 16/34 (48%); refractive errors 19/34 (55%) with myopia (14/19) occurring significantly more than hyperopia (2/19), type of refractive error unknown (3/19); nystagmus 12/34 (35%) and optic nerve anomalies in 4/34 (0.12%). One individual with G12A reported nystagmus and the second individual with G12A had nystagmus, myopia and esotropia. The individual with G13C reported nystagmus, and optic atrophy. Although, the remainder of the 31 patients had identical *HRAS* mutation G12S, the ocular features were variable. The high occurrence of myopia, nystagmus and strabismus suggests that *HRAS* plays an important role in human eye development and in ocular alignment. Variation in the phenotype caused by the same HRAS mutation, G12S suggest the role of other modifying factors such as genetic or environmental. Routine ophthalmic evaluation is recommended to improve the visual outcome by early interventions. In addition, a number of investigations on therapeutics targeting the Ras/MAPK pathway are underway. Further characterization of the ocular manifestations in a larger number of mutation positive Costello patients is important to clearly define the ocular phenotype, and to develop potential treatment strategies.

## 2525/F/Poster Board #41

**Branchio-Oto-Renal syndrome: a review of the phenotypic spectrum based on 18 patients.** *J. Hogue[1], L. Hudgins[2], E. Chen[1], L. Bird[3], A. Slavotinek[1].* 1) University of California San Francisco; 2) Stanford University; 3) University of California San Diego.

Branchio-Oto-Renal syndrome (BOR; OMIM 113650) is a condition characterized by branchial clefts, hearing loss, and renal anomalies. *EYA1* mutations are the most common etiology. The *EYA1* product is part of the Six-Eya-Dach network where a DNA-binding protein binds Eya1 enabling transcriptional activation. Consistent with this, mutations in *SIX1* and *SIX5* have also been found in BOR patients. Given *EYA1*'s function in a network, we hypothesized that manifestations of BOR may be broader than previously reported and that there may be a genotype-phenotype correlation.

We reviewed 18 patients with BOR. Hearing impairment was the most common manifestation (14/18, 78%). Branchial arch anomalies, preauricular pits, and outer ear anomalies were each seen in 72% of the patients. Renal anomalies were present in 50%. Other anomalies were facial asymmetry (4/18, 22%), ear tags (3/18, 17%), inner ear anomalies (3/18, 17%), palate abnormalities (2/18, 11%), and lacrimal duct stenosis (2/18, 11%). Anomalies found in single patients included ankyloglossia, congenital hip dysplasia, eye pterygium, thyroid nodules, torticollis, vocal cord paralysis, and mental retardation.

*EYA1* mutations were found in 3 of 5 patients. Two mutations, p.R407Q and p.D429G, reportedly cause classic BOR, and a c.1604delAAA was found in a male with BOR, abnormal ossicles and a facial palsy. An additional patient was found to have a deletion including *EYA1* by array CGH.

Two of our patients had findings outside of the usual BOR phenotypic spectrum. A 38 year old woman had congenital hip dysplasia, an eye pterygium, and a goiter in addition to common BOR features and had the p.R407Q *EYA1* mutation. A 19 year old man had intellectual impairment, short stature, cleft lip and palate, hypertelorism, an upper eyelid coloboma, a broad neck, and single transverse palmar creases in addition to common BOR manifestations. The cause of his BOR has not yet been determined, with normal *EYA1* sequencing.

In conclusion, BOR is a genetically heterogeneous condition. We have described the features of 18 patients with a clinical diagnosis of BOR and include anomalies not previously associated with BOR.

## 2526/F/Poster Board #42

**Phenotypically different presentations in 2 patients resulting from RECQL4 gene compound-heterozygous mutation.** *A. Nakatomi[1], K. Yoshioka[2], Y. Ushiroda[1], T. Hasuwa[1], H. Kuniba[1], K. Nakashima[1], H. Motomura[1], K. Motomura[1], A. Kamitamari[2], Y. Nakashita[2], N. Okamoto[4], T. Kondoh[3], H. Moriuchi[1].* 1) Pediatrics, Nagasaki University , Nagasaki city, Nagasaki prefecture, Japan; 2) Pediatrics,Sasebo General Hospital,Sasebo city, Nagasaki prefecture,Japan; 3) Division of Developmental Disability, the Misakaenosono Mutsumi Developmental, Medical, and Welfare Center, Isahaya city,Nagasaki prefecture, Japan; 4) Department of Planning and Research, Osaka Medical Center and Research Institute for Maternal and Child Health,Izumi city,Osaka.

Baller-Gerold syndrome (BGS; OMIM #218600) is a congenital condition characterized by craniosynostosis and radial dysplasia or hypoplasia. RECQL4 gene, the only causative gene of BGS, has also been associated with Rothmund-Thomson syndrome (RTS; OMIM #268400) and RAPADILINO syndrome (OMIM #266280), both of which have some clinical features overlapping with those of BGS. We detected RECQL4 gene compound heterozygous mutations in 2 patients who had considerably different clinical features. The first patient is an 11-month-old boy. He was born at overterm of 42 weeks and 2 days of gestation with birth weight of 1984g as the first child of unrelated parents. He had severe intrauterine growth retardation(IUGR), coronary craniosysnotosis,bilateral radial defect, absence of both thumbs, midfacial hypoplasia, cleft palate, low-set ears, auditory ossicle hypoplasia, imperforate anus, rectourethral fistula,left renal aplasia and congenital heart defect. He also presented growth delay and motor retardation at 11 months of age. Thus, he had typical clinical presentations for BGS. Direct sequencing of his RECQL4 gene revealed compound heterozygous mutations: c.423delG, p.K141fsX38 in exon 5 and c.1569delC, p.S523fsX34 in exon 9. The second patient is a 9-year-old boy. He was born at preterm of 32 weeks and 3 days of gestation with birth weight of 924g as the first child of unrelated parents.He had severe IUGR, hypoplasia of his right-sided thumb, midfacial hypoplasia,hypertelorism, sparse eyebrows, micrognathia, pear-shaped nose, and low-set ears at birth. He never had craniosynostosis. At age 4, he was referred for short stature and hyperpigmented skin. Endocrinological and hematological tests ruled out endocrinal dysfunction and Fanconi anemia, respectively. Re-evaluation of his minor anomalies gave suspicion of BGS/RTS complex condition. Direct sequencing of his RECQL4 gene revealed compound heterozygous mutations: c.1136G>A, p.W379X in exon 6 and c.1569delC, p.S523fsX34 in exon 9. Thus, although these 2 cases had similar mutations on the RECQL4 gene, their clinical presentations were considerably different. RECQL4 gene abnormality has been associated with several clinical conditions that are considered as different clinical entities with partially overlapping features. However,it may be more appropriate to regard all these conditions as one clinical entity resulting from the same gene mutations.

## 2527/F/Poster Board #43

**Late presentation of autosomal dominant congenital hyperinsulinism due to GCK gene mutation.** *M.A. Potter[1,2], L. Brick[2], J. Vandermeulen[2].* 1) Dept. of Laboratory Medicine, Hamilton Health Sciences, Hamilton, Ontario, Canada; 2) Dept. of Pediatrics, Hamilton Health Sciences, Hamilton, Ontario, Canada.

Congenital hyperinsulinism (CH) usually presents in the neonatal period with symptoms of hypoglycemia. Both autosomal recessive and autosomal dominant modes of inheritance have been described for many of the genes that have been implicated in CH. Alterations in the GCK gene (OMIM 138079), coding for glucokinase, have been shown to be a rare cause of hyperinsulinism. Mutations in this gene more commonly are associated with congenital diabetes, with heterozygous mutations causing MODY2 and homozygous mutations causing the more severe permanent neonatal diabetes. Here we describe a 1-year-old male who presented with hypoketotic hypoglycemia associated with an intercurrent illness. Initial blood-work showed the glucose to be 1.6 mmol/l with insulin 53 pmol/l (43-194 pmol/l) and growth hormone <1 mmol/l. Sustained hypoglycemia on intravenous glucose was associated with continued inappropriate insulin secretion, low growth hormone and absence of ketones (beta-hydroxybutyrate <0.02 mmol/L). Urine organic acids and plasma acylcarnitines were normal. Family history revealed that the child's father had been admitted to hospital from 3 months of age to 2 years of age for "low blood sugar problems" that were medically managed. The father is obese and has migraines when he doesn't eat regularly. Some of his siblings report symptoms consistent with fasting hypoglycemia as well. Work-up for growth hormone deficiency and hyperinsulinism in our patient was undertaken, and therapy was started with both growth hormone and diazoxide. MRI of the pituitary was normal and no pathogenic mutations were found in the genes more commonly associated with congenital hyperinsulinism (ABCC8 and KCNJ11), although a polymorphism (p.A1369S) in the ABCC8 gene was found that may be associated with increased insulin secretion in pregnancy. Because of the suggestive family history and relatively mild hyperinsulinism, sequencing of the GCK gene was also performed. A previously undescribed c.1a-84C>G mutation was found in the child and his father. The patient responded well to oral diazoxide and subcutaneous growth hormone and continues management with these medications. This case illustrates two important findings: one, milder congenital hyperinsulinism can present with symptoms in association with metabolic stress, mimicking a fatty acid oxidation defect, and two, possible associated growth hormone deficiency should be clinically evaluated and managed in cases of CH.

## 2528/F/Poster Board #44

**Somatic and Germline Mosaicism in individuals with Rubistein-Taybi Syndrome may not be as rare as we thought.** *A.C. Tsai[1], N.C Lee[2], Y.S Chien[2], W.L. Hwu[2], E. Spector[3], P.W. Chiang[3].* 1) Sect Clinical Gen & Metabolism, Childrens Hosp, Denver, B300, Denver, CO; 2) Department of Genetic Medicine and Department of Pediatrics, National Taiwan University Hospital, Taipei, Taiwan; 3) DNA Diagnostic Lab. University of Colorado at Denver Health Sciences Center.

Rubinstein-Taybi syndrome (RSTS) is a rare autosomal dominant genetic disease and is characterized by mental retardation and distinctive facial and other dysmorphic features. CREBBP and EP300 are the only genes currently known to be associated with RSTS. Mutations in CREBBP and EP300 were identified in approximately 50% and 3% of RSTS patients, respectively. Most of the identified mutations were assumed to be de novo mutations and the recurrence rate in a family was mentioned to be low. However, our clinical observations contradict the assumed low recurrence rate. Of the eight "classic" families seen in our genetic clinics, three families have more than one affected child from apparently normal parents. Family one was found to have one novel small 4 nucleotide deletion (6122-6125delCCAT; ref. seq. NC_000016.8) in exon 31 in two affected sisters but both parents were normal, highly suggesting the mechanism of germ-line mosaicism. Family two consists of one affected boy with one novel nonsense mutation (R1360X:c4078C>T; ref. seq. NC_000016.8) in exon 24, and an apparently normal father with low level mosaicism indentified in the in blood, oral mucosa and sperm cells; most significantly in the blood sample. Family three consists of two affected paternal half brothers; both brothers have classic facial and cognitive features as well as broad thumbs and great toes and the father is apparently normal with normal intellectual function. However, the family is not available for molecular analysis. Our study concurs with the previous study by[Bentivegna et al., 2006] that somatic mutations of CREBBP may not be uncommon. When the somatic mutations happen post-zygotically will lead to a spectrum from a low level mosaicism carrier (such as the father in family II) to a RSTS patient with almost complete RSTS phonotypical findings. We hypothesize this be the reason why the mutation could only be found in 50% of the affected individuals because the mosaicism was not readily detected in the blood. Our study, as seen in family I and III, also demonstrate germ line mosaicism might not be as low as the estimated 0.1%Larger scale analysis of RSTS families will be performed to confirm our hypothesis. Testing parental samples other than blood can be considered.

## 2529/F/Poster Board #45

**Supernumerary teeth associated with monogenic disorders.** *E. Severin, C. Albu, D. Albu, D. Stanciu.* "Carol Davila" Univ Med Pharm, Bucharest, Romania.

Background and aims: Monogenic disorder such as cleidocranial dysplasia is often associated with supernumerary teeth (ST) but teeth formed in excess to the normal dental number in beta-thalassemia are not a frequent feature. The aims of the study were to characterize the clinical features, both dental and non-dental, of patients and then to explore molecular genetic basis of ST in these patients. Subjects and Methods: the study was achieved by ascertaining 3 patients from Orthodontic Department. Full medical and dental history was obtained. Physical, oral and radiographic examinations were performed. Peripheral blood samples from each patient were used to isolate DNA for molecular investigations. Results: Two unrelated Caucasian female patients had multiple supernumerary teeth in association with cleidocranial dysplasia. The analysis of the entire RUNX2/CBFA1 coding sequence by PCR amplification identified the mutations R225W which is typical for CCD. RUNX2 gene is involved in tooth morphogenesis and its mutation has pleiotropic effects which can explain association of several congenital anomalies. One Caucasian male patient expressed in permanent dentition a single supernumerary tooth in the posterior maxilla (paramolar) associated with beta-thalassemia. His co-twin was concordant for beta-thalassemia but discordant for dental phenotype. HBB gene has no influence on tooth formation or discordant paramolar. The association of unrelated features, beta-thalassemia with ST, may represent the action of different causes on different developmental field by coincidence. Conclusions: the study showed that not all cases with ST had similar dental pattern or same etiology. It is of interest to remark that mutation of a single gene has pleiotropic effects including syndromic supernumerary teeth but actually no specific mutation was found providing isolated supernumerary tooth.

## 2530/F/Poster Board #46

**Variable Expression of Neurofibromatosis 1 in Monozygotic Twins.** *E.K. Schorry[1], M.B. Rieley[1], D.H. Viskochil[2], D.A. Stevenson[2], B.T. Tinkle[1].* 1) Div Human Genetics, Cincinnati Childrens Hosp, Cincinnati, OH; 2) Univ of Utah, Div of Medical Genetics, Salt Lake City, UT.

Monozygotic (MZ) twinning, which occurs in 1/250 live births, has historically been used as a valuable tool in studying genetic traits. MZ twins who are discordant for specific traits are thought to demonstrate non-genetic etiologies for those traits, as their genes are presumably identical. Recent studies have shown that MZ twins are not as genetically identical as originally assumed. Differences in copy number variants and in methylation patterns have been shown within pairs of MZ twins, raising speculation that these differences may contribute to discordancies of phenotype of MZ twins. We have studied a group of MZ twins with NF1 as a tool to understanding mechanisms behind the variable expression of this complex disorder. We collected data on 10 sets of multiples with NF1: 9 sets of MZ twins and 1 set of MZ triplets, ranging in age from 4-18 years. Features evaluated included numbers of café-au-lait spots and cutaneous neurofibromas; plexiform neurofibromas; optic nerve glioma and other CNS tumors; skeletal complications; and learning disabilities (LD). MZ twins were generally highly concordant in numbers of café-au-lait spots (90% concordance rate) and cutaneous neurofibromas (70% concordance). IQ scores were within 10 points for all twin pairs tested, and similar patterns of LD were noted. However, the twin pairs showed significant discordance for presence and location of tumors, particularly plexiform neurofibromas (20% concordance) and MPNST (discordant in one pair), as expected if post-natal second-hit events were responsible for these features. Optic pathway gliomas showed only 55% concordance, implying a combination of modifying genetic factors as well as stochastic factors. Skeletal complications were of particular interest. There was high concordance rate (80%) for presence or absence of pectus deformities of the chest. Two sets of multiples were concordant for scoliosis, but differed greatly in the degree of curvature, presence of dystrophic features, and need for surgery. This study has helped to document which features and complications of NF1 are likely influenced by modifying genes and which are related to stochastic events and other yet-to-be elucidated factors. Future studies may investigate modifying genes and epigenetic changes within these twins to look for other potential etiologies of the variable expression of NF1.

## 2531/F/Poster Board #47

**CONGENITAL MYASTHENIA DUE TO CHAT-MUTATIONS IN TWO FAMILIES WITH THE FETAL HYPOKINESIA SEQUENCE.** *J. van den Ende[1], R. Mercelis[2], L. Mahieu[3].* 1) Dept Med Gen, Univ Antwerp/ University Hospital, Antwerp, Belgium; 2) Dept. of neurology, University Hospital, Antwerp, Belgium; 3) Neonatal Intensive Care Unit, University Hospital, Antwerp, Belgium.

The fetal hypokinesia sequence is a condition at birth in which multiple congenital joint contractures are present, generally resulting from lack of intra-uterine fetal movement. This can be the consequence of a wide variety of conditions, and for the sake of recurrence risk it is very important to distinguish the genetic causes. Among these are neurological causes (90%), myopathies and congenital myasthenia syndromes (5-10%), and connective tissue disorders, like diastrophic dysplasia. We present several cases belonging to two families, born with the same condition of multiple contractures and a lethal course, in which thorough investigation revealed 2 mutations in the ChAT gene, responsible for autosomal recessive Congenital Myasthenia. The ChAT gene encodes choline acetyltransferase, which catalyzes the reversible synthesis of acetylcholine from acetylCoA and choline at cholinergic synapses. This is the first gene in which mutations cause a presynaptic congenital myasthenia syndrome (CMS). In literature patients were described with CMS due to Chat mutations, who showed episodic apnea, often leading to death in the neonatal period. In survivors anticholinesterase drugs can partly prevent the crises that recur with infections, excitement or overexertion.

## 2532/F/Poster Board #48

**Partial agenesis of the pancreas associated with mutation in hepatocyte nuclear factor-1 beta (HNF1β).** *H. Gregory[1], E. Edghill[2], J. Minton[2], S. Ellard[2], J.C.S. Dean[1].* 1) Department of Medical Genetics, NHS Grampian, Aberdeen, Scotland, United Kingdom; 2) Molecular Genetics Laboratory, Royal Devon & Exeter NHS Foundation Trust, Barrack Road, Exeter, United Kingdom.

A female aged 48 presented with abdominal pain, diarrhoea and weight loss. She was found to have mildly deranged liver function tests and pancreatic insufficiency. Investigations demonstrated partial agenesis of the pancreas, with absence of the body and tail. Abdominal ultrasound also showed multiple small cortical renal cysts. Regular monitoring shows continuing normal fasting blood glucose. She responded well to treatment with pancreatic enzyme supplementation.Family history included one male sibling with insulin dependant diabetes diagnosed age 30, father with extrahepatic bile duct carcinoma and paternal uncle with maturity onset diabetes. DNA testing of hepatocyte nuclear factor -1 beta (HNF1β) revealed a missense mutation, R235Q, in exon 3, c.704G>A. The mutation was also found in the male sibling with diabetes, who was subsequently found also to have cortical renal cysts. This mutation is associated with the Renal Cysts and Diabetes syndrome (RCAD). Features include maturity onset diabetes of the young (MODY), renal cysts and failure, liver dysfunction and uterine abnormalities. It has also previously been associated with pancreatic atrophy and exocrine pancreatic failure. The findings in this family support previous observations of the wide phenotypic variability of the RCAD syndrome.

**Hereditary Disorders with Clinical Overlap with Marfan Syndrome: A Practical Guide for Clinicians.** *M. Murphy-Ryan, A. Psychogios, N.M. Lindor.* Mayo Clinc, Rochester, MN.

**Background and Purpose:**Underlined Text Nearly all clinicians have a basic knowledge of Marfan syndrome, the prototypical genetic disorder of connective tissue. Clinical features involve the musculoskeletal, cardiovascular, respiratory, ophthalmologic, and cutaneous systems. There is a newly emerging and complex clinical and molecular differential diagnosis to be considered for patients evaluated for any one feature of Marfan syndrome. The aim of this project is to consolidate new clinical and genetic information in accessible matrices to facilitate the diagnostic evaluation of individuals with suspected disorders of connective tissue due to overlap with features of Marfan syndrome. **Methods:**Underlined Text Each of the clinical features of Marfan syndrome, as specified in the Ghent Criteria, were subjected to Pub Med and OMIM literature searches to identify other Mendelian syndromes or clinical entities that shared that feature. One table was constructed that contains the clinical features of Marfan syndrome and additional key features of all identified syndromes and a second table was constructed that contains the clinical entities and the molecular bases for those, if known, many of which are molecularly heterogeneous. **Summary:**Underlined Text Thirty three different clinical entities and 35 different genes or gene loci are identified that might overlap with one or more of the presenting features in Marfan syndrome. The clinical entities include Abdominal Aortic Aneurysms, Arterial Tortuosity Syndrome, Bicuspid Aortic Valve with Thoracic Aortic Aneurysm, Camurati-Engelmann Disease , CATSHL Syndrome, Congenital Contractural Arachnodactyly, Cutis Laxa, (AD, AR Type I, II, X-L), Familial Ectopia Lentis, Ehlers-Danlos Syndrome (Arthrochalasia, Cardiac Valvular, Classical, Dermatosporaxis, Kyphoscoliotic, Vascular, TenascinX types), Familial Thoracic Aneurysm, Homocystinuria, LH3 Deficiency Syndrome, Loeys-Dietz Syndrome Types I and II, Lujan Syndrome, MASS Phenotype, Mitral Valve Prolapse Syndrome, Persistent PDA with Familial Thoracic Aneurysm , Shprintzen-Goldberg Syndrome, Stickler Syndrome, and Weill-Marchesani Syndrome. The matrices constructed from this project may be of clinical use to geneticists as well as clinicians who encounter patients with apparent alterations affecting connective tissue.

## 2534/F/Poster Board #50

**Restrictive dermopathy with massive thrombosis - a previously uncreognized finding?** *A. Hinek[3], H.Y.B. Chung[1,2], P. Shannon[4], R. Teitelbaum[2], D. Chitayat[1,2].* 1) Division of Clinical and Metabolic Genetics, Hospital for Sick Children, Toronto, Ontario, Canada; 2) The Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital, Toronto, Ontario, Canada; 3) Division of Cardiovascular Research, The Hospital for Sick Children, University of Toronto, Toronto, Ontario, Canada; 4) Department of Pathology and Laboratory Medicine, Mount Sinai Hospital, Toronto, Ontario, Canada.

Restrictive dermopathy (RD) is a lethal genodermatosis characterized by IUGR, tight and rigid skin, prominent superficial vasculature, epidermal hyperkeratosis, typical facial features, sparse/absent eyelashes and eyebrows, thin dysplastic clavicles, pulmonary hypoplasia and arthrogryposis. It is caused by LMNA or, more frequently, ZMPSTE24 mutations. We report 2 siblings with RD and ZMPSTE24 mutations. Case report: The mother is 28y G2P1. The couple was 1st cousin of Pakistani origin. Family history was unremarkable. The 1st pregnancy resulted in IUD at 27w, preceded by decreased fetal movement, oligohydramnios and IUGR at 24w. Autopsy was inconclusive and G-banding was not possible. Placenta showed chronic deciduitis, subchorionic hematoma and fetal thrombotic vasculopathy. The 2nd pregnancy was complicated with GDM treated with insulin. She was also on heparin for previous miscarriage. IPS was negative. Serial ultrasounds were normal. She had decreased fetal movement with poor biophysical profile at 28w and delivered a stillborn by emergency CS. Autopsy revealed absent eyelashes, sparse eyebrows, flat nasal bridge with vertical indentation, poorly defined alae nasi, thin and poorly defined philtrum, protruding tongue, retrognathia with a midline cleft chin. The skin was pink and had tight shiny texture. There were severe multiple flexion contractures with fixed thumbs, camptodactyly, absent distal IP creases and dorsiflexed feet. Skeletal survey showed hypoplastic clavicle and scapulae. Internal examination showed left adrenal infarction with propagation of thrombus obstructing the IVC, organizing venous thrombi in the contralateral kidney, and acute microthrombi in the brain. Bilateral perinephric and germinal matrix haematoma were noted. Chromosome analysis showed 46, XY. Skin histology was consistent with RD. Sequencing of the ZMPSTE24 gene showed a homozygous mutation resulting in premature protein termination, p.Glu237Stop. Discussion: Coagulopathy is not well described in RD. From literature review, only 1 case showed evidence of coagulopathy with lenticulostriate vasculopathy and multiple old, calcified, organized thrombi and intimal fibrosis in the abdominal aorta [Chiang, et al, 2008]. Further studies are required to see if the coagulaopathy in RD is the result of vasculopathy or platelet abnormalities and may provide further insights into the function of ZMPSTE24 in coagulation.

## 2535/F/Poster Board #51

**Multi-site assessment of hypertension prevalence in short stature skeletal dysplasia.** *J. Hoover-Fong[1,2], J. McGready[3], J. Leadroot[1,2], G. Oswald[1,2], D. Miller[1,2], I. Berkowitz[2], M. Ain[2], T. Yost[2], W. Mackenzie[4], C. Ditro[4], K. Rogers[4], J. Hecht[5], D. Rimoin[6], K. Schulze[3].* 1) Greenberg Center for Skeletal Dysplasias, McKusick-Nathans Institute of Genetic Medicine, Baltimore, MD; 2) Johns Hopkins University, Baltimore, MD; 3) Bloomberg School of Public Health, Baltimore, MD; 4) AI duPont Hospital, Wilmington, DE; 5) University of Texas, Houston, TX; 6) Cedars Sinai Medical Center, Los Angeles, CA.

**Background:**Hypertension (HTN) is systolic blood pressure(SBP)≥140 mmHg, diastolic blood pressure (DBP)≥90 mmHg or use of anti-HTN medication[1].HTN is a leading cause of cardiovascular (CV) mortality, and HTN prevalence among US average stature adults is 24%[2].30% of hypertensive adults are unaware of their HTN, 42% aware are not treated, and 69% treated are not controlled.HTN prevalence is unknown in the short stature skeletal dysplasia population.However a 42 year follow-up of 793 achondroplasia subjects revealed 10 X greater CV mortality and 10 year reduced median survival compared to average stature[3]. Accurate blood pressure(BP) measurement is needed for basic healthcare and to understand CV disease-related mortality risk. **Methods:**Subjects were recruited from 3 clinic sites and Little People of America events.BP was measured with an automatic oscillometric device (Dinamap, GE Healthcare) and commercially-available short-long BP cuff (Critikon, GE Healthcare) on the upper extremity.A single representative BP from each subject was used for analysis.Anthropometry, medications, geographic region, and exercise were also assessed.**Results**:325 subjects with 26 skeletal dysplasias enrolled. 274(84%) had 8 diagnoses including achondroplasia (192), diastrophic dysplasia (22),Kniest/SED (18), pseudoachondroplasia (17), hypochondroplasia (9), OI (6), acromesomelia (5), or cartilage hair hypoplasia (5); 18(5.5%) were undiagnosed.265 were adults >18 years (108 M, 40.8±11.6 yrs; 157 F, 39.6±13.4 yrs) and 60 were children (22 M,38 F;2-17 yrs). In adults, SBP was ≥140 in 87 (33.0%), DBP was ≥90 in 42 (15.8%), and 41 (15.5%) took anti-HTN or cholesterol-lowering agents; 113 short stature adults (42.6%) met ≥ 1 HTN criteria.In hypertensive (n=113) vs normotensive (n=150) adults, BMI (kg/m2) was 38.2±9.5 vs 33.3±7.3 and wt was 58.3±17.1 kg vs 48.5±12.2 kg, (both p<0.00001).In a subset, 45% reported moderate to vigorous exercise, with a trend of lower wt, BMI and BP in exercisers vs sedentary.Preliminarily, regional differences parallel average stature US obesity and HTN trends. Discussion:In this adult short stature cohort, HTN prevalence was nearly double the general US population.Though meeting HTN criteria, only a fraction were treated. Aggressive BP screening with a well-fitted cuff, treatment, and monitoring is a healthcare priority. [1]US Joint National Committee on High Blood Pressure, 2000; [2]Gu et al, Annals of Epidemiology, 2008; [3]Wynn et al, AJMG, 2007.

## 2536/F/Poster Board #52

**Spinocerebellar ataxia type 7: a rare cause of infantile nephrotic syndrome.** *M.T. Gabbett[1, 2], B. Holland[1].* 1) Genetic Health Queensland, Royal Brisbane & Women's Hospital, Brisbane, Australia; 2) School of Medicine, The University of Queensland, Brisbane, Australia.

Spinocerebellar ataxia type 7 (SCA7) is caused by an expanded trinucleotide repeat in the ATXN7 gene. The hallmark features of SCA7 are progressive cerebellar ataxia and a pigmentary macular degeneration. However large trinucleotide expansions in ATXN7 can present as a very different and rare clinical phenotype. We report on a two year old girl with a suspected inborn error of metabolism who died after an illness characterised by profound nephrosis and progressive hypotonia. Her half brother was diagnosed with SCA7 six years after her death. It was subsequently apparent that the two year old died from very rare complications of SCA7. It was proven that the two year old had a large trinucleotide expansion in ATXN7. We present this case to illustrate that SCA7 can present as nephrotic disease in infancy. This is only the second reported case of SCA7 presenting with nephrosis.

## 2537/F/Poster Board #53

**Germ line WTX gene defect cause osteopathia striata with sclerosing skeletal dysplasia but does not lead to tumour development in affected individuals.** *S.G.M. Frints[1, 2], W. Van Hul[3], B. Perdu[3], F. De Freitas[3], K. van Roozendaal[1], I. Krapels[1], M. Schouten[1], J. Nijhuis[4], C.T.R.M. Schrander-Stumpel[1,2].* 1) Clinical Genetics, Maastricht University Medical Center, Maastricht, The Netherlands; 2) School of Oncology, Growth and Development, GROW, University of Maastricht, The Netherlands; 3) Department of Medical Genetics, University and University Hospital of Antwerp, Antwerp, Belgium; 4) Department of Gynecology & Obstetrics, Maastricht University Medical Center, Maastricht, The Netherlands.

Introduction: Osteopathia striata with cranial sclerosis (OSCS)(OMIM 166500) is a rare sclerosing bone dysplasia marked by linear striations in the metaphyseal region of the long bones and pelvis in combination with cranial sclerosis due to an increased osteoblast functioning. This condition is X-linked dominant with mostly mildly affected women but severely affected men, usually leading to lethality. Other clinical findings of OSCS include: macrocephaly, frontal bossing, ocular hypertelorism, broad nasal bridge, hearing loss, abnormalities of the palate and rarely cardiac, intestinal and genitourinary malformations. Family report: We present 20-year clinical genetic follow-up data of a woman with OSCS and her affected offspring. A WTX pathogenetic variation: c.337delG was identified in both. X-inactivation studies, using AR exon 1 methylation sensitive PCR showed random X-inactivation in both affected women. Discussion: Jenkins et al., Nat Genet, 2009, identified several WTX (Wilms tumour on the X-chromosome) gene defects in OSCS patients. Wtx is a component of the β-catenin destruction complex and negatively regulates the canonical wnt/ β-catenin signalling pathway. Somatic WTX gene defects are present in a subset of Wilms tumours and than show 100% skewed X-inactivation pattern in the tumour. As previously shown, WNT signalling is known to play an anabolic role in bone formation by osteoblasts. In mouse, wtx expression nicely correlates with the sclerotic skeletal phenotype seen in the affected female carriers. Conclusion: Further studies are needed to reveal how this WTX tumour suppressor gene can explain the pathogenesis of the intriguing bone phenotype of OSCS without apparently increasing risk for tumour formation.

## 2538/F/Poster Board #54

**Cerebello-Olivary degeneration of Holmes, further evidence from a new family.** *O. Caluseriu[1], L. MacDonald[1], J.N. Scott[2], R. Casey[1], O. Suchowersky[1].* 1) Dept Med Gen, Alberta Children's Hosp, Calgary, AB, Canada; 2) Dept of Diagnostic Imaging, Foothills Hosp, Calgary, AB, Canada.

Described more than 100 years ago by G. Holmes, cerebellar ataxia with hypogonadotropic hypogonadism represents a rare autosomal recessive entity and pathogenesis remains elusive. We describe a new family with variable expressivity in phenotype. The proband is a 30 year old male, son of first cousins of Caucasian origin. He presented with 2-year history of progressive slurred speech, short term memory loss, and depression. Visual complaints were absent, but he described decreased libido and erections. Previous medical history revealed endocrinological evaluation at 16 years of age for delayed puberty. He had delayed motor and speech milestones in infancy, but completed high school. No other affected family members were reported. On examination, the patient looked younger than stated age but there were no dysmorphic features. Development was Tanner stage 5 with small testes and slight gynecomastia. Neurological exam revealed mild limb hypotonia, diminished reflexes, ataxic gait, dysarthria and horizontal nystagmus. He had intention tremor in both arms and legs, dysdiadochokinesia, and dysmetria. Normal genetic and metabolic investigations included: chromosomes, molecular testing for Fragile X, FRDA, SCA 1, 2, 3, 6, 7 and 8, plasma amino- an organic acids, hexosaminidase, galactocerebrosidase, glucosidase, arylsulfatase A, methylmalonic acid, homocysteine, and VLCFA. Testosterone was low and thyroid function normal. Brain MRI showed patchy bihemispheric white matter T2 hyperintensities, diffuse cerebellar atrophy, and small pituitary gland, confirming the above diagnosis. In a family counseling meeting, it was noticed that his 29 years old sister had a wide-based gait and history of primary amenorrhea. A brain MRI demonstrated similar but milder abnormalities. Further familial investigations are planned, including homozygosity mapping.

## 2539/F/Poster Board #55

**Confirmatory report of Megarbane autosomal recessive oto-facial syndrome.** *M. Mathieu[1], G. Morin[1], B. Demeer[1], A. Hazard[1], B. Devauchelle[2], C. Kolski[3], B. Deschepper[4], T. Attie-Bitach[5], A. Receveur[6], H. Copin[6].* 1) Clinical Genetics, Amiens University Hospital, France; 2) Stomatology, Amiens University Hospital, France; 3) Otorhynolaryngology, Amiens University Hospital, France; 4) Radiology, Amiens University Hospital, France; 5) Genetics Department, Necker Hospital, Paris, France; 6) Cytogenetics, Amiens University Hospital, France.

In 2005, Megarbane et al reported two sisters from a Libanese consanguineous family (their parents were first cousins), with a new oto-facial syndrome. These patients presented microcephaly, dysmorphic features, very dysplastic low-set ears, malformation of the middle ear and short stature. In addition, one of the patients had a posterior cleft palate, and the other an oesophageal atresia. Because of the recurrence in sibs and the parental consanguinity an autosomal recessive mode of inheritance was suggested. We report a similar observation concerning an 18-year-old boy. This patient was the second of three children from non consanguineous parents. There was no remarkable familial history. He presented a mandibulo-facial dysostosis with microcephaly, extremely rudimentary and low-set helix of ears, absence of the external auditory channel, long nose with low columella, short philtrum, everted lower lip and small chin. A low implantation of the thumbs, with ankilosis of the right one, was noticed. The patient also presented a mild mental retardation and severe conduction deafness. The CT scan revealed hypoplastic middle ear cavity with absence of aeration and underdeveloped auditory ossicles. At the age of 18, the microcephaly persisted (-3 SD), stature was normal (171cm) but stayed inferior to the familial height. Chromosomal investigations (standard karyotype and array-CGH) were normal. The molecular screening of the CHD7 gene responsible of the CHARGE association was negative. We compare this observation with other known oto-facial syndromes and especially the familial observation of Megarbane. We discuss the importance of the oesophageal atresia and of the posterior cleft palate in this entity. The fact that both sexes were concerned by the disease, (boy in our observation and girls in Megarbane's patients) is compatible with the previously suggested autosomal recessive mode of inheritance.

## 2540/F/Poster Board #56

**SURGICAL CORRECTION OF PSEUDOTRIPHALIA ASSOCIATED WITH ANORECTAL MALFORMATION AND HYPOSPADIAS. A CASE REPORT FROM THE HOSPITAL PARA EL NINO POBLANO, MEXICO.** *F. Cuellar-López[1], J.M. Aparicio-Rodriguez[2,6], M. Barrientos-Perez[3], M.L. Hurtado-Hernandez[4], M.I. Ortega-Molina[5].* 1) Pediatric Urology; 2) Medical Genetics; 3) Endocrinology; 4) Cytogenetics; 5) Pediatric Surgery, Hospital Para el Nino Poblano, Puebla; 6) Estomatology, Benemerita Uiversidad Autonoma de Puebla, Mexico.

INTRODUCTION. Diphallia or penile duplication is a very rare congenital anomaly. We report in this study a pseudotripahalia were a total excision of ventrally located pseudopenis and excision of left phallus was performed. The case is being reported in view of its rarity and the successful surgical correction. CASE REPORT. A 2.8-years-old male child was studied with anorrectal malformation, double penis and extra pseudo penis. Examination of the external genitalia showed normal-appearing testis within each of the separated hemiscrotums. The dorsal penis had a penoscrotal hypospadias. Normal urethra and bladder could be easily catheterized were cystourethrogram revealed normality without no more internal tissues duplication. Therefore, the urethra opened through the normal bladder neck. There was no pelvic diastasis or other systemic anomalies. Karyotype was normal, showing a chromosome formula 46XY, normal male. SURGICAL PROCEDURES. The first-stage surgery was aimed at correcting the anorectal malformation by sigmoidostomy and anorrectoplasty. Then, after colostomy was finished, cystourethrogram was performed finding penoescrotal hypospadias, with the presence of three phallus. the upper phallus or pseudophallus full of lipid material, without any fistula, both of the other two phallus, the left one with a hypoplasic urethra without any bladder comunication and the rigth phallus with a normal urethra, verumontanum completely normal. Both, pseudophallus and left no communicated phallus were surgically excisionated. DISCUSSION. Less than 100 cases of penile duplication have been reported worldwide, and it is believed that a dyphalia with a third pseudophallus has no been reported yet. Therefore, the patient in this study had three phallus, and hypospadias, with 2 normal testes, cystourethrogram revealed a single bladder with a normal urethra and diagnosed as normal chromosomic male. Abnormality was corrected with excision of ventrally located pseudopenis and excision of left phallus, and rotation of right phallus. True diphallia has been considered to be a rare condition. Surgical correction should be individualized with the aims in order to obtain a proper urinary continence, urinary stream, and erection for a better quality of life for the future of the patient. REFERENCES. Gyftopoulos K, Wolffenbuttel KP, Nijman RJ. Clinical and embryologic aspects of penile duplication and associated anomalies. Urology 2002;60:675.

## 2541/F/Poster Board #57

**Patient with 17p11.2 deletion and clinical manifestations of Smith-Magenis syndrome with vermis hypoplasia, abnormal breathing pattern and cerebellar signs.** *C. Vinkler[1], M. Hasan[2], A. Singer[3], M. Michelson-Kerman[1], D. Lev[1].* 1) Inst Med Gen, Wolfson Med Ctr, Holon, Israel; 2) Metabolic-Genetic-Neurologic Clinic Wolfson Medical Center, Holon, Israel; 3) Institute of Medical Genetics Barzilai Medical Center, Ashkelon, Israel.

Smith-Magenis Syndrome (SMS) is a complex disorder characterized by variable mental retardation, sleep disturbance, craniofacial and skeletal anomalies and specific behavioral phenotype. The prevalence is around 1: 15,000-25,000. It is generally a sporadic disorder caused by an interstitial deletion involving chromosome 17p11.2 containing the RAI1 gene. It may also be caused by a mutation in the RAI1 gene. Various brain malformations have been previously described in SMS patients, involving primarily the ventricles and the cerebral cortex. Joubert syndrome (JS) is a rare autosomal recessive disorder comprised of mental retardation, hypotonia, truncal ataxia and either episodic hyperpnea or atypical eye movements or both. Todate at least 7 genes are known to be associated with this disorder none of them is located on the short arm of chromosome 17. The combination of SMS and Joubert-like phenotype, has been previously reported in one patient. We report a second case associating SMS with vermis hypoplasia and some clinical signs of JS. This 5 year old girl, presented with mental retardation, heart defect (three VSD's), dysmorphic features typical of SMS, including midfacial hypoplasia, brachycephaly and brachydactyly. She also had abnormal breathing pattern (alternating tachypnea), hypotonia, wide-based gait, truncal ataxia and vermis hypoplasia. all of which, may be clinical signs of JS. A "molar tooth sign" on brain MRI, is an obligatory criterion for the definition of JS and this sign was not found in our patient's brain MRI. CGH array revealed a 3.12-3.14Kb deletion on chromosome 17p at (p11.2p12) encompassing the SMS "critical region" and extending somewhat beyond it, both on its telomeric and centromeric boundaries. Seven protein coding genes are known to be located outside the "SMS region" in this particular case, non of which seem a good candidate gene to cause hypoplasia of the vermis. One explanation for this unusual clinical presentation may be the presence of a JS gene in proximity to the "SMS region". However, hypoplasia of the vermis although rare in this syndrome, may be still caused by genes within the "SMS critical region". Clinical signs of JS in patients with SMS who also have vermis hypoplasia, may therefore reflect a wider phenotype in these rare cases, which overlaps with the phenotype of Joubert syndrome. We suggest that brain MRI should be carried out in SMS patients with Joubert-like phenotype.

## 2542/F/Poster Board #58

**Detection of new candidate genes for congenital eye anomalies using whole genome oligo array CGH and high-throughput resequencing.** *G. Raca[1,2], C.A. Jackson[1], B. Wartman[3], L.A. Schimmenti[3].* 1) UW Cytogenetic Services, State Laboratory of Hygiene, Madison, WI; 2) Department of Pathology, University of Wisconsin-Madison; 3) Department of Pediatrics and Ophthalmology, Institute of Human Genetics and Developmental Biology Center, University of Minnesota.

Deletions and duplications in genomic DNA are common mutations causing congenital anomalies and monogenic diseases. High resolution whole genome array CGH therefore represents a powerful diagnostic tool and gene identification strategy. Additionally, the recent emergence of widely available high throughput sequencing platforms has enabled searching for disease-associated point mutations across greater genomic intervals and in larger numbers of individuals. Our study uses a combination of whole genome oligo array CGH and high throughput candidate gene resequencing to search for new genes causing congenital eye anomalies. Array CGH was used to survey the genomes of patients with coloboma, anophthalmia, and microphthalmia for deletions and duplications affecting genes involved in eye development. Nineteen patients were tested using a 2 million probe array from NimbleGen. One patient was found to have a 5.8Mb duplication affecting the Prader/Willi Angelman Syndrome critical region at 15q11.2q13.1. This abnormality has not been reported in association with eye anomalies, but could explain other clinical features present in our patient, including developmental delay and behavioral problems. Four additional deletions were detected at the following candidate chromosomal regions: 13q31.3, 8q23.1q23.2 and 7q34. The 13q31.3 deletion, detected in a patient with bilateral iris coloboma, was ~240 kilobases in size, and included only one known gene, glypican (*GPC5*). Interestingly, coloboma, microphtalmia and anophtalmia have previously been reported in association with deletions of the 13q31-q33 region. Additionally, a drosophila ortholog of the *GPC5* gene, *dally*, is known to affect cell division patterning in developing eye. To test our patients for base changes in genes associated with eye development, we designed a custom NimbleGen Sequence Capture array with more than 100 candidate genes, and tested it in combination with 454 GS FLX resequencing on two samples with known mutations in the PAX2 gene. Future studies to support the role of candidate genes within deleted loci or identified through resequencing efforts as the basis for eye malformations will include: 1) studying effects of their inactivation on eye development in zebrafish, and 2) surveying for mutations in additional patients. Ultimately, our study will not only detect new genetic causes of eye anomalies, but also develop methods for more comprehensive and efficient clinical diagnostics.

## 2543/F/Poster Board #59

**Characterization of the 2q31.1 microdeletion syndrome: role of the HOXD gene cluster in limb malformations.** *M. Artigas-Lopez[1], A. Bengoa-Alonso[1], RC. Narvaiza-Martínez[1], A. Pérez-Juana[1], B. Nieva[2], ME. Querejeta[2], MA. Ramos-Arroyo[1].* 1) Dept Genetics, Hosp Virgen del Camino, Pamplona Navarra, Spain; 2) Dept Genetics, Policlínica Donostia, Donosti, Spain.

We present a patient with a 2q31.1-2q31.2 microdeletion (6 Mb) detected by array-based Comparative Genomic Hybridation (array-CGH), which included the HOXD gene cluster, and study the phenotype-genotype correlation of published cases with overlapping deletions identified by array-CGH, FISH and/or microsatellite analysis. Patients with microdeletions of 2q31.1 share with our case a distinct phenotype characterized by moderate mental impairment, postnatal microcephaly and growth retardation, craniofacial dysmorphic features and characteristic limb anomalies of the hands and feet. Four patients also had genital anomalies. The minimum overlapping deletion consists of a 1.6 Mb segment containing 10 genes. Interestingly, this segment does not include the HOXD13 gene, a gene known to cause synpolydactyly (SDP). However, all cases with the common deletion present limb defects compatible with SDP or split-hand/split-foot malformation (SHFM). SDP defects could be explained by haploinsuficiency of HOXD13 gene or disruption of a long-range regulatory element for the HOXD genes. A locus for SHFM-V has been proposed to be located in a 5 Mb interval centromeric to EVX2 (2q31-q32), suggesting that SHFM-V may be caused by haploinsuficiency of the 5'HOXD, EVX2 or DLX1 and DLX2 genes. However, most patients with a deletion of the HOXD cluster, EVX2 and/or DLX2 genes show limb anomalies compatible with SPD, not with SHFM. It is therefore likely, that severe limb phenotypes may be caused by the existence of a regulatory cascade that involves other genes or epigenetic factors in addition to mutations or haploinsuficiency of the HOXD cluster, EVX2 and/or DLX2 genes.

## 2544/F/Poster Board #60

**Paternally inherited ABCC8 mutations: The underlying cause of prolonged hyperinsulinism in Beckwith-Wiedemann Syndrome?** *L.E. Brick[1], J. Holland[2,3], J. Vandermeulen[2,3], K. McAssey[2,3], M.A. Potter[4].* 1) Department of Genetics, McMaster Children's Hospital, Hamilton, Ontario, Canada; 2) Division of Pediatric Endocrinology, McMaster Children's Hospital, Hamilton, Ontario, Canada; 3) McMaster University, Hamilton, Ontario, Canada; 4) Pathology & Molecular Medicine, Hamilton Regional Laboratory Medicine Program, McMaster University Medical Centre, Hamilton, Ontario, Canada.

Beckwith-Wiedemann Syndrome (BWS) (OMIM 130650) is a congenital overgrowth syndrome that is clinically and genetically heterogeneous. Approximately 50% of infants with BWS have hyperinsulinism and associated hypoglycemia. In most cases, the hypoglycemia is mild and transient, resolving within the neonatal period. However, in rare cases, the hypoglycemia may be more severe, requiring aggressive management and intervention. The mechanism for prolonged hypoglycemia in this subset of patients is unclear. We present a case of an infant diagnosed with BWS, associated with prolonged hyperinsulinism and hypoglycemia. The baby girl was born at 39 weeks gestation and presented with macrosomia, subtle nevus flammeus, right ear lobe crease and persistent hypoglycemia. A diagnosis of BWS was confirmed with molecular genetic studies, demonstrating mosaic paternal uniparental disomy (UPD) of chromosome 11p15. Given this patient's uncharacteristically prolonged hypoglycemia, with failure of response to diazoxide and octreotide in conventional doses, additional genetic causes of hyperinsulinism were investigated. The patient was found to be heterozygous for a novel variant (c.3400-2A>G) at a splice acceptor site in the ABCC8 gene, residing at chromosome 11p15. Family studies showed this mutation to be paternally inherited. In focal congenital hyperinsulinism an inactivating mutation is inherited from the father and the resulting disease is due to loss of heterozygosity of the maternal allele. Thus, given the paternal UPD status of this patient at the 11p15 locus, it is presumed that the patient is mosaic for a homozygous ABCC8 mutation affecting the pancreas. [18F] DOPA PET scanning confirmed a 3cm focus in the head of the pancreas, consistent with loss of heterozygosity in this area and focal hyperinsulinism. This novel case highlights a possible mechanism for severe and prolonged hyperinsulinism and hypoglycemia in BWS.

**Facial dysmorphism, distal arthrogryposis and developmental delay in sisters: an additional family with Chitayat-distal arthrogryposis syndrome.** *C. Cytrynbaum, J. So, G. Yoon, R. Weksberg, D. Chitayat.* Division of Clinical & Metabolic Genetics, The Hospital for Sick Children, Toronto, Canada.

In 1990 Chitayat et al. reported a sister and brother with distal arthrogryposis, mental retardation and a characteristic facial appearance. Three subsequent reports of similarly presenting patients supported an autosomal recessive inheritance pattern, with Wortmann et al. (2007) referring to the condition as Chitayat syndrome. We report two sisters with the same condition born to healthy, non-consanguineous parents of Dutch descent. The older sister presented prenatally with polyhydramnios, ventriculomegaly, renal pelvic dilatation, bilateral clubfeet and was large for gestational age (LGA). Postnatally, she was noted to be LGA and had facial dysmorphisms, including a "boxy" skull, high forehead, deep-set eyes, broad nasal root, low-set ears, a small mouth with down-turned corners and retrognathia. She was hypotonic, had tapering fingers with flexion contractures resulting in clenched fists, scoliosis, bilateral talipes, atrial septal defect and abnormal esophageal motility. She was subsequently noted to have severe global developmental delay and required G-tube feeding. She showed decreasing growth velocity with preserved head circumference to age 3 years. Metabolic and genetic investigations, including karyotype and BAC microarray, were normal. Her sister was born after an uneventful pregnancy with reportedly normal fetal ultrasounds. Postnatally, she was found to be LGA with dysmorphic features similar to her sister (square-shaped head with frontal bossing, deep-set eyes, broad nasal bridge, low-set ears, a small mouth with down-turned corners and retrognathia). She was hypotonic with tapering fingers, camptodactyly of the fingers, clenched fists, limited extension of the knees and high arches of the feet with hammer toes. She had feeding difficulties and required G-tube placement at 3 weeks of age. The constellation of findings in the sisters presented here overlap with those found in the brother and sister first reported by Chitayat et al. (1990). The sisters reported by us here further delineate the clinical manifestations of this condition and support its autosomal recessive mode of inheritance.

## 2546/F/Poster Board #62

**Cornelia de Lange Syndrome: What causes the mild phenotypes?** *G. Gillessen-Kaesbach[1], A. Dalski[1], M. Albrecht[1], V. Bernard[1], J. Eckholt[1], R. Löffler[1], A. Rauch[2], C. Zweier[2], D. Wieczorek[3], F. Kaiser[1].* 1) Inst Humangenetik, Univ Schleswig, Luebeck, Germany; 2) Inst Humangenetik, Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany; 3) Inst Humangenetik, Univ Duisburg-Essen, Essen, Germany.

The Cornelia de Lange Syndrome (CdLS) is a multisystem developmental disorder. Affected individuals show growth and cognitive retardation, reduction defects of the upper limbs, gastroesophageal dysfunction, cardiac, ophthalmologic and genitourinary anomalies along with hirsutism and characteristic facial features. In addition to a wide range of clinical signs, various behavioural problems like self injurious, aggressive, and self restraining behaviour as well as autism-like features have been associated with CdLS. Intellectual development ranges from low normal intelligence to profound MR. Clinical experience has established the existence of two different phenotypes (severe and mild) which was already suggested by van Allan in 1993. In 2004, two independent groups reported that CdLS is due to mutations in the NIPBL gene (5p13.1) which are present in about half of patients with a CdLS phenotype. The mutational spectrum included missense, nonsense, splice site and frameshift mutations, deletions seem to be very rare. Subsequently, SMC1A on the X-chromosome and SMC3 on 10q25 have been identified to be causative for a smaller proportion of patients with a milder phenotype of CdLS. As a consequence there is still a considerable percentage of patients without a detectable molecular etiology. We were able to perform a clinical and molecular study in 66 patients (32 males and 34 females) with a CdLS phenotype ranging from mild to severe. In 21 (32%) of these cases we detected a mutation in the NIPBL gene, whereas in 45 (68%) patients we neither identified a mutation in the NIPBL gene nor in the SMC1A gene. Missense mutations and splice site mutations in the NIPBL gene frequently seem to be associated with a milder phenotype. Within our cohort we identified four new splice site mutations. All four patients are considered to be mildly affected. In addition, by CGH array analysis we identified a 3 generation family in which we detected a small deletion on chromosome 9 in a mildly affected boy and his affected mother. Many of the genes within this region do have a direct functional connection with sister chromatid cohesion genes. Mutational analysis in these genes are in progress. Beside SMC1A and SMC3 we speculate that other cohesion related genes may play a causative role for the milder phenotype in CdLS. Our present results contribute to this hypothesis.

## 2547/F/Poster Board #63

**Mutation spectrum and genotype-phenotype correlations in patients with Marfan syndrome: identification of forty novel mutations in the FBN1 gene.** *C. Hung[1], S. Lin[1,2], D. Niu[3], Y. Su[1,2].* 1) Department of Medical Genetic, National Taiwan University Hospital, Taipei, Taiwan; 2) Graduate Institute of Clinical Medicine, National Taiwan University College of Medicine, Taipei, Taiwan; 3) Department of Pediatrics, Taipei Veterans General Hospital, Taipei, Taiwan.

Background: Marfan syndrome (MFS) has been associated with approximately 562 mutations in the FBN1 gene. Mutation scanning of the FBN1 gene with DNA direct sequencing is time-consuming and expensive because of its large size. The aim of this study was to establish a national database of mutations in the fibrillin-1 (FBN1) gene that cause MFS in the Taiwanese population using high resolution melting analysis (HRM). Materials and Methods: In this study, we screened 294 patients from 157 families for the presence of FBN1 mutations using PCR/HRM. A total of 75 PCR amplicons (179-301 bp, average 256 bp) which covered the complete coding regions and splicing sites were evaluated on the 96-well Lightcycler system. Results: We identified 56 mutations in 62 of the 157 (40%) families including 49 single-base substitutions (36 missense mutations, 7 nonsense mutations, and 6 splicing sites), 1 small insertion, 4 small deletions, 1 small indel (insertion and deletion), and 1 large deletion (Exon 36). When family history was taken into consideration, the mutation detection rate rose to 91% (29 of 32). We further investigated the phenotypic data and found that one third (47 of 157) of the families fit the Ghent criteria for MFS. Based on that data, the mutation rate was 98% (46/47). Among the 56 mutations found in this study, 40 (71%) have not been registered in the Human Gene Mutation Database (HGMD). Conclusions: This is the first study of the mutation spectrum of MFS in a cohort of patients in Taiwan. Our results support the use of high-resolution melting analysis as an alternative method for the diagnosis of Marfan syndrome as well as its suitability for high-throughput mutation scanning of other large genes.

## 2548/F/Poster Board #64

**Rubinstein Taybi-like Phenotype in Patient with Distal 4q and Proximal 2q Chromosomal Microarray Abnormalities.** *L. Loomba-Albrecht[1], D. Styne[1], A. Hata[2], S. Boyd[2].* 1) Pediatric Endocrinology, UC Davis Medical Center, Sacramento, CA; 2) Pediatric Genetics, UC Davis Medical Center, Sacramento, CA.

Objective: We report a patient with dysmorphic features, developmental delay, recurrent pilomatrixomas and hypopituitarism. Chromosomal microarray analysis revealed a gain in copy number on proximal chromosome 2q and a loss in copy number on distal chromosome 4q. We postulate that a gene or genes located at these sites may be involved in the CBP/EP300 pathway, given that the patient has multiple features consistent with Rubinstein Taybi syndrome (RSTS). Patient and Methods: Patient is a 13 year old male with a medical history notable for developmental delay, myopia, strabismus, right cryptorchidism, hypopituitarism and recurrent pilomatrixomas. On physical exam, the patient was noted to have many findings typical of those seen in Rubinstein Taybi syndrome, including prominent forehead, a low frontal and posterior hairline, low-set and posteriorly rotated ears, mild ptosis, arched eyebrows, large beaked nose, partial mild syndactyly of the fingers and broad great toes and thumbs. Results: A high resolution karyotype revealed a 46, XY karyotype. Chromosomal microarray analysis revealed a gain in copy number on proximal chromosome 2q and a loss in copy number on distal chromosome 4q. Genetic testing specific for RSTS has not yet been performed. Discussion/Conclusions: Two causal genes have been identified in RSTS, but mutations in these genes account for fewer than 55% of cases. A loss of function mutation in CREBBP or CBP, which encodes the cAMP-response-element binding protein CREBBP, accounts for roughly 50% of cases. Loss of function mutations in EP300, encoding p300, account for far fewer. CREBBP and p300 are highly homologous genes known to function dually as transcriptional co-activators and histone acetyltransferases. Additional as yet unknown mutations are likely. We report the case of a male patient with Rubinstein-Taybi like features with a gain in copy number in the proximal long arm of chromosome 2 and a loss in copy number in the distal long arm of chromosome 4 by chromosomal microarray analysis. We postulate that one of these loci may be implicated in some patients with RSTS with normal EP300 or CBP genes. Of note, this is the first report of panhypopituitarism in a patient with apparent RSTS. Further genetic testing, including parental testing, is planned.

## 2549/F/Poster Board #65

**A heterogeneous duplication at 10q24 associated with ectrodactyly malformations in a Chinese family that concomitance with seizures.**

*Y. Luo, L. Cao, Y. Zhang, S. Wang, X. Zhang.* Research Center for Medical Genomics, China Medical University, Shenyang, Liaoning, China.

OBJECTIVE: Ectrodactyly or split hand-split foot malformation (SHFM) is a human limb malformation characterized by hypoplasia/aplasia of the central digital rays and variable fusion of the remaining digits. To date, at least five loci have been identified, including SHFM1 (7q21), SHFM2 (Xq26), SHFM3 (10q24), SHFM4 (3q27) and SHFM5 (2q31). Our aim in this study was to identify the disease-causing genetic alteration of ectrodactyly in a new Chinese SHFM family with a high risky of epilepsy. METHODS: Three affected individuals were examined physically and radiologically. Moreover, two affected individuals with seizures were examined by magnetic resonance imaging (MRI) and electroencephalogram (EEG). Haplotype analysis was performed to locate the causative gene, then quantitative PCR (qPCR) and long range PCR were employed to determine copy number of the alleles and to fine map the breakpoints. RESULTS: Photographs showed that of the affected individuals, 2 females present with only camptodactyly index fingers in both hands with dystrophic nails resulting in a typical monodactyly anomaly, while 1 male had no fingers in both hands. Besides, all affected individuals had no toes in both feet. In addition, 2 affected individuals suffered from seizures attacked. The male attacked tonic-clonic seizures and the epileptiform activities were found in his EEG. MRI showed that he had regional cerebromalacia and cortex atrophy of the right parietal lobe and a arachnoid cyst of right temporal lobe. Seizures of the female were related to sleep, except 2 times witnessed tonic-clonic seizures during the day time. MRI showed that she had a ventriculus sinister cerebri cyst. The potential haplotype shared by all affected individuals was detected only in the markers from SHFM3 locus. QPCR showed the normalized relative copy number was around 1.5, which indicated there was a genomic duplication in that region. Furthermore, the breakpoint positions were cloned by long range PCR. Sequence and blat analysis of the chimeric sequence indicated that the duplication region spanned 488,859bp in length and encompassed the entire LBX1, BTRC, POLL, DPCD, and FBXW4 genes. So the rearrangement may be caused by a NHEJ repair or a simplified FoSTeS event according to the junctions sequence. CONCLUSION: The heterogeneous duplication at 10q24 encompassed the entire LBX1, BTRC, POLL, DPCD, and FBXW4 genes is associated with ectrodactyly malformations concomitance with seizures.

## 2550/F/Poster Board #66

**Toward a clinical and molecular delineation of Acrocallosal syndrome.**

*H. Ulucan[1,2], D. Gül[3], D.B. Everman[4], J.A. Butman[5], J.J. Johnston[1], L.G. Biesecker[1].* 1) Genetic Disease Research Branch, National Human Genome Research Institute, NIH, Bethesda, MD, USA; 2) Department of Medical Genetics, Adnan Menderes University Medical Faculty, Aydin, Turkey; 3) Department of Medical Genetics, Gulhane Military Medical Academy, Ankara, Turkey; 4) Greenwood Genetic Center, Greenwood, South Carolina, USA; 5) Radiology and Imaging Sciences, Clinical Center, NIH, Bethesda, MD, USA.

Acrocallosal syndrome (ACLS) is inherited in an autosomal recessive pattern and is characterized by polydactyly of the hands and feet, mental retardation, craniofacial abnormalities, and agenesis of the corpus callosum. Clinical variability of the condition has been observed in the course of mapping studies on five published cases along with two additional cases. The neuroradiological findings among these cases suggest that there appears to be three distinct groups. A review of 67 published cases also shows that there is no consensus in the terminology of corpus callosum involvement, which is a key manifestation for differential diagnosis. In addition to the clinical variability of ACLS, this disorder can overlap with the severe end of the Greig cephalopolysyndactyly syndrome contiguous gene syndrome and one patient with acrocallosal syndrome has been found to have a c.2800G>C, p.Ala934Pro mutation in *GLI3*. The exons of *GLI3* were sequenced in five published ACLS cases and no pathologic variants were detected. Zoom in custom array CGH analysis of *GLI3* was also performed to exclude the GCPS contiguous gene syndrome but no deletions or duplications in *GLI3* were identified. Whole genome 380K genotyping of the five published cases was also performed. These data were analyzed for areas of overlapping homozygosity, reasoning that the high incidence of consanguinity in the communities from where the cases originated would be associated with identity by descent. No homozygous regions of significant size were detected. Our conclusion is that ACLS is more heterogeneous than previously believed. We suggest that new, more specific clinical criteria may be necessary for ACLS to improve clinical care, refine recurrence risk estimates, and facilitate mapping studies.

## 2551/F/Poster Board #67

**Array-CGH analysis to identify novel microdeletion/duplication syndromes and to extend the clinical phenotype associated with susceptibility regions.**

*F.T. Papa, E. Katzaki, M. Mucciolo, M.A. Mencarelli, V. Uliana, M. Pollazzon, A. Marozza, M.G. Bruccheri, V. Disciglio, F. Ariani, I. Meloni, F. Mari, A. Renieri.* Medical Genetics, University of Siena, Siena, Siena, Italy.

We investigated 332 patients with mild to severe mental retardation associated to facial dysmorphisms and/or congenital anomalies. Forty two cases (13%) were considered positive using the following criteria: i) de novo non polymorphic rearrangements (16/332 or 5%); ii) either inherited (15q11.2q13.2) or de novo rearrangements of known syndromes (22/332 or 6.6%); iii) either inherited or de novo rearrangements in susceptibility regions (15q13.3 and 16p11.2) (5/332 or 1.5%). The de novo non polymorphic rearrangements include: del2q24.3q31.1, del2q31.2q32.3, del3q27.3q29, del6p25.3p25, del6q24.3q25.1, del6q27, dup7q11.23, del7q22.1q22.3, del7q36.1q36.2, del8q22.3, dup8q22.3, del9q31.1, del14q12, dup17q12, del21q22.11q22.12 and a complex rearrangement of a del9p24.1p24.3 and a dup17p13.3. The group of known syndromes includes a case of 1p-, the shortest 4p- and 6q- known in the literature, two cases of Williams-Beuren syndrome, a case of a AS/PWS and two cases of AS/PWS reciprocal duplication, three cases of Potocki-Lupski, two cases of Smith-Magenis, four cases of 22q11 deletions and two cases of 22q11 duplication, one case of 22q13 deletion, two cases of dupXq28. Susceptibility regions include three cases with dup15q13.3, one with dup16p11.2 and one with del16p11.2. Parental inheritance has been verified in two cases. The patient carrying dup15q13.3 inherited from normal father shows hypotonia, mental retardation, recurrent infections, epilepsy and cerebral anomalies. The patient carrying dup15q13.3 inherited from normal mother shows mental retardation, behavioral disorder, cleft palate and skeletal anomalies. The third patient shows autistic traits, cerebral anomalies and recurrent infections. The patient with del6p11.2 shows recurrent infections, behavioral and phonological disorders. His mother does not present the deletion while analysis of his father and brothers which present dyslexia is ongoing. The patient with dup16p11.2 shows mental retardation, epilepsy and EEG anomalies. Latest data indicate a strong correlation of these two region with a pathological phenotype not only regarding autism and epilepsy but also variable clinical outcome. An accurate search of the literature allowed to identify patients with overlapping rearrangements delineating novel microdeletion/duplication syndromes or extending the phenotype associated with susceptibility regions.

## 2552/F/Poster Board #68

**Whole gene duplication of the PQBP1 gene in Renpenning syndrome.**

*M. Flynn[1,2], Y.S. Zou[1,2], A. Milunsky[1,2].* 1) Center for Human Genetics, Boston University School of Medicine, Boston, MA; 2) Department of Pediatrics, Boston University School of Medicine, Boston, MA.

Renpenning syndrome is a well-described X-linked multiple congenital anomaly and mental retardation syndrome [OMIM 309500]. Classic clinical features include mental retardation, microcephaly, dysmorphic features, short stature, small testes, and lean body build. Renpenning syndrome is caused by mutations in the PQBP1 gene. Missense mutations, insertions, deletions, and duplications within the gene have been well-described. We present a 46 year old male with typical clinical features of Renpenning syndrome. He has moderate mental impairment, seizures since infancy, short stature, and dysmorphic features. He had previously been verbally communicative and did not demonstrate significant behavioral issues. More recently, however, our patient has become uncommunicative, displaying little and unclear speech. He now exhibits memory and recognition loss, is uncooperative, and is sometimes aggressive, self-abusive, and incontinent. Testes volume has not been assessed. Of note, our patient is normocephalic. The reason for his regression within the past 3 years is unclear. A CT scan showed cerebral atrophy present at 14 years of age. Chromosome analysis and Smith-Magenis FISH analyses were normal. 500K SNP microarray analysis revealed a 4.7 Mb duplication at Xp11.22-p11.23. Multiple ligation probe analysis (MLPA) of the PQBP1 gene contained within this duplicated region confirmed a duplication of the entire PQBP1 gene. Multiple other genes are duplicated within this 4.7 Mb region and may contribute to our patient's phenotype. To our knowledge, this is the second report of a whole gene duplication of the PQBP1 gene responsible for a Renpenning phenotype. Bonnet et al. (2006) reported a male with the above-described duplication (5 Mb) who had moderate mental impairment, autistic-like behavior, short stature, and mild dysmorphic features. This duplication was de novo. Maternally-inherited Xp duplications have previously been described and skewed X-inactivation has been reported. Our patient's mother is deceased and a DNA sample is not available. His sister does not carry this duplication.

## 2553/F/Poster Board #69

**From Heterotaxy to VACTERL-H syndrome - The clinical variability of ZIC3-related disorders.** *S. Keating[3], H.Y.B. Chung[1,2], L. Shaffer[4], D. Chitayat[1,2].* 1) Department of Pediatrics, Division of Clinical and Metabolic Genetics, Hospital for Sick Children,Toronto, Ontario, Canada; 2) The Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital, Toronto, Ontario, Canada; 3) Department of Pathology and Laboratory Medicine, Mount Sinai Hospital, University of Toronto, Toronto, Ontario, Canada; 4) Signature Genomic Laboratories, Spokane, Washington, USA.

BACKGROUND: The ZIC3 gene functions as a transcription factor in early stages of left-right body axis formation. Mutations in ZIC3 gene cause a variety of clinical manifestations including isolated congenital heart disease (CHD), heterotaxy & other midline CNS, urogenital & hindgut malformations. We report a four generation family with X-linked heterotaxy associated with a deletion of the ZIC3 gene at Xq26.3. METHODS AND RESULTS: The proband was a 31y G2P1 woman of Italian descent and her husband was 33y and of the same descent. The couple was healthy, non-consanguineous and had a 3y daughter with a small VSD. The family history revealed a 4 generation pedigree consistent with X-linked pattern of multiple congenital anomalies. The maternal grandmother had a brother and two sons who were born with imperforate anus, developed cyanosis and died shortly after birth. Autopsy on an affected maternal uncle showed normal situs, hydrocephalus, vertebral abnormalities and anal atresia, which was compatible with VACTERL-H. His karyotype was 46, XY. The couple was seen during their 2nd pregnancy. Fetal ultrasound at 19w showed a male fetus and the stomach was not well visualized. A subsequent ultrasound at 23w revealed abnormal cardiac anatomy, bilateral enlarged kidneys, right-sided stomach, and polyhydramnios. Fetal echocardiography showed DORV, left atrial isomerism, interrupted IVC, unbalanced AVSD, and hypoplastic left ventricle. The pregnancy was terminated at 23.5w and the autopsy showed in addition imperforate anus. The karyotype was 46,XY. Oligoarray (SignatureChipOS) detected a 1.4Mb deletion in Xq26.3 including the ZIC3 gene. FISH analysis revealed that the proband, her daughter, sister, mother and grandmother were all carriers of this deletion. Echocardiography done on them showed no cardiac abnormalities and abdominal ultrasounds were normal. CONCLUSION: VACTERL-H is a genetically heterogeneous condition and some of the X-linked cases were found to be caused by a mutation in the FANCB gene associated with Fanconi anemia B. However, early reports pointed out there is higher incidence of rotational CHD, lung lobation defects and spleen anomalies in patients with VACTERL-H when compared to VACTERL, suggesting a potential linkage between VACTERL-H and the left-right patterning defects in embryogenesis. Our report support the suggestion that some of the cases with VACTERL-H syndrome may be caused by a mutation in the ZIC3 gene.

## 2554/F/Poster Board #70

**Associated malformations in patients with esophageal atresia.** *C. Stoll, Y. Alembik, B. Dott, M.P. Roth.* Genetique Medicale, Faculte de Medecine, Strasbourg, France.

Esophageal atresia is a common type of congenital malformation. The etiology of esophageal atresia is unclear and its pathogenesis is controversial. Because previous reports have inconsistently noted the type and frequency of malformations associated with esophageal atresia, we conducted this study in a geographically well defined population, evaluating the birth prevalence of esophageal atresia and associated malformations ascertained between 1979 and 2003 in 334,262 consecutive births. Of the 99 patients with esophageal atresia, 46 (46.5%) had associated malformations. These included patients with chromosomal abnormalities (8 patients,8 %); non chromosomal recognized syndromes 4 patients, including one each CHARGE syndrome, Fanconi anemia, Fryns syndrome, and Opitz G/BBB syndrome; associations including VACTERL (10 patients), and one schisis; one oculo-auriculo-vertebral spectrum; one malformation complex, a sirenomelia, and non syndromic multiple congenital anomalies (MCA) (21 patients, 21 %). Malformations of the cardiovascular system (24 %), urogenital system (21 %), digestive system (21 %), musculoskeletal system (14 %), and central nervous system(7 %) were the most common other congenital malformations occurring in patients with esophageal atresia and nonsyndromic MCA. We observed a high prevalence of total malformations and specific patterns of malformations associated with esophageal atresia which emphasizes the need to evaluate all patients with esophageal atresia for possible associated malformations. The malformations associated with esophageal atresia could be classified into a recognizable malformation syndrome or pattern in 25 out of 46 patients (54 %).

## 2555/F/Poster Board #71

**Analysis of microsatellite DNA markers in the diagnosis of Williams-Beuren Syndrome.** *R. Dutra[1,2], P. Pieri[1,2], F. Macaferri[2], R. Honjo[1], D. Bertola[1], L. Albano[1], C. Kim[1].* 1) Dept of Genetics, Instituto da Criança - FMUSP, São Paulo, Brazil; 2) Laboratory of Medical Investigation - LIM36 - FMUSP, São Paulo, Brazil.

Introduction: The Williams-Beuren syndrome (OMIM 194050) is caused by a hemizygous contiguous gene microdeletion at 7q11.23. Supravalvular aortic stenosis, mental retardation, overfriendliness, renal and dental abnormalities comprise typical symptoms in WBS. The commonest deletion includes 1.5 Mb, but atypical deletions of 1.8 Mb have also been reported. Deletions arise as a consequence of misalignment of the repetitive sequences - Low Copy Repeats (LCR) during meiosis followed by unequal crossing over. Although fluorescence in situ hybridization (FISH) is widely used, microsatellite DNA markers are considered highly informative and easy handling for confirmation of clinical suspicion of the syndrome. Purpose: To detect the microdeletion and the parental origin using three microsatellite DNA markers (D7S1870, D7S489 and D7S613) in the diagnosis of WBS. Subjects and Methods: For the study 99 patients with clinical diagnosis of WBS and their parents were included. Inclusion criteria were the presence of dysmorphic craniofacial abnormalities associated with cardiovascular abnormalities and behavioral characteristics or hyperacusis. FISH was previously performed in 21 patients. For the molecular study, the polymerase chain reaction (PCR) with three markers was used for amplification of the corresponding regions of interest. The samples were submitted to electrophoresis in a polyacrylamide denaturing gel (with 7.5% urea) and the results visualized with silver staining. Results: Among the markers studied, the D7S1870 was the most informative (80.8%) followed by D7S613 (76.8%) and D7S489 (71.7%). For 84 patients, DNA from both parents were available, for 12 patients we could not retrieve the father's DNA and only 3 patients presented only with their fathers. Except for 2 patients for whom father's DNA were not available, for all the 97 patients it was possible to determine the presence of the deletion, found in 86 (88.7%) patients, or its absence, found in 11 (11.3%) patients, even in those 13 cases for which the analysis included only one of the genitors. The deletion was proven to be maternal in 48/86 patients (55.8%) and paternal in 38/86 patients (44.2%). All the patients with positive FISH analysis were concordant with the microsatellite DNA markers results. Conclusion: This study reinforces the usefulness of microsatellite DNA markers in the detection of microdeletions to confirm the clinical diagnosis of WBS. (Supported by FAPESP 2008/55391-6).

## 2556/F/Poster Board #72

**Genodermatology, a multidisciplinary approach: Overview of five years collaboration.** *M. Vreeburg[1], Y.J.H.A. Detisch[1], C.T.R.M. Schrander-Stumpel1[1,3], M.A.M. van Steensel[2,3], D. Marcus-Soekarman[1].* 1) Department of Clinical Genetics, Maastricht University Medical Center, Maastricht, the Netherlands; 2) Department of Dermatology, Maastricht University Medical Center, Maastricht, the Netherlands; 3) Research Institute Growth & Development (GROW), Maastricht University, Maastricht, the Netherlands.

Since diagnosis of rare genetic syndromes is based on pattern recognition and requires specific expertise, as is the case with many skin diseases, we joined forces starting a multidisciplinary out-patient clinic "Genodermatology" in March 2004. Our goal was to evaluate patients with diagnostic questions in the combined field of dermatology and clinical genetics by the dermatologist and the clinical geneticist together. Patients were referred by either a dermatologist or a clinical geneticist (or other specialists) and were seen by both specialists and a genetic counselor. In a 5 years time-period 245 patients were counselled. Five patients were lost in follow up. The medical history of the patient and the pedigree were recorded. Clinical examination, followed by karyotyping, DNA-analysis, metabolic investigation and/or a skin biopsy (if indicated) were performed. Four main groups could be discerned, based on diagnosis: a. Oncogenetic syndromes (n= 58) b. hypermobility/ connective tissue disorders (n=50) c. disorders involving the X-chromosome (n=18) d. miscellaneous (n= 114) . Medication was prescribed by the dermatologist if indicated or referral to the department of dermatology if special treatment was needed, was arranged. In case of a hereditary condition, genetic counselling was offered to family members. Our results indicate that combined efforts are worthwhile to offer these specific patients. Moreover, in various cases light could be shed on the pathogenetic mechanisms leading to a particular skin disorder.

## 2557/F/Poster Board #73

**Cardio-Facio-Cutaneous Syndrome: Clinical and Molecular Diagnosis in the NICU.** *S. Jamal[1], Z. Wang[1,2], J. Milunsky[1,2,3].* 1) Ctr Human Genetics, Boston Univ Sch Medicine, Boston, MA; 2) Dept of Pediatrics, Boston Univ Sch Medicine, Boston, MA; 3) Dept of Genetics and Genomics, Boston Univ Sch Medicine, Boston, MA.

Cardio-Facio-Cutaneous (CFC) syndrome [MIM 115150] was first described by Reynolds *et al*. (1986) in eight unrelated individuals with multiple congenital anomalies, mental retardation, and characteristic facial features. Since its original description, 100-200 additional patients have been reported. In 2006, mutations in genes within the RAS-MAP kinase pathway were implicated as causative of CFC (Rodriguez-Viciana *et al*.; Niihori *et al*.). The CFC phenotype is known to be reminiscent of Noonan syndrome and Costello syndrome, and the differential diagnosis can be difficult, particularly in infancy. We describe a 3.5 month old male (ex 30 4/7 weeker; at birth paternal age was 51 years and maternal age was 38 years) with a clinical and molecular diagnosis of CFC. C-section delivery was required secondary to breech presentation and NRFHT. His birth weight was 1610g, birth length was 38.5cm, and birth OFC was 29cm. He developed hyperbilirubinemia requiring phototherapy for five days. On physical examination, he was noted to have a broad nasal bridge, epicanthal folds, downslanting palpebral fissures, low set ears with prominent upturned lobules, a broad short neck with an excess nuchal fold, wide low set nipples, and hypotonia. A renal ultrasound revealed a right duplex kidney. On DOL 29, given the patient's dysmorphic features and valvar pulmonic stenosis (gradient of 30mm Hg), RAS-MAP kinase conditions were queried. Molecular testing for CFC revealed a heterozygous reported mutation (T241P) in exon 6 of the *BRAF* gene. At 3.5 months (CA: 5 weeks) a repeat echocardiogram also detected mild LVH, possibly indicating HCM. In addition, the patient had sparse scalp hair, very sparse eyebrows, and sparse eyelashes. Since the molecular elucidation of CFC, *BRAF* mutations are known to be the most common, accounting for approximately 75-80% of patients. The T241P *BRAF* mutation was first described by Nava *et al*. (2007) in one patient, and again by Shulz *et al*. (2008) in two unrelated patients. We describe a premature male infant patient with CFC who further contributes to the clinical phenotype of *BRAF*-related CFC. To our knowledge, our patient may be the earliest postnatal molecularly confirmed case of CFC. Syndromes involving the RAS-MAP kinase pathway need to be considered in a neonate with pulmonic stenosis and dysmorphic features. Molecular testing is useful for confirmation of diagnosis and enables better anticipatory guidance.

**Spondyloepiphyseal dysplasia-bracydactyly and distinctive speech: a propos of a new male case.** *N.Y. Nunez-Reveles[1], J. Sanchez-Corona[2], G. Castaneda-Cisneros[3], J.E. Garcia-Ortiz[4], J.R. Corona-Rivera[1], N.O. Davalos-Rodriguez[1], G. Perez-Garcia[5], D. Garcia-Cruz[1].* 1) Instituto de Genetica Humana "Dr. Enrique Corona Rivera", Departamento de Biologia Molecular y Genomica, CUCS, Universidad de Guadalajara, Guadalajara, Jalisco, Mexico; 2) Division de Medicina Molecular, Centro de Investigacion Biomedica de Occidente, CMNO, IMSS, Guadalajara, Jalisco, Mexico; 3) Servicio Neurocirugia, Hospital de Especialidades, UMAE, CMNO, IMSS, Guadalajara, Jalisco, Mexico; 4) Division de Genetica, Centro de Investigacion Biomedica de Occidente, CMNO, IMSS, Guadalajara, Jalisco, Mexico; 5) Servicio de Genetica, Hospital Civil "Fray Antonio Alcalde".

Introduction. Spondyloepiphyseal dysplasia-brachydactyly and distinctive speech (SED-BDS), also called Fantasy Island syndrome, or Tattoo Dysplasia OMIM N° %671717 was first described by Cantu et al in 1991, although the first affected case was studied by J.R. Gorlin, an anecdotic report of a father and son by J. Hall and C.L. Johnson reported five more affected individuals. Clinically and radiologically is characterized by short stature with acral shortness, distinctive face, mild blepharophimosis, upslanted palpebral fissures, abundant eyebrows and eyelashes, thick and abundant hair and coarse voice; and radiologically by brachymetacarpalia, brachymetatarsalia and brachyphalangia of all fingers and toes, short and broad long bones with normal morphology and small pelvis. Case Report. The propositus aged 43 years old, was the product of the 3rd pregnancy from non-consanguineous parents; prenatal and delivery antecedents are unknown. He is an actor in a taurine show since 32 years ago. At physical examination his height was 130 cm (more than -3 SD), weight 36 kg (more than -3 SD), OFC 53.3 cm (-1.5 SD), armspan 134.5 cm, lower segment 55.5 cm, upper/lower segment ratio 1.34, total hand length 14 cm (more than - 3SD), foot length 19 cm (more than -3 SD). Clinically he showed disharmonic short stature, blepharophimosis, abundant eyebrows, upslanted palpebral fissures, depressed nasal bridge, long philtrum, large mouth with thick lower lip, round chin; short and wide neck; abundant and thick scalp hair; short thorax, rhizo-meso-acromelic shortness in the four extremities, limited pronosupination, short and stubby hands and feet with generalized brachydactyly; coarse voice was evident. The X-ray examination revealed cuboid-shaped vertebral bodies and lack of lumbar lordosis, hypoplastic pelvis, short and broad tubular bones, brachymetacarpalia and brachymetatarsalia, brachydactyly of all fingers and hypertrophy of the first ray on hands and feet. Conclusions. We report a new sporadic male case with (SED-BDS), corresponding to the 14th known case in the literature.

## 2559/F/Poster Board #75

**Infantile Convulsion Choreoathetosis Syndrome in a Hong Kong Chinese Family.** *C.W. Fung, H.Y.B. Chung, P. Ng, M. Zhao, W.L. Yang, V.C.N. Wong.* Department of Paediatrics & Adolescent Medicine, The University of Hong Kong, Queen Mary Hospital, Pokfulam Road, Hong Kong.

Background: Infantile convulsion choreoathetosis syndrome (ICCA) is inherited as an autosomal dominant trait. Seizures appear at 3-12 months, and are partial and may secondarily generalize. Seizures soon stop but paroxysmal choreoathetosis starts between 5-9 years. Genetic studies reveal evidence of linkage to the pericentromeric region of chromosome 16. No causative gene has been found to date. The SLC5A11 gene, encoding a sodium/glucose cotransporter and located in 16p12-p11 region, is postulated to be a candidate. However, no pathogenic mutation was found so far in families with ICCA. We report a Chinese family with ICCA syndrome. Method and Result: CWP was a 30-month-old boy who presented with 3 episodes of generalized tonic clonic convulsions, which may or may not be provoked by upper respiratory tract infection, between 6 and 7 months old. Physical examination and EEG was unremarkable. He was treated with low-dose valproate and remained seizure free since then. At 30 months, he had mild developmental language delay. His maternal 1st cousin, CWH, was a 16-year-old boy. He had multiple generalized tonic clonic seizures associated with upper respiratory tract infection at 11 months old. He was put on a week course of anticonvulsant then remained seizure-free. Since the age of 10, he had recurrent episodes of choreoathetosis involving all the 4 limbs. He had normal intelligence with normal neurological examination. The diagnosis of paroxysmal kinesigenic dyskinesia (PKD) was subsequently made. Once diagnosed, low-dose carbamazepine induced remission. 4 other family members had infantile convulsions with complete remission after few years of age. They did not have PKD. 2 more had transient PKD without infantile convulsion. They were not on treatment. Direct sequencing of the 15 coding exons of SLC5A11 gene from CWP, his mother and his normal sister did not show any coding mutations or splicing junction changes, indicating that this gene may not be involved in this family. Conclusion: Our family shows typical features of ICCA syndrome. Accurate diagnosis is very important as it is amenable to low-dose anticonvulsant treatment and in general of good prognosis. In agreement with other studies, our family may not be related to SLC5A11 gene mutation. Further linkage study is in progress.

## 2560/F/Poster Board #76

**Clinical aspects of Noonan syndrome in one Polish family with mutation p.L613V in *RAF1* gene.** *E. Ciara, A. Tańska, M. Kugaudo, D. Jurkiewicz, M. Gajdulewicz, A. Jezela-Stanek, K.H. Chrzanowska, D. Piekutowska-Abramczuk, M. Borucka-Mankiewicz, P. Kowalski, A. Barczyk, E. Popowska, M. Krajewska-Walasek.* Department of Medical Genetics, The Children's Memorial Health Institute, Warsaw, Poland.

Noonan syndrome (NS) is an autosomal dominant disorder, characterized by short stature, facial dysmorphism, a wide spectrum of congenital heart defects, chest deformity, scoliosis, hearing loss, motor and neurocognitive delay, various coagulation defects and lymphatic dysplasias. After 2006, mutations in the *RAF1* gene were reported to cause Noonan syndrome, in addition to the *PTPN11*, *SOS1*, *KRAS* genes, and now we can find the etiology of the disease in approximately 60-70% of NS cases. All these genes encode proteins of the Ras-MAPK signaling pathway. Mutations in the *RAF1* gene are rare and were detected in 3-17% of individuals clinically diagnosed with NS. To date, nearly 20 various missense mutations were identified in *RAF1* in NS patients. Most of them occurred *de novo*; only one substitution was of familial origin. In this study we report on a Polish family with an affected mother and three children (twins and their older sister) who have inherited Noonan syndrome caused by *RAF1* gene mutation. The family was refereed to our department 15 years ago for the evaluation of congenital heart defects and short stature. The observed heart anomalies were as follow: valvular and supravalvular pulmonary stenosis, hypertrophic cardiomyopathy in a twin boy, patent foramen ovale in a twin girl and valvular pulmonary stenosis in their older sister, in whom also personality disorders were diagnosed. The physical examination revealed the distinctive facial dysmorphism in all of them. It was severely expressed in the twins and resembled their mother's phenotype (curly, coarse hair, hypertelorism, low nasal bridge, posteriorly rotated low-set ears, low posterior hairline and short neck). No developmental delay was noted, twins had borderline development while the oldest patient's IQ score was very high. The patients' mother had short stature, no heart abnormality and high IQ score. In all 4 cases, the analyses of the *RAF1* gene (by SSCP or HRM and sequencing technics) revealed a nucleotide substitution c.1837C>G leading to p.Leu613Val missense mutation. This mutation is localized in the region of the *RAF1* gene coding for CR3 kinase domain and results in increased CRAF kinase activation. So far only two cases with the p.Leu613Val mutation in NS and one in LEOPARD syndrome have been described. We compare the clinical data of our family patients with the previously reported cases. The study was supported by MNiSW Project PB 0056/B/P01/2008/35 and by CMHI project 190/08.

## 2561/F/Poster Board #77

**WAGR Syndrome: Oral and Craniofacial Characteristics.** *D.L. Domingo[1], N. Tomona[1], K.M. Danley[2], M.K. Tune[2], J.C. Han[2].* 1) Clinical Research Core, NIDCR/NIH, Bethesda, MD; 2) DEB, SWHR, NICHD / NIH Bethesda, MD.

BACKGROUND: WAGR syndrome is a rare genetic disorder caused by heterozygous contiguous gene deletions of variable size on chromosome 11, and is characterized by Wilms tumor, aniridia, genitourinary anomalies, mental retardation, and, in those with deletion of the brain-derived neurotrophic factor gene, hyperphagia and obesity. OBJECTIVE: As part of a comprehensive phenotype-genotype study, we characterized clinical features involving the oral-craniofacial structures. METHODS: Nine WAGR patients (2 males, 7 females; 8-38 yrs, median 17 yrs, mean 19 yrs) were prospectively examined. Clinical, radiographic, and cephalometric findings were noted. RESULTS: Patients in permanent dentition (n=7) universally exhibited an anterior openbite and/or crossbite(s). Three presented with bilateral crossbites, 2 left unilateral, and 3 anterior. Unusual palatal morphology was highly prevalent, manifested as hypertrophic alveolar bone plates (n=9; 100%) and narrow palatal arches (n=8; 89%). In addition, a midline sagittal thick fibrotic palatal bridge was present in the oldest 6 patients (14-38 yrs) (67%). Among those who could cooperate with visualization of the oropharynx (n=7), deep surface fissures extending from the hard palate-soft palate junction were universally manifested. Cephalometric measurements (n=8) yielded the following: 1) upper pharyngeal constriction (n=8; 100%; range: 6-13 mm; norm: 15-20 mm); 2) shorter anterior cranial base (n=8; 100%; range: 44-70 mm; norm: 73-75 mm); and 3) protrusion of upper and/or lower lips (n=7; 88%). Assessment of hyoid bone position (n=7) yielded: 1) longer distances between the hyoid and base of mandible (range: 23-25 mm; norm: 10-14 mm) in 6 patients (86%); and 2) longer distances between hyoid and mandibular symphysis (range: 44-52 mm; norm: 40-44 mm) in the same six patients (86%), half of whom were obese. CONCLUSION: Our study identified novel features involving the oral-craniofacial tissues. The high prevalences of oral tissue irregularities and dental crossbites highlight developmental aberrations involving the maxillary apparatus. The inferior-posterior positioning of the hyoid bone is consistent with the measured pharyngeal constriction and may reflect co-existing obesity or could be an additional phenotype. By contributing to the clinical picture of WAGR syndrome, our preliminary findings may yield further insight into this complex condition.

## 2562/F/Poster Board #78

**A novel mutation in the SMC1A gene in a boy with Cornelia de Lange and severe clinical manifestations.** *F.J. Ramos[1,3], M.P. Ribate[1,2], C. Gil[2], M. Ciero[2], B. Puisac[2], M. Arnedo[2], J.C. de Karam[2], A. Luis-Díaz[2], J. Pie[1,2].* 1) Dpto. Pediatría, Facultad de Medicina, Universidad de Zaragoza, Zaragoza, Spain; 2) Laboratorio de Genética Clínica y Genómica Funcional, Dpto. Fisiología, Facultad de Medicina, Universidad de Zaragoza, Zaragoza, Spain; 3) Servicio de Pediatría, Hospital Clínico Universitario -Lozano Blesa- , Zaragoza, Spain.

Cornelia de Lange Syndrome (CdLS; OMIM 122470 and 300590) is an inherited multisystemic developmental disorder characterized by distinctive dysmorphic craniofacial features, growth and cognitive impairment and limb malformations. Mutations in two major genes (NIPBL and SMC1A) of the cohesin complex and its regulators have been found in about 60% of affected patients. To date, 11 different mutations in 14 unrelated individuals have been reported in the X-linked SMC1A gene. Here we present a 3 year-old male with mild CdLS facial appearance, microcephaly, postnatal growth retardation and moderate psychomotor retardation with absence of speech. He had no major limb defects, except for a bilateral brachyclinodactyly of the 5th finger and a 2-3 syndactyly in the feet. He also had congenital heart defect (ASD and PDA) and severe gastroesophageal reflux that caused Sandifer syndrome with cyanotic “seizure-like” episodes of up to a minute of duration. He was found to have a novel sporadic mutation in the SMC1A gene (p.R711Q) that altered a highly conserved residue and was not detected in his parents or in 50 control individuals. The mutation was located at the SMC coiled-coil domain and we hypothesize that it may affect its angulation within the proteína. This case underscores that, despite most mutations in the SMC1A gene generally cause a mild external phenotype, there are mutations that may result in severe physical and cognitive impairment. This work was in part supported by a grant from the Ministerio de Sanidad y Política Social of Spain (Ref. PI061343) and from the Gobierno de Aragón (Ref. B20).

## 2563/F/Poster Board #79

**SECKEL SYNDROME ASSOCIATED TO RENAL TUBULAR ACIDOSIS: TWO CASES REPORT AT THE HOSPITAL PARA EL NIÑO POBLANO, MEXICO.** *F.L.F. Hernandez[1], R.J.M Aparicio[2,3].* 1) Nephrology; 2) Medical Genetics, Hospital para el niño poblano, Mexico; 3) Estomatology, Benemerita Universidad Autonoma de Puebla.

INTRODUCTION. The Seckel syndrome or microcephalic primordial dwarfism is a congenital hereditary recessive disorder supposed to be caused by defects of genes on chromosome 3 and 18. One form of Seckel syndrome can be caused by mutation in the gene RAD3-related protein (ATR) which maps to chromosome 3q22.1-q24. This gene is central in the cell’s DNA damage response and repair mechanism. The main symptoms include severe mental retardation (more than half of the patients have an IQ below 50), achondroplasia, microcephaly, pancytopenia, cryptorchidism, low birth weight, dislocations of pelvis and elbow, unusually large eyes, low ears and small chin. CASE 1. A one and a half years old Male patient was estudied in 2005 at the Hospital due to low birth weitght, deshidratation and weight losses. He was diagnosed as Seckel syndrome with tubular acidosis, treated with sodium bicarnonate. Fenotipicallly, microcephaly, a bird-headed profile, unilateral ocular strabism, cryptorchidism and mental retardation. CASE 2. A one years old female patient was also estudies at the Hospital in 2005 due to low birth weitght, deshidratation and weight losses. She was diagnosed as Seckel syndrome with tubular acidosis, treated with sodium bicarnonate and metabolic acidosis with a normal GAP anion. Fenotipicallly, microcephaly, a bird-headed profile and and mental retardation. Both patients with normal Kidney structure reported with a renal ultrasound. CONCLUSIONS. Both patients were diagnosed as Seckel syndrome. However, both were treated with Sodium Bicarbonate, due to their association to Renal Tubular Acidosis. It would be important to find this renal alteration pathogenesis with this specific syndrome. REFERENCES. 1.- Cruz M, Bosch J. Atlas de síndromes pediátricos. EPAX 2003. Barcelona. Clinical and genetic heterogeneity of Seckel syndrome. Am J Med Genet 2002; 112:379-383.

## 2564/F/Poster Board #80

**Complex deletion/duplication rearrangement involving the X chromosome in a male with novel phenotype combining elements of Langer mesomelic dysplasia and severe rhizomelic shortening.** *R. Mendoza-Londono[1], L. Dupuis[1], P. Babyn[2], D.J. Stavropoulos[3].* 1) Division of Clinical & Metabolic Genetics and; 2) Department of Diagnostic Imaging and; 3) Department of Pediatric Laboratory Medicine; The Hospital for Sick Children, University of Toronto, Toronto, ON, Canada.

Langer-type mesomelic dysplasia (MIM 249700) is a recessive skeletal dysplasia that results from haploinsufficiency for *SHOX*, located in the pseudoautosomal region of chromosomes X and Y. It is characterized by severe mesomelic shortening and micrognathia. Radiologic findings include: mesomelia with short and broad ulna and radii, marked shortening of the tibia and rudimentary fibula. The rest of the skeletal elements are usually not involved. We present the radiologic and cytogenetic findings in a four month old boy who was identified during the prenatal period to have rhizomelic shortening. On assessment at 4 months of age he had mildly dysmorphic features given by a broad nasal bridge, micrognathia and plagiocephaly. His extremities were significantly short. His radiographs showed asymmetric marked bilateral shortening of the femurs with a triangular shape. The tibias and fibulas were poorly modeled and had moderate shortening. The humerii, radius, ulna and radii were markedly short and bowed. Both hands had ulnar deviation. X-rays of the parents demonstrated bilateral Madelung deformities in the mother. Cytogenetic analysis revealed a male karyotype with an unbalanced X chromosome harboring a terminal deletion with breakpoint at Xp22.33. The deleted region is replaced by an additional copy of chromosome region Xq28 to Xqter [46,Y,der(X)(qter->q28::p22.33->qter).ish der(X)(pter-,qter++)]. Array CGH with an oligoarray platform confirmed the terminal deletion/duplication. The deletion involves 62 oligonucleotide probes (0.749 Mb) and results in the loss of the *SHOX* gene on the X chromosome. The terminal duplication involves 136 oligonucleotide probes (5.898 Mb) and results in the gain of one copy of approximately 108 genes. Molecular testing for *SHOX* mutations in the other allele is underway Our patient presents with a novel phenotype including features of Langer mesomelic dysplasia as well as atypical findings including severe rhizomelic shortening. His phenotype is likely the result of haploinsufficiency and excess dosage for genes located in the area of the deletion/duplication. Further delineation of his rearrangement is underway to allow the identification of genes that may be critical for the development of the limb’s proximal segment.

## 2565/F/Poster Board #81

**A PATIENT WITH NEONATAL PROGEROID (WIEDEMANN-RAUTENSTRAUCH) SYNDROME AND COMPLEX CHROMOSOMAL REARRANGEMENT (CCR).** *A. Singer[1], K. Devriendt[2], D. Lev[3], C. Vinkler[3].* 1) Dept Clinical Gen Unit, Barzilai Med Ctr, Tel Aviv, Israel; 2) Kliniekhoofd, Centrum Menselijke Erfelijkheid, Leuven Belgium; 3) Institute of Medical Genetics Wolfson Medical Center, Holon, Israel.

The neonatal progeroid syndrome (NPS), or Wiedemann-Rautenstrauch (WRS), is a very rare autosomal recessive disorder. Approximately 30 patients with WRS have been reported. The clinical presentation is characterized by an appearance of premature aging, general absence of subcutaneous fat, prenatal growth deficiency, sparse scalp hair, eyebrows, and eyelashes, relative macrocephaly, persistent anterior fontanelle and natal teeth and mental retardation. We present a girl with a clinical diagnosis of NPS with deletion-duplication in chromosome 17. She is the first child of unrelated couple from Ukraine. Pregnancy was uneventful until shortly before 34w gestation when IUGR was diagnosed and early delivery was induced. Birth weight was 1230 gr, length was 37 cm, and head circumference was 28 cm. She had congenital glaucoma in her right eye and two natal teeth.. She underwent trabeculotomy and teeth excision. She had a small PDA and ASD. At the age of one year her height, weight and head circumference were 4SD below the average for her age and she was developmentally delayed. She still had widely open sutures and a permanently open fontanelle . Karyotype is: 46,XX. At the age of two years her weight, head circumference and height were around -6SD below the average for her age. She had prominent scalp veins, facial dysmorphism sparse eyebrows and hair and significant developmental delay. Brain MRI showed a Chiari 1 malformation, mild ventricular dilatation, and white matter changes. Hearing and vision were normal. Growth hormone and basal metabolic evaluation were normal. Array based genomic hybridization was done: 6q24.1(RP11-631F7)x1;17p13.3(RP11-216P6?RP11-233O10)x1;17p13.1(RP11-243K12?RP11-404G1)x3. Molecular karyotyping by means of BAC array with 1 Mb resolution revealed several chromosomal defects in this patient. (1) a submicroscopic microdeletion was detected on the long arm of chromosome 6. This microdeletion was inherited from the patient's father. (2) Both a deletion and a duplication were detected on the short arm of chromosome 17. These defects were confirmed by qPCR and occurred de novo. This is the first case of a complex chromosomal rearrangement associated with neonatal progeroid syndrome. Our data illustrate the important role for high-resolution investigation of apparently normal karyotype in patients with unexplained developmental delay and/or other clinical features.

## 2566/F/Poster Board #82

**Clinical and cytogenetic characterization of a familial duplication 16p11.2 using microarray-CGH technology. A new syndrome?** *A. Iglesias.* Dept Pediatrics, Div Genetics, Beth Israel Medical Ctr, New York, NY.

Duplications on chromosome 16p11.2 are rare, and have been considered non-pathogenic. However, recent reports have found them associated with an increase susceptibility for autism in about 1% of the cases. However, no evidence of developmental delay and/or dysmorphic phenotypes have been reported. A familial 16p11.2 duplication associated with a variable clinical presentation on the proband, her brother and her mother is described clinically and cytogenetically. The proband is a 26 month-old female, born at term after a pregnancy complicated for maternal seizure disorder that was well controlled. Delivery was vaginal. Birth weigh was 2.4 kg, length 45 cm and head circumference 32 cm. She was small for gestational age. Without complications she was sent home on day 2. By 9 months her development was delayed. On exam she was unable to sit without support. Language was also delayed. Weight was on the 5th percentile, length was normal and head circumference was 41 cm. Positive findings included microbrachicephaly, closed fontanels, hypertelorism, epichantal folds, downslanting palpebral fissures, and small nose with depressed nasal bridge, smooth philtrum, bowed upper lip and cupped ears. Axial hypotonia with normal strength and normal reflexes were found. Chromosome were normal, 46,XX. However, a microarray-CGH showed a duplication that at least 250 kb at band 16p11.2. Further evaluation of the proband at 13 months, showed no changes in her phenotype and mild progress in development. Maternal studies showed the same duplication. Moreover, the mother had a history of learning disability as a child and thereafter. In addition, she shares similar facial dysmorphic features with the proband. At the time of the maternal diagnosis, she was 7 months pregnant. She delivered a full term boy without complications. Microarray-CGH analysis showed the same duplication 16p11.2. On physical examination, the boy showed similar facial dysmorphic features, but normal development and growth by 2 months of age. He is currently on follow-up. To our knowledge, this is a unique report of a family carrying a duplication 16p11.2 associated with distinct physical dysmorphic features and developmental delay/learning disabilities; although the expression of the phenotype seems to be variable. Continuing follow-up of this family as well as further cases will give insights into this new syndromic condition associated with 16p11.2 duplication. .

## 2567/F/Poster Board #83

**A Case of XY Sex Reversal and Nail-Patella Syndrome Due to an Interstitial Deletion of Chromosome Region 9q33.3-9q34.11.** *D. Kostiner[1], C. Beattie[1], P. Jacky[2], D. Quigley[2], L. Jenkins[3].* 1) Dept. of Clinical Genetics, Kaiser Permanente PC, Portland, OR; 2) Dept. of Cytogenetics, Kaiser Permanente PC, Portland, OR; 3) TPMG Regional Genetics Laboratory, San Jose, CA.

We present the case of an XY female with mental retardation, small stature, skeletal defects and nail anomalies to add to the limited literature on 9q microdeletions involving the NR5A1 and LMX1B genes. The sex reversal in this pt. was known prenatally because genitals appeared female by ultrasound, but amniocentesis (performed for IUGR and club feet) revealed a 46,XY karyotype. The result was confirmed postnatally. Additional work-up revealed 11 pairs of ribs, absent ovaries, normal uterus, normal kidneys, and oddly-formed, hypoplastic nails of the thumbs and second digits. Smith-Lemli-Opitz was excluded with normal 7-dehydrocholesterol testing. Campomelic dysplasia was suspected, but sequencing of the SOX9 gene showed no mutation. At age 4 years, a CGH Array test was done. The result showed a 3.67Mb deletion from 9q33.3-9q34.11. Parental studies confirmed that the deletion was de novo. The deleted region contains at least 48 annotated genes, including the NR5A1 gene, reported to be associated with XY sex reversal, and the LMX1B gene, reported to be associated with nail-patella syndrome (although usually when mutated, not deleted). The literature reveals only a few other cases of 9q deletions involving these genes, but additional studies, such as "smallest region of overlap" (SRO) analysis, might further delineate the phenotypic features of these genes and others in the region.

## 2568/F/Poster Board #84

**Phenotypic comparison of Williams syndrome and its reciprocal duplication syndrome reveals significant differences in dysmorphic features, speech, cognitive ability, and type of anxiety.** *C. Morris[1], C. Mervis[2], S. Velleman[3], A. John[2], A. Currier[2], C. Rios[1], K. Kimberley[1], N. Crawford[2].* 1) Dept Pediatrics, Genetics Div, University of Nevada School of Medicine, Las Vegas, NV; 2) Dept. Psychology, University of Louisville, Louisville, KY; 3) Communication Disorders, University of Massachusetts, Amherst, MA.

Williams syndrome (WS) is caused by deletion of 25 genes on chromosome 7q11.23 mediated by nonallelic homologous recombination. Chromosome microarray technology resulted in detection of the reciprocal duplication of the region (Dup7). The study's purpose is to delineate the Dup7 phenotype, compare it to WS, and identify traits likely sensitive to gene dosage. Method: Physical, cognitive, language, and speech assessments were performed on 17 children and 6 adults with Dup7 and on 2 children with longer duplications including HSP27. Performance was compared to that of participants with WS. Results: Dup7: 11 males, 14 females; 11 cases sporadic, 14 familial. Dysmorphic features: prominent forehead (75%), high broad nose (70%), long columnella (52%), short philtrum (36%), facial asymmetry (95%). Birth defects were rare, including one person each with ASD/VSD, hydrocephalus, sagittal craniosynostosis, and severe micrognathia. Two had club feet. About 60% had ADHD, and 82% had anxiety (social phobia, separation anxiety). Mean standard scores on most measures were higher for the Dup7 group than the WS group. While the WS cognitive profile includes severe weakness in visuospatial construction, participants with DUP7 had DAS-II Spatial Cluster and VMI standard scores averaging ~20 points higher than for WS. Verbal standard scores averaged ~10 points higher than for the WS group. A particularly striking characteristic was current or former difficulty with speech; despite generally strong receptive language, 92% had severe speech delay and 95% had problems with motor speech and/or oral-motor movements. Some had symptoms of Childhood Apraxia of Speech. The combination of delayed speech and shyness/anxiety led to an inappropriate diagnosis of autism in some young children. Discussion: The facial phenotype of Dup7 is subtle, but recognizable. GTF2IRD1 has been implicated in the facial asymmetry in WS, and may be copy number sensitive, since it is a trait shared by the Dup7 group. Both groups share anxiety as a behavioral problem, but specific phobia is seen in WS, while separation and social anxiety are found in Dup7. The strong differences in speech and cognitive abilities between children with WS and those with Dup7 suggest that one or more genes in the WS region are dosage sensitive and that these genes, in transaction with other genes and the environment, are important for speech and cognitive development.

## 2569/F/Poster Board #85

**Haemolytic uraemic syndrome in a patient with 46XX,del(10)(p13).** *F. Gök[1], S. Vurucu[2], S. Kozan[3], D. Gül[3].* 1) Pediatric Nephrology, Gulhane Military Medical Faculty, Ankara, Ankara, Turkey; 2) Department of Pediatric Neurology, GATA Medical Faculty, Ankara, Turkey; 3) Department of Medical Genetics, GATA Medical Faculty, Ankara, Turkey.

The patients with short arm deletion of chromosome 10 show high phenotypic variability, and until now more than 50 cases have been reported. We present a 5-year-old girl with a partial monosomy involving chromosome segment 10p13→pter. The proposita, first product of a second cousin marriage was referred with complaints of oliguria and hematuria persisting about 5 days followed by fever, vomiting and diarrhoea at her 16th month. She had hypocalsemic convulsion at her 3rd month. In addition to growth retardation, craniofacial features were remarkable: mild dysmorphism, microcephaly, trigonocephalic head, frontal bossing, hypertelorism, short and down-slanting palpebral fissures, epicanthus, ptosis, strabismus, high and broad nasal bridge with anteverted nostrils, small low-set pinnae, asymmetric facial appearance with right gum hypertrophy and skin hyperpigmentation in the left preauricular region , low-set and underdeveloped ears, prominent upper lip, micrognathia, high palate, and short neck. Widely spaced nipples, a gap between toes 1-2 and mild cutaneous syndactyly of toes 2-3 bilaterally and congenital hip dislocation at left were also present. Right kidney was absent. The diagnosis of haemolytic uraemic syndrome (HUS) was made on the basis of thrombocytopenia, microangiopathic haemolytic anaemia and acute renal failure, associated with diarrhoea. The karyotype was 46,XX,del(10)(p13). The karyotypes of parents were normal. We here suggest that haemolytic uraemic syndrome may be a part of the 10p13 deletion syndrome. Renal abnormalities should also be considered in cases of postnatal growth and mental retardation together with craniofacial dysmorphism.

## 2570/F/Poster Board #86

**Further characterization of a microdeletion syndrome involving 2p15-p16.1.** *T.M. Felix[1], A.L. Petrin[2], M.T.V. Sanseverino[1], J.C. Murray[2].* 1) Servico de Genetica Medica, Hospital Clinicas Porto Alegre, Porto Alegre, RS, Brazil; 2) Department of Pediatrics, University of Iowa, Iowa City, IA, USA.

Screening of the whole genome for submicroscopic abnormalities in patients with multiple congenital anomalies and mental retardation (MCA/MR) using new technologies such as array-CGH or single nucleotide polymorphism (SNP) arrays has increased the number of previously unrecognized cytogenetic abnormalities. Recently, the use of array CGH contributed to the description of a new microdeletion syndrome involving the region 2p15-p16.1 (Rajcan-Separovic et al., 2008). The authors described two unrelated patients with a 4.5 and 5.7 Mb deletion respectively presenting with microcephaly, ptosis, short palpebral fissures, broad and high nasal root, camptodactyly, cortical dysplasia and mental retardation. A third case was described presenting with a 570 kb deletion in the 2p15 region (Chabchoub et al., 2008). We report a patient with mental retardation, prenatal and postnatal growth deficiency, microcephaly, ptosis, a high and broad nasal root and camptodactyly. Analysis of Affymetrix genome-wide human SNP array 6.0 showed a 3.35Mb deletion in 2p15-p16.1. Studies of selected SNPs in the deleted area in the proband and her parents showed Mendelian errors compatible with a paternal origin of the deletion. Based on the three cases described previously in the literature we narrowed down the critical region responsible for the 2p15-p16.1 microdeletion syndrome to the position 59,200,000 and 61,700,000. The common deleted area included several known genes with different functions. One of those genes is CCT4, which assists in the folding of actin and tubulin. We suggest that haploinsufficiency of CCT4 gene may play a role in the camptodactyly of 2p15-p16.1 syndrome and may be a good candidate gene for still unknown arthrogryposis syndromes.

## 2571/F/Poster Board #87

**Microdeletion 1q21.1: A locus newly found to be associated with wide phenotypic variability and reduced penetrance.** *T. Jewett[1], C. Haldeman-Englert[2], M.N. Berry[1], L. Terry[1].* 1) Dept Pediatrics, Med Gen, Wake Forest Univ Sch Med, Winston-Salem, NC; 2) Div Hum Gen, Children's Hospital of Philadelphia, Philadelphia, PA.

1q21.1 is a region rich in segmental duplications and low-copy repeats, predisposing to rearrangements at this site. Recurrent copy number abnormalities at this locus have recently been reported in association with numerous outcomes ranging from a normal phenotype to neuropsychiatric disorders to multiple congenital anomalies and/or intellectual disability. We present 5 individuals in 2 families with overlapping microdeletions of 1q21.1, each of whom has a distinctive phenotype, demonstrating the difficulty in predicting natural history. MK is a 2 4/12 year old girl who was evaluated in genetics clinic initially at 7 months of age due to congenital bilateral ptosis of the eyelid requiring surgical correction as well as laryngomalacia, gastroesophageal reflux, and mild developmental delays. Family history disclosed that MK's mother had ptosis of the left eyelid in childhood, microcephaly, and a history of learning difficulties warranting special education classes. MK's mother has a female paternal first cousin who is healthy and cognitively normal whose daughter, TS, has multiple anomalies including microcephaly, bilateral complete coloboma of the eye, postaxial polydactyly of the hands, and delayed development. Genetic testing has revealed that both girls and their mothers have a similar submicroscopic 1q21.1 deletion using array comparative genomic hybridization (CGH). SH is a 2 10/12 year old boy who was first evaluated by a medical geneticist at 8 months of age during his third hospital admission for failure to thrive. Physical exam on SH showed all growth parameters <3%, hypoplastic midface with epicanthal folds and telecanthus, broad nasal bridge and full nasal tip, and mild motor delays. Genetic testing revealed a submicroscopic 1q21.1 deletion using array CGH. His mother was tested for the deletion and is normal; father is unavailable for testing. The cases presented here further expand the spectrum of phenotypes associated with 1q21.1 microdeletions detected by array CGH and highlight the importance of carefully reviewing clinical and laboratory data in patients with genomic rearrangements. We will discuss the specific copy number abnormality discovered in our patients vis-à-vis those recently reported, together with possible mechanisms that account for variability and reduced penetrance.

## 2572/F/Poster Board #88

**Microdeletion of chromosome 9p21.1 associated with eye anomalies and mild developmental delays.** *M.L. Loscalzo[1,2], T.A. Becker[2], M. Sutcliffe[1,2].* 1) Dept Pediatrics, Univ South Florida Sch Med, St Petersburg, FL; 2) Ciinical Genetics, All Children's Hospital; St. Petersburg, FL.

An four year old girl presents with multiple eye anomalies including unilateral retinal detachment with chronic band keratopahy of the right eye and unilateral optic nerve coloboma on the left. This has been accompanied by mild developmental delay and regression particularly in vocal articulation. She currently is 8 ½ years old. She functions at approximately a first to second grade level. She has recently developed hypothyroidism. A routine G-banded karyotype was normal as was PAX6 DNA testing. Array comparative genomic hybridization showed an interstitial loss in copy number in the short arm of chromosome 9 at band p21.1. Parental studies ate pending. These results suggest a potential critical region for eye anomalies such as colobomas. Further investigation will be needed to investigate candidate genes in the region that may be associated with these features.

## 2573/F/Poster Board #89

**Chromosome 1q21.1 deletion: expanding the phenotype.** *J. McGaughran[1], G. Peters[2].* 1) Gen Hlth Queensland, Royal Brisbane and Women's Hospital, Brisbane, Australia; 2) Cytogenetics Dept, Children's Hospital at Westmead, Sydney, Australia.

Deletion of chromosome 1q21.1, detected using array comparative genomic hybridisation, is a newly-described molecular lesion that has a variable phenotype. The phenotype can vary from apparently unaffected carriers to individuals with intellectual impairment, congenital cardiac disease and limb anomalies. A male patient is described with a deletion of 1q21.1. He had significant short stature, ADHD and a number of dysmorphic features. He had a high narrow palate, bilateral preauricular tags, a supernumerary left nipple, small cafe au lait patch on his back and left 2/3 toe syndactyly. He also had high myopia. His features further expand the range seen in 1q21.1 deletion.

## 2574/F/Poster Board #90

**Identification of Unrecognized Submicroscopic Chromosomal Imbalances Associated with Human Disorders of Male Urogenital Development.** *M. Tannour-Louet[1], S. Han[2], S. Corbett[1], S. Yatsenko[3], L. Meyers[3], S.H. Kang[3], S.W. Cheung[3], D. Lamb[1,2].* 1) Scott Department of Urology, Baylor College of Medicine, Houston, TX; 2) Department of Molecular and Cellular Biology, Baylor College of Medicine, Houston, TX; 3) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Congenital abnormalities of the male urogenital tract, including undescended testicles, abnormal development of the penis/urethra and ambiguity of external genitalia, are among the most common human birth defects. The etiology of these reproductive disorders remains poorly understood. By using a clinically validated comparative genomic hybridization microarray (CMA), we reveal the existence of cryptic chromosomal rearrangements that totally evaded detection by high resolution karyotype in children born with cryptorchidism, hypospadias or genital ambiguity. Imbalances were found in about 31% of the 114 patients analyzed. Anomalies were scattered across the genome but notably clustered in gene- enriched subtelomeric loci. De novo duplications and deletions events were noted on 1p36.33, 9p23p24 and 19q12-q13.11 for ambiguous genitalia and 10p14 and Xq28 for cryptorchidism and 12p13 and 16p11.2 for hypospadias. The causality of the copy number variants was supported by the presence of common chromosomal rearrangements encompassing candidate genes such as FGFR2, DMRT1 and ZEB2 in several unrelated patients. These findings should have significant consequences for clinical diagnosis and genetic counseling and will pave the way for the elucidation of the molecular mechanisms underlying the pathogenesis of congenital urogenital defects.

## 2575/F/Poster Board #91

**Deletion of the SOX5 gene at 12p12.1 is associated with autistic-like behavior and severe language delays.** *A.N. Lamb[1], J. Rosenfeld[1], D. Keelean-Fuller[2], Z. Fan[2], J. Pouncey[3], K. Stevens[3], L. Mackay-Loder[4], D. Terespolsky[4], K. Rosenbaum[5], S. Vallee[6], J. Moeschler[6], R. Dineen[7], G. Hoganson[7], S. Girirajan[8], E.E. Eichler[8], B.A. Torchia[1], L.G. Shaffer[1].* 1) Signature Genomics, Spokane, WA; 2) University of North Carolina, Chapel Hill, NC; 3) TC Thompson Children's Hospital, Chattanooga, TN; 4) Credit Valley Hospital, Mississauga, ON; 5) Children's National Medical Center, Washington, DC; 6) Dartmouth-Hitchcock Medical Center, Lebanon, NH; 7) University of Illinois, Chicago, IL; 8) University of Washington, Seattle, WA.

SOX5 is a member of the Sox (SRY-related HMG box) family of transcription factors that is involved in the regulation of chondrogenesis and in the development of the central and peripheral nervous system. SOX5 spans about 1 Mb in band 12p12.1. Although infrequent, some larger cytogenetically visible deletions of the chromosome 12 short arm have been described, but there is a lack of published submicroscopic deletion cases characterized by array CGH. We describe four patients with small deletions within the SOX5 gene - two de novo and one inherited from a phenotypically abnormal mother - and four larger deletions (5.7, 5.4, 10.5, 8.7 Mbs) that include the complete SOX5 gene. Of the four patients with the small deletion, clinical information was available for two. Both had autistic-like features with severe delays in language development. Dysmorphic features tended to be minor, with butterfly vertebrae of the thoracic spine and mild scoliosis, and small simple ears and low nasal bridge in one patient. Both had low, normal growth for wt, ht, and head circumference. The 3rd patient with a small deletion had an indication of developmental delay and failure to thrive, and was inherited from the mother (4th patient) with developmental delay (details not yet available). In the individuals with larger deletions, the language impairment was also observed with severe speech delay in three (no details on 4th yet available) and developmental delays in all. No aggressive behavior was noted in this group. Other clinical features identified in at least two individuals included mild facial features, MRI abnormalities, digital anomalies, and minor spinal anomalies. Data on deletions in the SOX5 gene from a control population of 5674 samples (Itsara et al, 2009) show only one deletion in an intron of the gene. These cases suggest that deletions of SOX5 may represent a new microdeletion syndrome with autistic-like behavior and severe language delays, and larger deletions encompassing the gene also have additional dysmorphic features.

## 2576/F/Poster Board #92

**2q23.1 microdeletion involving the MBD5 gene - large deletion associated with a relatively mild phenotype.** *HYB. Chung[1], DJ. Stavropoulos[2], R. Weksberg[1], G. Yoon[1,3].* 1) Clinical & Metabolic Gen, Hosp Sick Children, Toronto, Canada; 2) Department of Paediatric Laboratory Medicine, Hospital for Sick Children, University of Toronto, Toronto, Canada; 3) Department of Paediatrics, Division of Neurology, Hospital for Sick Children, University of Toronto, Toronto, Canada.

Background: We report a female patient with a de novo interstitial deletion in chromosome region 2q23.1-23.3 identified by array-CGH. To our knowledge, this is the 6th reported case of a patient with a deletion corresponding to the same genomic region containing the MBD5 gene, a homologue of MECP2, implicated in the pathogenesis of Rett syndrome. Case Report: The proband was born at 41 weeks to healthy non-consanguineous Caucasian parents, with a birth weight of 9lb 1oz. She had significant global developmental delay affecting gross motor, fine motor and speech. She developed seizures at 3 years, which were not controlled despite trials of multiple antiepileptics. There was history of regression at age 6, with progressive difficulties with balance, loss of fine motor skills and worsening aggressive behavior. On examination at age 7 years, 3 months, she was profoundly microcephalic (HC << 2nd percentile, 50th centile for 13 months) and of short stature (height at 3rd percentile), while her weight was at the 75th percentile. She had dysmorphic features consisting of low anterior hairline, mild synophrys, almond-shaped eyes, long nasal columella, short philtrum, thin upper lip, and small teeth. On neurological exam, speech was dysarthric but she was able to speak in complete sentences. She demonstrated repetitive hand movements but did not have the wringing movements typical of Rett syndrome. Gait was wide-based and unsteady, and she held her arms in high guard when walking. Results: Karyotype, MECP2 testing, chromosome 15 methylation studies, UBE3A sequencing, MRI/MRS brain, and metabolic studies were all normal. BAC microarray revealed a de-novo deletion at 2q23.1 to 2q23.3 with an estimated size between 3.725 - 5.632Mb. Conclusion: Published cases of 2q23.1 deletion (Vissers et al 2003, Koolen et al 2004, De Vries et al 2005, De Gregori et al 2007, Jaillard et al 2008) suggest an overlapping region of 250 kb involving the MBD5 gene is responsible for the phenotype. Our patient shares similar clinical features to those reported, including microcephaly, developmental delay, speech impairment, seizure and ataxia. She differs by having milder delay in development, with reasonably preserved speech. Interestingly, she had a larger deletion compared to the reported cases, with telomeric extension involving the CACNB4 gene. This case adds to the phenotypic heterogeneity of the newly described "Angelman-like" or "Rett-like" microdeletion syndrome.

## 2577/F/Poster Board #93

**Situs inversus totalis in a fetus with a deletion at 7q36.2 detected on microarray analysis.** *G. Andelfinger[3], M.P. Hitz[3], S. Keating[4], J. Mercier[3], R. Teitelbaum[2], A. Richter[3], H.Y.B. Chung[1,2], D. Chitayat[1,2].* 1) Division of Clinical and Metabolic Genetics, Hospital for Sick Children, Toronto, Ontario, Canada; 2) The Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital, Toronto, Ontario, Canada; 3) Department of Pediatrics, CHU Sainte Justine, Montreal, Quebec, Canada; 4) Department of Pathology and Laboratory Medicine, Mount Sinai Hospital, Toronto, Ontario, Canada.

Laterality disorders are a heterogeneous group of disorders associated with maternal diseases (maternal IDDM), maternal exposures to teratogens (retinoic acid), chromosome abnormalities and single gene disorders (ZIC3 mutation). We report on a fetus with a submicroscopic deletion at 7q36.2 with right atrial isomerism (RAI). CASE:The mother was a 30y G4P1SA2L1 and the father was 35y. Both were healthy and non-consanguineous and their family history was non-contributory. They had a healthy son and daughter and had two miscarriages. MSS was negative. Detailed fetal U/S and echocardiography at 20w showed: RAI with levocardia, L-sided liver and R-sided stomach with common atrium, unbalanced AVSD, hypoplastic LV, DORV, unobstructed aorta arising anteriorly from RV, hypoplastic pulmonic valve and branched pulmonary arteries. The pulmonary veins drained into a confluence and entered the back of the common atrium slightly L- sided. The couple decided to terminate the pregnancy. The autopsy confirmed the ultrasound findings and in addition, detected trilobed L lung, asplenia and bilateral eparterial bronchi. The fetal karyotype & FISH for 22q11.2 were normal. Microarray analysis (SignatureGenomic®) showed deletion at 7q36.2. FISH analysis showed that the father is mosaic for this deletion. CONCLUSION:Genome-wide, array-based CNV confirms the presence of the deletion, shared by affected fetus and his father. Overlapping deletions described in the Decipher database do not show the same phenotype. Based on the deleted interval in the affected fetus, all isoforms of the DPP6 gene are predicted to be haploinsufficient. Looking at the other de novo and shared CNVs, we could not identify other candidate gene directly involved in left right axis patterning. However, a de novo deletion of the KCNC3 gene was detected. Interestingly, DPP6 interacts with the potassium channels of the KV- type. Although these channels have not been described to play a role in LR patterning, several other potassium channels do play a role in LR asymmetry in model organisms. These studies propose a mechanism in which a change in potassium current at the cell membrane leading to a change in the movement of the cilia which are crucial for proper left right axis formation. Thus, the deletion of KCNC3 and DPP6 may act in an epistatic fashion, consistent with a two-hit model affecting potassium channel assembly and, subsequently, cilia movement and LR patterning.

## 2578/F/Poster Board #94

**The first reported case of the DRAGON gene deletion in human. A case with a de-novo interstitial deletion of chromosome 5q15-21.1.** *G. Brenner[4], H.Y.B. Chung[1,2], P. Shannon[3], A. Toi[5], L. Shaffer[6], D. Chitayat[1,2].* 1) Department of Pediatrics, Division of Clinical and Metabolic Genetics, Hospital for Sick Children, Toronto, Canada; 2) Mount Sinai Hospital, The Prenatal Diagnosis and Medical Genetics Program, Toronto, Canada; 3) The Department of Pathology and Laboratory Medicine, Mount Sinai Hospital, University of Toronto, Toronto, Otario, Canada; 4) Department of Anesthesia and Critical Care, Massachusetts General Hospital, Harvard Medical School, Boston, MA, USA; 5) The Department of Diagnostic Imaging, Mount Sinai Hospital,University of Toronto, Toronto, Ontario, Canada;; 6) Signature Genomic Laboratories, Spokane, Washington, USA.

Chondrodysplasia punctata (CDP) is an etiologically heterogenous condition caused by single gene disorders, chromosome abnormalities, maternal diseases or exposures to teratogens. We report a male fetus with rhizomelic CDP associated with deletion at 5q15-5q21.1. This segment contains the DRAGON gene, a bone morphogenetic factor co-receptor, also known as RGMb (repulsive guidance molecule b). It is postulated that its haplo-insufficiency is associated with the phenotype in this fetus. The mother (30yo, G2P0SA1L0) was referred at 19.3 weeks for abnormal antenatal ultrasound findings of short limbs, short splayed digits, brachycephaly, small cistern magna, hypoplastic inferior cerebellar vermis, micrognathia, multiple intra-cardiac echogenic foci and 2-vessel umbilical cord. There was no history of maternal disease/ exposures. The pregnancy was terminated at 21 weeks. Autopsy confirmed the ultrasound findings and in addition showed brain hypomyelination with ventriculomegaly. Biochemical studies revealed normal plasmalogen and cholesterol biosynthetic function. Radiograph showed numerous abnormal calcific stipplings and prematurely calcified ossification centers. There was rhizomelic shortening of proximal long bones, abnormal calcification/ossification in the cervical, thoracic and sacral spine and poorly formed with platyspondyly of the cervical and thoracic spine with thin ribs. The findings were in keeping with rhizomelic CPD. The Agilent 105K array (Signature Genomics) shows a de novo 3.4Mb deletion at 5q15-5q21.1. The region does not contain any OMIM disease genes and has not been reported in the DECIPHER Initiative. It contains 3 genes including the DRAGON (RGMB) gene, which is of interest as its encoding protein is a bone morphogenetic protein (BMP) co-receptor. BMPs induce ectopic bone and cartilage formation in experimental animals. They are important for skeletal patterning and are involved in the development of many tissues including bones, craniofacial structures and nervous system. As a co-receptor for BMPs, DRAGON is important in neural and neural crest patterning early in development. DRAGON is also found to be expressed in brachial arches, somites and the tail bud of developing mouse and Xenopus but its function in skeletal patterning is not well described. Since a copy of the DRAGON gene is deleted in our patient, we postulate that haplo-insufficiency of this gene is related to the pathogenesis of the CDP phenotype.

## 2579/F/Poster Board #95

**Molecular genetic study on a new case of a fetus prenatally diagnosed with Agnathia-Otocephaly.** *F. Morin[1], J. Gekas[2], D. Kamnasaran[1,3].* 1) Laval Hospital Research Centre, Quebec, Quebec, Canada; 2) Human Genetics Research Unit, Centre de recherche de l'Hôpital Saint-François d'Assise, Quebec, Canada; 3) Department of Pediatrics, Laval University, Quebec, Canada.

Otocephaly is a severe and lethal malformation of the first and second branchial arches in the developing fetus, with a prevalence of ~ 1 to 60 out of every 70,000 pregnancies. These cases are sporadic with an etiology associated with both genetic and environmental factors. We report a new case of a fetus prenatally diagnosed with Agnathia-Otocephaly from a 24-year-old G1 P0 woman. The family history was unremarkable and the mother was healthy during the pregnancy with no use of medications or abusive substances. The fetus presented striking Otocephalic features including agnathia, astomia with a hypoplastic oropharynx cavity, synotia, and a proboscis. There was no evidence of fetal maceration. In addition, all organs were normal. Comprehensive cytogenetic analyses found a normal karyotype in the fetus (46,XX) with no evidence of deletions, duplications, inversions or complex rearrangements. We first examined the OTX2 gene, encoding a transcription factor, mapping to human chromosome 14q23, as a candidate. Mice that are heterozygous for a null allele in the Otx2 orthologue are born with Otocephalic features (Genes Dev. 1995 9(21):2646-58). Unfortunately, we were unable to identify any evidence of mutations in this gene in the fetal DNA. However, we believe that this finding is not surprising since patients born with human chromosome 14 aberrations have not yet been reported with Otocephalic clinical features. We also considered the human PGAP1 gene, which maps to human chromosome 2q33, since mice that are heterozygous for a null allele of the Pgap1 orthologue are also born with Otocephalic features (J Biol Chem. 2007 282(42):30373-80). We were however unable to screen this gene for mutations in the fetal DNA due its large size (> 27 exons encompassing >11 kb of coding sequence). In addition, we believe that the human PGAP1 gene is not associated with the phenotype in our fetus, since patients born with aberrations of human chromosome 2 have not yet been described to date with Otocephalic clinical features. We suggest that the Agnathia-Otocephaly phenotype in our fetus is due to a mutation in a yet to be identified gene. Since no gene or chromosome aberrations are yet known to be definitively associated with Otocephaly in humans, the use of ultrasonography on pregnant mothers will have to prevail as the current preferred choice for the antenatal diagnosis of these cases.

## 2580/F/Poster Board #96

**Microdeletion 2p16.3 Associated with Familial Multi-Organ Cystic Disease in the Females without Hepatic and Renal Involvement.** *C. Pan[1], C. Li[2].* 1) McGill University, QC, Canada; 2) Pediatrics, McMaster Children's Hosp, Hamilton, ON, Canada.

We report familial multi-organ cystic disease (MOCD) in a 5-generation pedigree of Spanish/German and Irish descent. Multiple individuals, aged from newborn with prenatal onset to 72 years of age are affected with cystic changes variably involving the brain, the spine, the ovary and uterine, the cervix, the breast, the stomach, the eye, and the carotid artery. The proband was a baby girl with symblepharon, periventricular cysts and ovarian cysts. Array CGH analysis revealed a 483-kb deletion of 2p16.3 involving the first four exons of NRXN1, a gene noted to be linked to autism, mental retardation, vertebral anomalies and schizophrenia by a number of studies. This same deletion was also found in her 27 year-old mother who has cystic ovaries, carotid cyst, brain cyst, mood disorder, seizure disorder and acidic sweat. She also reported to be a hyperactive and socially inadequate child. The family history is remarkable for multiple individuals clinically manifesting with migraine headaches, psychiatric (primarily mood disorders) and fertility problems associated variably with cysts involving multiple organs. They also appear to have a higher incidence of benign and malignant tumors associated with these cysts. Additionally, several affected individuals have been reported to have abnormal "acidic sweat". All affected individuals are of normal intelligence and are non-dysmorphic. Interestingly the kidneys and the liver are not known to be affected. The family history is also negative for other birth defects, recurrence miscarriages, stillbirth, dementia and sudden death. Of interest, all eight affected individuals are females spanning five generations. At least one obligate man carrier who has affected mother, sister and daughter has no clinical manifestations at the age of 51. Further investigations of male relatives are pending. In conclusion, del2p16.6 involving the NRXN1 gene in this pedigree has not been associated with autism, mental retardation, vertebral anomalies and schizophrenia. Rather, mood disorder without psychosis, and cystic changes involving multiple organs, in particular the ovaries, the breast and the brain, but not the kidneys and the liver, are linked to this particular microdeletion. Whether the penetrance of this deletion is sex-dependent or sex-influenced or not remains to be determined.

## 2581/F/Poster Board #97

**Congenital Diaphragmatic Hernia and Multiple Congenital Anomalies due to 4p duplication/Xp deletion syndrome.** *M. Dasouki[1], L. Cooley[2], A. Parthiban[1], P. Parimi[1], I. Ekekezie[2], E. Taboada[2].* 1) Dept Pediatrics, Univ Kansas Med Ctr, Kansas City, KS; 2) University of Missouri Kansas City Children's Mercy Hospital Kansas City, MO.

Neonatal congenital diaphragmatic hernia (CDH) is a serious malformation when encountered as part of a multiple congenital anomalies syndrome. Approximately 40%-50% of affected individuals have complex CDH as part of a single gene disorder or chromosomal abnormality. Various chromosomal malformation syndromes in which CDH rarely occurs include autosomal trisomies (13,18, 21) and deletion 4p16 (Wolf-Hirschhorn syndrome). Three genomic loci for diaphragmatic hernia (DIH1, DIH2, DIH3) had been mapped to chromosomes 15q26.1, 8p23.1 and 8q23 respectively. We report a Caucasian female newborn with multiple congenital anomalies that included CDH diagnosed prenatally at 32 weeks gestation. The fetus also had features of Fryns syndrome and Turner syndrome. She died at 80 days of life following surgical closure of her CDH which was complicated by ECMO support and Pseudomonas sepsis. Autopsy showed bifid uvula, short neck, short distal phalanges and dysplastic nails, hypoplastic and abnormally lobulated left lung, abnormal left hepatic lobulation, midgut malrotation, small accessory spleens, large patent ductus arteriosus, coarctation of the aorta, fibrotic & myxomatous dysplastic cardiac valves leaflets, bilateral streak gonads and small uterus. Blood chromosome and FISH analyses showed a de-novo deletion of Xp and partial trisomy of chromosome 4 from an unbalanced translocation [46,X,-X,+der(4)t(X;4)(q12;q21.3).ish der(4)t(X;4)(wcpX+,wcp4+,DXZ1-,CEP4+,XIST+). X-chromosome inactivation studies were not done. We predict that complete inactivation of the derivative chromosome 4 which retained the XIST locus would have produced the equivalent of monosomy X and Turner syndrome phenotype. The spectrum of anomalies found in this child suggests that the derivative chromosome 4 remained active. The rare occurrence of CDH in children with Wolf-Hirschhorn syndrome coupled with our observation of duplication of "4pter-q21.3" suggests that a gene locus for CDH may exist on chromosome 4 and probably within 4p16-pter. Studies of gene expression in the developing diaphragm have recently been reported (Am J Physiol Lung Cell Mol Physiol 294: L665-L675, 2008). In Silico analysis of these data may help narrow this putative "CDH" gene locus.

## 2582/F/Poster Board #98

**Genetic analysis of Midline Facial Defects with Hypertelorism patients detected two submicroscopic chromosomal rearrangements in different locations of the genome.** *E.L. Freitas[1,4], S.M. Gribble[2], M. Simioni[1], T.P Vieira[1], E. Prigmore[2], D.G. Melo[3], A.C. Krepischi-Santos[4], C. Rosenberg[4], N.P. Carter[2], V.L. Gil-da-Silva-Lopes[1].* 1) Departamento de Genética Médica, Faculdade de Ciências Médicas, UNICAMP, Campinas , SP, Brazil; 2) The Wellcome Sanger Institute, Hinxton, Cambridge, United Kingdom; 3) Centro de Ciências Biológicas e da Saúde, Departamento de Medicina, UFSCAR, São Carlos, SP, Brazil; 4) Departamento de Genética e Biologia Evolutiva, Instituto de Biociências, USP, São Paulo, SP, Brazil.

The Midline Facial Defects with Hipertelorism (MFDH) are a rare and heterogeneous group of craniofacial disorders mainly characterized by ocular hypertelorism and bifid nose. The pathogenesis of these conditions is still unknown. We excluded monogenic disorders and weel-known syndromes in all 14 individuals in this study. They were previously investigated by clinical, dysmorphologic and neurological evaluation, skull and facial X-rays, CT and MRI of the brain, and ophthalmologic and otorhynolaringologic evaluation. They also had normal karyotype. The evaluations demonstrate facial alterations, structural and functional anomalies of the central nervous system, indicating, mainly, cortical migrations errors, perfusion variances and cerebella involvement. Based upon these observations and review of the literature, we determined an initial molecular investigation strategy. The phenotypes suggested genes related to face and CNS development such as SHH, FGF8 and PAX3 may be involved in these disorders. These genes have been reported to participate in embryological development and are associated with some syndromes with craniofacial anomalies. Therefore, the objectives of this study were to investigate the etiology of the MFDH affected individuals through SHH, FGF8 and PAX3 candidate genes study and to identify possible chromosomal anomalies using array-CGH. The SHH, FGF8 and PAX3 genes were screened by direct sequencing and to complement these studies, the whole genome tiling path array-CGH technique was performed and the results were confirmed by automatic genotyping and FISH. It was not possible to relate any punctual mutation in the studied genes associated to the malformations since none pathogenetic alteration was found. Although, two chromosomal anomalies in different locations of the genome were detected in MFDH patients: a partial monosomy 9 and partial trisomy 20 derived from a maternal translocation (9;20)(p24;p13); and a familial case with interstitial deletion of chromosome 2 region (2q36.1-2q36.3). In the latter case, the PAX3 gene was inside the deleted region, supporting the initial hypothesis that some development genes are involved in the MFDH etiology. Several CNV described in HapMap were also found. Therefore, it could be concluded that in MFDH patients, the array-CGH investigation can be useful to detect a wide range of chromosomal anomalies and the genetic counseling must be individualized.

## 2583/F/Poster Board #99

**Interstitial Microduplication of Xq27.3 in a Male with Mental Retardation, PDD-NOS, Absent Speech, and Overgrowth.** 
*A. Battaglia[1,2], A. Novelli[3], E. Santocchi[1], L. Bernardini[3], A. Capalbo[3], R. Tancredi[1].* 1) Stella Maris Clinical Research Inst. for Child & Adolescent Neuropsychiatry, Calambrone, Pisa, Italy; 2) Division of Medical Genetics, Dept Pediatrics, University of Utah, SLC, UT, USA; 3) CSS-IRCCS Hospital S. Giovanni Rotondo & CSS Mendel Inst., Rome, Italy.

In XY males, duplication of any part of the X chromosome, but the pseudoautosomal region, leads to functional disomy of the corresponding genes. We describe a male patient with severe mental retardation, PDD-NOS with absent speech, overgrowth, and minor anomalies. Using whole genome array comparative genomic hybridization (array CGH) at a resolution of about 10 Kb (244K chip; Agilent Techonologies), fluorescent in situ hybridization (FISH), and quantitative PCR, we have identified and characterized an interstitial microduplication of Xq27.3 (approx. 0.7 Mb in size), inherited from the healthy mother. The X inactivation test showed that in the mother the chromosome X carrying the duplication was preferentially inactivated. The duplicated segment encompasses 2 RefSeq genes: SPANX-N1, encoding a sperm protein, and SLITRK2. This latter gene is a member of the SLITRK integral membrane proteins with 2 N-terminal leucine-rich repeat (LRR) domains. Most SLITRKs, including SLITRK2, also have C-terminal regions that share homology with neurotrophin receptors. SLITRKs are expressed predominantly in neural tissues and have neurite-modulating activity. In the mouse, slitrk2 suppresses neurite outgrowth, including cAMP-induced outgrowth. In situ hybridization of developing mouse brain shows broad Slitrk2 expression, mainly in the ventricular layer, subventricular zone, cortical plate, pyramidal layer of hippocampus, subicular neuroepithelium, thalamus, hypothalamus, and spinal cord. Highest SLITRK2 expression in adult is in the cerebral cortex. Of note, LRR-genes have been associated with PDD susceptibility in populations of European ancestry.

## 2584/F/Poster Board #100

**Congenital valproate syndrome or unknown epilepsy syndrome.** 
*D. Albu[1], C. Albu[1], E. Severin[1], A. Toma[2].* 1) Dept Human Genetics, Carol Davila Univ Med & Pharm, Bucharest, Romania; 2) Panait Sirbu Hospital, Bucharest, Romania.

Aim: to present an unusual case of dysmorphic newborn born from a mother with epilepsy treated with Valproate Material and method: repeated clinical examinations of the newborn were performed. A head ultrasound, a heart ultrasound and an abdominal ultrasound were performed too. In order to exclude any chromosomal abnormality, a karyotype has been made. Results: The case of a term newborn is presented. The mother was known with epilepsy, grand mal, the first episode as a teenager. She is presently in treatment with Valproate, 1500 mg/day (upper limit of safe dose) The neonate presented with a particular facies, proeminent forehead, hypertelorism, low set ears, palmar and plantar grif. The ultrasounds undertaken excluded a head, heart or internal organ malformation. The neurological exam revealed a neonate with axial and periferic hypotonia. The karyotype indicated a normal male, 46 xy. The facial and neurologic features are not consistent with congenital valproate syndrome. Conclusions: This could be a new case of a syndrome of facial dysmorphic features and neurologic deficit, occurring in a mother with neurological deficit (epilepsy), not associated with chromosomal abnormalities.

**A new case of CLSD implicates genetic heterogeneity.** 
*S. KIM[1], J. Liu[1], A. Hata[1], C. Haldeman-Englert[2], E. Zackai[2], S. Hamamoto[3], R. Schekman[3], J. Kim[1], S. Boyadjiev[1].* 1) Section of Genetics, Departmento of Pediatrics, University of California-Davis Medical Center, Sacramento, CA 95817, USA; 2) Chilren's Hospital of Philadelphia; 3) Department of Molecular and Cell Biology, Howard Hughes Medical Institute, University of California, Berkeley, CA 94720, USA.

We identified a novel autosomal recessive syndrome, cranio-lenticulo-sutural dysplasia (CLSD, Boyadjiev-Jabs syndrome) due to SEC23A missense mutation in a large consanguine family. Characteristic features of this disease are late-closing fontanels, sutural cataracts, facial dysmorphisms and skeletal defects. Prominent cellular features of skin fibroblasts from these patients are secretion defect and marked distension of the endoplasmic reticulum (ER), concordant with the function of SEC23A in protein export from the ER. A second CLSD case with a heterozygous mutation M702V in a highly conserved region of SEC23A was recently identified by our group. The M702V allele was inherited from his clinically unaffected father and no maternal mutation has been identified so far. Cultured skin fibroblasts from this new patient show secretion defect of collagen and enlarged ER, suggesting that other mutations of maternal origin must contribute to this autosomal recessive disease. Indeed, the expression levels of SEC24A and SEC24B COPII components were significantly reduced in the fibroblasts of the M702V patient. These results suggest that compound deficiency of COPII components is not lethal and can synthetically cause craniofacial anomalies. Collectively, our data suggest that defective ER export is a common basis for CLSD. We have obtained parental fibroblasts and are in the process of analyzing them. We are also sequencing SEC24A and SEC24B to identify possible mutations.

## 2586/F/Poster Board #102

**Severe Non-Lethal Recessive Type VIII Osteogenesis Imperfecta: Clinical, Radiographic, Biochemical and Histological Features.** 
*J. Marini[1], W. Chang[1], F.H. Glorieux[2], T.E. Hefferan[3], F. Rauch[2], M. Abukhaled[1], P.A. Smith[4], D. Eyre[5].* 1) Bone/Extracellular Matrix, NICHD/NIH, Bethesda, MD; 2) Shriners Hospital for Children, McGill Univ, Montreal, Quebec; 3) Mayo Clinic, Rochester, MN; 4) Shriners Hospital for Children, Chicago, IL; 5) Univ Washington, Seattle, WA.

Type VIII osteogenesis imperfecta (OMIM #601915) is a recently define recessive form of lethal or severe OI caused by null mutations in *LEPRE1*, the gene encoding collagen prolyl 3-hydroxylase 1. Most type VIII OI is lethal in infancy. We present here the first complete description of two non-lethal cases of type VIII OI. The probands are two boys, a 17 yr old Pakistani who is homozygous for a c.1656C>A which creates a premature termination codon in exon 11, and a 10 yr old Sri Lankan who is a compound heterozygote for a 7 nt duplication (c.1383_1389 dup GAACTCC) and an 11 nt deletion (c.1924_1934 delCAGCCTCAGTG), which also lead to PTCs. Both probands were term babies who were SGA. They have extreme growth deficiency - the 17 yr old has the length of a 3yr old and the HC of a 9 yr old, while the 10 yr old has the length of a 14 month old and the HC of a 22 month old. They have white sclerae and normal dentin. Their extremities are rhizomelic with popcorn epiphyses. Their hands, however, have normal length for age, with short metacarpals. They have severe scoliosis with multiple vertebral compressions; the DEXA L1-L4 z-scores were -6.3 and -5.8, which is at the severest end of the OI spectrum. The dermal collagen fibrils of the probands have average diameter equivalent to matched controls, but have greater diameter variability and multiple border irregularities on cross-section. On mass spectrometry, the level of Type I collagen Pro986 hydroxylation was <5% of normal in dermis, iliac crest bone and collagen secreted by cultured fibroblasts and osteoblasts, demonstrating that there is no redundancy of P3H function in skin and bone. Serum test results were distinctive compared to other OI types, with elevations of both BSAP, an osteoblast product, and TRAP, an osteoclast product, consistent with elevated bone turnover. Iliac crest histomorphometry confirmed elevated osteoblast surface, low bone volume, extremely high bone turnover, along with elevated mineral apposition rate and faster matrix mineralization (lower MLT). Stained bone sections display the distinctive feature of a broad ostoid seam on all trabecular surfaces. In addition, osteoblast morphology is abnormal, with irregularly shaped cells piled up in several layers on the newly deposited matrix, rather than the normal monolayer of cuboidal osteoblasts. These clinical and histological features provide a diagnostic guide for clinicians.

## 2587/F/Poster Board #103

**Familial congenital mirror movements maps to chromosome 18q21.1-q22.1.** *M. Srour[1,2], JB. Rivière[2], F. Richer[3,4], MP. Dubé[1,5], S. Chouinard[1,3], G.A. Rouleau[1,2].* 1) Department of Medicine, Université de Montréal, Montreal, Quebec, Canada; 2) Center of Excellence in Neuromics, Centre Hospitalier de l'Université de Montréal, Montreal, Quebec, Canada; 3) Unité des troubles du mouvement André Barbeau, Centre Hospitalier de l'Université de Montréal, Montreal, Quebec, Canada; 4) Université du Québec à Montréal, Montreal, Quebec, Canada; 5) Montreal Heart Institute, Montreal, Quebec, Canada.

Mirror movements are involuntary movements that occur in the contralateral homologous muscle upon voluntary unilateral activation. Mirror movements are common in early childhood, however their persistence beyond the age of 10 years is usually pathological, and can be associated with abnormalities of the corticospinal tract such as in X-linked Kallmann's syndrome, Klippel-Feil syndrome or congenital hemiplegia. We have recently described a large 4-generation French Canadian family with autosomal dominant familial congenital mirror movements with no associated neurologic abnormalities. There are no known causative genes identified for this condition. We genotyped 23 individuals, including 11 affected, using the Human cnv370-quad beadchip from Illumina. Two-point linkage analysis was carried out, and uncovered a 21 Mbp locus between markers rs1017781 (42,496,503 bp) and rs574539 (64,361,369 bp) on chromosome 18 with a maximal LOD score of 3.18. Chromosome 18q21.1-q22.1 is the first locus to be mapped for familial congenital mirror movements.

## 2588/F/Poster Board #104

**Haploinsuficiencies of FOXF1 and FOXC2 genes in a neonate with lethal alveolar capillary dysplasia and complex congenital heart disease.** *D.L. Zwick, L. Shao, S. Yu.* Children's Mercy Hospital, Kansas City, MO.

Neonatal deaths in infants account for about 67% of all deaths during the first year of life in the USA. Genetic defects are important factors contributing to neonatal deaths with or without congenital anomalies. Here we report the identification of a 1.37 Mb hemizygous deletion of chromosome 16q24.1q24.2 by microarray-based comparative genomic hybridization (aCGH) technique in a newborn boy with lethal severe alveolar capillary dysplasia with misalignment of pulmonary veins and underdeveloped alveoli, and complex congenital heart disease with hypoplastic left ventricle, pulmonary valve atresia, ventricular septal defect, overriding aorta; persistent left superior vena cava connected to the coronary sinus; patent ductus arteriosus, and atrial septal defect. There are five annotated genes (IRF8, FOXF1, MTHFSD, FOXC2, and FOXL1) identified within the 1.37 Mb deleted region. Of them, the FOXF1 gene participates in the regulation of pulmonary genes as well as embryonic lung development, as well as other organs. Knockout mice embryos (Foxf1-/-) die around E9 due to absence of vasculogenesis in the yolk sac and allantois resulting from defects in mesodermal differentiation. Half of newborn Foxf1-/+ mice die from perinatal pulmonary hemorrhage, severe defects in alveolarization and vascularization, and fusion of lung lobes and arteries resulting from haploinsufficiency of the Foxf1 gene. Haploinsufficiency of FOXF1 identified in our case represents the first observation of its pathogenic link to malformation in human beings with remarkable similarity to the phenotypes observed in the mouse model. Additionally, haploinsufficiency of the FOXC2 gene due to the deletion identified in this patient represents a novel genetic mechanism leading to lymphedema-distichiasis syndrome, an autosomal dominant disorder characterized by obstruction of lymphatic drainage of the limbs, double rows of eyelashes, venous insufficiency resulting from incompetent venous valves, and cardiac defects etc. Our observation in this case emphasizes the significance of high resolution human genomes scanning for identifications of micro-imbalances as pathogenic causes in neonates with congenital anomalies and idiopathic clinical features.

## 2589/F/Poster Board #105

**Triphalangeal and triangular thumb and preaxial polydactyly: Locus versus allelic heterogeneity.** *D. Gül[1], H. Ulucan[2,3], J.J. Johnston[2], L.G. Biesecker[2].* 1) Department of Medical Genetics, GATA Medical Faculty, Ankara, Turkey; 2) Genetic Diseases Research Branch, National Human Genome Research Institute, NIH, Bethesda, MD, USA; 3) Department of Medical Genetics, Adnan Menderes University Medical Faculty, Aydin, Turkey.

We have analyzed a large family with 36 affecteds, whose phenotypes range from triphalangeal thumb and/or preaxial polydactyly to a very unusual manifestation of anterior (preaxial) duplication. This manifestation comprises duplication of the proximal phalanx of the first digit with a third aberrant phalanx that connects the distal aspect of these two digit 1 proximal phalanges, forming a triangle with its apex at the metacarpal phalangeal joint. Thus, this aberrant third phalanx is perpendicular to the proximo-distal axis of the anterior ray. This clinical manifestation suggests a severe perturbation of anterior digit patterning with a 90 degree rotation of the digit axis. The phenotype in this family is most similar to triphalangeal thumb-polysyndactyly syndrome (TPTPS; # 174500), which manifests widely variable degrees of triphalangeal thumb, polydactyly, and syndactyly. It is transmitted in an autosomal dominant pattern with complete penetrance and variable expressivity. Syndactyly type IV (#186200) is also inherited in an autosomal dominant pattern and manifests cutaneous syndactyly and polydactyly. This latter phenotype is less similar to the family we report here. Previous reports show that both TTTPS and Syndactyly type IV are caused by point mutations in ZRS, the limb specific enhancer of *SHH*, and duplications encompassing the ZRS. Therefore we performed candidate linkage analysis of a subset of the family to the ZRS locus. Linkage was unlikely, but could not be excluded, with a crossover close to the ZRS. As the locus could not be excluded, we performed zoom in custom array CGH for that region in six affecteds but no duplications were identified. Sequencing of the ZRS revealed no significant variants. We conclude that this phenotype is unlikely to be allelic to these two ZRS-related disorders. We cannot exclude a novel mutational mechanism that affects the ZRS but it is more likely that the locus for this phenotype lies elsewhere in the genome. Linkage analysis of additional family members is underway.

## 2590/F/Poster Board #106

**Hypotonia As A Feature of Connective Tissue Disorders: Lessons from A Hypotonia Specialty Clinic.** *E. Lisi, H. Dietz, G. Oswald, R. Cohn.* Inst Genetic Medicine, Johns Hopkins Univ, Baltimore, MD.

Background: The Johns Hopkins Center for Hypotonia was established in January, 2007 as a multidisciplinary clinic designed for the diagnosis and management of children with hypotonia. Because of its specialized nature, we are now able to better categorize patients based on severity of the hypotonia and associated symptoms, providing more accurate prognostic information and guidance. Methods and Results: Of the 214 patients we have seen as of May, 2009, we have noted that 17 (7.9%) have mild hypotonia and joint hyperflexibility that is more significant than would be expected for their degree of hypotonia. We have ordered an echocardiogram in 10 of 17, finding evidence of aortic enlargement in 6 of those 10 (60%). Of particular interest are two patients: Patient 1 is a 7 year old male who was evaluated in our clinic for hypotonia, pectus excavatum, and umbilical hernia. An echocardiogram revealed an aortic root size of 2.55 cm with a Z-score of 3.88. Subsequently, he had a seizure-like episode with a vascular abnormality diagnosed on head CT. Thus, we ordered genetic testing for Loeys-Dietz syndrome and found a T775G mutation in the TGFBR2 gene. Patient 2 is a 7 year old female with trisomy 21, but more significant hypotonia than would be expected for her age. She came with her karyotypically normal 4 year old sister with mild hypotonia as well. Both sisters had hyperextensibility, easy bruising, and translucent skin. Echocardiograms are pending. Both were diagnosed as have underlying connective tissue disorder, causing the sister with trisomy 21 to exhibit more significant hypotonia than typical. Conclusion: The association of hypotonia with connective tissue disorders (CTDs) has historically been underappreciated. However, we have a series of 17 patients with hypotonia, hyperflexibility, and other soft signs of an underlying CTD, and 60% of those with echocardiograms exhibit aortic enlargement. Thus, appropriate management of a hypotonic patient with hyperextensibility should involve an echocardiogram. Careful evaluation of the hypotonic child for signs of Loeys-Dietz syndrome or other known CTDs is crucial, even if another etiology such as Down syndrome is established . Finally, a new, undescribed CTD may be the underlying etiology for many of our patients with mild hypotonia and hyperflexibilitywhich seems to have a more favorable prognosis than many other described syndromes associated with congenital hypotonia.

## 2591/F/Poster Board #107

**Two Turkish brothers with cold-induced sweating syndrome caused by a novel missense mutation in the *CRLF1* gene.** *B. Tüysüz[1], G. YeÅŸil[1], O. Kasapcopur[2], PerM. Kanppskog[3], H. Boman[3].* 1) Cerrahpasa Pediatric Genetics, Istanbul University, Istanbul, Turkey; 2) Istanbul University, Cerrahpasa Medical Faculty, Department of Rheumatology, Istanbul, Turkey; 3) Center of Medical Genetics and Molecular Medicine Haukeland Hospital, Helse Bergen HF, N-5021 Bergen, Norway.

Cold-induced sweating syndrome is a very rare autosomal recessive disorder characterized by excess sweating induced by cold exposure, reduced pain sensitivity, camptodactyly and kyphoscoliosis. It was initially described by Sohar et al. (Lancet 1978; 312:1073-4) in two Israeli sisters. Knappskog et al. (Am J Hum Genet 2003; 72: 375-83) performed genetic studies, and found out that the Israeli sisters as well as two Norwegian brothers with similar clinical manifestations were homozygous for the mutations in *CRLF1* gene. A second locus was also identified in an Australian patient who was compound heterozygous for the mutations in *CLFC1* (*CISS2*) gene on 11q13.3 (Hahn et al., J Neurol Sci 2006; 250: 62-70). Our patients (22 and 13 years old boys) were second and third child of first cousin and healthy parents. Both brothers had excess sweating induced by cold exposure, operated severe dorsal scoliosis, camptodactyly, reduced pain sensitivity, short and smooth tongue and operated cryptorchidism. Their sweating problem and scoliosis were noted at the age of approximately 12 years. Both patient' weight, height and head circumference were normal. Older brother had atypical facial features including chubby cheeks, broad nose with anteverted nostrils, short philtrum and bifid uvula. He had also chewing and swallowing problems which were arised in infantile period. His intelligence was normal and he was working as a laboratory staff. However, younger brother had similar facies to his brother but he also had severe mental retardation due to cortical atrophy and history of neonatal hypoxic ischemic encephalopathy. Dorsal severe scoliosis was noted even after the operation. Their electromyelography and blood muscle enzyme levels were normal. We considered cold induced sweating syndrome in these brothers. The coding and flanking regions of all the 8 exons of the *CRLF1* gene were amplified, sequenced and the data analyzed mainly as previously described (Knappskog PM et al. Am J Hum Genet 2003; 72:375-83). The patients were homozygous and their parents were heterozygous for a novel missense mutation in *CRLF1* c.413C>T (p.Pro138Leu). This variant is situated in a predicted (NCBI) EpoR ligand-binding domain. We presented first family with cold induced sweating syndrome from Turkey and fourth family which reported to date. Our patient findings differ from the other reported patients as they have late onset but progressive scoliosis and sweating.

## 2592/F/Poster Board #108

**Lowry-Wood syndrome: a further case and review of the literature.** *K. Becker[1], K. Weerasinghe[2], C.M. Hall[3].* 1) North Wales Clinical Genetics Service, Glan Clwyd Hospital, Rhyl, United Kingdom; 2) Department of Paediatrics, Wrexham Maelor Hospital, Wrexham, UK; 3) Department of Radiology, Great Ormond Street Hospital for Sick Children, London, UK.

Lowry-Wood Syndrome was first described in 1975 and is characterised by multiple epiphyseal dysplasia, short stature, microcephaly, variable learning difficulties and nystagmus. The two brothers originally reported later developed diffuse pigmentary retinal degeneration, with optic atrophy in the older boy aged 17 years. Six additional patients have been reported, including two brother-sister pairs. Autosomal recessive inheritance has been postulated. Our patient, an eight year old girl, presented with short stature (height <0.4th centile), borderline microcephaly (head circumference on 3rd centile), mild learning difficulties, congenital horizontal nystagmus and pale optic discs, and the typical findings of multiple epiphyseal dysplasia on skeletal survey, with a very delayed bone age of 5.4 years at 8.1 years. She is the only child of unrelated parents.

## 2593/F/Poster Board #109

**A novel autosomal recessive MR/MCA syndrome comprising short stature, brachydactyly and pectus excavatum maps to 5q23-q32.** *k. kahrizi[1], M. Garshasbi[1,2], F. Behjati[1], H.H Ropers[2], A.W Kuss[2], H. Najmabadi[1], A. Tzschach[2].* 1) Genetics Research Center , USWR, Tehran, Tehran, Iran; 2) Max Planck Institute for Molecular Genetics, Berlin, Germany.

We report on a family in which three mentally retarded siblings suffer from an apparently novel autosomal recessive MR/MCA syndrome characterized by borderline mental retardation, cataract, short stature, brachydactyly of the feet and pectus excavatum. The patients - two brothers and a sister - were born to healthy Iranian parents who were first cousins. They had one healthy brother who was of normal height. Secondary sexual characterization is missing in the affected female. The shortening of the fourth and fifth metatarsal and phalanges in all affected sibs with generalized hypodensity was reported by X-Ray. Chest X-ray showed no abnormalities. Three affected patients had history of seizure. Brain MRI revealed no brain malformations. Endocrinological profile and blood metabolites were normal in two male sibs but slightly increased of PTH and FSH in the affected female. Serum calcium level was normal but phosphorus was minimally increased. Metabolic tests and chromosome analysis revealed no abnormalities in the patients. The pedigree structure suggested autosomal recessive inheritance, and homozygosity mapping using a 250K SNP array (Affymetrix) identified one large (24 Mb) interval in 5q23.1-q32 flanked by SNP markers rs1427941 and rs10036966. The LOD score for this interval was 2.5. A second interval in 3q13.11 had a size of only 0.5 Mb (flanked by SNPs rs6791670 and rs2961221; LOD score 2.5) but contained no known genes. We therefore presume that the large and gene-rich interval in 5q harbours the causative gene defect in this family, and screening of candidate genes will eventually elucidate the underlying mutation.

## 2594/F/Poster Board #110

**Autosomal dominant 46,XY disorder of sexual development: Evidence for a novel locus.** *K.M. Boycott[1], S. Douglas[2], C. Goldsmith[1], D.E. Bulman[2].* 1) Dept Genetics, Children's Hospital of Eastern Ontario, Ottawa, ON, Canada; 2) Ottawa Hospital Health Research Institute, Ottawa, ON, Canada.

The 46,XY disorders of sexual development (DSD) are a genetically heterogeneous group of disorders characterized by a 46,XY karyotype, ambiguous genitalia with mild to severe penoscrotal hypospadias, dysgenetic testes, reduced to no sperm production and a range of Mullerian structure development. These disorders can be inherited in an autosomal dominant, autosomal recessive, X-linked, or Y-linked manner depending on the gene involved. Mutations in the *SF1* and *DHH* genes account for approximately one-third of autosomal dominant 46,XY DSD and duplications of *DAX1* or *WNT4* are a very rare cause of this phenotype. Here we report a four-generation family with five individuals affected with a 46,XY DSD. Male-to-male transmission was observed in this family consistent with an autosomal dominant disorder. The phenotype is characterized by penoscrotal hypospadias ranging from mild to severe in three males, ambiguous genitalia in one individual later raised as male and normal appearing female genitalia in a 46,XY child with absent Mullerian structures. All of the adult affected males report significantly reduced fertility and endocrine testing indicates hypergonadotropic hypogonadism. Pathology from the gonads removed from the affected child identified infantile testis with mild Leydig cell hyperplasia and one small microscopic focus of ovarian stroma containing a few oocytes. *DHH* and *SF1* sequencing was negative. Evidence for a *DAX1* or *WNT4* duplication was absent on a chromosomal microarray (Affymetrix, 6.0 SNP). Haplotype analysis ruled out *WT1* or *SOX9* as being involved. This data suggests that the 46,XY DSD in this family is novel and further studies are underway to map and identify the gene for this developmental disorder.

## 2595/F/Poster Board #111

**Mendelian predisposition to Herpes Simplex Encephalitis - a novel category of Primary Immunodeficiencies.** *V. Sancho-Shimizu[1], R. Perez[1], L. Lorenzo[1], SY. Zhang[2], A. Cardon[1], E. Jouanguy[2], L. Abel[1], JL. Casanova[2].* 1) Laboratory of Human Genetics of Infectious Disease, Faculty of Medicine Necker, University Paris Descartes, Paris, France; 2) Laboratory of Human Genetics of Infectious Disease, Rockefeller University, 1230 York Ave, New York, NY USA.

Herpes simplex encephalitis (HSE) is a rare disease affecting young children as well as adults due to primary infection with herpes simplex virus-1 (HSV-1). HSV-1 is a nearly ubiquitous virus commonly infecting humans however most do not develop HSE, suggesting that these children possess an underlying genetic susceptibility to HSV-1. Notably, these patients are otherwise healthy and able to mount a normal adaptive immune response to HSV-1, pointing to the likelihood that they harbor an unidentified form of primary immunodeficiency disease affecting their innate immune system. We have recently identified the first two genetic etiologies UNC93B and TLR3 deficiencies in HSE patients validating our hypothesis. We have subsequently identified at least two other patients among our cohort of HSE patients with impaired production of type I IFN following viral and double stranded RNA activation. Here we investigate these particular HSE patients using a candidate gene approach to identify other gene(s) underlying HSE by cellular and immunological phenotyping. UNC93B and TLR3 deficiencies in these patients have been excluded based on sequence analysis and immunological phenotyping. Further molecular studies have shown that these patients' cells showed a specific decrease in interferon regulatory factor-3 (IRF3) dimerization consistent with the lack of IFN production. Sequencing and expression of all known genes in the TLR3-UNC93B-IFN pathway are currently underway and we have excluded the involvement of seven genes in this pathway so far. The identification of novel genes involved in HSE will present important biological and medical implications, providing us with a better understanding of HSE pathogenesis.

## 2596/F/Poster Board #112

**A Novel Human Immunodeficiency Disorder associated with a Mutation in the T Cell Receptor $\alpha$ subunit constant gene (TRAC).** *N.V. Morgan[1], S. Goddard[2], T.S. Cardno[3], F. Rahman[1], A. Ciupek[3], A. Straatman-Iwanowska[1], S. Pasha[1], G. Anderson[4], A. Huissoon[2], W.P. Tate[3], E.R Maher[1,5].* 1) Med & Molec Gen, Univ Birmingham, Birmingham, United Kingdom; 2) Regional Department of Immunology, Heartlands Hospital, Birmingham, UK; 3) Department of Biochemistry, University of Otago, Dunedin, New Zealand; 4) MRC Centre for Immune Regulation, The Medical School, University of Birmingham, Birmingham, UK; 5) West Midlands Regional Genetics Service, Birmingham Women's Hospital, Birmingham, UK.

We describe two families with a novel autosomal recessively inherited immunodeficiency disorder characterised by increased susceptibility to infection, autoimmunity, eczema and alopecia. Genetic linkage studies mapped the disorder to 14q11.2 and a homozygous G to A substitution was identified at the last base of exon 3 immediately following the translational termination codon (c.*1G>A) in the T Cell Receptor $\alpha$ subunit constant gene (TRAC). RT-PCR analysis in the 2 affected individuals revealed loss of the last coding exon (exon 3) from the mutant TRAC transcript. The mutant TCR $\alpha$-chain protein was predicted to lack part of the connecting peptide domain and all of the transmembrane and cytoplasmic domains. Previous studies have shown these domains to have a critical role in the regulation of the assembly and/or intracellular transport of TCR complexes. We found that T cells from affected individuals did not express TCR$\alpha\beta$ complex and in vitro studies demonstrated a failure to respond to mitogens such as OKT3. This is the first report of a human TRAC mutation. Absent TCR$\alpha\beta$ expression may be associated with a surprising level of protection against infection, but an abnormal T cell population is associated with immune dysregulation and autoimmunity.

## 2597/F/Poster Board #113

**Male Infant with Congenital SMA and Xq11.1 Triplication.** *C. Saunders[1], A. Kats[1], S. Yu[1], L. Cooley[1], M. Strenk[1], J. Jones[2], M. Friez[2], H. Ardinger[1].* 1) Children's Mercy Hospitals and Clinics, Kansas City, MO; 2) Greenwood Genetics Center, Greenwood, SC.

Our patient is a male infant with a condition resembling the neonatal form of spinal muscular atrophy, including extreme hypotonia, lack of reflexes, no suck or swallow, little to no movements, and congenital contractures. He died of respiratory failure at 3 weeks of age. His autopsy showed severe muscle fiber atrophy with prevalence of myofibrillar disorganization consistent with a lower motor unit disorder. The spinal cord had rare anterior horn cells with alterations suggestive of early chromatolysis. His genetic workup for hypotonia included normal gene testing for SMA (with two copies of SMN1 present), myotonic dystrophy and methylation analysis for Prader-Willi syndrome. The karyotype was normal at the 475-725 band level. Array-CGH revealed a 745 kb triplication of Xq11.1 from 62,662,985-63,408,000, which includes 4 genes: ARHGEF9, FAM123B, ASB12, MTMR8. The family history did not identify other similarly affected relatives, and no other males are available to test. The child's asymptomatic mother also tested positive for this triplication but has skewed X inactivation (90:10). We hypothesize that overexpression of a gene in this region may cause an SMA-like phenotype. One gene of interest, ASB12, is a member of the ankryin repeat and SOCS box family of proteins, which have been shown to regulate muscle development in mice and interact with the ubiquitination pathway.

## 2598/F/Poster Board #114

**Germline mutations in the tumour suppressor WTX cause a sclerosing bone dysplasia but do not predispose to Wilms tumor.** *M. van Kogelenberg[1], Z.A. Jenkins[1], T. Morgan[1], S. Holman[1], A. Jeffs[2], R. Fukuzawa[3], A.V. Hing[4], T. Fiskerstrand[5], R.C.M. Hennekam[6], S. Mansour[7], V. Cormier-Daire[8], A.E. Reeve[3], S.P. Robertson[1], the OSCS study Group.* 1) Paediatrics and Child Health, University of Otago, Dunedin, New Zealand; 2) Pathology, Dunedin School of Medicine, Otago University, Dunedin 9054, New Zealand; 3) Cancer Genetics Laboratory, Department of Biochemistry, Dunedin 9054, New Zealand; 4) Division of Craniofacial Medicine, Department of Pediatrics, University of Washington School of Medicine, Seattle, Washington 98195, USA; 5) Center for Medical Genetics and Molecular Medicine, Haukeland University Hospital, Bergen N-5021, Norway; 6) Clinical and Molecular Genetics Unit, Institute for Child Health, London WC1N 3JH, UK; 7) South West Thames Regional Genetics Unit, St George's Hospital, London SW17 0RE, UK; 8) Département de Génétique, Hôpital Necker-Enfants Malades, Paris 75743, France.

Osteopathia striata congenita with cranial sclerosis (OSCS) is an X-linked sclerosing bone dysplasia characterized by increased bone density and craniofacial malformations in females and lethality in males. To elucidate the pathogenesis of OSCS we performed a genome wide array on DNA from a proband which presented with X-linked OSCS. We identified a >2.1-Mb *de novo* deletion at Xq11.1. One of the four affected genes, *WTX (FAM123B)*, was a candidate monogenic contributor given its role in repression of canonical WNT signalling. Screening of 25 OSCS patients demonstrated 23 premature termination and two entire gene deletions of *WTX*. Molecular studies of the mouse homolog *Wtx* showed predominantly endogenous expression patterns of in the developing skeleton and skull. An alternatively spliced transcript was detected by RT-PCR deleting the primary determinant that localizes WTX to the plasma membrane. The differential cellular functions of the WTX splice form could implicate the plasma membrane localization as a factor associated with survival in males with OSCS. The distribution of *WTX* mutations in OSCS mirror somatic *WTX* mutations identified in 11-29% of Wilms tumor, the most common solid organ tumor in children. However, OSCS individuals did not seem to have a predisposition to Wilms tumor. The lack of tumor susceptibility in OSCS patients may imply the existence of a temporal or spatial constraint on whether a *WTX* mutation will be cancer predisposing or not.

## 2599/F/Poster Board #115

**The variable phenotype of 1q21.1 deletion syndrome in a multigenerational family.** *E. Chow[1,2], A. Thomas[3], M. Shago[4], D. Skidmore[3].* 1) Clinical Genetics Service, Centre for Addiction and Mental Health, Toronto, Ontario, Canada; 2) Departmnet of Psychiatry, University of Toronto, Toronto, Ontario, Canada; 3) Maritime Medical Genetics Services iWK Health Centre, Halifax, Nova Scotia, Canada; 4) Clinical cytogenetics laboratory, Hospital for Sick Chilren, Toronto, Ontario, Canada.

The 1q21.1 Deletion Syndrome (1q21.1DS) is a newly identified microdeletion syndrome with a variable phenotype (Mefford et al., 2008). Reported features have included cognitive, psychiatric, neurological, cardiac, and musculoskeletal. It has an estimated prevalence of ~0.4% in the general population. We will present detailed physical and psychiatric phenotypic data on a mother (proband) and daughter pair with 1q21.1DS. The grandmother is currently being tested for 1q21.1DS. The 26-year-old proband of English and East European Jewish background was identified through a psychiatric genetics service and suffers from mild mental retardation, ADHD and psychosis not otherwise specified but is medically well. Physical examination revealed short stature (<3rd percentile), small and deep-set eyes, low set ears, bossing forehead, and small hands with short fingers. She was born with mid-lumbar spinal bifida occulta with a tethered cord and a forme fruste of a meningocele. The 8-year-old daughter was born premature at 31 weeks and experienced bilateral interventricular haemorrhages. Prenatally she was noted to have two seemingly normal kidneys. Postnatally, the left kidney was noted to be dysplastic and it has now evoluted in its entirety. There have been intermittent concerns about right-sided hydronephrosis. By age 7 she was noted to have multiple minor dysmorphic features, significant hypotonia, short stature (<3rd percentile), and a moderate degree of non-progressive developmental delay. The grandmother is a 50 year-old woman with a height of 158 cm, small eyes, and bossing forehead. She has no history of congenital anomalies or major medical problems. She was a slow learner in school and suffered from depressions and anxieties (untreated) in her adult life. Prior to the birth of the proband, the grandmother had two miscarriages and a child who died at birth because of unspecified congenital anomalies involving the brain and the heart. Should a 1q21.1 microdeletion be confirmed in the mother, this will the first, detailed, three-generational report on the phenotype of 1q21.1DS. This family highlights the variability of the phenotype, even within a single family. It also highlights the high frequency of neuropsychiatric manifestations. Early assessment and intervention for neuropsychiatric manifestations are recommended for individuals with 1q21.1DS.

## 2600/F/Poster Board #116

**Cardio-Renal-Epilepsy-Digital-Oculo (CREDO) syndrome: a "new" syndrome of developmental delays and multiple malformations.** *R. Lebel, R. Miller, N. Havernick, N. Dosa, B. Braddock, F. Smith, R. Shprintzen.* SUNY Upstate Medical University, Syracuse, NY.

The non-consanguineous marriage of healthy individuals with French-Canadian and German ancestry produced three pregnancies, at maternal ages 22, 24 and 26. The first was a female (now 9 years of age) whose pregnancy was complicated by oligohydramnios and intrauterine growth restriction; at birth she was noted to have pulmonic stenosis, bicuspid aortic valve, renal dysplasia and hypotonia. Since then, she has revealed developmental delays, mixed hearing deficit, cataracts with microcornea and myopia, gastroesophageal reflux, epilepsy, microcephaly with corpus callosum agenesis, growth delays; she has been noted to have eyelid ptosis, joint laxity, fetal finger pads, and hanging columella. The second child, also subject to oligohydramnios and IUGR, was a male with more complex heart disease (bicuspid and stenotic aortic valve with coarctation, absent left pulmonic artery and large patent foramen ovale) which proved fatal at seven months of age (before he could manifest many of the features seen in his siblings). He also was found to have GERD, microcephaly, poor weight gain, renal dysplasia, and hypotonia. The third child (now five years of age) was a male whose prenatal course had been uneventful (normal fluid levels and fetal growth) but who was found to have pulmonic stenosis with bicuspid aortic valve, renal dysplasia, microcornea, epilepsy, eyelid ptosis, hanging columella, fetal finger pads, hypotonia and hyperextensible joints. All three children had normal chromosomes by routine analysis and by subtelomere FISH. The first and third children had normal findings on Signature Genomics oligo-microarray analysis. All three children had a characteristic and highly similar facial gestalt. We think this family represents a previously unreported autosomal recessive delays-malformation syndrome, and we offer it for consideration as the CREDO (Cardio-Renal-Epilepsy-Digital-Oculo) syndrome.

## 2601/F/Poster Board #117

**Multiple Intestinal Atresia with Immunodeficiency: Gene Expression and SNP Genotyping.** *K. Chen[1], S. McGhee[1], M.I. Garcia, Lloret[1], I. Grinberg[2], E.R.B. McCabe[2].* 1) Dept Pediatrics, Univ California, Los Angeles, Los Angeles, CA; 2) University of California, Los Angeles, Los Angeles, CA.

Background: Multiple intestinal atresia with immunodeficiency (MIA-I) is an exceptionally rare disorder characterized by atretic regions throughout the gut, often from the pylorus down through the colon, with heterogeneous forms of combined immunodeficiency. Histologically, the intestinal atresias demonstrate a sieve-like appearance. Although the pathogenesis of MIA-I is unknown, familial cases suggest an autosomal pattern of inheritance. Purpose: To characterize the disorder of MIA-I and to identify genes potentially involved in its pathogenesis using expression microarray and genomic single nucleotide polymorphism (SNP) microarray platforms. Methods: Clinical history was obtained from medical records. Immunologic evaluation was completed using standard laboratory methods. RNA was isolated from whole blood and primary T cell cultures, and was analyzed using a genomic RNA expression microarray platform. A genome-wide SNP microarray platform was used for genotyping. Genes of interest were identified by gene expression differences of more than three-fold compared to controls. We explored common signaling pathways that were upregulated or downregulated in MIA-I using Ingenuity Pathways Analysis web-based software. We genotyped individuals from three families, each with affected and unaffected members. Results: At our institution, two unrelated patients with MIA-I were found to be panhypogammaglobulinemic and lymphopenic. Both demonstrated diminished lymphocyte proliferation to mitogens. Conclusions: MIA-I is a rare disorder that results in catastrophic loss of gut function and death from severe infections. Care should be taken to evaluate neonates with MIA-I. MIA-I may involve a single gene defect or partial defects in multiple pathways that alter both gastrointestinal and lymphocyte development. Mediators of embryonic patterning may be involved in the pathogenesis of MIA-I and should be further explored.

## 2602/F/Poster Board #118

**Neonatal primary spontaneous pneumothorax in 5 members of a family.** *B. Hall[1,2], M.E. Pierpont[2,3].* 1) Minnesota Perinatal Physicians, St Paul, MN; 2) Children's Hospitals and Clinics of Minnesota, Genetics Division, St. Paul, MN; 3) University of Minnesota, Minneapolis, MN.

Primary spontaneous pneumothorax (PSP) results in partial or complete lung collapse. It occurs more frequently in adolescent or adult males. Additional risk factors for PSP include smoking, increased height, and family history. Neonatal onset of pneumothorax has been reported to have an incidence of 1-2% at term and 6% in preterm infants and is usually associated with underlying complications such as meconium aspiration, hyaline membrane disease, or vigorous resuscitation. Rarely has neonatal pneumothorax been described as familial. We describe a family with 5 affected individuals in 2 generations with neonatal presentation of PSP. Three female siblings developed documented bilateral pneumothoraces, and the first 2 (born in 1969 and 1971) died in the first day of life. The third sister born at 35-36 weeks was treated and survived. Her childhood health was unremarkable and without recurrence. She had 3 sons, 2 of whom developed bilateral pnuemothoraces shortly after birth requiring treatment. There have been no further pnemothoraces in these boys to ages 5 and 7 years. It has long been suggested that an underlying abnormality of the connective tissue may be involved in the etiology of familial PSP. Disorders such as Ehlers Danlos syndrome(EDS), Marfan syndrome, alpha-1- antitrypsin deficiency (AAT) have been considered in the differential diagnosis. More recently, mutations in the FLCN gene have been found in families with apparently isolated PSP as well as in those with a disorder characterized by skin folliculomas and renal cancer, called Birt-Hogge-Dube syndrome. Examination of these boys and their mother does not support a clinical diagnosis of Marfan syndrome nor EDS. Due to a history of early cirrhosis and emphysema in a maternal great aunt, testing for AAT was performed and was negative. No mutation was found by sequencing of the FLCN gene. Array CGH was normal. PSP usually occurs in older individuals. Only 3 reports describing neonatal onset of familial PSP were noted upon review of the literature. Two of the 3 reports involved affected siblings while the 3rd had affected persons in more than one generation. Previous case studies have suggested dominant with reduced penetrance, polygenic, X-linked or recessive inheritance patterns. It is unclear at this time if individuals who experience PSP later in life do so as the result of the same underlying cause as the few reported cases of neonatal PSP.

## 2603/F/Poster Board #119

**Screening of 1033 patients with mental retardation, developmental delay and/or dysmorphic features by aCGH.** *O.K. Rodningen, B.E. Kristiansen, C. von der Lippe, H.S. Sorte, M. Moller, K.L. Eiklid.* Department of Medical Genetics, Oslo University Hospital, Ulleval, Oslo, Norway.

Microarray-based comparative genomic hybridization (aCGH) is a powerful method for detection of genomic imbalances in individuals with mental retardation, developmental delay and/or dysmorphic features. The method allows for the detection of DNA copy number changes not previously detected by conventional cytogenetic techniques. We present the results of aCGH analysis in 1033 probands, of which the majority were karyotyped (G-banded chromosome analysis at a resolution of 450-550 bands) before aCGH was performed. DNA was extracted from blood, fibroblasts or FFPE (Formalin Fixed and Paraffin Embedded) tissue, and aCGH was performed using 44K, 105K or 244K Human Genome CGH Oligo Microarrays (Agilent Technologies). Microdeletions and/or microduplications were detected in 261/1033 probands (25,3%). An abnormal karyotype had previously been detected in 75 probands, hence aCGH was performed in order to specify the origin of extrachromosomal material, to identify deletions or duplications in translocation breakpoints, or to map genes involved in the aberrations. Of these 75 probands, 13 had no copy number changes detectable by aCGH, indicating a balanced aberration. In the remaining 62 probands, the fine mapping provided new information about the complexity of the rearrangements, and identified additional pathogenic aberrations that would have been missed without aCGH. Of the microdeletions/duplications identified in the probands with a normal karyotype, 54 were similar to, or overlapping regions associated with known syndromes, and 145 were previously undescribed. In most instances, the chromosomal anomaly was judged to be the underlying cause, or probable cause, of the patient's abnormal phenotype. Our data demonstrates the utility of aCGH as a powerful diagnostic tool for detection of genomic imbalances.

## 2604/F/Poster Board #120

**Delineation of a novel lethal autosomal condition characterized by alveolar capillary dysplasia and limb reduction anomalies.** *A. Innes.* Dept Med Gen, Alberta Children's Hosp, Calgary, AB, Canada.

Alveolar capillary dysplasia (ACD) is amongst the common causes of lethal primary pulmonary hypertension (PPHN) in the newborn. It is ultimately unresponsive to inhaled nitric oxide and ECMO. Definitive diagnosis requires lung biopsy, and is characterized by a reduction in number of capillaries, with a decreased blood-air interface. The deficit likely occurs during the pseudoglandular and canalicular stages of lung development. Over 100 cases have been reported. The etiology of most cases is unknown, but many familial cases have been reported. Associated malformations are seen in over 50% of patients, recurrent anomalies involve the cardiovascular, genitourinary and gastrointestinal systems. Mutations in STRA6 have been identified in patients with anophthalmia and malformations including ACD. Until recently, the molecular basis for the majority of children with ACD was unknown. However, microdeletions of chromosome 16q24.1q24.2 or heterozygous mutations in FOXF1 at that locus, have recently been identified in a cohort of patients with ACD and associated congenital anomalies (Stankiewicz et al, 2009). These patients did not have major limb anomalies. One previous study excluded mutations in two candidates: BMPR2 and EMAPII (Sen et al, 2004)in children with ACD. We have encountered 5 children from 3 families born to consanguineous parents (2 different ethnic groups) that presented with limb reduction anomalies and died of PPHN as newborns. In those who had autopsy, ACD was confirmed as the etiology of the PPHN. Previously, a consanguineous family had been reported where 3 children had variable features of ACD and/or limb anomalies(Witter et al, 2001). Review of the literature identified 3 other reports of 4 children with limb reduction anomalies and ACD (Cullinane et al, 1992; Simonton et al, 1993; Steinhorn et al, 1997). Therefore, we are aware of 12 patients with ACD and limb reduction anomalies. Given consanguinity in 4 families, this is likely an autosomal recessive condition. This paper will include a clinical delineation of this syndrome, with a focus on the clinical details of the 4 consanguineous families. As mice deficient in the gene eNOS have a pulmonary phenotype reminiscent of ACD and variable limb malformations (Han, 2006), this was a potential candidate gene. However, linkage was excluded to eNOS in one family we studies. A homozygosity mapping approach will be applied in an attempt to identify the gene for this lethal disorder.

## 2605/F/Poster Board #121

**New dominant osteochondrodysplasia with brachydactyly and short humerus.** *D. Lacombe[1], M.A. Delrue[1], S. Mundlos[2], A. Toutain[3], J.F. Chateil[4].* 1) Dept Medical Genetics, CHU Bordeaux, Université de Bordeaux, Bordeaux, France; 2) Dept. Genetics, Charité Hospital, Berlin, Germany; 3) Dept. Genetics, CHU Tours, France; 4) Dept Radiology, CHU Bordeaux, Université de Bordeaux, France.

We report a three-generation family affected with a chondrodysplasia transmitted as an autosomal dominant trait. The phenotype mainly associates short humerus, incurvation of radius and brachydactyly and is not already reported to the best of our knowledge. Enzo was born at 39 WG by cesarean section, after a pregnancy marked by ultrasound identification of shortness of humeri (< 3° centile). At bith, weight was 3000 g, height was 50 cm, and OFC was 35.5 cm. Examination showed short arms, a radial deviation of hands, and brachydactyly. At age 7 months, height was 68 cm and weight 8.6 kg. Mental development were normal. X-rays noted short humerus, incurvation of radius with hypoplasia of the proximal part of the ulna, short metacarpals except abnormally shaped second one (probable fusion between 1st and 2nd metacarpals), short 2nd, 4th, and 5th middle phalanges, and short metatarsals. Audiogram was normal. This was the first child of a 31-year mother. Her height was 154 cm, weight was 51 kg, and OFC 56 cm. She had short arms, a radial angulation of forearms, brachydactyly of hands and feet with short second phalanges of hands. X-rays showed short and broad humerus, incurvation of radius with relative hypoplasia of the lateral condyle, short metacarpals, short 2nd, 4th, and 5th second phalanges, and short 1st, 4th and 5th metatarsals. Vertebrae were normal. She had a normal hearing. She had two brothers, one affected and one non-affected. Height of the affected brother was 180 cm. He had the same skeletal phenotype including triphalangeal thumbs and associated a mixed deafness. The great-mother also had the same osseous dysplasia with brachydactyly and short second phalanges. Her height was 155 cm and she had a limitation of prono-supination. She had a deaffness since age 15 years. She also had a brother affected with the same chondrodysplasia and a height of 160 cm. This combination of skeletal features does not fit into any identified phenotype. The brachydactyly is closed to the A1 type (Farabee) of brachydactyly due to IHH gene mutrations. A mutation was excluded by sequencing of the entire coding regions in the IHH gene encoding the Indian Hedgehog protein and in the GDF5 gene in Enzo and in his mother. It seems to be a new chondrodyplasia phenotype or part of the A1 brachydactyly spectrum.

## 2606/F/Poster Board #122

**Ryzomelic shortening, cardiac malformation, didelphic uterus, and accessory spleen: a new syndrome.** *Z.D.N.M Lumack[1], D. Brunoni[1], N.L. Sobreira[2], A.B. Perez[1].* 1) Centro de Genética Médica (CGM) - Universidade Federal de São Paulo (UNIFESP)-São Paulo, Brasil; 2) Institute of Genetic Medicine, Johns Hopkins University of Medicine - Baltimore, MD.

Skeletal dysplasias are a heterogeneous group of more than 200 disorders characterized by abnormalities of cartilage and bone growth, resulting in abnormal shape and size of the skeleton and disproportion of the long bones, spine, and head. Their modes of inheritance are heterogeneous and some of them have known molecular bases. Diagnosis of skeletal dysplasia is based on the most severely affected segment of the skeletal; rhizomelic shortening (short proximal segments) is present in patients with achondroplasia, hypochondroplasia, the rhizomelic type of chondrodysplasia punctata, the Jansen type of metaphyseal dysplasia, spondyloepiphyseal dysplasia (SED) congenita, thanatophoric dysplasia, atelosteogenesis, diastrophic dysplasia, and congenital short femur. Certain clinical features may be of value as diagnostic indicators, although they may not be specific or consistent, for example, heart anomalies are associated with chondroectodermal dysplasia, lethal short-limbed skeletal dysplasias, and Majewski syndrome. He we describe a 19 years-old Brazilian girl, born to consanguineous parents, who has disproportionate short stature with rhizomelic shortening, macrocephaly, short neck, hypertelorism, increased intermamillary distance, pectus carinatum, brachydactyly, single flexion crease in both hands, small feet, increased space between first and second toes. Abdomen USG showed accessory spleen, endovaginal USG showed didelphic uterus, and echocardiogram showed interventricular septum dyskinesia, moderate pulmonary valve stenosis, interauricular communication type ostium secundum, hypertrophy of right chambers, mitral insufficiency and mild tricuspid insufficiency. C-banded karyotype: 46,XX. X-ray showed dolicocephaly, bilateral rudimentary cervical ribs, narrowed humeral head and colo, short and vertically narrowed iliac bones, defective fusion of the spinal process of sacral vertebraes, short femur, patella luxation, genu valgo, reduction of proximal tibial epiphyses, and shortness of 1st metatarsus. The manifestations in that patient do not match any of the skeletal dysplasia known to be associated with rhizomelic shortening or with anyone of the others radiographic features described here. We consider that the constellation is unique and apparently represents a previously unrecognized syndrome.

## 2607/F/Poster Board #123

**Autosomal dominant connective tissue disorder presenting with short stature, clubfeet, sparse hair, hyperextensible joints, hernias and distinctive facial features - a new syndrome?** *D. Myles Reid[1], E. Goh[2], C. Barnett[2], B. Lee[3], A. Hinek[4], D. Chitayat[1,2].* 1) Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital, Toronto, ON, Canada; 2) Division of Clinical and Metabolic Genetics, Hospital for Sick Children, Toronto, ON, Canada; 3) Department of Humanities, York University, Toronto, ON, Canada; 4) Heart Centre - Cardiovascular research, Hospital for Sick Children, Toronto, ON, Canada.

Heritable connective tissue disorders is a family of more than 200 disorders that result from gene mutations causing change in the structure and development of skin, bones, joints, ligaments, teeth, heart, blood vessels, lungs, eyes, ears and hollowed viscera. The most known conditions are Ehlers-Danlos syndromes, Marfan syndrome, Loeys-Dietz syndrome and osteogenesis imperfecta. Most of these conditions are associated with life threatening manifestations including fractures, rupture of the aortic root and arch and other blood vessels, spontaneous pneumothoraces and rupture of hollowed viscera including the intestine, eye globe and uterus. We report a hitherto new autosomal dominant connective tissue disorder. The proband, a 56-year-old female, was born to non-consanguineous parents of English, German and Scottish descent, had short stature, hyperextensible joints, right talipes, thin translucent skin, abnormal fingers and toes, sparse hair, osteopenia and some thrombocytopathy. She had ruptured colonic diverticulum, an epigastric hernia, left abdominal wall incisional hernia and a left inguinal hernia. Her echocardiogram was normal. She had easy bruisability, a history of difficulties in blood clotting and menorrhagia. Family history showed that her mother, her two sisters, a nephew and a niece, born to one of these sisters, have the same clinical manifestations. Immunohistochemistry done on cultured skin fibroblasts obtained from the proband, revealed normal deposition of elastic fibers and lack of fibrillin 1 in the microfibrillar scaffold. Surprisingly the microfibrillar structures demonstrated strong presence of fibulin 1 organized in microfibrills. Since rtPCR analysis demonstrated normal expression of fibrillin 1, we conclude that the main problem here could be due to the lack of normal proteolytic processing of newly synthesized fibrillin 1, which prevents their polymerization and assembly into the microfibrills. Further studies are needed to identify the candidate proteinase responsible for fibrillin 1 processing that may be deficient in this patient. A similar situation where decreased production of fibrillin 1 can be compensated by increased production of fibulin 1 occurs in Marfan syndrome. However, in this case the genetic expression of fibrillin 1 was normal and the clinical manifestations are not consistent with Marfan syndrome.

## 2608/F/Poster Board #124

**Familial tracheomalacia associated with a 5p15.33 microdeletion.** *D. Abuelo[1], N. Shur[1], J. Padbury[2], S.R. Gunn[3].* 1) Dept Pediatrics, Divion of Genetics,Rhode Island Hosp and Hasbro Childrens' Hosp, Providence, RI; 2) Dept Neonatology, Women and Infants' Hosp, Providence, RI; 3) Combimatrix Molecular Diagnostics, Irvine, CA.

Congenital or primary tracheomalacia is a rare condition caused by abnormal cartilage which is insufficient to maintain airway patency during the respiratory cycle. It can be associated with several genetic conditions, including 22q-, CHARGE, Larsen and Kniest syndromes. Although congenital autosomal dominant laryngomalacia has been described (OMIM 150280), congenital tracheomalacia is not listed in OMIM. We report a mother and 3 children with dominantly inherited congenital tracheomalacia associated with a chromosome 5p microdeletion. The mother, now age 27, was born with respiratory distress which was treated with a tracheostomy. She has short stature, learning disabilities and a weak, high-pitched voice. She has had 3 children with 3 different fathers, all of whom also have congenital tracheomalacia. The oldest son, now age 6, was born at 30 weeks gestation and was hospitalized 5 times for tracheomalacia and respiratory distress between the ages of 2 months and 3 years. He continues to have stridor with exertion and respiratory infections. Psychomotor development has been delayed, and he has subtle dysmorphism, consisting of almond shaped palpebral fissures and a prominent nasal root. His 2 ½ year old sister has tracheomalacia, mild dysmorphism and developmental delay. The 9 month-old sister has tracheomalacia, a short neck, mild hypertelorism and relative microcephaly. Oligonucleotide array CGH analysis showed a single copy number decrease of 4.18Mb of the region 5p15.33→ pter in all four affected family members. FISH results confirmed the deletion. There are approximately 30 genes between the breakpoints. Of interest is that this 5p microdeletion is smaller, but has some overlap with the 5p deletion associated with cri-du-chat syndrome. A mouse model has shown that an evolutionary conserved transmembrane protein called TMEM16A is required for normal cartilage formation, however its locus is on chromosome 11. One or more of the deleted genes in our family must also be important for normal tracheal cartilage formation.

## 2609/F/Poster Board #125

**Hand dysmorphology: Dermatoglyphics-A neglected clue to suspect microdeletions.** *Y. Lacassie[1], V. Myrtle[2], S. Sathyamoorthi[3].* 1) Dept Ped/ Div Clin Gen, LSU Hlth Sci Ctr, New Orleans, LA; 2) Volunteer Children's Hospital and Pre-med student at University of Georgia, Athens, GA; 3) Volunteer Children's Hospital and Pre-med student at Tulane University, New Orleans, LA.

With the advent of aCGH techniques, most clinicians, ignoring the usefulness of detailed evaluation, immediately request laboratory testing rather than spending time on PE. Often, the examination of face, hands, and feet provide the most important diagnostic clues. The examination of hands and feet, other than looking for single transverse palmar flexion crease, is frequently omitted. For more than 40 years, the senior author has used the analysis of hands, particularly dermatoglyphics to suspect cryptic chromosomal abnormalities (Lacassie, Y, Stahls, PF. Chromosomal abnormalities predicted by the absence of "d" triradius. AJHG Suppl Vol 61 (#4)-47th Annual Meeting ASHG, 1997, Baltimore). The advent of aCGH is allowing the detection of a large number of microdeletions/ duplications missed with standard high resolution chromosomal techniques. We were interested in finding out if dermatoglyphic abnormalities are also suggestive of microdeletions/duplications. Material and methods. Between June 1, 2007 and June 1, 2009, the senior author had 1217 encounters corresponding to 984 patients. In 157 patients with an evident genetic disorder but unspecific diagnosis (syndromes in identification or SINID) we performed aCGH (15.9%), obtaining 57 (36.3%) with abnormal results. These 157 patients do not include patients with recognizable classic numerical or structural chromosomal disorders. We are currently analyzing the dermatoglyphics findings in both groups, those patients with normal and abnormal microarrays. Although the absence of d (or a and b) triradius is highly predictive of a more substantial chromosomal abnormality, the preliminary results show that there are several minor dermatoglyphic traits that seem to be more frequent in the population with microdeletions and/or duplications. During this presentation, for the benefit of the audience we will review the normal dermatoglyphics traits and the most common abnormalities associated with some recognizable chromosomal syndromes. We will stress those features that suggest the possibility of a microdeletion/duplication. We conclude that the use of some dermatoglyphic findings associated with the antecedents of intrauterine and postnatal growth retardation, delayed developmental milestones and /or mental retardation or autism, dysmorphic features and/ or congenital malformations and neurological manifestations, help to yield a higher percentage of cryptic chromosomal abnormalities.

## 2610/F/Poster Board #126

**Novel copy number alterations from the Korean child with craniofacial microsomia.** *J.O. Lee[1], E.J. Seo[1,2], K.R. Jun[1,2], M. Hong[1], H.W. Yoo[1,3], I.S. Park[1,3].* 1) Genome Research Center for Birth defects and Genetic disorders, Asan Medical Center, Seoul, Korea; 2) Dept. of Laboratory Medicine, University of Ulsan College of Medicine and Asan Medical Center, Seoul, Korea; 3) Dept. of Pediatrics, University of Ulsan College of Medicine and Asan Medical Center, Seoul, Korea.

Hemifacial microsomia is characterized by facial asymmetry, preauricular facial tags, ear malformations, and hearing loss. Ear malformations can include microtia, anotia, or aural atresia, and hearing loss. We studied copy number alterations (CNAs) from the Korean 3-yr-old male with craniofacial microsomia. He had left small-sized deformed ear, hearing loss, facial asymmetry, microcephaly, and development delay. We detected two CNAs, 1.3 Mb heterozygote deletion on 10p12.31 and 227 kb hemizygous duplication on Xq21.1, by array comparative genomic hybridization using Agilent's Human Genome CGH Microarray Kit 244A. Deleted region on 10p12.31 contains only one gene, PLXDC2 (plexin-domain containing 2) which encodes for the relatively uncharacterized transmembrane protein with an area of nidogen homology and a plexin repeat (PSI domain) in its extracellular region. In the mouse study, Plxdc2 is expressed in the embryonic mouse, with particular emphasis on the developing central nervous system and developing heart. The hemizygous duplication on Xq21.1 caused duplication of transcription factor gene, TBX22, involving the regulation of developmental process. Mutations of this gene causing loss of function have been found in patients with cleft palate with ankyloglossia. We validated copy number changes of PLXDC2 and TBX22 using quantitative real-time PCR. These two genes are not harbored within CNV region from public CNV database and showed normal copy numbers in 126 normal Korean individuals. This study suggests that PLXDC2 deletion and TBX22 duplication appear to be novel CNAs and either of them can be associated with craniofacial microsomia.

## 2611/F/Poster Board #127

**A Novel Autosomal Recessive Syndrome with Congenital Stargardt-like Macular Dystrophy and Corpus Callosum Agenesis.** *P. Bitoun[1], E. Pipiras[2], J. Gaudelus[3], B. Benzacken[2], A. Delahaye[2].* 1) Gen Med, CHU Paris-Nord, Hopital Jean Verdier, Bondy, France; 2) Histology Embryology and Cytogenetics, CHU Paris Nord, Hopital jean Verdier, Bondy; 3) Pediatrics, CHU Paris Nord, Hopital Jean Verdier, Bondy.

Introduction: Many forms of macular dystrophies have been described including Stargardt disease with ABCA4 mutations , dominant Stargardt-like disease due to ELOVL4 mutations , Best disease with mutations in the VMD2 gene,Carolina macular dystrophy, Bietti's disease with crystalline deposits, and age related macular degeneration linked to ABCA4, CFH, C2 and ARMS2 mutation or predisposing risk alleles. Diffuse Retinal dystrophy associated with corpus callosum agenesis has been described in Aicardi syndrome which often involves developmental delay. Patients and Methods: The authors describe a patient with a novel syndrome with congenital macular dystrophy presenting with congenital nytagmus and low vision associated with corpus callosum agenesis. This 5 year-old girl presenting with low vision was seen for genetic counseling. Parents have given informed consent for participation in genetic research. Results: She was born at term from consanguineous first cousin parents with nystagmus by 6 month and corpus callosum agenesis seen on prenatal ultrasound and normal karyotype on amniocytes . She has a healthy brother and sister. Cranial ultrasound confirmed corpus callosum agenesis. Her distance visual acuity was 20/200 bilaterally and near acuity of Parinaud 4. She had no photophobia nightblindness or dyschromatopsia. Her fundus examination showed bilateral oval lesions of macular atrophy . Angiography confirmed macular atrophy without autofluorescence. Electrophysiology showed bilateral normal flash ERG and flicker response and symetrical pattern VEP showing good response to 60° and 30° but no response to 15° pattern VEP at right and a delayed P100 response at left . These anomalies are compatible with macular bundle dysfunction. OCT examination showed complete macular atrophy with thinning of the retina and interruption of the photoreceptor layer in the macular area . Macular thickness was 102 microns at right(60% normal) and 92 (50% normal) at left ,Macular volume was 4.65 mm3 at R and 4.32 mm3 at L. 15 Hue Desaturated color vision test showed slight dyschromatopsia. She had a normal karyotype, psychomotor development and intelligence.Gene testing was negative for ABCA4 mutations. Both parents had normal vision, ERG, VEP, OCT and angiography. Conclusion: This is the first presentation of a congenital developmental Stargardt-like macular dystrophy syndrome with corpus callosum agenesis and apparently recessive inheritance.

## 2612/F/Poster Board #128

**De novo Triple Segmental Aneuploid of 1p, 1q and 4q in a Girl with Hypertrophic Cardiomyopathy, Muscle Hypotonia and Multiple Congenital Anomalies.** *G. Ma[1,2], Y. Ke[1,3], D. Lee[1], M. Chen[1,4,5,6].* 1) Department of Medical Research, Department of Genomic Medicine and Center for Medical Genetics, Changhua Christian Hospital, Changhua, Taiwan; 2) Institute of Biochemistry and Biotechnology, Chung Shan Medical University, Taichung, Taiwan; 3) Department of Pediatrics, Changhua Christian Hospital, Changhua, Taiwan; 4) Department of Obstetrics and Gynecology, Changhua Christian Hospital, Changhua, Taiwan; 5) Department of Obstetrics and Gynecology, College of Medicine and Hospital, National Taiwan University, Taipei, Taiwan; 6) Department of Medical Genetics, College of Medicine and Hospital, National Taiwan University, Taipei, Taiwan.

Segmental aneuploids are a significant cause of morbidity and mortality in children, with an estimated incidence of 0.7-1 in 1000 births. Different segment aneuploids often have different clinical effects, depending upon the genes included in the aberrant regions. Children with hypertrophic cardiomyopathy (HCM) combining with muscle hypotonia (MH) are rare and the underlying case remains unclear. We report on a girl with HCM, MH and multiple congenital anomalies, in whom a de novo triple segmental aneuploid involving 1p13-1p21 trisomy, 1q32-1qter trisomy and 4q35-4qter monosomy was demonstrated by molecular cytogenetic analyses (G-banding, FISH, SKY and array-CGH). We examined the breakpoints, sizes and genes included of the segmental aneuploids, and discussed the possible genotype-phenotype correlations of the composite aneuploidy, with an emphasis on the two rare pediatric conditions of HCM and MH. By reviewing the literature we suggest that: (1) the 1q32.2-qter trisomy plays a major role in the appearance of the clinical phenotype and results in distal 1q trisomy syndrome in our patient; (2) increased gene dosages of two sarcomeric genes, TNNT2 and ACTA1, in distal 1q could be responsible for HCM; (3) the 4q35-qter monosomy could contribute to MH; (4) the critical regions for distal 1q trisomy syndrome and Kabuki make-up-like syndrome were located at 1q42 and 1p21-p22, respectively.

## 2613/F/Poster Board #129

**An unusual case of thrombocytopenia explained by a balanced translocation (Xp; 11q) in a female with random X-inactivation.** *N. Shur[1], P. Cotter[2], M. Gorre[2], E. Enriquez[2], G. Harappanhaly[1], D. Abuelo[1].* 1) Rhode Island Hospital 593 Eddy Street Providence, RI 02906; 2) Combimatrix Molecular Diagnostics 310 Goddard Suite 150 Irvine, CA 92618.

A 19-year-old female with a developmental delay and seizures was hospitalized for a six month history of thrombocytopenia . Her medications included phenyotoin, which she had taken for a number of years and valproic acid, which had been added in the last year. Hematology-oncology transfused her with platelets and performed a bone marrow biopsy which ruled out leukemia. Review of her history revealed that she was the 8 1/2 pound product of a full-term uncomplicated pregnancy to a 28 year-old G2 mother. Syndactyly between her right second and third finger was noted, which was repaired at age 3, but otherwise she appeared normal. At 5 months of age, a seizure disorder was diagnosed. She walked at age 2 ½ and began using two word sentences at age 7. An extensive metabolic work-up was done prior to referral at age 8 to genetics clinic. A high-resolution karyotype revealed 46X, t(X; 11) (p11.1; q25). On our P.E, weight and height were normal, and she had a head circumference of 52.5 cm (10-20%). Dysmorphic features included a slightly low anterior hairline, bushy eyebrows, a broad nasal bridge, slight hypertelorism, borderline low-set ears, and a high-arched palate. She had diffuse bruising. Neurological examination revealed mild ataxia. She was able to carry on a simple conversation. We concluded that she had the phenotypic effects of a partial 11q deletion disorder -- caused by partial inactivation of the X with the translocation. 11q deletion syndrome, also known as Jacobson syndrome: characteristics include dysmorphic features; syndactyly; global delays; and Paris-Trousseau syndrome characterized by thrombocytopenia and platelet dysfunction. Seizures have not been widely reported. FISH analysis showed a signal pattern with a translocation disrupting the 11q25 region corresponding to BAC clone Rp11-298F20. X-inactivation studies revealed a random inactivation pattern. An oligoarray returned as normal. In patients with 11q deletions, medications like phenytoin and valproic acid, which can exacerbate platelet dysfunction, should be avoided. After genetics consultation, our patient was switched to a ketogenic diet. Her thrombocytopenia resolved. This case is the first reported of Jacobson caused by a Xp; 11q translocation. Our patient's story demonstrates the importance of reviewing any rare genetic diagnosis in a patient presenting with seemingly mysterious symptoms.

## 2614/F/Poster Board #130

**Junctional epidermolysis bullosa. The identification of rare novel mutation in the LAMA3 gene.** *E. GUZMAN, H. SHUHAIBER, HANS H., K. ANYANE-YEBOA.* COLUMBIA UNIVERSITY MEDICAL CENTRE- NEW YORK PRESBYTERIAN HOSPITAL, DEPARTMENT OF PEDIATRICS, NEW YORK, N.Y.

Junctional epidermolysis bullosa (JEB) represents a genetically heterozygous group of bullous disorders characterized by dermo-epidermal separation resulting from mutations affecting the main dermo-epidermal adhesion factor, laminin-5, its cellular receptor, integrin alpha6B4, or collagen XVII. We report the identification of a new mutation of LAMA3, encoding laminin-5 alpha3 subunit in one infant of a Lebanese family. 8- day- old newborn descending from 1st degree consanguineous marriages, presented a lethal form of EBJ-Herlitz.. She had yellow and peeling blisters noted over hands, sacrum and buttocks also recurrent esophageal blisters leaving her unable to feed and gain weight. Histologic, ultrastructural and immunofluorescence studies were performed in order to ascertain the diagnosis and to direct genetic analysis. Immunohistology of frozen skin samples revealed an extremely reduced immunoreactivity for the alpha3 laminin-5 subunit. Our patient was found was found homozygous for c.4335dupA mutation in exon 32 of LAMA3 gene. The c.4335dupA is a single base duplication(A) causing a frameshift starting with codon Leu1446, changing residue to Isoleucine, then creating a premature Stop codon at position 11 of the new reading frame, denoted Leu1446Ilefs11. This expected to result in nonsense-mediated mRNA decay or in protein truncation. Susequently, testing both parents showed heterozygous carriers of the c.4335dupA Mutation in the LAMA3 gene. Ayoub et al 2005 first described this founder mutation in two Lebanese families. This newly identified mutation results in reduced synthesis of alpha3 chain and truncation of its C-terminal domain, which is crucial for the intermolecular interactions of laminin-5. This new case further underscores the geographical specificity of EBJ mutations linked to founder effects which are amplified by consanguineous marriages in genetically isolated populations who have immigrated to the United States.

## 2615/F/Poster Board #131

**Absent orbicularis oris and 22q11.2 deletion.** *R. Madankumar[1], L.C. Higgs[2], N. Chandy[2], D. Kronn[2].* 1) Dept. of Reproductive Genetics, Montefiore Medical Center, Albert Einstein College of Medicine, Bronx, NY; 2) Dept. of Medical Genetics, Westchester Medical Center, Valhalla, NY.

Background: Deletion of 22q11.2 may present as a variety of syndromes such as DiGeorge(DGS), Velocardiofacial(VCFS)and Conotruncal face anomaly. CATCH22(Cardiac anomaly, Abnormal facies, Thymic hypoplasia, Cleft palate, Hypocalcemia)is used to encompass these syndromes which share a common genetic etiology. Case report: A 15 month old girl was seen for asymmetric smile due to absence of right orbicularis oris muscle. She was born to 32 year old G2P1001, full term by NSVD, birth weight was 6lbs 14oz and apgars were 8 & 9. Pregnancy was unremarkable and she has a healthy 3 year old sister. Since birth she was noted to have asymmetric facial movements, prominent while crying or smiling. Paternal history is notable for Factor V Leiden mutation. During her initial genetic evaluation at 10 months, her milestones were felt to be age appropriate with no facial dysmorphism except for asymmetric smile and a high arched palate. Other systems were normal clinically. Although initially reported normal, a subsequent review of her echo reveals an insignificant atrial septal defect and her hearing evaluation was normal. At 15 months of age she was not walking, her height was at 10th and weight and head circumference were at less than 5th percentile. Her karyotype revealed 46,XX,del(22)(q11.21q11.23) and FISH analysis revealed a deletion within 22-ish del(22)(q11.2q11.2)(-TUPLE1-), suggesting DGS/VCF syndrome. Calcium level, CD3 and CD4 counts were normal. The patient is a heterozygote for factor V Leiden mutation and additional thrombophilia workup was negative. Oligonucleotide micro array analysis, early intervention evaluation and a feeding study were requested on the patient and FISH 22q analysis was sent on the parents. Discussion: Asymmetric smile should alert one to suspect a 22q11.2 deletion. To date, the genes responsible for all features of this contiguous gene syndrome have not been identified. Loss of one particular gene, TBX1, has been found to be responsible for cardiac defects and studies have shown that CRKL gene which maps within the 22q11.2 region was associated with cardiac, parathyroid and craniofacial anomalies. Chromosome and FISH analysis alone will not always help to determine the expected phenotype. More studies on genotype and phenotype correlation in conjunction with microarray techniques may better define the syndrome. Prenatal microarray studies in future may assist in counseling mothers carrying pregnancies detected with 22q11.2 deletions.

## 2616/F/Poster Board #132

**A microduplication of the Rubinstein-Taybi region on 16p13 in a girl with cleft palate and severe mental retardation.** *G. YESIL[1], BWM. VAN BON[2], A. HOISCHEN[2], JA. VELTMAN[2], BBA. DE VRIES[2], B. TUYSUZ[1].* 1) Istanbul University, Cerrahpasa Medical Faculty, Deapartment of Medical Genetics, Turkey; 2) Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands.

A 2,5 years-old female child was admitted to our unit with cleft palate and multiple congenital anomalies. She was the third child of non-consanguineous healthy parents. On physical examination, weight, height and head circumference were 9600 gr (<3p), 79 cm (<3p) and 47 cm (3-50p), respectively. She had cleft palate, hypertelorism, short palpebral fissures, a flat and broad nasal bridge, left ptosis and epicanthus, right esotrophia, large and anteverted nares, long philtrum, large mouth, hypoplastic, large and low set ears, microretrognathia, sparse and fine hair and eyebrows, clinodactyly, nail hypoplasia on fifth fingers and short hands. Radiological findings showed short distal phalanges on the both hands and feet and coxa valga. Small ASD was revealed on echocardiography. Psychomotor development was delayed as she sat unsupported at 11 months and walked at 32 months. At the age of 6 years, her language skills were very poor as she could say only 10 words. The karyotype revealed 46, XY. A genome wide single nucleotide polymorphism array (SNP array 6.0) was done according to the standard of Affymetrix GeneChip protocol (Affymetrix Inc, Santa Clara, California, USA). Array analysis showed a duplication of 1091 markers of the Rubinstein Taybi region on 16p13.3. The gain had a size of 2.1 Mb (chr16: 2, 645, 930-4, 728, 276 Mb, Hg18). Only three patients have been reported with microduplication of the Rubinstein Taybi region on 16p13.3. The patients had dysmorphic facies, moderate mental retardation, atrial septal defect, vertebral fusion on C5-C6, pes cavus and clawed toes and equinovalgus. The presented patient had overlapping features with previously studies like short palpebral fissure, hypertelorism, broad nasal bridge, malformed and low set ears, sparse hair and ASD. Our patient also showed short stature, cleft palate and severe mental retardation with delayed speech had not been reported previously. These findings were reported in patients who had cytogenetically apparent 16p13 duplication. It seems that the severity of the condition in our patient is strongly related with the large duplication with 2.1 megabases.

## 2617/F/Poster Board #133

***MEF2C* haploinsufficiency is associated with severe mental retardation, seizures, hypotonia, thinning of corpus callosum and delay of white matter myelinisation.** *B. Nowakowska[1], E. Obersztyn[1], K. Szymanska[2,3], D.W. Stockton[4,5], A. Patel[6], M. Bekiesinska-Figatowska[7], E. Bocian[1], K. Szczaluba[1], S.W. Cheung[6], P. Stankiewicz[1,6].* 1) Dept of Medical Genetics, Institute of Mother & Child, Warsaw, Poland; 2) Dept of Clinical and Experimental Neuropathology, Mossakowski Medical Research Center, Polish Academy of Sciences, Warsaw, Poland; 3) Dept of Child Psychiatry, Medical University of Warsaw, Warsaw, Poland; 4) Wayne State University School of Medicine, Division of Genetic and Metabolic Disorders, Detroit, MI; 5) Children's Hospital of Michigan Division of Genetic and Metabolic Disorders, Detroit, MI; 6) Dept of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 7) Dept of Diagnostic Imaging, Institute of Mother & Child, Warsaw, Poland.

Myocyte enhancer-binding factor 2C (MEF2C) is as a transcription factor expressed at high level in muscle, heart precursor cells, and brain. In brain, MEF2C has a crucial function in the homeostatic control of activity-dependent synaptogenesis that plays a role in the establishment of functional neuronal circuits during development and memory storage. We present three patients with severe mental retardation, in whom we identified overlapping deletions in 5q14.3 involving *MEF2C* using a clinical oligonucleotide array CGH. In case 1, array CGH (CMA V7.4) revealed an ~ 110 kb deletion encompassing first three exons of *MEF2C* in a 3 year old patient with severe psychomotor retardation, periodic tremor and abnormal motor pattern with mirror movement of the upper limbs observed during infancy, abnormal EEG, epilepsy, absent of speech, autistic behavior, bruxism and mild dysmorphic features. MRI of brain showed mild thinning of corpus callosum and delay of white matter myelinisation in the occipital lobes. Case 2, an ~ 1.8 Mb deletion of *TMEM161B* and *MEF2C* was found in a child with severe developmental delay, hypotonia, and agenesis of corpus callosum. Case 3, an ~ 5.6 Mb deletion containing *EDIL3*, *COX7C*, *RASA1*, *CCNH*, *TMEM161B*, and *MEF2C* was identified in a patient with developmental delay, hypo- / hypertonia, microcephaly, seizures with abnormal EEG, and hirsutism. MRI and PET studies showed abnormal basal ganglia and globus pallidus, and cortical dysplasia. The common clinical features observed in all three patients include severe psychomotor retardation, seizures, hypotonia, abnormal EEG and MRI results with mild thinning of corpus callosum and delay of white matter myelinisation. Cardoso et al (2009) reported three overlapping deletions in 5q14.3q15 distal and adjacent to the common deleted region in our patients, associated with periventricular heterotopia, mental retardation, and epilepsy, and suggested candidate genes, *GPR98*, *CETN3*, *NR2F1* and *MCTP1*. One of these deletion contained *MEF2C* and in two other cases, the proximal breakpoints of the deletions mapped close but distal to *MEF2C*. We suggest that position effect cannot be excluded. *MEF2C* was postulated to play an important role in heart development; however, no heart defect was observed in any of the cases. We propose that haploinsufficiency of *MEF2C* is responsible for the severe neurological phenotype in our patients.

## 2618/F/Poster Board #134

**Familial 18q22.3→18q23 Deletion.** *D.L. Pickering[1], B.J. Dave[1], J.D. Eudy[2], A. Haskins Olney[1], R. Lutz[1], K. Platt[3], W.G. Sanger[1].* 1) Department of Pediatrics and Human Genetics Laboratory, Munroe Meyer Institute for Genetics and Rehabilitation, University of Nebraska Medical Center, Omaha, NE; 2) Department of Genetics, Cell Biology and Anatomy, University of Nebraska Medical Center, Omaha, NE; 3) Boystown National Research Hospital, Omaha, NE.

We describe a family with an 18q22.3-q23 interstitial deletion and corresponding clinical features of the 18q22-qter deletion syndrome. The clinical phenotype of the proband and two maternal half-siblings includes short stature, a seizure disorder, developmental delays, hearing loss, and aural atresia with clefting of the soft palate. The deletion was initially identified by BAC aCGH followed by confirmatory FISH studies. Precise definition of the breakpoints was achieved by using oligonucleotide aCGH which redefined the minimum region of deletion as a 4.1 megabase interstitial deletion at 18q22.3-q23, from linear location 70565916bp - 74719434bp (hg18). The previously defined region associated with the cleft palate component in the 18q22.3-qter deletion syndrome has been reported to be 7.2 megabases, our study has helped refine this minimum deleted region. There are nine genes located in the deleted region, and two of them are strong candidates that might account for at least three of the observed anomalies. We assert that a strong candidate gene for two of these anomalies, cleft palate and congenital aural atresia, is teashirt zinc finger-1 (*TSHZ1*), an evolutionarily conserved putative zinc finger transcription factor. Galanin receptor-1 (*GALR1*), a receptor for the neuropeptide galanin, could be considered a candidate for seizures in these patients and may explain the association of epilepsy with 18q deletion syndrome. Oligonucleotide aCGH more accurately defines the breakpoints while identifying the specific genes involved in chromosomal deletions. Particularly in this familial study, the use of oligonucleotide aCGH facilitated precise phenotype/genotype correlations and has helped refine the minimum deleted region associated with 18q deletion syndrome. Our study underscores the importance of using high resolution aCGH in clinical investigations for accurate definition of the genetic anomaly and help gain a better understanding of the functional role of specific genes located within the critical regions.

## 2619/F/Poster Board #135

**Use of chromosome microarray analysis to map an Xq interstitial deletion in a female.** *M.E. Pierpont[1,2], B. Hall[1,3], D. Freese[4].* 1) Children's Hospitals and Clinics of Minnesota, St Paul, MN; 2) University of Minnesota, Minneapolis, MN; 3) Minnesota Perinatal Physicians, United Hospital, St. Paul, MN; 4) Mayo Clinic, Rochester, MN.

Chromosome microarray analysis (CMA) has allowed for better definition of cytogenetic deletions. We report a 4 year old girl who was seen for initial evaluation at age 18 months with developmental delay, hypotonia, macrocephaly, macrosomia, and extensive liver hemorrhages. Facial features include broad forehead, pale irises, epicanthal folds, depressed nasal bridge, protruding ears, and curly hair. Sotos syndrome was initially suspected but FISH analysis and sequencing of NSD1 gene were negative. Cytogenetic analysis at the 600 band level revealed a Xq27.2q28 deletion. A concurrent FISH study showed no evidence of a terminal deletion or rearrangement involving the subtelomere region. Additional studies included FMR1 gene testing which showed a CGG repeat number of 30 on both alleles. Due to our suspicion that the FMR1 gene may be involved in the Xq deletion, copy number analysis was performed for FMR1 which confirmed a whole gene deletion on one allele. At age 40 months, the patient experienced a second life threatening episode of intraparenchymal liver hemorrhages. Due to worsening liver failure and renal failure, the patient was treated with dialysis and eventually liver transplantation. Since that time, the patient has been relatively well. At age 4 years, she continues to be developmentally delayed. She is able to walk and can speak a few words. Recently, CMA was performed which further defined the boundries of the deletion to Xq27.1q28. Major genes that were deleted as a result include F9, FMR1, AFF2 (FRAXE), SOX3, IDS and MTM1. Deletions of FMR1 and AFF2 are known to be associated with cognitive and developmental delay and overgrowth. This patient displays a phenotype consistent with that reported in other females with a deletion of FMR1. What is unusual about her is that she had life threatening episodes of liver dysfunction and intraparenchymal hemorrhages, which have been reported in some patients with myotubular myopathy (MTM). She lacks the classic facial appearance of MTM but exhibits mild hypotonia. CMA analysis has allowed a more complete understanding of the genes involved in this deletion and how they contribute to the patient's phenotype and the potential for associated medical complications.

## 2620/F/Poster Board #136

**A Japanese infant with 1q41q42 deletion detected by using array-CGH.** *H. Yoshihashi[1,2], S. Hayashi[3], N. Furuya[2], K. Kurosawa[2], J. Inazawa[3].* 1) Division of Medical Genetics, Gunma Children's, Medical Center, Shibukawa, Japan; 2) Division of Medical Genetics, Kanagawa Children's, Medical Center, Yokohama, Japan; 3) Department of Molecular Cytogenetics, Medical Research Institute and School of Biomedical Science, Tokyo Medical and Dental University, Tokyo, Japan.

Array-based CGH has enabled the detection of novel genomic disorders using a genotype-first approach. We have screened genomic aberrations in patients with multiple congenital anomalies and mental retardation (MCA/MR) using MCG Whole Genome (WG) Array, which harbors 4523 BACs throughout the human genome (Hayashi S et al. ASHG 2007). Here, we report on a case with a small interstitial deletion of 1q41q42. Case: The propositus was a 3-year-old boy. At 38 weeks of gestation, he was born by Cesarean delivery due to CPD. Birth weight was 2680g (-0.7SD), length45.0cm (-1.9SD), and head circumference 34.0cm (+0.5SD). He had right club foot, and distinctive facial appearance (down-slanting palpebral fissures, thick lips, spaced teeth, long philtrum, upturned nares). Standard karyotype was normal. In infancy, his other complications included developmental delay, strabismus, laryngomalacia, undescended tesitis, and febrile seizures. Cytogenetic study: Decreases in the ratio of BAC clones around 1q41 were detected [arr cgh 1q41q42.11(RP11-211K12→239E10)×1], consistent with a heterozygous deletion. Based on our FISH mapping analysis, we estimated the size of monosomic region of about 6.1Mb< from 1q41 (RP11-224O19) to 1q42.11 (RP11-367O4). This case was found with de novo deletion of 1q41q42, resulting from the parental chromosomal study. Conclusions: Deletions of 1q41q42 have been infrequently reported. Shaffer et al. delineated clinical manifestations and breakpoint locations for the seven subjects with 1q41q42 deletion (Shaffer et al.,2006). Some clinical findings of our patient (facial features, club foot, seizures, mental retardation) shared common manifestations to those of the group with 1q41q42 deletion. The deleted region of our subject included the smallest region of overlap (<1.17 Mb) and contained the DISP1 gene, suggested as a candidate gene causing the features in the previous report. The common clinical features and cytogenetic results found in our case support that deletion of 1q41q42 is a new microdeletion syndrome. In conclusion, aCGH provides a useful strategy to investigate cryptic genomic aberrations responsible for unknown MCA/MR, and/or to establish a new syndrome.

## 2621/F/Poster Board #137

**Proximal interstitial 4q deletion associated with macrocephaly, plagiocephaly, ptosis, intraventricular hemorrhage, hypotonia, and growth and global development delays.** *R. Zambrano[1], E. Lisi[1], S. Morsey[2], D. Batista[2,3], T. Wang[1].* 1) Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) Kennedy Krieger Institute, Baltimore, MD; 3) Department of Pathology, Johns Hopkins University, Baltimore, MD.

Proximal 4q deletions are rare and not well characterized cytogenetically and phenotypically. The majority of the reported cases were studied using standard karyotyping methods with loosely defined clinical features including macrocephaly; facial dysmorphism; small hands with short fingers and clinodactyly; hypotonia, developmental delays and growth retardation. Delineation of the deletions is important to understand the clinical phenotype, implicate novel genes that underlie the pathogenesis, and differentiate disease-causing genomic imbalances from benign copy number variations. We report clinical and molecular cytogenetic studies of a *de novo* genomic deletion involving chromosome 4q in a 19 month-old male with macrocephaly, plagiocephaly, recurrent intraventricular hemorrhage; ptosis, nasolacrimal duct obstruction; facial dysmorphism; mild hydronephrosis; hypotonia; significantly delayed global development, physical growth, and bone age. BAC-microarray CGH with 4200 clones (BlueGnome) identified a genomic deletion at 4q21.21-21.23 that was confirmed by FISH. The deletion boundaries (79,156,795 to 86,063,181 bps) and size (6.9Mb) were determined using the Illumina 610,000 SNParray platform. A total of 30 annotated genes were identified within the deleted region using KaryoStudio 1.0.3 Build 36.1 (Illumina) and are predicted to be monosomic in this patient. Among these, at least 6 genes are known to express at high levels in the brain, at least 3 genes (*BMP3*, *BMP2K* and *PRKG2*) are known to be involved in long bone growth and maturation; 1 gene, *ANXA3* has been implicated as a novel angiogenic factor; and *FRAS1* encodes an extracellular matrix protein essential in normal dermal adhesion during development, and homozygous mutations in this gene have been implicated in Fraser syndrome 1. Further characterization of genes that are involved in this deletion should help to understand the genetic basis for the constellation of findings in this patient and implicate important genes in normal brain and skeletal development in humans.

## 2622/F/Poster Board #138

**Unique deletion 1q42: phenotype-genotype correlation in a patient with corpus callosum agenesis and MCA.** *I. Filges[1], B. Roethlisberger[2], N. Boesch[1], P. Weber[3], A.R. Huber[2], K. Heinimann[1], P. Miny[1].* 1) Division of Medical Genetics, University Children's Hospital and Department of Biomedicine, Basel, Switzerland; 2) Center of Laboratory Medicine, Cantonal Hospital, Aarau, Switzerland; 3) Division of Neuropediatrics, University Children's Hospital, Basel, Switzerland.

Interstitial deletions of 1q are rarely reported. Deletions of different extent as well as a variable phenotype have been described. Dysmorphic features, developmental delay and midline defects are common clinical features. Severe phenotype apparently resembles Fryns Syndrome. We report on a female patient who is the 3rd child of healthy, non-consanguineous parents with uneventful family history. Agenesis of the corpus callosum has been diagnosed prenatally by ultrasound and MRI. The child was born at term with growth parameters in the lower normal range. After delivery she presented with dysmorphic features including frontal bossing, midface hypoplasia and very high nasal bridge, hypoplastic nails, bowed lower extremities and bilateral cataract. Bilateral cleft palate was diagnosed, agenesis of the corpus callosum was confirmed and heart malformation was excluded, radiologic skeletal survey was normal. At the age of 5 months she presented with global developmental delay, but did not develop seizures until to date. Standard karyotyping revealed 46,XX. Array-CGH analysis (NimbleGen HG18 WG Tiling 385k CGH v2.0) showed a 5.45Mb interstitial deletion on the long arm of chromosome 1. The centromeric breakpoint is situated at 221.886-221.895 Mb, the telomeric breakpoint is located at 227.323-227.340 Mb. The deleted region comprises at least 53 genes and can be cytogenetically defined as 46,XX,del(1)(q41q42.13). Locus-specific FISH-analysis of both parents did not reveal an imbalance. This unique de novo deletion mainly affects the proximal region of 1q42 and includes only 0.2Mb in the 1q41 region. In contrast, patients decribed in the literature (Shaffer LG et al., 2007; www.decipher.sanger.ac.uk) show a deletion mainly exceeding into the 1q41 region. The deletion of our patient is not including the DISP1 gene which has been considered as a possible candidate for the developmental defects in the phenotype (Shaffer LG et al., 2007). We suggest a more distal region 1q42.11q42.12 being critical especially for cleft palate. To our knowledge only one additional patient with a deletion 1q42 is known with an agenesis of the corpus callosum (Puthuran MJ et al., 2005), but a critical region had been rather proposed to 1q44 (van Bon BWM et al., 2008). Positional effect and gene interaction might contribute to the disease model.

## 2623/F/Poster Board #139

**Atypical Simpson-Golabi-Behmel syndrome phenotype in a patient with duplication of *glypican-4* (GPC-4), and normal *glypican-3* (GPC-3).** *G. Scharer[1], A. Dameron[1], M. Raymond[1], B. Lunt[2], M. Springer[2], K. Swisshelm[2].* 1) Dept. of Pediatrics, Div. of Clinical Genetics & Metabolism, The Children's Hospital/ University of Colorado Denver, Aurora, CO; 2) Colorado Genetics Laboratory, Dept. of Pathology, University of Colorado Denver, Aurora, CO.

Simpson-Golabi-Behmel syndrome (SGBS) is an X-linked disorder associated with cognitive disabilities, pre/postnatal macrosomia, including macrocephaly, and other characteristic physical features. Most cases have been linked to mutations in the *glypican-3* gene (GPC-3) in chromosome region Xq26. Here we report the case of a 7 year old male with phenotypical features very similar to SGBS, with hypotonia and marked cognitive disabilities (absent speech), but with low normal growth and microcephaly. Routine genetic/metabolic work-up was negative, except for a subtle copy number variation (CNV), a one BAC clone duplication at 132.29 Mb on Xq26, detected by whole-genome array based comparative genetic hybridization (aCGH, Blue Genome CytoChip v2.01 BAC array). Interestingly, the duplication affected a known gene, *glypican-4*, which is located in close proximity to *glypican-3* (132.50-132.95 Mb). Clinical testing for deletions/duplications (MLPA) in GPC-3 did not show an extension of the duplication into the reading frame of that gene. Concurrent parental DNA studies did reveal maternal inheritance of the Xq26 duplication. While the mother did not have physical features consistent with SGBS, she did have a history of seizures and mild learning disabilities; and at least 2 maternal male relatives were reported with hypotonia, cognitive disabilities and motor developmental delays. While we can only hypothesize that the identified CNV on Xq26 is the actual cause for our patient's clinical presentation, the phenotypical overlap with SGBS and the involvement of a gene (GPC-4) in the glypican family of cell surface heparin sulfate proteoglycans, which is tightly clustered with GPC-3, make a dose-dependent effect more likely. There is currently no evidence that both genes interact in a counter-regulatory fashion, but the contribution of GPC-4 should be considered in the variability of the SGBS phenotype.

## 2624/F/Poster Board #140

**A 7 Mb partial trisomy 13q34 links postaxial polydactyly to an uncharacterized gene PCID2.** *Y. Ning[1], J. Meekins[1], M. Butler[1], M. Skinner[2], R. Shippy[3], C. Greene[2].* 1) Dept Pathology, Univ Maryland, Baltimore, MD; 2) Dept Pediatrics, Univ Maryland, Baltimore, MD; 3) Affymetrix, Santa Clara, CA.

Postaxial polydactyly is a frequent congenital malformation characterized by fifth digit duplication in hands and/or feet. It can be inherited as an isolated trait or occur as a part of a syndrome. Mutations in the GLI3 gene on 7p have been well-documented to result in postaxial polydactyly in a number of families. Another candidate region was indicated by the observation of postaxial polydactyly in approximately 75% of trisomy 13 cases. Several case reports described that this phenotype was associated with partial trisomy 13q22-qter. Here we report our recent finding of a newborn boy with hypertelorism, wide flat nasal bridge, cleft lip and palate, as well as postaxial polydactyly on both hands. Karyotype analysis showed a terminal deletion of 4p15.2, consistent with a clinical diagnosis of Wolf-Hirschhorn syndrome. The presentation of postaxial polydactyly, which is unusual for the Wolf-Hirschhorn syndrome, prompted fluorescence in-situ hybridization (FISH) investigation to rule out a cryptic translocation. A 13q telomeric probe revealed an unbalanced 4;13 translocation, with monosomy for 4p15.2 and trisomy for 13q34. The mother's chromosomes were normal and the father was not available. In order to determine the size of the unbalanced translocation and establish a genotype-phenotype correlation, we used SNP-oligo microarray approach and identified a terminal 7 Mb of trisomy 13 in our patient. A database search led to the identification of 36 genes in this region. Thirty genes appear to have known functions, and 6 genes are currently uncharacterized. One of these 6 genes is PCID2, PCI domain containing 2. The PCI domain is a highly conserved domain, predicted to be involved in protein-protein interaction. Significantly, PCID2 was found, through large scale "interactome mapping" using a yeast two-hybrid system, to be interacting with SHFM1, encoding split hand/foot malformation (ectrodactyly) type 1. These findings suggest that PCID2 is a candidate gene involving the postaxial polydactyly phenotype. Further characterization of this gene will advance our understanding of the molecular basis of trisomy 13-associated postaxial polydactyly.

## 2625/F/Poster Board #141

**Dissecting the 13q14 microdeletion syndrome to define the critical region for mental retardation.** *M. Amenduni[1], F.T. Papa[1], R.D. Clark[5], M. Bruttini[1], V. Disciglio[1], M.A. Mencarelli[1], M.C. Epistolato[2], P. Toti[2], A. Marozza[1], F. Mari[1], T. Hadjistilianou[3], S. De Francesco[3], A. Acquaviva[4], E. Katzaki[1], M. Mucciolo[1], F. Ariani[1], A. Renieri[1].* 1) Molec Biol, Medical Genetics, Siena, Siena, Italy; 2) Department of Human Pathology and Oncology, University of Siena, Siena, Italy; 3) Retinoblastoma Referral Center, Department of Ophtalmology, University of Siena, Siena, Italy; 4) Department of Pediatrics, Obstetrics and Reproductive Medicine, Italian retinoblastoma registry, University of Siena, Siena, Italy; 5) Divisions of Medical Genetics and Ophthalmology, Retinoblastoma Program, Childrens Hospital Los Angeles, Los Angeles, CA, USA.

Retinoblastoma (RB) is the most common intraocular cancer of early childhood. Tumor development is caused by inactivation of both alleles of RB1 gene, located in 13q14.2. In most cases RB1 is inactivated by point mutations, but also complete gene deletions and gross-sized molecular deletions have been observed. When the deletion involves part of the RB1 surrounding genome, it causes a contiguous gene deletion syndrome characterized by retinoblastoma, mental retardation and dysmorphic facial features. In a previous work, using array-CGH, we defined two critical region for mental retardation (MR) and dismorphic features (Caselli et al.,2007). These regions contained 50 genes and 4 of them appeared to be good candidates for the neurological phenotype: NUFIP1, HTR2A, and the protocaderin genes PCDH8 and PCDH17. Recently we collected five additional patients, three with isolated retinoblastoma and an RB1 large deletion and two presenting RB together with MR and dismorphic features. In these patients, we performed array-CGH (Agilent 44K and 105K) to better define the critical region for MR. In two patients with isolated RB, the deletions included only the RB1 gene, while in the third patient we identified a larger rearrangement of about 8 Mb. We compared the deleted region with the 11 Mb and 34 Mb rearrangements, detected in the two patients presenting also MR. The comparison of these overlapping deletions, allowed us to restrict the critical regions previously identified. The centromeric sub-region now contains 7 genes and NUFIP1 and HTR2A are excluded as candidates genes. The telomeric sub-region now contains 28 including PCDH8 and PCDH17. These results contributed to narrow the critical regions for MR and dysmorphic features and to dissect the syndrome, pointing the attention on the possible role of protocaderin in the generation of the neurological phenotype. These proteins are, indeed, integral membrane proteins which are thought to function in signalling pathways and in cell adhesion in a central nervous system specific manner.

## 2626/F/Poster Board #142

**Genotypic-Phenotypic Association Study of Chromosome 8p inverted duplication deletion syndrome.** *J. Youngblom[1], R. Davis[2], J. Gregg[2], G. Fisch[3], E. Stark[1].* 1) Dept Biol Sci, California State Univ, Turlock, CA; 2) M.I.N.D. Institute, University of California, Davis, Sacramento, CA; 3) Colleges of Dentistry and Nursing, New York University, New York, New York.

Individuals diagnosed with chromosome 8p inverted duplication deletion manifest a wide range of clinical features and cognitive impairment. To date, a systematic genotypic -phenotypic association study has not been conducted on individuals with this cytogenetic diagnosis. The purpose of this study is to employ array CGH technology to more precisely define the cytogenetic breakpoints and regions of copy number variation found in different individuals with this cytogenetic condition, and compare these results with their phenotypic features. Three families were included in the study, and each family has only one affected child. Blood samples were obtained for array CGH analysis from the affected children and each of the parents for two of the families. The array results were compared with the clinical presentation and cognitive assessment of each patient. The latter included IQ tests, VABS for behavior assessment, and CARS for autism. Comparison of the microarray results among the patients showed regions of consistency where chromosomal deletions and duplications occurred. For example, 2 of the 3 patients have terminal deletions with the breakpoints near the boundary between 8p22 and 8p23.1. However the existence of this deletion did not correlate with the severity of the clinical outcome, i.e. both of the patients with the deletion were less severely affected overall than the patient without the deletion. Additionally, 2 (one most severe and the other least affected) of the 3 patients have a small deletion near the 8p11.22 and 8p11.23 boundary. The duplicated segments show greater variability among the patients. A common core duplicated region was found in all 3 patients that includes all of 8p22 and extends midway into 8p21.3. One of the patients showed an interesting triple stepwise increase in duplication of adjacent segments within this exact region, with no other duplicated regions involved. The other 2 patients have duplications that extend from this core region, albeit in opposite directions, and both are more severely affected physically and cognitively. All the parents showed normal microarray results, except one parent showed a duplication in a region on chromosome 5q of unknown significance. This study will assist in providing a more refined prognosis for patients given this cytogenetic diagnosis, and may help to identify critical genes responsible for the specific physical and cognitive features associated with this condition.

## 2627/F/Poster Board #143

**Clinical and genetic characterization in a patient with complete deletion of TSC2.** *D.R. Amrom[1, 2], F. Andermann[2, 3,4,7], J. Hall[2,5], B. Zifkin[4], E. Andermann[1,2,6].* 1) Neurogenetics Unit, Montreal Neurological Hospital and Institute, Montreal, Quebec, Canada; 2) Department of Neurology & Neurosurgery, McGill University; 3) Epilepsy Service, Montreal Neurological Hospital and Institute; 4) Seizure Clinic, Montreal Neurological Hospital and Institute; 5) Department of Neurosurgery, Montreal Neurological Hospital and Institute; 6) Department of Human Genetics, McGill University; 7) Department of Pediatrics, McGill University.

Purpose Tuberous sclerosis complex (TSC) is caused by a wide spectrum of mutations within the TSC1 and TSC2 genes, mostly point mutations and small indels, while large deletion/duplication mutations are much less frequent and mostly identified in the TSC2 gene. We report the clinical and molecular data of a patient with TSC due to a single copy loss of TSC2. Methods We performed a study of the TSC phenotype and genotype in a patient with a clinical diagnosis of TSC. TSC1 and TSC2 DNA sequencing, as well as TSC2 DNA deletion test were performed, followed by an oligonucleotide microarray using 1543 loci. Results A 28-year-old man had focal seizure onset at 1 year of age well controlled by phenobarbital. TSC was diagnosed at age 5 years. He attended regular school until age 17 years, but had learning difficulties. An intraventricular tumor was found and remained stable for several years. At age 22 years, he developed cognitive deterioration and ataxia, repeat CT scan showed an increased volume of the intraventricular lesion and hydrocephalus. A right frontal subependymal giant cell astrocytoma (SEGA) was resected and seizures recurred. At the age of 26, CT scan and sonography of the abdomen showed angiomyolipomas of the liver, and multiple small angiolipomas as well as several cysts of both kidneys. Two years later, seizures increased and an MRI showed a residual right intraventricular SEGA with an increased cystic component and hydrocephalus, as well as multiple cortical and subcortical tubers. He had endoscopic fenestration of the intraventricular cyst, resection of the glial scar and right residual intraventricular SEGA. He developed left hemiparesis due to an epidural hematoma which was subsequently drained. DNA studies revealed deletion of all exons (1-41) of the TSC2 gene. Microarray analysis detected a single copy loss of 25 oligonucleotide probes from the short arm of chromosome 16 at 16p13.3. This was estimated to be approximately 194.3 Kb in size; it overlapped the TSC2 locus and extended in the 5' direction, containing at least 10 other genes. There was no evidence for TSC in available family members. Quantitative dosage analysis of genomic DNA in the mother and brother did not show any TSC2 deletion nor abnormal DNA sequence variants; the father was not available for genetic testing. Conclusions To our knowledge, the variant detected here has not been previously reported. It appears to be associated with a severe TSC phenotype.

## 2628/F/Poster Board #144

**Marinesco-Sjögren syndrome (MSS): Genotype-Phenotype Correlation and Heterogeniety.** *A. Parsian[1], S. El-sayed[2], E. El-Sobky[2], F. Kok[3].* 1) Div Neuroscience & Behavior, NIAAA/NIH, Bethesda, MD; 2) Department of Pediatrics, University of Ain Shams, Cairo, Egypt; 3) Department of Pediatrics, University of Sao Paulo, Sao Paulo, Brazil.

Marinesco-Sjögren syndrome (MSS [MIM 248800]) is an autosomal recessive multisystem disorder characterized by congenital cataracts, cerebellar ataxia, progressive muscular weakness (chronic myopathy), growth and mental retardation. Peripheral neuropathy, acute rhabdomyolysis, hypergonadotrophic hypogonadism and skeletal deformities have been described occasionally. We sequenced BAP/SIL1gene using genomic DNA from members of an Egyptian pedigree and found a homozygous mutation at position 1312 (C to T) in exon 10 that creates a stop codon (Q438X) in all four affected members. However, two of the older affected pedigree members did not present any sign of ataxia. Sequencing the same gene using genomic DNA from a proband from a Brazilian family revealed a G deletion in exon 2 of the gene that also creates a stop codon. Some of the symptoms of this proband include severe developmental delay, muscular dystrophy and severe apendicular and axial ataxia. A detailed comparison of the phenotypes of the five affecteds in these two pedigrees and related genotypes will be presented. This study clearly shows the effect of the position of the mutations and the severity of the phenotypes.

## 2629/F/Poster Board #145

**Concordance in Genotype and Discordance in Phenotype found in Monozygotic Twins with Allagile Syndrome.** *H. SHUHAIBER, E. GUZMAN, K. ANYANE-YEBOA.* PEDIATRICS, COLUMBIA UNIVERSITY MEDICAL CENTRE, NEW YORK, N.Y.

Alagille syndrome(AGS) is an autosomal dominant disorder affecting multiple organ systems. The phenotype in Alagille syndrome is highly variable both within families. We report monozygotic twins with Alagille syndrome concordant for a mutation in Jagged1 but discordant for clinical phenotype. The twins' monozygosity was confirmed by molecular testing. This heterozygous C>T was identified in exon 23 resulting in replacement of an arginine codon with a stop codon from CGA to TGA at amino acid position 900. The mutation is denoted as c.2698 C> T at the cDNA level or p.Arg900Stop (R900X) at protein level. Twin A had cholestasis with ductopenia on liver biopsy. Whereas, twin B had paucity of bile ducts with mild centrilobular cholestasis. Both twins had a normal eye exams. Twin A had a Tetrology of Fallot whereas Twin B had a normal heart. The twins described here, demonstrated to be monozygous by molecular testing, share an identical de novo mutation in JAG1 yet display a conspicuous discordance in clinical phenotype.Krantz- 1998; was the first to describe the variability in phenotypic manifestations in AGS among family members sharing the same mutation. In particular, cardiac defects, which are more common in monozygotic twins, usually affect only one of the twin pair. Several genetic hypotheses have been proposed to account for discordance in phenotype in monozygotic twins; among these are somatic mosaicism, differences in deletion size when chromosome deletions are present, and modifying genetic loci. The relationship between genotype and phenotype in AGS remains unclear. Both girls are clearly significantly affected by their mutation, but the pattern of the disease significantly differs by their organ involvement. Twin A being liver and heart, whereas twin B being purely liver . However, it remains difficult to conclude whether the phenotypic discordance results from factors arising from the twinning process, or from the same mechanism that generates the variability seen in family members sharing the same mutation, or in fact a combination of both mechanisms. It is possible that the genotype predisposes individuals to disease and the twinning process adds to the severity of the effect. Currently, testing is underway for the parents to see if one of them carries this mutation since both of them are completely asymptomatic. Further studies are necessary to elucidate the factors that modify the effects of JAG1 mutations on phenotype.

## 2630/F/Poster Board #146

**Increased Bone Mineral Density and Body Mass Index in Families of Osteogenesis Imperfecta: a New Type of OI?** *C. Li.* Dept Pediatrics, McMaster Children's Hosp, Hamilton, ON, Canada.

Osteogenesis Imperfecta (OI) type I is the mildest type of OI and typically manifest with decreased bone density and increased risks for fractures. The patient usually is of thin built, of borderline short stature and with blue sclera. They may also experience dental problems, hearing problems, easy bruising and joint laxity. I report two pedigrees with a milder form of OI confirmed by molecular analysis. Interestingly affected individuals have higher bone density and body mass index. Joint laxity appears to be more pronounced in these affected individuals as well. The first pedigree is of Iraqi origin with at least 37 individuals with a history of multiple fractures. Four of them, age 10, 10 (twins), 13 and 52, were assessed by the author. In addition to blue sclera and fractures, novel features on clinical examination include facial features that are not reminiscent of OI. All of them were overweight. Severe joint laxity was noted in one of them. Bone mineral density studies revealed generalized increased bone density in all four of the affected, up to +3.5 standard deviations from age-match means, most pronounced in the spine. Molecular analysis revealed a mutation c.3359A>C; p.Asp1120Ala in one allele of COL1A2 in the carboxy terminal proteolytic conversion site of procollagen to collagen, in these four affected individuals . Another family of European Caucasian background was assessed by the author. The proband is a 2-year old boy referred for assessment of behavioral issues. He was noted to have blue sclera, joint laxity and dental crowding but no history of fracture. His father, a half-sister by the same father, paternal grandmother and two paternal grandaunts were reported to have blue sclera, joint laxity/ dislocation and dental crowding as well. The father is overweight, of a stocky built. Molecular analysis revealed a novel mutation in the COL1A2 gene, c.380G>A, p. Gly127Asp in the triple helix in the proband and his father. The proband was noted to have osteosclerostic changes on X rays. In summary, I report two pedigrees of multiple individuals with OI confirmed by molecular analysis. Although they exhibit some features commonly associated with OI type 1, affected and presumed (by history, not assessed by author) affected members of both families have increased bone density and are overweight, two features very distinctly contrary to the typical findings of OI and suggest a new type.

## 2631/F/Poster Board #147

**Spondyloperipheral dysplasia - Clinical and radiographic delineation of a novel COL2A1 missense mutation in the C-Propeptide.** *C.T. Thiel[1], H.-G. Doerr[2], H. Sticht[3], A. Rauch[1,4].* 1) Institute of Human Genetics, University of Erlangen-Nuremberg, Erlangen, Germany; 2) Children's and Adolescents' Hospital, University of Erlangen-Nuremberg, Erlangen, Germany; 3) Institute of Biochemistry, Division of Bioinformatics, University of Erlangen-Nuremberg, Erlangen, Germany; 4) Institute of Medical Genetics, University of Zurich, Schwerzenbach-Zurich, Switzerland.

Mutations in the type II collagen gene (COL2A1) result in a broad spectrum of skeletal dysplasias. Most of these are located in the coding region for the helical part of the $\alpha$1(II)-chain and lead to alterations of the triple helix formation or to nonsense-mediated decay (NMD) as observed in Stickler syndrome. In contrast, truncating mutations coding for the C-propeptide have been recently identified as the underlying cause of spondyloperipheral dysplasia [SPD, MIM 271700]. We present an 11 year-old female with characteristic features of SPD-like short-trunk dwarfism and brachydactyly E-like changes. Growth retardation was first noted at 25th week of gestation and she was born at 36th weeks of gestation with a birth weight of 1990 g (-1,7 SDS) and length of 41 cm (-2,9 SDS). Psychomotor development was normal. Her HC followed the 50th to 97th c. whereas her growth remained below the 3rd c. with a proposed adult height of 145 cm. Growth hormone treatment was futile. There have been no signs of hearing impairment or eye problems as reported in other cases of SPD. X-ray evaluation at 11 years of age confirmed a spondyloepiphyseal dysplasia with an accelerated bone age, delayed ossification of the pubic and ischial bones and degenerative changes of the femoral head, horizontal acetabulae, epiphyseal changes and shortening of the metarcapals and the distal phalanges, mild metaphyseal widening at the knee joint and a platyspondyly with fish-mouth vertebrae. Mutational analysis of the COL2A1 gene revealed the de-novo missense mutation c.4250T>C (p.F1417C) within the C-propeptide coding region. All known mutations in patients with SPD result in a premature stop codon within the C-propetide disrupting disulfide bonds formed by cysteine residues or trimer association specific recognition sequences. Therefore, it has been proposed that the C-propeptide plays a crucial role in the association of the procollagen chains in helix formation, which might be disturbed by truncating mutations. As our patient presented with mild clinical and characteristic radiographic features of SPD caused by the first reported missense mutation forming a new cysteine residue, this results support the hypothesis of a conformational change of the C-propeptide by alteration of the disulfide bonds composition. This is of special relevance as accumulation of free procollagen II chains with a calcification-promoting effect of the C-propeptide has been proposed as the underlying cause of SPD.

## 2632/F/Poster Board #148

**Noonan syndrome and related disorders: genotype & phenotype correlations.** *B. Lee[1,2,3], C. Cheon[4], J. Kim[2], G. Kim[2,3], J. Park[3], H. Woo[1,2,3].* 1) Pediatrics, Asan Medical Center, Seoul, Korea; 2) Genome Research Center for Birth Defects and Genetic Disorders, Asan Medical Center, Seoul, Korea; 3) Medical Genetics Clinic and Laboratory, University of Ulsan College of Medicine, Asan Medical Center, Seoul, Korea; 4) Department of Pediatrics, Children and Adolescent Hospital, Pusan National University, Gyeongsang-nam-do, Korea.

Noonan syndrome (NS) and related disorders (NSLD) are caused by dysregulation or gain-of-function mutation in a member of RAS-MAPK signaling pathway. With more causative genes identified, their genotypic and phenotypic heterogeneities emerge as complex and overlapped. In this study, we analyzed genotype-phenotype correlations with 71 Korean cases with NS or NSLD. Clinical diagnosis were NS in 59 (83%) and NSLD in 12 (17%) cases; 5 with Cardiofasciocutaneous syndrome (CFC), 5 with Costello syndrome (CS) and 2 with LEOPARD syndrome (LS). Male predominance (76%) was noted in NS, but short stature and delayed development were more common in NSLD. Mutations were identified in 34 cases with NS (57.6%): PTPN11 in 19, SOS1 in 11, RAF1 in 3 and KRAS in 1 case. Five cases with CFC carry mutations in BRAF and the rest in MEK1. All the 5 cases with CS and 2 cases with LS harbor mutations in HRAS and PTPN11, respectively. No mutation was found in MEK2. Three cases with RAF1 mutation have hypertrophic cardiomyopathy. Patent ductus arteriosus was more common in cases with PTPN11 mutation than SOS1. Developmental delay was more common in cases with mutation in BRAF or HRAS, with CFC or CS, than cases with PTPN11. There was no correlation in pulmonary stenosis, chest deformity, abnormal genitalia, lymphedema, hearing difficulty, or bleeding tendency. In conclusion, although genotype-phenotype overlap exists between NS and NSLD, searching for common genotypes according to each phenotype can be recommended. Developmental delay is an important sign for the differential diagnosis of NS and NSLD. Further study is needed to identify new mutations in NS with unknown genotypes.

## 2633/F/Poster Board #149

**Axenfeld-Rieger anomaly and Axenfeld-Rieger syndrome; clinical and genomic analyses on three patients with chromosomal defects at 6p25.**
*H. Tonoki[1,2], N. Harada[3], O. Shimokawa[3], T. Shinpo[2], N. Kudo[2], K. Sato[4], R. Kosaki[5], A. Sato[6], N. Matsumoto[7].* 1) Dept Pediatrics, Hokkaido Univ Grad Sch Med, Sapporo, Hokkaido, Japan; 2) Dept Pediatrics and Sec Clin Genetics Tenshi Hospital, Sapporo, Hokkaido, Japan; 3) Kyushu Medical Sicence Nagasaki Lab, Nagasaki, Japan; 4) Dept Pediatrics, Sapporo Kosei General Hospital, Sapporo, Hokkaido, Japan; 5) Dept Clin Genetics and Mol Med, Natl Center for Child health and Development; 6) Dept Pediatrics, Faculty Med Univ Tokyo, Tokyo, Japan; 7) Dept Hum Genetics, Yokahama City Univ Grad Sch Med, Yokohama, Kanagawa, Japan.

Axenfeld-Rieger anomalies, a group of genetically and phenotypically heterogeneous disorders leading to aberrant development of the anterior chamber of eyes, frequently accompany a variety of major and minor anomalies of systemic organs. So far mutations in two genes, FOXC1 and PITX2, which code transcription factors, are known to cause Axenfeld-Rieger anomalies. We encountered three unrelated Japanese patients with Axenfeld-Rieger anomalies accompanied by a variety of anomalies of systemic organs. GTG-banded chromosome analysis showed terminal deletions of a short arm of chromosome 6 in two patients and inv(6)(p25q14) in the other. FISH and DNA array analyses revealed that the former two patients had 5.0-5.7 Mb and 6.6 Mb 6p terminal deletions, respectively, and FOXC1 is apparently deleted in both. In the other patient, the inversion break point at 6p25 is in or very close to FOXC1 locus since BAC clones encompassing FOXC1 gave split signals while clones RP11-157J24 and RP11-265E5, distally and proximally closest neighbors to FOXC1, gave single signals at the original and inverted position on the inv(6), respectively. We characterized the spectrum of extra-ocular findings in these patients and compared them with those in the literature in accordance with several common genetic causes; mutations of FOXC1, 6p terminal deletion including FOXC1, and PITX2 mutations. Patients with PITX2 mutations seemed to have umbilical and dental anomalies more frequently than those with FOXC1 mutations. On the contrary, patients with FOXC1 mutations tend to have hypertelorism and defects in heart and central nervous system much more than those with PITX2 mutations. Patients with 6p terminal deletion usually have mental defects and major systemic anomalies as results of haploinsufficiency of multiple genes. Recognition of the difference in the spectrum of extraocular findings in patients with Axenfeld-Rieger anamalies may lead better clinical management.

## 2634/F/Poster Board #150

**Co-segregation of autosomal recessive polycystic disease and Bardet-Biedl syndrome.**
*K. Dahan[1], N. Godefroid[2], L. Messiaen[3], O. Devuyst[2], Y. Pirson[2].* 1) Ctr Human Gen, Univ Catholique Louvain, Brussels, Belgium; 2) Division of Nephrology, Univ Catholique de Louvain, Belgium; 3) Department of Genetics UAB, University of Alabama at Birmingham.

Autosomal recessive polycystic disease (ARPKD) is associated with enlarged kidneys and biliary dysgenesis. The disease phenotype caused by mutation in *PKHD1* is highly variable, ranging from neonatal death to later presentation with minimal kidney disease. A different kidney phenotype as well as discordance for postaxial polydactyly in two affected patients from a family prompt us to report the present observation. The first fetus presented at 24 weeks of pregnancy with massively enlarged kidneys and oligohydramnios leading to abortion at 26 weeks. Kidney and liver specimens showed radially oriented collecting tubule cysts and hepatic fibrosis. This fetus carry two distinct missense mutations in *PKDH1* gene inherited from both parents. Whereas the first fetus had no associated clinical features except fibrosis of the liver, the second fetus presented at 20 weeks with postaxial polydactyly and hyperechogenic kidneys without corticomedullary differentiation. Diagnosis of Bardet-Biedl (BBS) phenotype was established at birth on the combination of clinical findings and compound heterozygosity for at least the common *BBS10* mutation and the maternal *PKD1* mutation. Further molecular testing is in process (collaboration with N Katsanis). We show for the first time that (1) co-segregation of mutations at *PKDH1* and *BBS10* genes may cause BBS phenotype,(2) discordance for clinical presentation in affected siblings with primary cilium defect may reflect a multiple mutations loading.

## 2635/F/Poster Board #151

**Exon-focused microarray analysis of candidate genes in Autism.**
*P.B.S. Celestino[1], M. Shinawi[1], T. Sahoo[1], R. Zascavage[1], J.R. German[1], A. Porter[1], P. Fang[1], D.E. Treadwell-Deering[1,2], S. Peters[2], C. Skinner[3], S.A. Skinner[3], R.E. Stevenson[3], R.P. Goin-Kochel[1], C. Shaw[1], P. Stankiewicz[1], J. Li[4], A.L. Beaudet[1].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Menninger Department of Psychiatry and Behavioral Sciences and Department of Pediatrics, Texas Children's Hospital, Houston, TX; 3) JC Self Research Institute of Human Genetics, Greenwood Genetic Center, Greenwood, SC; 4) Structural and Computational Biology & Molecular Biophysics, Baylor College of Medicine, Houston, TX.

We hypothesize that de novo and recent mutations cause a major fraction of autism cases. These mutations would not be detected by genome-wide linkage studies. Much progress in understanding the etiology of autism is derived from the use of array technologies to detect genomic deletions and duplications followed by sequencing of candidate genes within these genomic regions. Objectives: The goal of this work is to discover novel genomic deletions and duplications causing autism with a particular focus on determination of exon copy number to identify small deletions and duplications that would implicate a single protein coding gene. Genes suspected of causing autism via haploinsufficiency would then be sequenced in other autism individuals. Methods: Customized Agilent arrays were designed to cover all the exons of tens to hundreds of autism candidate genes. Genes were selected based on literature support that they might cause autism (73 genes), on neurological or synaptic function (253 genes), or on an implied role in epigenetic regulation (294 genes). A one-million oligonucleotide array to test copy number for nearly all exons in the genome was also developed. The study group included 98 patients from South Carolina Autism Project, 64 local patients, and 22 autistic individuals from AGRE collection. Results: These experiments identified several very small and apparently benign copy number variants (CNVs). Multiple lymphoblast cell lines were trisomic for various chromosomes. These were interpreted to represent cell culture artifacts. We found 5 cases with pathogenic alterations. Three of these abnormalities were deletions: a 15q13.3 deletion encompassing the CHRNA7 gene, a paternally inherited 2-Mb deletion causing haploinsufficiency of the BDNF and LIN7C genes, and a 6p23 deletion. In addition, there were two duplications involving X-linked genes and the 15q11-q13 imprinted domain. The X-linked duplication was detected in males and included a maternally inherited 615-kb duplication encompassing the OCRL1 gene. Conclusions: These data provide additional support for the importance of copy number variants in the etiology of autism and suggest that exon-focused microarrays may be an effective method for detecting these chromosomal imbalances and identifying specific causative genes. The utilization of arrays that cover all exons in the genome is predicted to increase the detection of these chromosomal imbalances.

## 2636/F/Poster Board #152

**X-inactivation studies in a familial case of Simpson-Golabi-Behmel Syndrome.** *S. Yano[1], A. Bagheri[1], K. Moseley[1], Y. Watanabe[2], B. Baskin[3], P.N. Ray[3], A. Nishimura[4], N. Matsumoto[4].* 1) Pediatrics/Gen Div, 1G24, LAC+USC Med Ctr, USC, Los Angeles, CA; 2) Department of Pediatrics and Child Health, Kurume University, Kurume, Japan; 3) Division of Molecular Genetics, Department of Pediatric Laboratory Medicine, The Hospital for Sick Children, Toronto, Canada; 4) Department of Human Genetics, Yokohama City University Graduate School of Medicine, Yokohama, Japan.

Introduction: Simpson-Golabi-Behmel syndrome (SGBS) is an overgrowth/multiple congenital anomalies syndrome with X-linked inheritance and a wide clinical spectrum. Most cases of SGBS attributed to mutations in the glypican 3-gene (GPC3). Typical clinical features include pre/post natal overgrowth, macrocephaly, characteristic facies with prominent eyes and macroglossia, congenital heart defects, kidney anomalies, and skeletal anomalies, including vertebral fusion, pectus excavatum rib anomalies, and polydactyly. Developmental delay is often associated. Childhood cancer is found in about 10 %. Obligate carrier females with GPC3 mutations are usually not affected although they can have a milder phenotype. We describe three affected siblings and their mother in a family carrying c.256C>T (p.Arg86X) mutation in the GPC3 gene. All three siblings showed typical symptoms of SGBS. The mother, however, was asymptomatic. We conducted X-inactivation studies in the carrier females. Case Report: Patient 1 is a 3-year-old Jordanian male, prenatally diagnosed with hydronephrosis, hydroureters, and polyhydramnios. All of his body measurements are larger than 97%ile. He has clinical findings consistent with SGBS. His developmental milestones are delayed. Patient 2 is a 2-year-old younger brother of patient 1. He was born as one of the twins at 34 weeks (BW 3800g), was also prenatally diagnosed with hydronephrosis, hydroureters, and macrocephaly. His development has been delayed. Patient 3 is a female, twin sister of patient 2 (BW 2196g, at 50%ile). She had a congenital diaphragmatic hernia and a large PDA. Her development at age 5 months revealed fine motor delay. By age 8 months she showed signs of overgrowth. Their mother is an asymptomatic carrier of the gene mutation. Molecular Studies: X-chromosome inactivation studies were performed on the androgen receptor (AR) gene. The results indicated the paternal X-chromosome was preferentially inactivated (83 % inactivated) in patient 3. X-inactivation studies revealed uninformative results in the asymptomatic carrier female (the mother) due to homozygous alleles of the AR gene. Discussion: There were no reports of molecular studies in carrier females of GPC3 mutations. X chromosome inactivation studies were conducted to evaluate relationship of skewed X inactivation and SBGS female phenotype. The studies showed significantly skewed X-inactivation in the female with SBGS phenotype.

## 2637/F/Poster Board #153

**Mild phenotype of the dominant negative mutation in the tyrosine kinase domain of *KIT* may suggest a second modifier gene for piebaldism.** *N. Oiso[1], T. Suzuki[2], K. Fukai[3], T. Motokawa[4], K. Yokoyama[4], Y. Hozumi[2], A. Kawada[1].* 1) Dept Dermatology, Kinki Univ Sch Med, Osaka-Sayama, Japan; 2) Dept Dermatology, Yamagata Univ Sch Med, Yamagata, Japan; 3) Dept Dermatology, Osaka City Univ Grad Sch Med, Osaka, Japan; 4) Cutaneous Drug Research Dept, POLA Chemical Industries, Inc, Yokohama, Japan.

Piebaldism is a congenital disorder characterized by white forelock and localized leukoderma. In some piebald patients, café-au-lait spots are present. Human piebaldism is caused by a mutation of the *KIT* gene encoding the transmembrane receptor tyrosine kinase, c-kit. The pathogenesis is assumed that a defect is present in the migration and differentiation of melanoblasts from the neural crest. In piebaldism, genotype-phenotype relationship in *KIT* is commonly present. We would like to present a unique family with piebaldism. The mutation detected was a missense mutation, supposedly causing severe phenotype, however the phenotype of the proband, the brother, and the fathere was mild, very mild and unpenetrant, respectively. A 4-year-old girl had leukoderma on the forehead and three of four extremities, and café-au-lait spots on the normally pigmented skin. The proband's 7-year-old brother had patchy leukoderma on the left wrist and café-au-lait spots. The proband's 35-year-old father did not have poliosis or leukoderma. However, the father had café-au-lait spots. Sequence analysis revealed a missense mutation p.F584L in the tyrosine-kinase domain of the *KIT* gene in the proband, the brother and the father. It is believed that a missense mutation in the intracellular tyrosine kinase domain have a dominant-negative effect, reducing *KIT* function by ~75%, resulting in a characteristically severe phenotype. The phenotype in the affected members in this study was expected to be severe. The mild to unpenetrant phenotype in this family may suggest an existence of a modifier gene for the phenotype of piebadism. Recently, we reported a very severe Japanese piebald patient with auburn hair color caused by a novel loss-of-function missense mutation p.P832L in *KIT* and homozygous inactive variants p.I120T in *MC1R* (in press, *Br J Dermatol*). This indicated the *MC1R* gene as a modifier gene for piebaldism. We hypothesized that activating variants of the *MC1R* gene might be present in the family, resulting in the milder phenotype of the leukoderma. However, the sequence result of the *MC1R* gene showed no variants altering the function of MC1R. Identification of modifier gene which upregulates or compensates the function of c-kit may offer a novel therapeutic strategy in piebaldism. The family may give a new insight into the function and regulation of SCF/c-kit signaling in melanogenesis.

## 2638/F/Poster Board #154

**Co-occurring diagnoses among FMR1 premutation allele carriers.** *J. Hunter, J. Rohr, S. Sherman.* Dept Human Genetics, Emory Univ, Atlanta, GA.

Following the discovery of two disorders associated with premutation alleles of the fragile X mental retardation gene (FMR1), primary ovarian insufficiency (FXPOI) and a tremor/ataxia syndrome (FXTAS), numerous studies have examined other potential co-morbid conditions, including neuropsychological deficits. Here, the frequency of self-reported diagnoses obtained through medical history interviews from FMR1 premutation carriers and non-carriers ages 18 to 50 were analyzed. Study subjects included 537 women, 334 of whom carry the premutation, and 151 men, 37 of whom carry the premutation. Men with the premutation did not report any medical conditions at higher rates compared with non-carriers, controlling for age, ethnicity/race, and household income. Women with the premutation reported mental health disorders (i.e., ADHD, anxiety and depression) more often than non-carriers. However, after adjusting for covariates, these increased rates were not statistically significant. Additional follow-up analyses examined the consequence of ovarian dysfunction as a cause of co-occurring conditions. Women with an indication of ovarian insufficiency (i.e., irregular cycles) reported more thyroid problems, depression/anxiety, and gastrointestinal problems. Since only women, not men, reported these conditions more often, the relationship between FXPOI and hormone irregularities in women should be explored for a potential link with the increase in the reported medical conditions.

## 2639/F/Poster Board #155

**PTPN11 genotype and phenotype correlation of Noonan syndrome.** *Y. Ke[1,2], D. Lee[1], G. Ma[1], M. Chen[1,3,4].* 1) Center for Medical Genetics, and Department of Medical Research, Changhua Christian Hospital, Changhua, Taiwan; 2) Department of Pediatrics, Changhua Christian Hospital, Changhua, Taiwan; 3) Department of Obstetrics and Gynecology, and Department of Medical Genetics, College of Medicine and Hospital, National Taiwan University, Taipei, Taiwan; 4) Department of Obstetrics and Gynecology, Changhua Christian Hospital, Changhua, Taiwan.

Noonan syndrome (NS) is a developmental disorder caused mainly by mutations in PTPN11 gene. Here, we used the NS scoring system of van der Burgt et al (1994) [Am J Med Genet 53:187-191] for diagnostic criteria of NS. Besides, we performed PTPN11 mutation analyses in six NS patients and one prenatal chylothorax case. Five missense PTPN11 mutations were identified in five cases: three mutations were in exon 3, one in exon 8 and the other one in exon 12. Two patients carried the 922A>G (Asn308Asp) has classic NS symptoms with mild mental retardation. Two cases carried the 182A>G (Asp61Gly) , one has classic NS symptoms and the other is a prenatal case with chylothorax. One patient with 1403C>T (Thr468Met) has classic NS facial symptoms with dominant hypertrophic cardiomyopathy; while the diagnosis of this patient was changed to LEOPARD syndrome thereafter since the mutant site is known to be the common mutant site of LEOPARD syndrome and the patient developed café-au-lait spots at the age of 5 year-old. The other one patient with the mutation 218C>T (Thr73Ile) was suffered from juvenile myelomonocytic leukemia (JMML) with the initial presentation of pancytopenia suspect of severe sepsis. Our results, together with recent reports, suggest that: (1) all the neuro-cardio-facial-cutaneous syndromes share a common genetic and pathophysiologic basis; (2) dysregulation of the RAS-MAPKinase pathway is caused by germline mutations in genes involved in this pathway; (3) more genes causing related syndromes and other disease will be discovered in the near future since a substantial number of genes involved in the pathway are not yet associated with known syndromes or diseases.

## 2640/F/Poster Board #156

**Is PiSS Alpha-1 Antitrypsin Deficiency Associated with Disease?** *D. McGee[1], L. Schwarz[1], R. McClure[1], L. Peterka[1], F. Rouhani[2], M. Brantly[2], C. Strange[1].* 1) Division of Pulmonary and Critical Care Medicine, Medical University of South Carolina, Charleston, SC; 2) Division of Pulmonary and Critical Care Medicine, University of Florida Health Science Center, Gainesville, FL.

BACKGROUND: Alpha-1 antitrypsin deficiency (AAT) is an inherited condition that predisposes to lung and/or liver disease. The most common allele found at the SERPINA1 locus is the M allele that codes for normal amounts of AAT in a codominant manner. The two most common deficiency alleles are Z and S. Currently, there is little data available regarding clinical risks associated with the PiSS genotype. METHODS: Participants were recruited through the Alpha Coded Testing study and the Alpha-1 Foundation Research Registry. Nineteen study participants (PiSS) and 29 age, sex, and state matched control participants (PiMM) were telephone interviewed by a certified genetic counselor using a standardized questionnaire. Demographic features, cigarette smoking, vocation, medication history, and clinical diagnoses were subjected to comparison. Statistical analysis was performed. Finally, a comprehensive literature review was performed by two investigators. RESULTS: 12/19 (63.16%) study participants reported the presence of lung and/or liver disease compared to 12/29 (41.38%) control participants. There was no difference in the frequency of psychiatric diagnoses (anxiety, depression, bipolar disorder) in study participants (47.4%) vs. controls (48.3%) or fetal loss (14.7% vs. 13.9%) in the biological mother of the participants. There was a higher frequency of medication allergies in the study population (42.11% vs. 6.90%). CONCLUSIONS: The PiSS genotype was associated with a high incidence of obstructive lung disease in the study population. Selective bias intrinsic in testing for AAT deficiency and the rarity of the PiSS genotype will make future study of this association dependent on population-based tests.

## 2641/F/Poster Board #157

**Holoprosencephaly mutations in the Dutch population.** *A.D.C. Paulussen[1], C. Schrander Stumpel[1,2], J. Herbergs[1], C. de Die Smulders[1], S. Stegmann[1], Y. Arens[1], M. Vreeburg[1], G. Tan-Sindhunata[6], M. Collee[3], A. van Haeringen[4], A. Hoogeboom[5], K. Lichtenbelt[3], A. Lachmeijer[6], W. Kerstjens Frederikse[7], M.L. Kwee[6], J.A. Maat Kievit[5], G. Mancini[5], M. Simon[5], I. Stolte Dijkstra[7], H.J. Smeets[1,2].* 1) Dept Clinical Genetics, Maastricht University Medical Center, Maastricht, Netherlands; 2) Research Institute Growth and Development (GROW), University Maastricht, Maastricht, The Netherlands; 3) Department of Clinical Genetics, University Medical Center, Utrecht, The Netherlands; 4) Department of Human and Clinical Genetics, Leiden University Medical Center, The Netherlands; 5) Department of Clinical Genetics, Erasmus University Medical Center, Rotterdam, The Netherlands; 6) Department of Clinical Genetics, VU University Medical Center, Amsterdam, The Netherlands; 7) Department of Genetics, University Medical Center Groningen, Groningen, The Netherlands.

Holoprosencephaly (HPE) is a severe malformation of the brain that involves abnormal formation and septation of the developing central nervous system. The prevalence is 1:250 during early embryogenesis, but the live born prevalence is only 1:16,000. The etiology of HPE is extremely heterogeneous and can include both a teratogenic and/or genetic basis. We studied four genes known to be involved in HPE, namely SHH, ZIC2, SIX3 and TGIF by sequence and MLPA analysis. A series of in total 80 sporadic and familial HPE cases with a variable clinical spectrum has been analysed. We detected 19 pathogenic mutations (24%) in total, of which 3 in SHH, 7 in ZIC2 and 9 in SIX3. Only one mutation (Alanine-tract expansion in ZIC2) was reported previously and detected twice in this population, all others were novel. Two mutations were complete gene deletions (one SIX3, one ZIC2 deletion) of which the deletion sizes were further characterized using the 250K Nsp I Affymetrix SNP array. The ZIC2 deletion was too small to be detected with this array, the SIX3 deletion also comprised the SIX2 gene and was approximately 1,37 Mb in size. The familial mutations displayed considerable heterogeneity in clinical expression, which makes it difficult to establish genotype-phenotype correlations and indicates that although the mutation detected is essential, it is not the only factor involved. Additional environmental factors and modifier genes will play a role as well. HPE development is probably a multihit process, which implicates more genes, illustrating the importance of further identification of new genes or risk-factors.

## 2642/F/Poster Board #158

**A t(5q;17q) in a patient with acampomelic campomelic dysplasia.** *H. Vernon[1], N. Sobreira[1], E. Lisi[1], E. Wohler[2], J. Hoover-Fong[1], G. Thomas[2], D. Valle[1], A. Hamosh[1].* 1) Inst Gen Med, Johns Hopkins Hosp, Baltimore, MD; 2) Kennedy Krieger Institute, Baltimore, MD.

Campomelic dysplasia (CD), MIM #114290, is an osteochondrodysplasia caused by point mutations in *SOX9* on 17q24.3 or by chromosomal aberrations with breakpoints primarily upstream *SOX9* (Smith et al., 2009). About 10% of the cases do not exhibit campomelia, acampomelic CD (ACD). ACD is more frequent in patients who survive neonatal period and is associated with translocations and breakpoints upstream *SOX9*. A diagnostically important aspect of CD/ACD is male-to-female sex reversal that occurs in about two-thirds of affected 46,XY males. The published CD/ACD translocation breakpoints upstream of *SOX9* fall into 2 clusters: a proximal cluster 50-375 kb and a distal cluster 789 kb to 932 kb upstream of *SOX9*. In a single CD case with a complex but balanced translocation, the 17q breakpoint is exceptional and maps ~ 1.3 Mb downstream of *SOX9*. Here we described an 18 month old boy with ACD. He has a flat round face, midface hypoplasia, flat supraorbital ridges, hypertelorism, small palpebral fissures, flat nasal bridge, small nose, low-set ears, cleft palate, micrognathia, short neck with redundant posterior skin folds, hydrocephalus, and tracheobronchomalacia. He also had pyloric stenosis, a feature not described in CD/ACD. X-rays showed short thorax with kyphoscoliosis, 11 pairs of ribs, no scapulae bilaterally, short but unbowed long bones, and normal skin. His karyotype was interpreted as being apparently balanced, 46,XY,t(5;17)(q23.2;q24). SNP array analysis (Illumina 550) revealed a 100 kb region on 5q23.2 (123,742,816 to 123,843,769 bp) in the area of the cytogenetic breakpoint containing 26 genotyped SNPs with reduced intensity and apparent loss of heterozygosity, indicating a hemizygous deletion. This region lacks annotated genes (UCSC). Chromosome 17q was normal by this assay. Interestingly, *ITGB4*, 3.5 Mb downstream of *SOX9*, has been implicated in epidermolysis bullosa lethalis with pyloric atresia (MIM #226730). This observation together with the occurrence of pyloric stenosis in our patient suggests that his chromosomal rearrangement may also affect *ITGB4* expression. Further analysis of the chromosome 17q breakpoint in our patient may disclose new distant regulatory elements affecting *SOX9* and/or *ITGB4*.

**An atypical case of pseudoxanthoma elasticum with abdominal cutis laxa: evidence for a clinical disease spectrum.** *O. Vanakker[1], B. Leroy[1,2], L. Schurgers[3], I. Pasquali-Ronchetti[4], D. Guerra[4], P. Coucke[1], A. De Paepe[1].* 1) Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium; 2) Department of Ophthalmology, Ghent University Hospital, Ghent, Belgium; 3) VitaK & Cardiovascular Research Institute, Department of Biochemistry, University of Maastricht, Maastricht,The Netherlands; 4) Department of Biomedical Sciences, University of Modena and Reggio Emilia, Modena, Italy.

Introduction. Pseudoxanthoma elasticum (PXE) is characterized by papular lesions in flexural areas of the skin, a retinopathy and cardiovascular complications, resulting from calcification and fragmentation of the elastic fibre core. Recently, a PXE-like syndrome (PXE-L) was identified, featuring generalized cutis laxa, associated with a mild retinopathy and a clotting deficiency. Contrary to the ABCC6 mutations in PXE, PXE-L is caused by mutations in the GGCX gene, encoding a $\gamma$-carboxylase responsible for activation of vitamin K (VK)-dependent calcification inhibitors such as matrix gla protein (MGP) and osteocalcin (OC). We present a patient with a clinical, histological and biochemical overlap phenotype between PXE and PXE-L. Methods. Molecular analysis of ABCC6 and GGCX was done via direct sequencing. Biochemical measurements of mineralization inhibitors and VK were done in serum using sandwich and competitive ELISA. Immunohistochemical (IHC) stains on lesional skin biopsies from the neck and abdomen were done using conformation-specific antibodies against carboxylated (c) and uncarboxylated (uc) MGP and OC. Results. The proband presented with clinical features typical for PXE - a yellowish reticular pattern in the anterior neck and severe retinopathy - though his phenotype was dominated by a marked cutis laxa of the abdomen, as in PXE-L. Ultrastructural evaluation of the skin revealed calcium deposits in the periphery of elastic fibres, typical for PXE-L. IHC stains revealed marked staining for ucMGP and ucOC, seen in PXE and PXE-L, but its distribution was not confined to the middermis - as in PXE - but rather affected the whole dermis as in PXE-L. Measurement of circulating levels of c- and ucMGP and OC revealed an elevated ucOC/cOC ratio, as in PXE-L (normal in PXE), while ucMGP/cMGP ratios were normal, as in PXE (elevated in PXE-L). Molecular analysis revealed the patient to be compound heterozygous for 2 known ABCC6 mutations, while the GGCX gene harboured a reported gain-of-function polymorphism. Circulating VK levels were however severely decreased, possibly neutralising the effect of the latter. Conclusion. The findings in this patient, reminiscent of both PXE and PXE-L, suggest that PXE-L may represent a spectrum of ectopic calcification disorders who are clinically and pathogenetically related to PXE. In addition, the low VK serum levels may suggest that a deficient VK status has a role in the pathogenesis of these disorders.

## 2644/F/Poster Board #160

**The p.L145F Mutation in the LRP5 Gene Responsible for Familial Exudative Vitreoretinopathy was Identified in a Patient with Osteoporosis-Pseudoglioma Syndrome.** *Y. Watanabe[1], S. Yano[2], S. Narumi[3], T. Hasegawa[3], M. Yoshino[1], T. Matsuishi[1].* 1) Dept Pediatrics, Kurume Univ, Kurume, Japan; 2) Dept of Genetics/Pediatrics, Univ of Southern California, CA, USA; 3) Dept of Pediatrics, Keio Univ School of Medicine, Tokyo, Japan.

**Background:** Osteoporosis-pseudoglioma syndrome (OPS; MIM 259770) is an autosomal recessive disorder characterized by severe osteoporosis, bone fragility, hyperextensible joints, and early infantile onset blindness. Mutations in the low-density lipoprotein receptor-related protein 5 gene (*LRP5*) are thought to be responsible for this rare genetic condition. Besides OPS, mutations in *LRP5* are also identified in patients with autosomal dominant and recessive forms of familial exudative vitreoretinopathy (FEVR), and autosomal dominant Osteopetrosis/Hyperostosis/Osteosclerosis. There have been more than 65 mutations reported in *LRP 5* and at least 57 missense/nonsense mutations have been identified. Genotype/phenotype correlation has been established at some extent in the LRP5 gene mutations (Minrong et al. 2005). **Case Report:** A 23-year-old Japanese male was diagnosed with OPS at age 10 years with the typical clinical findings. Mutation analysis of *LRP5* showed compound heterozygous mutations with p.T552M/p.L145F. The mother was asymptomatic at age 32 years when her son was diagnosed. She was also tested for *LRP5* mutations and her bone mineral density was evaluated. The mother was found to be heterozygous for p.L145F and her bone mineral density was found to be significantly reduced. Ophthalmologic examination on the mother was unremarkable. The father of the patient was unavailable for the studies. **Discussion:** The p.T552M mutation has not been reported in any clinical phenotypes associated with *LRP5* mutations. Qin et al. (2005) reported a familial case of autosomal dominant type FEVR due to p.L145F: three children with typical FEVR and the mother who exhibited mild retinal findings and reduced bone mineral density. In our case, the mother of the proband carried p.L145F although she did not develop FEVR. It is unclear why this particular mutation showed detrimental effects in the eye development in one family and did not in another. Our familial case may indicate weak genotype/phenotype correlation in *LRP5* mutations and may suggest involvement of other epigenetic factors particularly in the eye development. **References:** Minrong et al.: Clinical and molecular findings in Osteoporosis-Pseudoglioma syndrome. Am J Hum Genet: 77:741-753, 2005 Qin et al.: Complexity of the genotype-phenotype correlation in familial exudative vitreoretinopathy with mutations in the LRP5 and /or FZD4 genes. Human Mutation: 26;104-112, 2005.

## 2645/F/Poster Board #161

**Evidence suggesting digenic inheritance of Waardenburg syndrome type II with ocular albinism.** *T.L. McGregor[1], E. Spector[2], P.W. Chiang[2].* 1) Pediatrics, Vanderbilt School of Medicine, Nashville, TN; 2) Pediatrics, UC Denver School of Medicine, Aurora, CO.

Waardenburg syndrome (WS) is a series of auditory-pigmentation disorders inherited in an autosomal dominant manner. In most patients, WS2 results from mutations in the *MITF* gene (WS2 type A). *MITF* encodes a basic helix-loop-helix transcription factor that activates transcription of tyrosinase and other melanocyte proteins. The clinical presentation of WS is highly variable, and we believe that Tietz syndrome and WS2 with OA are likely two variations of WS2 due to the presence of modifiers. One family with molecular diagnosis of WS2 co-segregating with ocular albinism (OA) has previously been reported. A digenic mutation mechanism including a *MITF* mutation and the *OCA1/TYR*$^{R402Q}$ hypomorphic allele was proposed to be the cause of OA in this family. Here, we present a second WS2 family with OA and provide evidence suggesting the *OCA1/TYR*$^{R402Q}$ allele could not cause OA in this family. A child who presented with OA and a familial history of WS2 is presented. No other family members with WS2 exhibited the OA phenotype. The patient and selected members of his family underwent molecular analysis of multiple genes involved in the pigmentation pathway. We hypothesize the presence of a novel *OCA3/TYRP1* mutation together with the *MITF* del R217 mutation account for the OA phenotype in this family. Since *MITF* is a transcription factor for pigmentation genes, a mutation in *MITF* plus a heterozygous mutation in *OCA3/TYRP1* together provide an adverse effect crossing a quantitative threshold; therefore, WS2 with OA occurs. We have previously hypothesized that the clinical spectrum and mutation mechanism of OCA depend on the pigmentation threshold of an affected individual. This unique family has provided further evidence supporting this hypothesis.

**The 12q14 microdeletion syndrome, 4 further cases.** *R. Regan[1], S.A. Lynch[2], C. Costigan[3], N. Foulds[4], A. Collins[4], A.C. Thuresson[5], F.H. Sharkey[6], D.R. Fitzpatrick[6].* 1) School of Medicine and Medical Science, University College Dublin, Dublin 4, Ireland; 2) National Centre for Medical Genetics, Our Lady's Children's Hospital , Crumlin, Dublin 12, Ireland; 3) Department of Endocrinology & Diabetes, Our Lady's Children's Hospital, Crumlin, Dublin, Ireland; 4) Wessex Clinical Genetics Service, Southampton University Hospitals Trust, Princess Anne Hospital, Southampton, UK; 5) Department of Genetics and Pathology, Rudbeck Laboratory, Uppsala University, Uppsala, Sweden; 6) Medical Genetics Section, MRC Human Genetics Unit, Western General Hospital, Edinburgh, UK.

The 12q14 microdeletion syndrome is characterised by low birth weight, failure to thrive, short stature and developmental delay. Osteopoikilosis has been described in some cases. We report 4 children with chromosomal deletions, detected by microarray analysis, that extend between 12q13 to 12q15. Cases 1 and 2 have severe growth retardation with a diagnosis of query Silver-Russell syndrome, one with deletion of 8.4Mb spanning 12q13.3 to 12q14.3. This child weighed 2 kg at birth. The second child has a 11.2 Mb deletion of 12(q13.2;q15) and also has short stature and weighed 1.9 kg at 37 weeks. She is currently requiring PEG feeding. A third case has normal growth but his abnormality, a 6.2Mb deletion of 12(q13.3;q14.2), ends proximally at 12q14.2 suggesting that the major growth gene lies between 12q14.2 to 12q14.3. Two of the children (case 1 & 3) had similar facial dysmorphism with long eyelashes and a cupids bow. There was no evidence of osteopoikoilosis in any of our cases. A previous report by Menten and colleagues (2007) described three patients with a deletion of 12q14 who presented with growth retardation & osteopoikilosis. There was a 3.44 Mb common deleted region which contains 13 RefSeq genes, including LEMD3, the causal gene for osteopoikilosis. Mari et al. (2009) recently described a case with primordial dwarfism and a smaller deletion of the 12q14.4 region. The child, a boy, had severe pre and postnatal growth failure and mild developmental delay. There was a history of poor feeding and failure to thrive, similar to the phenotype of primordial dwarfism or severe Silver-Russell syndrome (SRS). Buysse et al (2009) described two children, one of whom had an intragenic deletion of HMGA2 and short stature providing evidence that HMGA2 is the likely growth gene. HMGA2 lies at 12q14.3 which would explain the normal growth in our Case 3 whose deletion ended proximal to this region. Loss of function of Hmga2 in the mouse results in the pygmy phenotype that combines pre and postnatal growth failure, with resistance to the adipogenic effect of overfeeding. We conclude that the 12q14 microdeletion syndrome is a recurrent deletion syndrome and our cases, particularly Case 3 provide further evidence that HMGA2 is the causative gene for growth retardation.

## 2647/F/Poster Board #163

**A boy with atypical phenotype of NF1 with a type 1 microdeletion.** *M. Poyhonen[1,2], H. Kehrer-Sawatzki[3], T. Lonnqvist[4], P. Alhopuro[2], P. Hoglund[5], L. Valanne[6], L. Messiaen[7], S. Kivirikko[2].* 1) Dept Med Gen, Univ Helsinki, Helsinki, Finland; 2) Dept Clin Gen, Univ Hospital, Helsinki, Finland; 3) Inst Hum Gen, Univ Ulm, Ulm, Germany; 4) Hosp Children and Adolescent, Helsinki, Finland; 5) Rinnekoti Foundation, Espoo, Finland; 6) Dept Radiology, Univ Hospital, Helsinki, Finland; 7) Dept Gen, Univ Alabama Birmingham, AL, US.

Patient was born as a first child of healthy, non-consanguineous Caucasian parents at week 38+5. During pregnancy hydronephrosis was seen at 19 weeks of gestation. Birth weight was 3890 g, length 47 cm and head circumference 35 cm. As a newborn dysmorphic facial features, anterior anus and an anocutaneal fistula was seen. The chromosomes (400 bands) were normal. He walked independently at the age of 2 years 4 months, but did not speak. His height was 87.5 cm (slightly below his target height), body mass index (BMI) 16.2 and head circumference 53 cm. His facial features were distinct with high anterior hairline, thick eyebrows, epicanthal folds and hypertelorism. The nasal tip was broad and he had anteverted nostrils. The filtrum was long and the upper lip was thin. The ears were thickened and the ear lobules were uplifted. He had one classical cafe au lait spot. In addition he has had severe feeding problems because of an intestinal malrotation. His MRI revealed high signal intensity lesions of posterior fossa, thalamus and cortical area. The spinal cord was thickened with increased signal at Th8 - Th10. A de novo interstitial deletion of 1.3 Mb in 17q11.2 was detected by commercially available high-resolution oligonucleotide CGH array. Using MLPA P122-C1 NF1 area (MRC-Holland), we found a ~ 1.4Mb type 1 microdeletion, including the *SUZ12P* gene (~363 Kb centromeric of NF1 exon 1) and the LRRC37B probe (661Kb telomeric of the last *NF1* exon). Nearest flanking non-deleted genes probed on the assay are CPD and ZNF207. Some dysmorphic features, intestinal malrotation and some of the brain abnormalities have not been reported previously to be associated with NF1 microdeletion patients. Further work is needed to fine-map the deletion breakpoints.

## 2648/F/Poster Board #164

**Molecular and Clinical Characterization of Bardet-Biedl syndrome in the Saudi Population.** *L. Abu Safieh[1], M. Aldahmesh A[1], H. Shamseddin[1], M. Hashem[1], R. Shaheen[1], H. Alkuraya[2], S. Hazzaa[3], A. Al-Rajhi[2], FS. Alkuraya[1, 4,5].* 1) GENETICS MBC #03, KING FAISAL SPECIALIST HOSPITAL & RESEARCH CENTER, RIYADH, RIYADH, Saudi Arabia; 2) Vitreoretinal Division, King Khaled Eye Specialist Hospital, RIYADH, Saudi Arabia; 3) Department of Surgery, King Faisal Specialist Hospital and Research Center, RIYADH, Saudi Arabia; 4) Department of Pediatrics, King Khalid University Hospital and College of Medicine, King Saud University, RIYADH, Saudi Arabia; 5) Department of Anatomy and Cell Biology, College of Medicine, Alfaisal University, RIYADH, Saudi Arabia.

Bardet-Biedl syndrome (BBS) is a rare autosomal recessive disorder characterized by chronic renal failure,polydactyly,mental retardation,retinal dystrophy,obesity and genitourinary abnormalities.To date 14 genes have been reported to be associated with the disease.Our aim of this study is to genetically and phenotypically characterize BBS in Saudi Arabia not only to make the results available for counseling but also to draw patterns of genotype/ phenotype correlation as well as to discover novel genes which could potentially improve our understanding of the development and function of the organs involved and the retina in particular.We have so far recruited a total of 37 patients representing 16 unrelated families.We applied homozygosity mapping and candidate gene screening approach to identify the disease causing gene(s).Mutations have been identified in 7 families, linkage is already established for 3 families and work is still ongoing for the remaining 6 families. All identified mutations are novel and involve one of three previously reported BBS genes, BBS1, BBS3 and BBS4.While work is still ongoing, several themes seem to emerge from our study:1)Intronic mutations, some were quite deep within the introns, which we have demonstrated their detrimental effect on RNA splicing, are more prevalent than missense mutations in our cohort.In one instance, homozygosity allowed us to reanalyze a gene that was reported by a DNA diagnostic lab to be negative for BBS1 mutations.2)While it has been shown before that BBS3-related BBS tends to be on the milder end of the spectrum, we were able to enroll a family that represents the extreme of this observation where RP was the only abnormality observed in all three affected individuals despite extensive phentoyping.3-)Data on the facial profile of patients with BBS is scarce.However, our analysis suggests that careful dysmorphic exam can suggest the gene involved and we are in the process of calculating the predictive value of the facial profile in prioritizing BBS genes for mutation analysis.In conclusion homozygosity mapping is an extremely powerful tool in the setting of molecular diagnosis of the genetically heterogeneous BBS.When possible, cDNA should be the starting material for mutation analysis among Saudi BBS patients.We confirm earlier reports of the milder phenotype associated with BBS3 mutations.We also suggest that some genotype/phenotype correlation also exists at the level of BBS-related dysmorphia.

## 2649/F/Poster Board #165

**The association of genetic factors in retinopathy of prematurity.** *M. Hiraoka[1], H. Takahashi[1], H. Orimo[2], M. Hiraoka[3], T. Ogata[4], N. Azuma[3].* 1) Ophthalmology, Nippon Medical School, Tokyo, Japan; 2) Biochemistry, Nippon Medical School, Tokyo, Japan; 3) Ophthalmology, National Center for Child Health and Development, Tokyo, Japan; 4) Endocrinology and Metabolism, National Research Institute for Child Health and Development, Tokyo, Japan.

Purpose: Retinopathy of prematurity (ROP) is a major cause of childhood blindness in developed countries. It is known to occur along environmental factors such as preterm gestational age and early oxygen exposure, but even same condition with controlled environment can lead to diversity in ROP phenotype. These facts lead that other internal factors, especially genetic variants may involve in the development of ROP. Familial exudative vitreoretinopathy (FEVR) is hereditary vitreoretinal disorder that has similar clinical manifestations to ROP. In X-linked recessive FEVR, mutations were found in Norrie disease (ND) gene. Mutations of frizzled 4 (FZD4) gene were seen in autosomal dominant FEVR. Low density-lipoprotein receptor-related protein 5 (LRP5) gene was reported to have variants in both autosomal dominant and recessive pattern of FEVR. To evaluate the genetic involvement in ROP, we have screened advanced ROP for those three candidate genes of FEVR. Methods used: Seventeen advanced ROP subjects were enrolled in this study. All cases have received surgical treatment in their eyes. Genomic DNA from each patient underwent PCR and direct sequencing of ND, FZD4, and LRP5 genes respectively. As for ND and FZD4 genes, coding region and 5' untranslated regions (UTR) were examined. Entire coding regions of twenty-three exons were examined for LRP5 gene. Summary of results: One case showed heterozygous mutation in 5' untranslated regions (UTR) of ND gene. Two cases had heterozygous mutations in coding region of LRP5 gene. No case showed mutaion in FZD4 gene. These findings suggest that genetic changes contribute to the development of ROP.

## 2650/F/Poster Board #166

**46,XY,del(1)(q23q25),t(4;11)(q31.3;q21) possibly associated with significant short stature.** *A. Nishimura[1], Y. Hiraki[2], N. Matsumoto[1].* 1) Dept Human Gen, Yokohama City Univ Med, Yokohama, Japan; 2) Hiroshima Municipal Center for Child Health and Development, Hiroshima, Japan.

We report a case of 46,XY,del(1)(q23q25),t(4;11)(q31.3;q21) associated with significant short stature. The case at 3 4/12 years of age presented with growth retardation [height 65 cm (-8.5 SD), weight 5,890 g (-4.5SD)], developmental delay, prominent forehead, strabismus, high arched palate, cryptorchidism, bilateral simian lines, and bilateral inguinal hernia. Growth hormone defect and antithrombin III deficiency were also noted. We analyzed the genomic structure by high-resolution SNP array 6.0 (Affymetrix). We could detect del(1)(q24.3q31.2). No other obvious chromosomal abnormalities were found. Long PCR successfully amplified the fragment spanning the 1q24.3-q31.2 deletion breakpoints, which later determined at the nucleotide level. The deletion size was 19,497 Kb. Furthermore, we analyzed the t(4;11)(q31.3;q21) by FISH. All the chromosomal abnormalities occurred as *de novo*. The antithrombin III deficiency is supposed to be caused by the *ATIII* (*SERPINC1*) deletion (1q25.1). The possible association between these chromosomal abnormalities and clinical features including short stature will be discussed.

## 2651/F/Poster Board #167

**COL1A1 gene mutation analysis and phenotype picture of Czech osteogenesis imperfecta patients.** *I. Mazura[1,2], I. Marik[3], D. Zemkova[3,4], M. Kuklik[3], O. Hudakova[3], F. Nutsu-Mazurova[3], M. Sedova[1,2], S. Mazurova[5], J. Zvarova[1,2].* 1) Dept. of Biomed.Informatics, Institute of Computer Science, Prague, Czech Republic; 2) Institute of Computer Science, Academy of Science CR, Prague, Czech Republic; 3) Ambulant Centre for Defects of Locomotor Apparatus, Prague, Czech Republic; 4) Department of Pediatrics, University Hospital Motol, Prague, Czech Republic; 5) 1st Medical Faculty, Charles University Prague, Prague, Czech Republic.

**Introduction.** Osteogenesis imperfecta (OI) is inherited disorder, the most common inborn disease of fibrous connective tissue characterized by increased fragility of skeleton. First four types (I.-IV.) are characterized by COL1A1 and COL1A2 gene mutations. Nucleotide structure of two COL1A1 gene regions (helical domain) plays important role in interaction between collagen monomer and fibronectin, cartilage oligomeric matrix protein, different integrins and metalloproteinases. **Aim of study.** In this study the COL1A1 gene mutations were compared with clinical, anthropological, biochemical and radiological results. **Patients and methods.** Group of 55 patients (27 M/ 28 F) aged from 1.5 to 56 years were classified into particular types of the OI according to both Sillence (1979) and the new Glorieaux (2003) classification. All the collected data of patients were gathered into the complex database and statistically evaluated trying to find some relations among genetic, anthropometric, clinical and radiological parameters. **Results.** The most important factor which affected the severity of disease was the type of OI, determined by the severity of collagen affection. We analysed two COL1A1 regions rich in lethal mutations (regions 691-823 and 910-964) and we summarized list of mutations of Czech OI patient group according to Marini's study (2007). The most important phenotype parameters distinguishing the types are body height and length of lower extremities. Platyspondyly, deformity of ribs and dentinogenesis imperfecta are parameters explaining the variability in body height among patients within the same type of OI. **Conclusion.** Dividing of OI types according to the new clinical classification and detail molecular genetic analysis of binding sites of COL1A1 gene give more consistent pictures of the OI types. The type of OI determines the severity and progress of the disease. One of the most important parameter is body height. This work was partially supported by the grant no. 1M06014 of Ministry of Education, Youth and Sport, Czech Republic.

## 2652/F/Poster Board #168

**Potocki-Lupski SyndromeA Microduplication Syndrome Associated with Oral Pharyngeal Dysphasia and Failure to Thrive.** *C.R. Soler-Alfonso[1], K.J. Motil[2], P. Robbins-Furman[1], J.E. Friedman[2], A. Eifert[2], J.R. Lupski[1], K. Fraley[2], L. Potocki[1].* 1) Molecular and Human Genetics , Baylor College of Medicine, Houston, TX; 2) Children's Nutritional Research Center, Department of Pediatrics, Texas Children's Hospital. Houston, TX.

Objective: Failure to thrive is a recognized feature in children with Potocki-Lupski Syndrome (PTLS) [duplication 17p11.2]. This study describes the growth characteristics of 19 subjects with PTLS from birth through adolescence in conjunction with relevant physical features and objective data from swallow function studies. We hypothesized that failure to thrive observed in PTLS is in part due to oral and motor dysphasia and hypotonia. Study design: We studied 19 individuals with PTLS who were evaluated through an Institutional Review Board (IRB)-approved clinical protocol at Texas Children's Hospital. Height and weight measurements were obtained by standardized methods and from review of medical records. These measurements were converted to weight-for-age, length-for-age and weight-for-length Z-scores. A swallow function study performed with a speech pathologist present was performed in order to assess phases of swallowing. Otolaryngologic examination delineated anatomical contributing to swallowing difficulty. Results: While only 10% of PTLS newborns fell into the small for gestational age range, as a group, children with PTLS have birth weights and lengths that are, on average, one standard deviation (SD) below the mean. Although there is a trend towards more normal growth in early childhood, these children follow their own growth curve over time and remain one SD below the mean for weight-for-age and weight-for-length. Poor feeding during neonatal period and infancy was observed in 89% (17/19), infantile hypotonia was reported in 84% (16/19), 68% (13/19) had a history of failure to thrive, and 26% (5/19) required tube feedings. Swallow function studies indicate that all subjects have at least one abnormality observable, and the most common finding is gastroesophageal reflux (GERD) seen in 53% (10/19). Conclusions: Our results indicated that as a group, newborns with PTLS weigh less than the general population and do not catch up to the normal curve in childhood. Factors such as hypotonia and oral pharyngeal dysphasia likely contribute to the lack of catch-up growth; however, our data, in conjunction with data from animal models of PTLS strongly suggest that intrinsic factors have a major impact on growth in this chromosomal microduplication syndrome. This study supports that a diagnosis of PTLS should be considered in the differential diagnosis of failure to thrive, hypotonia, and/or oral pharyngeal dysphasia.

## 2653/F/Poster Board #169

**Losartan for Ehlers Danlos IV.** *P.J. Benke.* Pediatric Genetics, Joe Dimaggio Children's Hosp, Hollywood, FL.

A 4 year old boy was brought to Florida from the Dominican Republic for diagnosis and treatment. His small size, easy bruisability, hyperextensible joints, thin skin, thin hair, poor subcutaneous tissue with highly visible veins, and thin knee scars suggested Ehlers Danlos Syndrome IV (ED IV). This was confirmed by demonstration of c.3554 G>A mutation in Exon 49 of the Col3A1 gene. The parents were informed that there was no known therapy and that anticipated surgical treatment of abdominal crises and anticipated arterial aneurysms in the second and third decades of life was extremely difficult. Because recent studies on a different collagen disorder, Marfan Syndrome, suggested that Losartan, which blocks Angiotensin II receptors and cytokine signals, was effective in treating aortic root dilation, Losartan was suggested as an off-label use of an approved drug. A dose of 25 mg/day was started and was well tolerated. The dose was increased to 50 mg/day in 1 month, and 75 mg/day in 6 months. After 3 months, his skin became thicker (from 0.5 to 0.9 cm), his hair thicker, he demonstrated less bruising, and his abdominal veins were not as visible. Continued improvement over a year was noted, and no side effects or hypotension were observed. The appearance of the veins over his wrists and feet did not change, and his growth rate did not improve. Losartan may not be the answer to all the vascular defects found in EDIV and may not help other patients. However, abdominal vein appearance and skin thickness and skin bruisability in this patient appeared to improve with Losartan therapy.

**Terminal osseous dysplasia with pigmentary defects: follow-up of the initial reported family, refinement of the critical region, and exclusion of some candidate genes.** *C. Bacino[1], P. Piccolo[1], D. Del Gaudio[1], I. Van den Veyver[1,2], N. Brunetti-Pierri[1].* 1) Dept Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Ob-Gyn, Baylor College of Medicine, Houston, TX.

Terminal osseous dysplasia with pigmentary defects (TODPD) is an X-linked syndrome with distal limb anomalies and pigmentary skin defects. We have previously described this syndrome in several females from a large, four-generation pedigree. This condition appears to be male lethal. The clinical presentation consists of multiple limb anomalies including brachydactyly, syndactyly, camptodactyly, digital elongation, and distal digital fibromatosis. Other clinical features include hypertelorism, multiple frenula, and characteristic punched-out pigmentary abnormalities over the face, temporal regions, and scalp. The phenotype is highly variable thus suggesting that X-inactivation plays an important role in the expression of the disease. We have recently performed a detailed skeletal evaluation in 4 of the affected individuals. The skeletal surveys showed significant findings including: osteopenia, methapyseal involvement, striation of the distal long bones, vertebral flattening, carpal coalition reminiscent of osteolysis, and brachydactyly among some of the features. These findings suggest that the bone involvement is generalized and not restricted to the distal limbs as previously indicated. Previous molecular studies by our group showed linkage to Xq27.3-Xq28. Using a 6,056 SNP array we have further refined the critical region within the Xq28 region. We have tested a few candidate genes in the region including *BGN* (encoding biglycan), *FLNA* (encoding filamin A), and *FAM58A* which has been recently found to be involved in STAR syndrome that shares some phenotypic similarities with TODPD. However, no pathogenic mutations in any of these genes were found. The identification of the gene responsible for this rare condition will shed light on the molecular pathways leading to the various congenital anomalies of TODPD, in particular the rather unique skeletal phenotype. The identification of the responsible gene will also allow a more accurate genetic counseling to the affected families.

## 2655/F/Poster Board #171

**Incidence of Caffey disease in a tertiary care center: Increasing frequency or increasing awareness?** *A. Guerin[1], E. Goh[1], L. Dupuis[1], E. Cory[2], M. Shouldice[2], J. Maguire[3], A.W. Howard[4], R. Mendoza-Londono[1].* 1) Division of Clinical and Metabolic Genetics and; 2) SCAN Program and; 3) Division of Pediatric Medicine and; 4) Division of Orthopaedics; The Hospital for Sick Children, University of Toronto, Toronto, ON, Canada.

Caffey disease (CD-MIM 114000) is a rare genetic condition characterized by infantile episodes of massive subperiosteal new bone formation involving the diaphyses of long bones, mandible and clavicle, sparing the epiphyses and metaphyses. CD is transmitted in an autosomal dominant manner with incomplete penetrance; the age of onset is typically before 5 months of age and resolves spontaneously around 2 years. Gensure et al (2005) identified a common mutation in the *COL1A1* gene (R836C) in affected individuals. Professional awareness remains an important tool to distinguish CD from other possible etiologies of hyperostosis such as vitamin A intoxication, congenital syphilis, osteomyelitis, and non-accidental injury. We present the clinical and radiological features in four cases evaluated at the Hospital for Sick Children for possible CD between November 2005 and March 2009. Only one case had an identified positive family history of the disease. None of the families were related, and all of the patients were from different ethnic backgrounds. Male to female ratio was 1:1. The first presenting symptom in all cases was swelling and pain of the tibia with radiological findings of periosteal reaction and hyperostosis in the absence of trauma. The age of onset ranged from birth to 10 weeks. In all four cases the children presented to peripheral centres, and were then referred to orthopedics or the suspected child abuse and neglect (SCAN) clinics. All had radiological findings consistent with CD. Molecular analysis identified the common R836C mutation in *COL1A1* in 2 cases. Results for the remaining two are pending. CD is a rare genetic condition with approximately 100 reported cases, many identified before molecular testing was available. Penetrance for the phenotype is incomplete and only 79% of mutation carriers will manifest symptoms. It remains unclear as to why in our referral base four such cases would present in such a short period of time. Our findings suggest that CD may be more common that previously described. Factors that may explain this include better access to healthcare and increased parental and physician awareness of potential genetic diagnoses in the differential diagnosis for child abuse and neglect. There is also the possibility of a yet unidentified environmental trigger. Systematic evaluation and follow-up of these patients may allow for better understanding of CD and its presentation and improved counseling for families.

## 2656/F/Poster Board #172

**Achondrogenesis Type IA (Houston-Harris) Case Report.** *P. Paez[1], J. Acosta[2], I. Zarante[2], M. Olaya[3], C. Carvajal[2].* 1) Dept Cundinamarca, Universidad el Bosque, Bogota, Colombia; 2) Instituto de Genética Humana, Pontificia Universidad Javeriana, Bogotá Colombia; 3) Departamento de Patologia, Pontificia Universidad Javeriana, Bogotá Colombia.

Introduction: It is considerated as the most severe forms of chondrodysplasia in humans. Apperars to be autosomal recessive, but the mutant gene is unknown. It is characterized radiographically by deficient ossification in lumbar vertebrae and absent ossification in the sacral, pubic and ischial bones and clinically by stillbirth or early death. Also they present severe micromelia, a disproportionately large cranium due to marked edema of soft tissues. Case Report: We describe the case of 22 years old Colombian (South America) woman, who said that during her third pregnancy initiated controls at twenty third week with the first prenatal ultrasound examination revealed severe shortened limbs anomaly because made prenatal detail ultrasound showed enlargement of the lateral ventricles, narrow thorax, severe pulmonary hypoplasia, a poorly ossification of vertebral bodies, severe micromelia, extremely shortened limbs and multiple fractures of long bones and ribs, club foot varo and clou hands. All of these sonograms findings gave us a presumptive prenatal diagnosis. At 26th week is induced labor and she gave stillbirth to 900 gram and 39 centimeter female with evidence of the disproportionately large head and micromelia. Then, the pathology report was compatible with Achondrogenesis type IA (OMIM: 200600) and the radiology report was severe poorly ossification of vertebral bodies and sacrum, hypoplasia and fractures ribs, and shortened limbs. It may be differentiated from other skeletal dysplasias.

## 2657/F/Poster Board #173

**Dramatic vascular phenotype in an Indian cohort of FBLN4 mutant patients.** *A. De Paepe[1], F. Malfait[1], M. Renard[1], M. Kappanayil[2], K. Kumar[2], V. Sunitha[2], S. Nampoothiri[2], B. Loeys[1].* 1) Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium; 2) Departments of Pediatric Genetics and Pediatric Cardiology, Amrita Institute of Medical Sciences and Research Center, Kochi, India.

Autosomal recessive cutis laxa, type 1 (AR-CL I) is a genetically heterogeneous group of disorders with variable systemic involvement. Both mutations in FBLN-4 and FBLN-5 (fibulin-4 and 5) have been identified. FBLN4 mutations were found in AR-CL I patients with aortic/arterial aneurysm, tortuosity and stenosis. We report 8 unrelated patients (4M/4F) from the same ethno-religious background of North-Kerala, India. Consanguinity is documented in 4/8 families. All patients presented with cardio-respiratory problems during infancy. Echocardiography and CT-scan revealed marked dilatation and tortuosity of the complete aorta, neck vessels, and dilatation or stenosis of pulmonary arteries. Other shared phenotypic features included generalized hyperextensible skin, umbilical or inguinal hernia, generalized hypotonia with delayed gross motor development and mild facial dysmorphism, including micrognathia, hypertelorism, long face and high palate. Seven out of eight patients died during infancy (15 days-17 months), mostly due to cardiorespiratory failure. Direct sequencing of FBLN4 revealed a homozygous single base substitution (c.608A>C) in 7 out of 8 probands. This mutation results into an p.Asp203Ala substitution which affects the highly conserved DINE consensus sequence of the fourth cbEGF domain. In the only surviving 8th proband (3 years old), we found compound heterozygosity for this mutation with a c.679C>T, causing a p.Arg227Cys in the same cbEGF domain. The individuals reported here share several characteristics with two previously reported patients with an FBLN4 mutation, including (mild) cutis laxa, tortuous systemic vessels, aneurysm of the aorta and pulmonary arteries and cardiorespiratory problems. Most patients suffer from severe disease resulting in perinatal or infantile death. The mutations reported in this cohort of 8 patients have not been reported before but affect similarly highly conserved residues in the cbEGF domains of fibulin-4. The identification of a single mutation in several individuals from the same ethno-religious background strongly suggests a founder effect. Whereas the FBLN4-associated phenotype is predominated by the vascular abnormalities, mutations in FBLN5 are associated with severe cutis laxa and emphysema, compromising life expectancy. Study of a fbln4 mouse model and human aortic tissues have revealed a dysregulation of the TGFbeta signaling pathway, confirming an key role for this pathway in aneurysm formation.

**Psychiatric disorders in neurofibromatosis-1: Mayo Clinic experience.**
*M. Icen[1], E. Mihci[2], S.R. Stevens[3], M.W. Olsen[4], D. Babovic-Vuksanovic[5].* 1) Dep of HSR, Div of Epidemiology, Mayo Clinic, Rochester, MN; 2) Dep of Pediatrics, Div of Clinical Genetics, Akdeniz University School of Medicine, Antalya, Turkey; 3) Dep of HSR, Div of Biomedical Statistics and Informatics, Mayo Clinic, Rochester, MN; 4) Dep of Pediatric and Adolescent Medicine, Div of Child and Adolescent Psychiatry , Mayo Clinic, Rochester, MN; 5) Dep of Medical Genetics, Mayo Clinic, Rochester, MN.

Background and Aim: Neurofibromatosis type 1 (NF-1) is the most common autosomal dominant disorder in the general population. The association between NF-1 and psychiatric disorders is not well understood. The aim of this case-control study is to investigate the occurrence and spectrum of psychiatric disorders in subjects with NF-1 and evaluate the association between patient characteristics and psychiatric comorbidities. Methods: Medical records were screened to identify the subjects having diagnostic codes for both NF-1 and psychiatric disorders between 1994 and 2007. An age and sex matched control group with a diagnosis of NF-1 and no psychiatric disorders was formed. Medical records of cases and controls were reviewed manually for case ascertainment and data on demographics and clinical characteristics were collected. A Wilcoxon signed rank test was used to compare case-control pairs for continuous variables and McNemar's test was used to compare pairs for categorical variables. Results: Case group comprised 112 NF-1 subjects (50 [44.6%] female) with psychiatric disorders. The median age of the cases at the time of initial evaluation at the institution was higher than the controls (18 vs 16, respectively, $p<0.001$). The most common psychiatric diagnoses in the case group were attention deficit hyperactivity disorder (44, 39.3%), depression (41, 36.6%) and anxiety (23, 20.5%). In the paired analysis, absence of subdermal neurofibromas was significantly associated with psychiatric disorders in the NF-1 population (14.3% of cases had subdermal neurofibromas compared to 32.1% of the controls, $p=0.0007$). Disruptive behavior disorders were significantly associated with presence of café au lait spots ($p=0.001$) and Lisch nodules ($p=0.01$). Mood disorders were significantly associated with presence of cutaneous ($p=0.008$) and spinal neurofibromas ($p=0.04$). Anxiety disorders were significantly associated with presence of cutaneous neurofibromas ($p=0.008$). Conclusions: The most common psychiatric disorders observed in NF-1 population were attention deficit hyperactivity disorder, depression and anxiety. Defining a possible association between clinical characteristics and the development of psychiatric disorders in NF-1 patients may help in identifying subjects at risk.

## 2659/F/Poster Board #175

**Clinical Features of Taiwanese Patients with Osteogenesis Imperfecta.**
*HY. Lin[1,2,3,4], SP. Lin[1,2,3], CK. Chuang[2], MR. Chen[1,3], CY. Chang[1], DM. Niu[4].* 1) Department of Pediatrics, Mackay Memorial Hospital, Taipei, Taiwan; 2) Department of Medical Research, Mackay Memorial Hospital, Taipei, Taiwan; 3) Mackay Medicine, Nursing and Management College, Taipei, Taiwan; 4) Institute of Clinical Medicine, National Yang-Ming University, Taipei, Taiwan.

Background and Purpose: Osteogenesis imperfecta (OI) (MIM# 166200, 166210, 259420, and 166220) is a congenital disorder characterized by increased bone fragility and low bone mass. Despite its prevalence, information regarding the clinical features of this genetic disorder is lacking in Taiwan. Thus, this study aimed at characterizing the clinical features of OI patients in Taiwan so that a practical correlation could be established for distinguishing different clinical subtypes of OI. Methods: Review of medical records identified 48 patients with OI (33 females and 15 males; age range, 2 months to 53 years) during the study period from January 1996 through June 2008. Diagnosis and classification, using the classification system of Sillence et al, were based on clinical and radiological characteristics. We also analyzed the data of these patients among different subtypes, including clinical presentations, physical examinations and bone mineral density findings. Results: There were 33 females and 15 males with age ranging from 2 months to 53 years. Among these patients, 19 were classified as type I, 10 as type III, and 19 as type IV. Height SDS were $-0.76\pm0.91$ in type I, $-9.54\pm4.36$ in type III, and $-3.02\pm2.70$ in type IV. BMD SDS were $-3.16\pm2.00$ in type I, $-5.35\pm2.13$ in type III, and $-4.19\pm1.77$ in type IV. The clinical feature of blue sclera was present in 89% patients of type I, 80% of type III, and 58% of type IV. Eighty percent of type III patients had DI, in contrast to 5% in type I and 42% in type IV. Annual fracture rate was $0.8\pm0.7$ in type I, $4.4\pm0.6$ in type III, and $2.0\pm0.7$ in type IV. In type I patients, 84% had a family history of OI, compared to 0% in type III, and 37% in type IV. Among three subtypes, there existed statistically significant differences ($p<0.05$) in the following clinical features: height SDS, weight SDS, BMD SDS, DI, bone deformity, scoliosis, walking ability, annual fracture rate, and family history. However, no significant differences were found in blue sclera ($p=0.075$) and hearing loss ($p=0.832$). Conclusion: Nine of the 11 clinical features examined, including height SDS, weight SDS, BMD SDS, dentinogenesis imperfecta, bone deformity, scoliosis, walking ability, fracture rate, and family history, were significantly different among three types of OI patients, which may be of help to evaluate patients and to establish their prognosis.

## 2660/F/Poster Board #176

**MULTIDISCIPLINARY STUDY OF PEDIATRIC PATIENTS WITH DUCHENNE MUSCULAR DYSTROPHY. 28 CASE REPORTS AT THE HOSPITAL PARA EL NINO POBLANO.**
*R.G. Ruiz[1], J.R.M. Aparicio[2,8], A. Ortiz[3], M.A. Cubillo[4], F.E. Romero[5], C.M. Gutierrez[6], H.M.L. Hurtado[7], E. Huitzil[8], P.F. Sierra[9], S.M. Chatelain[10].* 1) Pediatric Rheumatology; 2) Medical Genetics; 3) Ortopedics; 4) Rehabilitacion; 5) Nutrition; 6) Pediatrics; 7) Cytogenetics, Hosp para el nino Poblano, Puebla, Mexico; 8) Estomatology, Benemerita Universidad Autonoma de Puebla, Mexico; 9) Medical Genetics, Hospital de la Mujer SSA, Puebla, Mexico; 10) Biotechnology, Universidad Autonoma Metropolitana, Mexico DF.

INTRODUCTION. Duchenne muscular dystrophy (DMD) is an inherited disorder characterized by rapidly progressive muscle weakness beginning in the lower part of the body including pelvis later affecting all the body DMD is the most common form of muscular dystrophy and hypertrophy. It usually affects male patients, but in rare cases it can also be observed in female patients. It is considered an X-linked recessive inherited disease. A milder form of this disease is known as Becker Muscular dystrophy (BMD). In BMD, most of the symptoms are similar to Duchenne, but the onset is diferent. MATERIAL AND METHODS. A group of 28 pediatric patients were diagnosed as Duchenne muscular dystrophy by enzimatic tests (CPK, DHL and Aldolasa), muscular biopsy and the dystrophine proteine was also investiated. Tne patient was also studied by its clinical syntoms includings Gowers sign. All of them were treated with deflazacort and L-carnitine, their different clinical evolution among them was then analyzed. Weigth, size, arterial measure and glucose every three months as control was also performed. CONCLUSIONS. DMD is named after the French neurologist Guillaume Benjamin Amand Duchenne (1806-1875), who first described the disease in the 1860s. One third of the cases are known to be caused by development of spontaneous mutations in the dystrophin gene. Boys with DMD develop weak muscles because the muscle fibers become distrophic and hipertrphic, loosing their natural function, due to mutations in the dystrophin gene, which is located at the sexual chromosome X, which encodes a cell membrane protein in myocytes. L-carnitine and deflazacort dose concentration was used acording to clinical evolution, if muscular strenght decreased, the dose of deflazacort was used at 0.3mg/kg. This study shows that L-carnitine and deflazacort have an important impact on health, improoving their muscle function and providing a better quality of life. Few side effects were observed during the treatment among the patients REFERENCES. | 1. Cardamone M, Darras BT, Ryan MM Inherited myopathies and muscular dystrophies. ## 2661/F/Poster Board #177

**High incidence of progressive postnatal cerebellar enlargement in Costello syndrome.**
*K.W. Gripp[1], E. Hopkins[1], W.B. Dobyns[2].* 1) Division of Medical Genetics, A. I. duPont Hospital for Children, Wilmington, DE; 2) Department of Human Genetics, University of Chicago, Chicago, IL.

Costello syndrome (CS) is a Ras-MAPK pathway disorder resulting from heterozygous germline *HRAS* mutations. Physical manifestations affect all organ systems and cognitive impairment is typical. Structural CNS anomalies have not been systematically assessed. We hypothesized that an identifiable phenotype of structural CNS abnormalities contributes significantly to morbidity. **Methods:** CNS imaging studies on 24 pts with *HRAS* mutations (20 p.G12S; 2 p.G12A; 1 each p.G13C, p.T58I) were reviewed and correlated to clinical data. **Results:** Features included relative macrocephaly resulting in a prominent forehead (22/24), ventriculomegaly (11/24), and crowding of the posterior fossa due to a large cerebellum (filling the lowest portion of the posterior fossa in 20/24; narrowing the extra-axial space around the cerebellum in 16/24; and frank Chiari 1 malformation in 7/24). Progression of the herniation was apparent in 9/11 with serial studies. Cerebellar herniation resulted in compression of the medulla or high cervical cord in 9/24. Posterior fossa crowding led to syrinx formation in 5/16. Surgeries included shunt placement in 4, posterior fossa decompression in 6, tethered cord release in 2, and 3rd ventriculostomy in 1. **Conclusion:** While macrocephaly and prominent forehead are well-recognized in CS, the high frequency of cerebellar enlargement relative to the posterior fossa (83%) was unexpected. We speculate that, similar to the process suspected in macrocephaly-capillary malformation syndrome, abnormally rapid postnatal growth of the cerebellum leads to narrowed extra-axial spaces, reduced CSF resorption, and increased intracranial pressure leading to ventriculomegaly, progressive postnatal tonsillar herniation and syrinx formation. CNS abnormalities contribute significantly to morbidity with 8/24 (33%) individuals requiring a shunt, ventriculostomy or posterior fossa decompression. Symptoms of tonsillar herniation are similar to the typical presentation of infants with CS, including poor feeding, respiratory distress with mixed apnea, ocular palsy and constant arching. Older children complain of headache, which may present as severe irritability in infants. Individuals with a syrinx were more likely to have progressive scoliosis. While we don't have sufficient data to make specific treatment recommendations, baseline MRI studies should be considered, and upward crossing of OFC percentiles or new neurologic symptoms should prompt further studies.

## 2662/F/Poster Board #178

**CUTIS LAXA AUTOSOMAL RECESSIVE ASSOCIATED TO CONTRACTURE.** *F. Suarez, J. Acosta.* Inst de Gen Humana, Univ Javeriana, Bogota, Colombia.

INTRODUCTION Among the genetic disorders of connective tissue is the cutis laxa, defined as a skin disorder characterized by “loose” skin (redundant) and compromise of various internal organs as a result of the shortage of elastic fibers, it can be local or generalized. Its inheritance can be autosomal dominant, autosomal recessive or X linked recessive CASE REPORT We describe a male patient, first pregnancy, mother 22 years old, father 28 years old, no relatives. Preterm delivery, weight 2700 grams, length 48 cms, congenital hypotonia and pulmonary hypertension. Currently, patient with low weight, low height, microcephaly, plagiocephaly, punctiform anterior fontanel, bulging front and widow’s peak- Marcus Gunn phenomenon with tears, bilateral inguinal hernia, diastasis rectus. Bilateral rhizomélic shortening and contractures in the hands, with marked limitation fingers extension, clubfoot. Redundant loose skin on the neck and extremities. Generalized hypotonia, poor sucking, Moro’s reflex incomplete. The pacient also presents hip dislocation and dysplasia, metaphisiary craniosynostosis, widening, long bones, agenesis of the corpus callosum, colpocefalia. Skin biopsy with scattered irregular papillary dermis, elastic fibers and decreased granular appearance. CONCLUSION In this case the authors believe that the patient has an autosomal recessive Cutis Laxa Type II whose main features are delayed growth and development, bulging front, skeletal dysplasia, including hip dysplasia, pulmonary/vascular compromise, hernias and diverticula in mucosas. It is remarkable that in this case the classic joint hiperlaxitud is not present and, contrary, the limb contractures are evident, as well as malformations in the central nervous system; These finding makes us think about a new association of Cutis Laxa so far not described in the medical literature indexed.

## 2663/F/Poster Board #179

**Late Manifestations of Tricho-Rhino-Pharangeal syndrome: Expanded Skeletal Phenotype in Adulthood.** *K. Izumi[1], M. Takagi[2], AS. Parikh[1], A. Hahn[1], SN. Miskovsky[3], G. Nishimura[4], C. Torii[2], K. Kosaki[2], T. Hasegawa[2], DE. Neilson[5].* 1) Dept Gen, Case Western Reserve Univ, Cleveland, OH; 2) Dept Pediatrics, Keio Univ, Tokyo, Japan; 3) Dept Orthopaedic Surgery, University Hospitals Case Medical Center, Cleveland, OH; 4) Dept Radiology, Tokyo Metoropolitan Kiyose Children’s Hospital, Tokyo, Japan; 5) Division of Human Genetics, Cincinnati Children’s Hospital Medical Center, Cincinnati, OH.

Tricho-Rhino-Phalangeal syndrome (TRPS) is characterized by sparse or fine hair, bulbous and pear-shaped nose, and digital abnormalities. This syndrome is caused by mutations or deletions of TRPS1 gene. Although the longevity of the patients with TRPS is believed to be unchanged from the general population, late onset symptoms and adult phenotypes related to TRPS have not been well studied. In a 31-year-old male with chronic joint pain, hypotrichosis, and morphologic findings suggestive of TRPS, radiologic evaluation revealed ostepenia (lowest T scores of -2.3 evaluated by dual-energy x-ray absorptiometry) and severe osteoarthritis contributing to the multiple joint pains. Direct sequencing of the entire coding regions of TRPS1 revealed a heterozygous c.2755C >G transition leading to a missense mutation of a highly conserved amino acid, p.Leu919Val, in exon 6 of TRPS1. Given the functional role of TRPS1 in chondrocyte proliferation and apoptosis in growth plate, and the anatomic location of TRPS1 expression, TRPS1 represents a candidate gene for bone homeostasis regulation. Osteopenia might be an under-recognized phenotype in adulthood due to the altered function of TRPS1. We propose that bone mineral density assessment using dual-energy x-ray absorptiometry scan should be included in the routine evaluation of TRPS patients in adulthood.

## 2664/F/Poster Board #180

**Cross-Sectional and Longitudinal Assessment of Aortic Dilation in Ehlers-Danlos Syndrome.** *C.L. Atzinger, R.A. Meyer, P. Khoury, Z. Gao, B.T. Tinkle.* Cincinnati Children’s Hospital Medical Center, Cincinnati, OH.

The Ehlers-Danlos syndromes (EDS) are a group of inherited connective tissue disorders characterized by joint hypermobility and dermal findings. Previous studies have found aortic dilation in patients with the hypermobile and classic types of EDS (Wenstrup et al., 2002; McDonnell et al., 2006). However, the small sample size and cross-sectional nature of these studies did not allow for comment on the progression and clinical implications of these findings. Clinical experience suggests that progression of aortic dilation is rare and aortic root measurement tends to normalize with age. However, there has been no longitudinal study looking at the natural history and clinical significance of the aortic root findings in these patients. The purpose of this study was to assess aortic root dilation in a larger population of patients with hypermobile and classic EDS as well as provide longitudinal data regarding aortic growth to help define management. All patients with EDS seen in the Ehlers-Danlos Syndrome clinic at Cincinnati Children’s Hospital routinely receive echocardiograms as part of clinical care. A retrospective chart review of patients seen from 1995 to present was conducted. Of the 214 patients with a diagnosis of hypermobile or classic EDS who had an echocardiogram during this time, 22 (10.3%) had a dilated aorta on their first echo. Of the 98 patients who had at least 2 echocardiograms during this time, 26 had echocardiograms both in early childhood (before age 14) as well as in late childhood or adulthood (after age 14). In early childhood, 23% (6/26) of patients had aortic root dilation while after age 14, only 4% (1/26) showed aortic dilation. This change was statistically significant (p=0.0253). No patient with a normal aortic root in childhood developed dilation in later childhood or adulthood. These results suggest that while patients with hypermobile or classic EDS have an increased risk for aortic dilation, this dilation tends to remain stable or normalize. The lack of progression suggests that intervention may be unnecessary and that adults with normal aortic measurements may not need continued screening by echocardiogram.

## 2665/F/Poster Board #181

**Lowry-Wood Syndrome: Is this a rare or under-recognised condition?** *D. Josifova[1], K. Becker[2], M. Bober[3].* 1) Clinical Genetics, Guy’s Hospital, London, United Kingdom; 2) North Wales Clinical Genetics Service, Glan Clwyd Hospital, Rhyl, and Institute of Medical Genetics, University Hospital of Wales, Cardiff, UK; 3) Division of Genetics-AIDHC 1600 Rockland Road Wilmington, DE 19803-3607.

Lowry-Wood Syndrome (LWS) is a rare, multi-system disorder presenting with prenatal onset, non-progressive microcephaly, multiple epiphyseal dysplasia, short stature and developmental delay. In approximately half of the reported cases a degree of visual impairment was also observed. The ocular phenotype included congenital nystagmus, optic hypoplasia and retinitis pigmentosa which developed in the late teens or early twenties. Although this may reflect the variability of the condition, it is possible that the visual impairment becomes more prevalent with age. All the patients had learning difficulties within the moderate range. The natural history of LWS is poorly understood and long term prognosis difficult to predict. Orthopedic complications such as joint dislocations, early arthritis and limited joint mobility are likely to occur at a young age. Progressive visual deterioration affects at least a proportion of patients. There is no evidence that the life span may be reduced however, co-morbidity secondary to the reduced mobility and/or repeat surgery may have impact on the quality of life. The aetiology of LWS is unknown. Autosomal recessive inheritance has been considered however with few exceptions, all the reported cases have been singleton suggesting that a new dominant mutation is a plausible explanation. Chromosome analysis and CGH array testing have been normal. We present four new cases of LWS: identical twin sisters and two unrelated patients, and review the literature.

**Case Report: A New born with Camphomelyc Dysplasia.** *J. Bernal, A. Palacios, G. Gordillo, I. Zarante.* Inst Gen Humana, Univ Javeriana, Bogota, Colombia.

The Campomelic Dysplasia is a chondrodysplasia with a estimated prevalence of 1/100.000 to 1.6/100.000 births and a autosomal dominant inheritance. It's characterized by early death (50% of the cases are either born dead or dies within the firsth 24 hours) secondary to respiratory distress as a result of small thoracic cage, narrow larynx, hypoplastic trachea and possibly, CNS-bases hypotonia. It's a heterogeneous disorder with bent, short bones, extreme hypotonia at birth, characteristic cranio-facial features like: frequent macrodolicocephaly, wide fontanel, short, narrow and upslanted palpebral fissures, ocupal hypertelorism, flat nasal bridge, long philtrum, micrognathia, cleft palate; congenital bowel lower limbs with pretibial skin dimples, short limbs, short neck, narrow thorax, talipes equinovarus, fewer ribs. The external genitalia range from unambiguous female external genitalia to hypospadias with a bifid scrotum and an enlarged clitoris in genotypic XY males. We described a new born product of a second pregnancy, with prenatal US that report Ambiguous genitalia and presumed Osteogenesis Imperfecta type II. Delivery was by cesarean section because of podalic presentation. To the physical examination the first day of life we found abnormal face with high forehead, flat, small face, hypertelorism, depressed nasal root, micrognathia, cleft palate, low-set ears; he has an s mall thoracic cage and secondary respiratory distress; the limbs are short with cutaneous dimpling over bowed tibias and bilateral talipes equinovarus. In the genitalia level the new born has a Transposition penis-scrotum. During the hospitalization they order an echocardiogram which turns out to be normal, an thorax X-Ray which shows 10 pair of ribs. We see him again at 30 days of life, the physical examinations shows low weight, short height which accentuate the phenotype. The parents brings and abdominal ultrasound scan with normal report; the karyotype reports 46,XX in all studied cells. All the findings in this case have been previously reported in the literature. We report this case because of the genitalia findings; usually the patients present a declare pattern of ambiguous genitalia, specially on genotypic males, but our case present finds compatible with a masculine phenotype.

## 2667/F/Poster Board #183

**Three women with Hallerman-Streiff syndrome.** *H. Numabe[1,2], K. Muto[3], Z. Yamagata[4].* 1) Department of Medical Ethics, Kyoto University Graduate School of Medicine, Kyoto, Japan; 2) Department of Clinical Genetics, Kyoto University Hospital, Kyoto, Japan; 3) Department of Public Policy, Human Genome Center, The University of Tokyo, Tokyo, Japan; 4) Department of Health Sciences, Interdisciplinary Graduate School of Medicine and Engineering, University of Yamanashi, Yamanashi, Japan.

Hallermann-Streiff syndrome (HSS) was characterized by early-onset cataract, microphthalmia, small pinched nose, and hypotrichosis. We present three adult female cases. Two of them have children. Case 1: A 37-year-old woman was born to a 22-year-old mother and a 26-year-old father at 40 weeks of gestation. Birth weight was 2750 g, height 49 cm, and head circumference 31.5 cm. At the age of 2 years, she was diagnosed as HSS because of cataract, growth retardation, and dysmorphic phenotype. She is married, but has no child. She is suffering from mild spinal canal stenosis. Case 2: A 38-year-old woman was born to a 24-year-old mother and a 31-year-old father at 41 weeks of gestation. Birth weight was 3100 g, height 50 cm, and head circumference 31 cm. She was diagnosed as HSS because of cataract, growth retardation, and dysmorphic features. She is suffering from obstructive sleep apnea and glaucoma. At the age of 26 years, she delivered a boy by Caesarean section at 33 weeks of gestation. His birth weight was 1760 g, height 38 cm, and head circumference 30 cm. He is now 12-year-old, not affected and healthy. Case 3: A 41-year-old woman was born to an 18-year-old mother at 41 weeks of gestation. Birth weight was 3050 g, height 49 cm, head circumference 32 cm. At the age of 2 years, she was diagnosed as HSS after a cataract operation. She had been suffering from glaucoma, and trabeculectomies were done 3 times. At the age of 21 years, she was delivered a boy by Caesarean section at 39 weeks of gestation. His birth weight was 2830 g, height 47 cm, head circumference 32 cm. At the age of 25 years, she delivered a girl by Caesarean section at 38 weeks of gestation. Her birth weight was 2600 g, height 48 cm, head circumference 31.5 cm. They are now 20-year-old and 16-year-old respectively, not affected and healthy. All the women have congenital cataract, growth retardation, hypotrichosis, characteristic facial feature, and normal intelligence. Secondary glaucoma associated with microphthalmia and cataract operation is the major complication. We thank the members of "Yui-yui"; a Japanese Hallarmann-Streiff syndrome self-support group for their kind information.

## 2668/F/Poster Board #184

**VACTERL Association In A Male Fetus With an Inherited *NIPBL* Gene Duplication.** *A.F. Wagner[1], P.L. Wilson[1], M. Williams Jr.[1], A.G. Wlodaver[2], J. Lee[2], S. Li[2], F.G. Ramji[3], A.A. Elimian[1].* 1) OB/GYN, Univ Oklahoma HSC, OKC, OK; 2) Pediatrics, Univ Oklahoma HSC, OKC, OK; 3) Radiology, Univ Oklahoma HSC, OKC, OK.

We present a 20yo Hispanic female $G_1P_0$ who was referred to our center at 32-5/7wks for multicystic dysplastic kidneys and anhydramnios. An initial ultrasound confirmed these findings as well as a muscular ventricular septal defect and a two vessel umbilical cord. A complete anatomical assessment could not be performed due to the anhydramnios. She was counseled to the grim prognosis for the fetus due to the development of pulmonary hypoplasia. She spontaneously delivered a 2765g male fetus in breech presentation with APGARs of $1^1 1^5 1^{10}$. An intubation attempt was made, but was unsuccessful due to a tracheal band. He passed away at 26min. Cord blood was sent for a karyotype and microarray analysis.

A gross genetic evaluation revealed deformational Potter facies and clubbed feet consistent with anhydramnios. The anus was patent. The right upper extremity had an angulated and shortened forearm with an absent thumb. The left upper extremity was normal.

A skeletal survey was performed which revealed absent right radius and thumb, small thorax with hypoplastic lungs, block vertebrae from L3-5 with a right L4 hemivertebra. There was gas in the stomach indicating a tracheo-esophageal communication, an unusual lucency in the chest, and a dilated esophagus which point to a type 2 tracheoesophageal fistula.

The karyotype came back with a 46,XY karyotype. Whole genome oligonucleotide microarray analysis found a ~312 kb duplication of the *NIPBL* gene. Parental studies found the same duplication in the father. Paternal genetic evaluation is pending.

The constellation of abnormalities in the fetus is consistent with the VACTERL (**v**ertebral, **a**nal, **c**ardiovascular, **t**racheo-**e**sophageal, **r**enal, and **l**imb defects) association. The condition results from a primary polytopic developmental field defect that results from an early prenatal insult to the developing embryo. Previous reports of the *NIPBL* duplication have not shown features consistent with VACTERL except for one case with an absent thumb. The father's probable normal phenotype most probably indicates that the duplication is only a copy number variant and not a cause for the complex anomalies. We recommend that further study of VACTERL cases would benefit from looking for the duplication.

## 2669/F/Poster Board #185

**CFC Syndrome with BRAF mutation at exon 15 in a patient with marked cutaneous symptoms.** *E. Nishi[1], S. Mizuno[1], T. Niihori[2], Y. Aoki[2], Y. Matsubara[2].* 1) Dept Pediatrics,Central Hosp, Aichi Human Service Ctr, Kasugai, Aichi, Japan; 2) Dept Med Genet, Tohoku Univ Sch Med,Sendai,Japan.

Cardio - facio - cutaneous (CFC) syndrome is characterized by cardiac abnormalities , distinctive craniofacial appearance and cutaneous abnormalities. Recent studies have revealed that mutations in BRAF, MAP2K1, MAP2K1/2 and KRAS cause CFC syndrome. Somatic mutations in BRAF have been identified at a high frequency in numerous cancers including melanoma. We here report a detailed clinical description of 19-year-old female with severe mental retardation, intractable epilepsy and significant cutaneous symptoms showing BRAF mutation at exon 15. The patient was a 19-year-old female. She was born to healthy unrelated parents at 38 weeks gestation. Her pregnancy and delivery were not remarkable. Her birth weight was 3494g (97th centile). She began to show failure to thrive and developmental delay during the neonatal period. She also had growth retardation, severe mental retardation, intractable epilepsy, distinctive facial appearance and significant cutaneous symptom during infancy but no cardiac anomaly. She had been unable to walk and confined to bed. Standard chromosome analysis showed normal karyotype. She was initially diagnosed as having Costello syndrome. She was noted to have a number of pigmented naevi, eczema and apparently-circumscribed, protruded proliferative lesion like pemphigus vegetans. Histological examination of affected tissue showed the formation of abscesses with neutrophilic inflammation, but with no malignancy. Mutation analysis for screening the RAS/MAPK-related disorders in her leukocytes disclosed a heterogeneous missense mutation in BRAF within the coding sequence of exon 15. Consequently, she was diagnosed as having CFC syndrome. Her neurological symptoms and cutaneous symptoms were very severe. It shows that BRAF mutation causes various phenotype of neurological and cutaneous manifestations. Somatic BRAF mutations are often found in benign skin lesions and a majority of benign naevi. In our case, the activation of MAPK signaling by the BRAF mutation might be one of the causative factors of the cutaneous lesions. To clarify the genotype-phenotype correlation in tissue lesions of RAS/MAPK disorder syndromes, we have to accumulate a detailed phenotypic description of the various cutaneous symptoms of the syndrome as well as molecular findings.

## 2670/F/Poster Board #186

**Non chromaffin paragangliomas (glomus jugulare tumors) and hearing loss. Mother and daughter in a Mexican family.** *L. Hernandez-Gomez[1], S.G. Juarez Garcia[2], E. Hernandez Gomez[3], D.O. Gomez Torres[4].* 1) Servicio de Audiologia,(turno vespertino) Instituto Nacional de Rehabilitacion, Mexico. D. F; 2) Servicio de Neuropsicología Infantil (Turno Vespertino), Instituto Nacional de Rehabilitación, Mexico. D. F; 3) Facultad de Estudios Superiores, Iztacala, Universidad Nacional Autónoma de México, Biología; 4) Investigación. Instituto Nacional de Rehabilitación. México. D. F.

Non chromaffin paragangliomas may be isolated or familial. In the head and neck region involve the tympanic, and yugular glomera, (23%), glomus vagale (6%), carotid glomus (84%). Jugulo-tympanic paraganglioma is the most commonly recognized neoplasia involving the middle ear, arising from chemopressure receptors. Auditory findings: pulsative tinnitus occurs in over 50%-70%, otalgia (7-18%), aural fullness (4-18%), and otorrea (3-8%). Hearing loss can be conductive, mixed, or sesorinueral. dizziness and cranial nerve palsies. This tumor usually occurs in middle aged women and its presentation may be familiar, sporadic, bilateral or multicentric. The form of presentation and symptomology do not differ between isolated and familial cases. Clinical presentation of jugulotympanic paraganglioma, when it isn't associated with evidence of hormone secretion. In event of localized disease, paragangliomas often can be treated by surgical excision, but some cases need radiation therapy. Gene map locus 11q23. familial paragangliomas-1 (PGL1) is caused by mutation in the SDHD gene. We We report a Mexican family with 2 affected members with glomus jugulare tumor in 2 generations, in which mother and her daughter are affected. CASE 1: female patient 89-year-old, probando' s mother, hearing loss and glomus jugulare tumor, onset at 60-year-old.Physical exploration feminine with auditory conduct hearing loss, voice and language with alterations. Audiometric test showed sensorineural bilateral middle hearing loss. Speech audiometric test showed sensorineural deficit. Timpanogram: curves A of Jerger bilateral, right saw patron. Stapedial reflex: absent bilateral. Vestibular response to caloric is markedly reduced. CASE 2: female 64 year old, pulsated tinnitus at ear right, constant, being but perceivable in environment silent. Physical exploration feminine with auditory conduct normal, voice and language without alterations. Audiometric test showed normal audition. Speech audiometric test showed normal. Timpanogram: curves A of Jerger bilateral. Stapedial reflex: present bilateral right saw patron. Vestibular response to caloric is normal. Computed tomography of ears. The presence of increase in the caliber of the right jugular vein is identified, being an important reinforcing with the resistance means administration, demonstrating itself the presence of increase in the diameter.

## 2671/F/Poster Board #187

**Pallister-Hall syndrome; report a new case.** *S. Juarez-Garcia[1], L. Hernandez Gomez[2], D.O. Gomez Torres[3], E. Hernandez Gomez[4], V. Valadez Jimenez[5].* 1) Dept Neropsicologia (turno vespertino), Instituto Nacional de Rehabilitacion, Mexico, D.F; 2) Dept Audiologia (turno vespertino), Instituto Nacional de Rehabilitacion, Mexico, D.F; 3) Investigación. Instituto Nacional de Rehabilitacion, Mexico, D.F; 4) Facultad de Estudios Profesionales. Iztacala, Universidad Nacional Autonoma de Mexico. Biologia; 5) Dept Foniatria (turno vespertino), Instituto Nacional de Rehabilitacion, Mexico, D.F.

Pallister-Hall syndrome is caused by mutations in the GLI3 gene, Pallister-Hall syndrome is a pleiotropic autosomal dominant disorder comprising hypothalamic hamartoma, pituitary dysfunction, central polydactyly, and visceral malformations. Clinical features: imperforate anus, laryngeal cleft, abnormal lung lobation, renal agenesis or dysplasia, short 4th metacarpals, nail dysplasia, multiple buccal frenula, hypoadrenalism, microphallus, congenital heart defect, hydronephrosis and hydroureter with absent left kidney and intrauterine growth retardation. All cases were sporadic and chromosomes were apparently normal. The parents were nonconsanguineous. No environmental exposure was common to all cases. Pallister-Hall syndrome is due to an autosomal dominant gene, that most cases are sporadic and the result of new mutation, and that the gene manifests variable expressivity. We present a new case: female Mexican child 4 year moths-old is the first chil of young non consanguineous parentes obteind pretermino. She presented holoprosencephaly, microphthalmia left, cleft lip and palate, bent larynx, agenesis of nasal septum, imperforate anus, hypotelorism, ectopia left kidney, complex urogenital malformations, hidrocolps. with double vagina, uterus bicornis, persistence of arteries conduct That present language disabilities , characterized by being found to level at level of sentences, well directed and structured with articulatory distortions. EEG normal. Test audiometric shower normal audition ABR response in 30dB. Normal intelligence. Karyotype normal.

## 2672/F/Poster Board #188

**De novo chromosomal deletion and duplication in a child with developmental delay and hypotonia.** *E.C. Tan[1], E.C.P. Lim[1], B. Cham[2], I.S.L. Ng[2].* 1) KK Research Center, KK Women's & Children's Hospital, Singapore; 2) Genetics Service, KK Women's & Children's Hospital, Singapore.

The three-year old boy was born full term following an uncomplicated pregnancy to non-consanguineous parents of mixed ethnicity. The pregnancy was reportedly uncomplicated and he was born at term by spontaneous vaginal delivery. Birth weight was 4090g, Apgar scores were 3 at 1 minute and 6 at 5 minutes. During the last stage of labor, fetal heart decelerations were noted on cardiotocography. He was limp at birth, with bradycardia and no spontaneous respiration. Intubation was required for a few minutes. Urine organic acids and amino acids analyses were normal. He was referred to genetics clinic for evaluation because of cleft palate and hypotonia with gross motor and fine motor delay. Cleft palate had been repaired and his facial appearance was normal with no marked dysmorphism. On physical examination, physical growth parameters were found to be within normal limits. Muscle tone was generally decreased, but reflexes were normal. An ejection systolic murmur in the left sternal edge was heard. Brain MRI was reported to be normal but echocardiogram revealed moderate atrial septic defect. He also has sensitive airways and recurrent otitis media requiring grommet tube insertion. His karyotype was reported to be 46, XY, add(11)(?q24). Multiplex ligase-dependent probe amplification analysis using a subtelomeric probe panel revealed gain in 3p26 and loss in 11q25. Quantitative RT-PCR confirmed the gain at Cell Adhesion Molecule L1-like gene (CHL1) at 3p and loss at the Non-SMC condensing II Complex Subunit D3 gene (NCAPD3/KIAA0056) on 11q. Array-CGH with NimbleGen's 384K Human Genome CGH using the MAUI Hybridization System confirmed the copy number changes in the two regions with the loss on 11q estimated to be from q24.2 to qter (approximately 5.8 Mb) and the gain on chromosome 3 from q24.2 to qter (approximately 24.5 Mb). This appears to be a de novo event as chromosome analyses on his parents showed that the father was normal 46,XY and the mother 46,XX. He also has an older sister and a younger sister who are both phenotypically normal. The chromosomal abnormalities involving chromosomes 3 and 11 in this patient suggest that there are genes in these two regions associated with the multiple phenotypic abnormalities. We will further characterize the exact regions duplicated/ deleted and the breakpoints to identify the potential gene loci contributing to the clinical features.

## 2673/F/Poster Board #189

**Single Gene Causes of Isolated Developmental Disability: 7q31 deletion of FOXP2 in a non-dysmorphic, well-grown male with verbal dyspraxia.** *W. Al-Hertani[1,2], M.E. McCready[1,2], J. McGowan-Jordan[1,2], G.E. Graham[1,2].* 1) Genetics, CHEO, Ottawa, ON, Canada; 2) Pediatrics, CHEO, Ottawa, ON, Canada.

Up to 3% of individuals in the general population have some degree of developmental disability (DD), but well-grown, normocephalic and non-dysmorphic individuals with unexplained DD are not typically referred for a Genetics assessment due to the assumption that they are unlikely to have a single gene or chromosomal condition. Our clinic is somewhat unusual, as we often receive referrals from psychiatrists for adult patients with unexplained DD irrespective of the presence of other features. Here we report on a 27-year-old male whose very specific pattern of DD led us to suspect the involvement of FOXP2. An assessment of our patient by a developmental pediatrician at 39 months of age revealed that while some aspects of his development were as high as a 4-year-old level, his receptive language skills were at the level of a 30-36 month old, and his expressive language skills were at the level of a 12-18 month old. Psychometric assessment at 20 years of age showed his verbal skills in the mild intellectual disability range, while non-verbal skills were within the normal range (7th-27th centile). Our patient's past medical history included mild strabismus, astigmatism, major depressive episodes (resolved), generalized anxiety disorder and sleep difficulties that are well controlled by medications. He is otherwise healthy and there is no family history of developmental or speech delay. Physical examination demonstrated a non-dysmorphic, normocephalic male. Chromosome studies showed a normal 46,XY karyotype at a 500-550 band resolution. The role of FOXP2 in language development was first elucidated in 1990 by Hurst et al. Based on recently published reports (Lennon et. al. 2006, Feuk et al. 2006 and Zeesman et. al. 2005) we hypothesized that our patient may have a FOXP2 mutation, but mutation screening of this gene was not available on a clinical service basis and we were unsuccessful in finding an interested research laboratory. We instead ordered a SNP microarray test (Genome-Wide Human SNP Array 6.0, Affymetrix, Inc.), which fortuitously demonstrated a 1.89Mb deletion at 7q31.1-q31.2 (chr7:113,310,091-115,099,094) that included the entire FOXP2 gene. We are investigating the parents for this deletion, although it is most likely de novo in our patient. This case demonstrates that the Genetics clinic can play a role in determining the etiology of unexplained and apparently isolated DD.

## 2674/F/Poster Board #190

**Chromosome 21q21.1 single clone loss identified in a family with spectrum of developmental delays, learning difficulties, and behavioral problems.** *E. Prijoles[1], M. Pavan[2], P. Newkirk[1], M. Sutcliffe[1,3].* 1) Deptartment of Pediatrics/Division of Medical Genetics, University of South Florida, Tampa, FL; 2) Department of Pediatrics, Division of Child Development, University of South Florida, Tampa, FL; 3) Department of Pathology, All Children's Hospital, Saint Petersburg, FL.

Array comparative genomic hybridization (aCGH) has helped identify novel genomic disorders in patients with developmental delay, cognitive impairment, and mental retardation. The technology has also enabled us to detect copy number variants (CNVs) whose contributions to genetic variation and clinical significance are not yet well understood. We report a family with a single clone chromosome 21q21.1 loss, confirmed by fluorescence in-situ hybridization (FISH), and a spectrum of developmental delays, learning difficulties, and behavioral problems. The proband presented at 21 months of age for language delay, sleep problems and tantrums. Parents reported head-banging behavior and unusual movements. They also questioned the possibility of autistic spectrum disorder. On exam, he was noted to be healthy-appearing without obvious dysmorphic features. EEG and brain MRI were unremarkable. High resolution chromosome analysis and Fragile X DNA testing were normal. Array CGH revealed a single clone loss in copy number within band 21q21.1 with nearest adjacent proximal clone located 0.92 Mb and distal clone 1.33 Mb away. Parents and two siblings of the proband were subsequently tested. Both the mother and 6 year-old sister were confirmed with the loss by FISH. The mother had behavior and learning problems in childhood and has epilepsy, ADHD, and bipolar disorder. She continues to have problems with reading and writing. The sister has behavior problems and learning difficulties, requiring additional assistance in school. She is being treated for ADHD and is being monitored for signs of bipolar disorder. The younger brother had no imbalance confirmed by FISH and clinically presented with mild developmental delay. The proband's father also had no imbalance and has normal intelligence. Additional maternal family history is significant for bipolar disorder, epilepsy, and mental retardation in an uncle and learning problems and mental illness in grandparents. A paternal half brother of the proband is reported to have autism. The chromosomal 21q21.1 imbalance appears to be segregating in those family members with more severe developmental disorder. However, further evaluation of additional family members and delineation of the region is now indicated to investigate the possible clinical significance of this observation.

## 2675/F/Poster Board #191

**Concomitant presence of Cyclopia and sirenomelia in a stillbirth infant before the epidemic focus of sirenomelia in cali - Colombia.** *H. Pachajoa[1], C. Isaza[2].* 1) PhD Student, Genetica, Universidad del Valle, Cali, Colombia; 2) MD, Genetica, Universidad del Valle, Cali, Colombia.

Introduction Sirenomelia and cyclopia are congenital malformations due by early blastogenic defects, with similar epidemiologic patterns, and possible common etiopathogenicity. The sirenomelia or mermaid syndrome is a congenital structural anomaly characterized by an abnormal development of the caudal region of the body with different degrees of fusion of the lower extremities and bears resemblance to the mermaid of Greek mythology. Cyclopia is the most severe form of holoprosencephaly, is characterized by the presence of one central eye product of the fusion of the two eyes and the alobar holoprosencephaly. The prevalence of this two pathologies has been estimated close to 1 in 100 000 births, including stillbirths. Case report We describe the findings in a stillbirth infant with sirenomelia, cyclopia and cephalocele occipital. Born of non consanguineous parents, mother of 16 years old and father of 23 years old by the time of birth; the mother manifested to have used misoprostol at the beginning of pregnancy (first 4 weeks) as a method to abort the fetus. Discussion Recently, a cluster of sirenomelia in the city of Cali was published. This city is located in the Colombian pacific coast. In a maternity follow up by ECLAMC (Latin-American Collaborative Study of Congenital Malformations), an epidemic focus of sirenomelia was reported during a 55-day period between 12.09.04, and 02.02.05. During that period of time 1,064 children were born and four cases presented this rare disease, which was considered unusual and suggesting of the presence of a cluster. The evidence of an infant with both sirenomelia and cyclopia suggest an epidemiologic pattern, and possible common etiopathogenicity in the city of Cali.

## 2676/F/Poster Board #192

**Congenital defects and genetic diseases in prehispanic communities of the colombian and ecuadorian pacific coast, (300 a.c.-600 d.c.).** *C.A. Rodriguez[1], C. Isaza[2], H. Pachajoa[3].* 1) Museo Arqueologico, Universidad del Valle, Cali , Colombia; 2) MD, Dept Morfología, Universidad del Valle, Cali, Colombia; 3) MD, PhD estudent, Dept Morfología, Universidad del Valle, Cali, Colombia.

Introduction: The Tumaco-Tolita culture inhabited the geo-historical region of the colombo-ecuadorian pacific coast during the years 300 A.C.-600 A.D. This culture was characterized for capturing with impressive realism the different pathologies that suffered their population, as well as evidence of genetic illnesses, congenital malformations, and the processes of aging and death. Objetive: To describe the phenotypical evidences of congenital defects and genetic diseases in the ceramic of the Tumaco- Tolita culture of the main museums of Pre-Columbian ceramics of Colombia.. Methods:, A medical geneticist, a doctor with training in medical genetics and an archaeologist examined the collection of the Tumaco-Tolita culture of the main museums of Pre-Columbian ceramics of Colombia. The cases that displayed evidences of congenital defects and genetic diseases were documented. Results: : Out of the 5000 examined pieces, there were found ceramics with clear or suggestive evidence of congenital defects and genetic diseases like Down syndrome, Crouzon syndrome, Achondroplasy, mucopolysaccharidosis (hurler syndrome and Morquio syndrome), sirenomelia and cleft lip. Conclusions: The Tumaco-Tolita culture represented the congenital defects and genetic diseases in their ceramics, and it constituted one of the first registries of these conditions in the Pre-Columbian American cultures and the world, in addition it was found clear evidence that some conditions generated status within the society.

## 2677/F/Poster Board #193

**Provision of Medical Genetic Services in Thailand - Siriraj Experience.** *P. Wasant.* Dept Ped/Div Med Gen, Siriraj Hosp/Mahidol Univ, Bangkok, Thailand.

Genetic Services at the Department of Pediatrics, Siriraj Hospital Faculty of Medicine was established since 1960s' , providing genetic counseling and cytogenetic laboratory. Since 1987 , the Clinical Genetic Services has expanded to include other areas with a mandate of "providing for comprehensive genetic services with a primary role in genetic diagnosis , counseling and prevention" 1. Genetic counseling program. 1.1 Genetics Clinic received referrals from Bangkok and provincial hospitals all over the country ; mainly systemic genetic disorders , dysmorphology , suspected chromosomal disorders , sex differentiation disorders and some cases of prenatal diagnosis. 1.2 Birth Defects Clinic (established in 1991) providing services for infants/ children with cleft lip/palate , neural tube defects, arthrogryposis, congenital hip dislocation etc. 1.3 Genetic Skeletal Dysplasia Clinic (1992) providing services for infants/children with achondroplasia , osteogenesis imperfecta , pyknodysostosis , metabolic bone diseases e.g. mucopolysaccharidosis etc 1.4 Down Syndrome Clinic (1993) serving more than 500-600 families , providing genetic counseling , medical check up , referral to early stimulation program and assisting these children toward integration. 2. Genetic Screening program. e.g. newborn screening for genetic metabolic disorders (congenital hypothyroidism and phenylketonuria) is being planned for routine screen in year 2000 ; including prenatal genetic counseling and maternal serum screening for Down syndrome and Neural tube defect for pregnant women on voluntary basis. 3. Genetics laboratory. Initially only conventional cytogenetic analysis was performed, subsequently biochemical and molecular genetics laboratory is being established. Currently numerous genetic metabolic / inborn errors of metabolism e.g. amino acid , carbohydrate , urea cycle, organic acid, fatty acid oxidation, peroxisomal and lysosomal storage disorders are being identified. The Genetic Metabolic Center was established since June 2000 and has served infants / children with IEM all over the country. 4. Non-governmental organization. Down Syndrome Parents' Support Group at Siriraj Hospital was founded in 1993 , providing for more holistic and personal services to individuals and their families.

## 2678/F/Poster Board #194

**Providing Clinical Utility: from large-scale bioinformatics to specific audiences.** *D. Maglott[1], A. Astashyn[1], A. Brooks[3], E. Buford[2], F. Cunningham[2], R. Dalgleish[3], P. Flicek[2], L. Forman-Neall[1], J. Lee[1], S. McDaniels[1], W. McLaren[2], L. Phan[1], R. Tully[1].* 1) Natlional Center for Biotechnology Information (NCBI), NIH/NLM, Bethesda, MD; 2) European Bioinformatics Institute (EBI), Hinxton Cambridge, CB10 1SD, UK; 3) University of Leicester, Leicester, UK.

Ever-increasing throughput in generating sequence data has created a wealth of information for investigators to map, analyze, align, compare, view and model. One challenge, therefore, is to identify well-supported content relative to specific regions of the genome. Unfiltered data about genes, proteins, or sequence variants known to be associated with specific diseases may be too much to process for major classes of potential customers of these data. Genetic counselors, physicians, diagnostic testing laboratories, patients and others seeking to support, understand, manage and improve clinical treatment need rapid, reliable methods to retrieve data of interest. Over the past several years, the NCBI has been integrating resources and working directly with the clinical user base to develop and implement tools, displays, and databases that can better meet their praxis needs. We provide an overview of NCBI's strategies to improve access to and representation of clinically relevant data. Included are 1) recent modifications to Online Mendelian Inheritance in Man (OMIM), GeneReviews, and GeneTests, 2) establishing reference gene-specific sequence standards via RefSeq, RefSeqGene and Locus Reference Genomic (LRG), 3) integrating information about variants of clinical interest from multiple sources, and (4) new tools to interrogate multiple databases at the same time.

The LRG project is of particular interest, as it is the product of an international collaboration among EBI, the GEN2PEN consortium, and NCBI to build upon the RefSeqGene project and provide a set of stable gene-specific, genomic standard sequences for reporting variation. The LRG sequences are stable (not versioned), and can represent an idealized allele. Each LRG will also include fixed locations of exons and coding regions for one or more transcripts of the gene. In addition to the static data, the LRG will provide infrastructure for displaying up-to-date information, such as chromosome coordinates, related databases, alternate exon and protein numbering systems. When an LRG is established, the corresponding RefSeqGene sequence will be identical in sequence and exon annotation, and the RefSeqGene will report the LRG accession. This presentation will provide practical examples of these resources (http://www.ncbi.nlm.nih.gov; http://www.lrg-sequence.org).

## 2679/F/Poster Board #195

**MISDIAGNOSIS OF PRADER-WILLI/ANGELMAN SYNDROME DUE TO TECHNICAL LABORATORY ERRORS.** *M. Pervaiz, B. Coffee, L. Bean, M. Hedge, N. Hjelm, S. Askree, M. Adam.* Department of Human Genetics, Emory University School of Medicine, Decatur, GA.

The diagnosis of many genetic conditions relies on the combination of clinical suspicion followed by confirmatory genetic testing. We report two cases in which technical laboratory errors led to the misdiagnosis of either Angelman syndrome or Prader-Willi syndrome. Patient 1 is an 11 year old male with mild to moderate mental retardation. Very little was known regarding his early medical history, as he was in foster care. At the time of presentation to our clinic, he was speaking in complete sentences, had recently been toilet trained, and had gained a fair amount of weight over a short period of time. His foster mother reported a history of hyperphagia and hyperactivity.We recommended testing for PWS. DNA based methylation studies were done.The methodology involves methylation based PCR techniques which can analyze the DNA methylation status of any groups of CpG sites in a CpG island. Sodium bisulfite treatment is the first step in the conversion of unmethylated cytosine to uracil under conditions in which methylated cytosines remain unchanged. The duration of bisulphite treatment can lead to 90% degradation of the DNA. In this case, the maternal allele was overdegraded, leading to maternal allele dropout, and a preliminary positive result for Angelman Syndrome. As his clinical history did not suggest this diagnosis, a confirmatory southern blot test was done and was negative. Our second patient is a 27 month old female who was referred to us with an established diagnosis of PWS by methylation studies. She did not have classic clinical features of this condition, such as hypotonia, feeding difficulties, failure to thrive, or short stature. Therefore a repeat test by methylation sensitive PCR was done in our lab, and again was positive for PWS. Because of our experience with Patient 1, a second methodology was used the confirm this positive result and was negative for PWS. Further analysis demonstrated that the patient DNA contained a SNP within the primer sequence used for the PCR, leading to decreased annealing of the paternal allele, resulting in paternal allele dropout. The same PCR primers for PWS are used by almost every lab in the United States (Kubota et al, 2007), which is the reason that 2 separate clinical laboratories both erroneously reported a positive result for this patient. These 2 cases reinforce the importance of clinical judgment in the diagnosis of patients. Sometimes a positive test result should be confirmed by a second method.

## 2680/F/Poster Board #196

**Frequency of congenital malformations in newborn infants in the Civil Hospital of Tepic. México.** *LE. Wong-Ley[1,2], J. González-Zapata[1], M. Pérez-Nuño[2].* 1) Dept Gen, SSN, Tepic, Mexico; 2) Dept Gen, UAN, Tepic, Mexico.

Summary. Congenital malformations constitute an emerging problem in developing countries due to the fact that other causes are being controlled. México occupies the first place in Latin America and the Caribbean. The objective of this work was to determine the incidence of congenital malformation in the maternity area at the Civil Hospital of Tepic and to analyze its main characteristics. A retrospective study of the newborn's clinical records was realized from January 1, 2007 until December 31, 2008. Objetive. To know the frequency of congenital malformations (CM) in alive new born of the Civil Hospital of Tepic, Mexico and to identify possible risk factors. Material and methods. During 2 years, from January 1st, 2007 to December 31, 2008, they were captured those alive newborn with external congenital malformations, grouping for apparatuses and systems, comparing our results with that reported in the literature. Results. Of total of 9,166 alive births; 4,716 (51,4%) were female, 4,446 (48,5%) male and 2 (0,1%) with the ambiguous genitals. 274 cases were captured of recently born with external congenital defects corresponding to 3%, which determines an incidence of 29,9 cases by each 1.000 new born. It prevailed in the feminine sex (52.7%). Of term they were 67% and preterms 33%. The most frequent malformations were related to the digestive system, heart disease, skeletal malformations and central nervous system and less frequent defects of the genitourinary. In half of the pregnancies prenatal ultrasonography was useful for the diagnosis. The frequency found was upper than that reported by other studies in our country. The most important risk factors were, mothers older than 35 years, multiparity and some consanguinity degree between parents. Conclusions. The congenital malformations constitutes a significant problem of health in our country, some differences were observed in the prevalence of congenital malformations. The CM are an important cause of morbimortality in newborns and we must learn to identify the risk factors that influence its presentation. Key words. Congenital malformations, alive newborn .

## 2681/F/Poster Board #197

**Detecting genetic associations with rare variants.** *G. Bhatia[1], V. Bansal[2], O. Harismendy[2], E. Topol[2], K. Frazer[2], V. Bafna[1].* 1) Computer Science Department, UC San Diego, La Jolla, CA; 2) Scripps Research Institute, La Jolla, CA.

Genome-wide association (GWA) studies, which search for association between single, common genetic markers and a disease phenotype, have shown varying degrees of success. Recent studies suggest that multiple rare variants at different loci may act in concert to influence etiology of common diseases. However, current GWA studies depend upon the Common Disease Common Variant hypothesis and are not powered to account for disease-causing rare variants (CDRV).

We consider a simple CDRV model where a subset of rare variants at a locus is independently deleterious. These rare variants have modest penetrance (their presence increases disease likelihood significantly), but each explains only a small fraction of the diseased individuals. For this model, we describe an algorithm that efficiently computes a subset of rare-variants that best associate with the disease. We test our approach using extensive simulations. Neutral rare-variants are simulated according to models proposed by Fu, and causal variants are assumed to be under purifying selection are simulated according to Wright's equation. Our method is robust in detecting associations with modest odds ratios in relatively small cohort studies. It significantly outperforms previously proposed collapsing strategies, and is robust to other CDRV models.

Our simulations suggest that associated regions with an odds ratio of 1.5 can be identified with a case control study of 640 cases and 640 controls, with unadjusted p-values of $10^{-16}$. Associated regions with odds ratios of 2.2 can be identified with about 200 case/200 control individuals, while still maintaining genome wide significance. These results suggest that genome wide association using an analysis of rare variants is feasible.

The method was applied to a cohort of 289 individuals, 143 with high BMI and 146 with relatively low BMI. Two genes (187 kb) were sequenced in this cohort using next-generation sequencing. We identified two subsets of co-located variants that showed significant association with BMI (out of a total of 1088 rare variants). These subsets associated showed association with un-adjusted chi-square P-values of 3.6 x 10-4 and 1.4 x 10-4, and permutation based P-values of 0.004 and 8.04 x 10-4. In comparison, the most significant association using single marker tests had a chi-square P-value of 0.002.

**Informatic Sample Handling Processes: A High Throughput Genotyping Facility's Workflow for Sample Information Tracking.** *B. Craig, C. Ongaco, M. Zilka, M. Barnhart, D. Leary, K. Hetrick, B. Marosy, M. Adams-Carr, O. Osimokun, Y. Sun, F. Kistenev, J. Romm, J. Goldstein, E. Pugh, L. Watkins, C. Boehm, K. Doheny.* Center for Inherited Disease Research, Johns Hopkins University, Baltimore, MD.

The Center for Inherited Disease Research was established at Johns Hopkins University in 1996. CIDR provides high quality genotyping services and statistical genetics consultation to investigators working to discover genes that contribute to common disease. The handling of large numbers of samples requires a mechanism for tracking detailed information throughout experimental processes. Progress can be recorded and results retrieved in a manner appropriate to the individual lab's custom procedures. CIDR processes approximately 100,000 samples each year, tracking this information through unique combinations of database types, Web, Java and Perl applications and integration with robotics for sample movements. Use of MySQL®, Oracle® and MS SQL® databases have allowed CIDR to create new and adapt legacy schemas to store changing information about samples for use in downstream processes and release to investigators. Creation of Java and Perl applications to integrate with databases provides the flexibility to implement and adapt custom validation frameworks. These methods are put into operation through unique sample map construction, verification of pedigree and other investigator supplied information, confirmation of sample receipt, recording history of sample movements, queuing samples into production workflows, tracking of problems and recording auxiliary information and quality control (QC) metrics. Development of custom laboratory information management systems (LIMS) for CIDR's Affymetrix® 6.0, Illumina® Infinium and BeadXpress services using JavaScript, Java and the Google Web Toolkit allow for rapid changes to workflows and improved troubleshooting methods based on input from CIDR personnel or vendors. The use of liquid and tube handling robotics has allowed CIDR to streamline sample processing by re-arraying samples with investigator-supplied plating criteria to better mix sample phenotype information prior to processing. Samples can be removed, re-genotyped or replaced based on problems identified throughout CIDR's workflow, thereby optimizing processing time and reagent use. Automated processes perform genotype calling and QC analysis which are linked to the sample for reporting to CIDR personnel and investigators. The use of these resources, as well as the experience to adapt or engineer new ones as needed, permit CIDR to efficiently receive and process large sample studies at present and allow for continued growth into the future.

**Hypertrophic cardiomyopathy multigene analysis by next generation sequencing.** *S. Dames[1], J. Durtschi[1], J. Stephens[1], K. Geiersbach[1], K.V. Voelkerding[1,2].* 1) ARUP Institute for Clinical and Experimental Pathology, Salt Lake City, Utah; 2) University of Utah Department of Pathology, Salt Lake City, Utah.

**Introduction.** Hypertrophic cardiomyopathy (HCM) is an autosomal dominant disorder of sarcomere structure/function. At least 16 genes with over 450 mutations have been implicated in HCM. Next generation sequencing (NGS) offers a new approach for complex multi-gene analysis. The goal of the current study was to compare the performance of the Illumina Genome Analyzer and Roche 454 GS FLX platforms for targeted resequencing of genes implicated in HCM. **Methods.** A normal human genomic DNA sample was used for analysis. HCM genes were enriched by long range PCR and equimolar pooled. The pooled amplicons were divided and single end libraries for Illumina and GS FLX sequencing were prepared and sequencing conducted following manufacturer's protocols. Analysis of sequencing data was performed with platform-specific software and DNAstar SeqMan alignment tools using HGB 36.3 reference sequences. All NGS identified HCM exon sequence variations were analyzed by Sanger sequencing for verification. **Results.** Illumina and GS FLX sequencing resulted in coverage averages of 798 and 198 with read lengths of 36 and 235 (ave) bases, respectively. Forty-two GS FLX and 45 Illumina exon variants were identified using >30-fold coverage and >20% read percentage criteria. Thirty-two variants were concordant with 31/32 confirmed by Sanger sequencing. Of non-concordant variants, all were wild type compared to the reference sequence, with half under 30% read percentage. Analysis indicates the remaining variants resulted from short-read misalignments due to high homology between sequenced genes and homopolymer sequencing errors. Over 20 Kb of Sanger sequencing data did not reveal any sequence variants unreported by the NGS technologies. **Discussion.** The current study represents an initial phase in the development of a multi-gene analysis for HCM with the future goal of implementation for diagnostics. The data demonstrate the feasibility of multi-gene enrichment by LR-PCR coupled with NGS for targeted resequencing. The high degree of platform concordance suggests that either Illumina or Roche 454 technologies would be suitable for this application. Each platform has unique features (e.g., read lengths and sequencing chemistries) that need to be considered with respect to data analysis and evaluation/confirmation of variants. Ongoing efforts include the use of pair end Illumina sequencing and evaluation of additional algorithms for variant identification.

**Classifying genomic data using combination of bagging and rank aggregation.** *S. DATTA, V. PIHUR, S. DATTA.* University of Louisville, LOUISVILLE, KY.

Machine learning methods such as clustering and classification are essential tools for analyzing genomic data. However, no single classifier can reliably classify all data sets. Similarly, for a given data set, the results may vary greatly depending on the classifier used and the user's level of sophistication. This is particularly true for high dimensional data sets arising out of microarray and proteomic studies as illustrated by the results of a recent classification competition of grouping breast cancer patients from SELDI spectra held at Leiden University. In this work, we propose to use a collection of classifiers to make the final analysis relatively stable. Also care is taken so that the analysis is adaptive - that is the ultimate classification is close to that obtained using a hypothetically "optimal" classifier for a given data set. The optimization part is carried out using multiple performance measures and a rank-based aggregation. This is different from the traditional "ensemble classifier" whose general goal is to improve the accuracy by averaging individual models constructed using "weak" classifiers. We illustrate the usefulness of our method using a gene expression data set on Acute Lymphoblastic Leukemia and a proteomic data set on prostrate cancer.

**A statistical framework for differential network analysis (DNA) from microarray data using partial least squares.** *S. DATTA, R. GILL, S. DATTA.* UNIV OF LOUISVILLE, LOUISVILLE, KY.

It has been long well known that genes do not act alone; rather groups of genes act in consort during a biological process. Consequently, the expression levels of genes are dependent on each other. Experimental techniques to detect such interacting pairs of genes have been in place for quite some time. With the advent of microarray technology, newer computational techniques to detect such interaction or association between gene expressions are being proposed which lead to an association network. While most microarray analyses look for genes that are differentially expressed, it is of potentially greater significance to identify how entire association network structures change between two or more biological settings, say normal versus diseased cell types. We provide a recipe for conducting a differential analysis of networks constructed from microarray data under two experimental settings. At the core of our approach lies a connectivity score that represents the strength of genetic association or interaction between two genes. In this paper we use a score that is based on a partial least squares analysis of expression data that was introduced in our previous work. In this presentation, we use these scores to propose formal statistical tests for each of following queries: (i) whether the overall modular structures of the two networks are different, ii) whether the connectivity of a particular set of “interesting genes” has changed between the two networks, and (iii) whether the connectivity of a given single gene has changed between the two networks. We carried out our method on two types of simulated data: Gaussian networks and networks based on differential equations. We show that, for appropriate choices of the tuning parameters, our method works well on simulated data. We also analyze a real data set involving normal versus heavy mice and identify an interesting set of genes that may play key roles in obesity.

**Identification of disease-associated copy number variation using classification techniques.** *J.Y. Hehir-Kwa[1], N. Wieskamp[1], C. Webber[2], C. Gilissen[1], R. Pfundt[1], C.P. Ponting[2], J.A. Veltman[1].* 1) Radboud University Nijmegen Medical Centre, Department of Human Genetics, Nijmegen; 2) MRC Functional Genomics Unit, University of Oxford, Oxford.

Genomic copy number variation (CNV) has recently been recognized as a common form of genomic variation in humans. Hundreds of CNVs can be detected in any individual genome using genomic microarrays or whole genome sequencing technology, but their phenotypic consequences are poorly described. Rare CNVs have been reported as a frequent cause of neurological disorders such as mental retardation (MR), schizophrenia and autism, prompting widespread implementation of CNV screening in diagnostics. For clinical applications it is however essential to reliably distinguish pathogenic from apparently benign CNVs. In previous studies we have extensively studied the genomic content of benign CNVs (Nguyen et al. 2008) and in addition shown that in contrast to benign CNVs MR-associated CNVs are significantly enriched in genes whose mouse orthologues, when disrupted, result in abnormal axon or dopaminergic neuron morphologies (Webber et al. in press). In this study we developed and validated a novel computational method for differentiating between benign and disease-associated CNVs using structural and functional genomic features. After training, we show that a Naïve Bayesian Tree classifier achieves a high accuracy (94%) and negative predictive value (99%) on a blinded test set of CNVs from a large cohort of individuals with unexplained MR. In total 13 features contributed to the classification, with LINE density (-6%) and mouse knockout phenotypes (-5%) having the highest contribution to the classifier’s accuracy. These results indicate that this classification method can be used for objectively prioritizing CNVs in clinical research and diagnostics. Results from this method can easily be combined with information on CNV frequency and inheritance, thereby greatly enhancing clinical interpretation of this important class of genomic variations. **Detection of parent-of-origin effects mediated by SNPs which generate or destroy CpG sites.** *B.M. Herrera[1,2], C.A. Anderson[1], J.C. Randall[1], W. Yuan[1], K. Elliott[1], R. Mott[1], A.P. Morris[1], C.M. Limdgren[1,2].* 1) Wellcome Trust Centre for Human Genetics, Oxford University, Oxford, UK, OX3 7BN; 2) Oxford Centre for Diabetes, Endocrinology and Metabolism, Oxford University,Oxford, UK OX3 7LJ.

Parent-of-origin effects (POEs) such as imprinting and histone acetylation, result in deviations from Mendelian inheritance and modify gene expression in a manner determined by the sex of the parent from which the locus is inherited. POEs are often mediated by epigenetic mechanisms like methylation at CpG islands. To establish the presence of SNPs which affect gene expression through *cis*-acting mechanisms, in particular those SNPs which may mediate POE through the creation or destruction of CpG islands (meth-SNPs). We used publically available gene expression and SNP genotype data from HapMap families. Out of 47,294 transcripts in 30 Caucasian (CEU) and 30 Yoruba (YRI) trios, we considered only genes expressed with a standard deviation $\sigma$0.5 (CEU=1,013 and YRI=1039). A linear regression method was employed to detect POEs. In order to detect *cis*-effects, only SNPs located 500Kb upstream and 50Kb downstream of the transcript were considered. CEU and YRI trios were analyzed separately and then meta-analysed, and a genome-wide significance threshold of $p \leq 10^{-5}$ applied. The lists of genes obtained were then queried using a gene candidacy program (genesniffer) to generate imprinting-candidacy scores for each gene. In YRI families, we observe POEs for 96 genes (annotated by 345 SNPs, of which 21.1% are meth-SNPs). In CEU families, we observe POEs for 73 genes (annotated by 392 SNPs, of which 22.7% are meth-SNPs). The meta-analysis detected a total of 106 genes with POE effects (annotated by 324 SNPs of which 24% are meth-SNPs). Among the genes identified by the meta-analysis, we observed one known imprinted gene *NDN*, adjacent to one of the 15q11 imprinting centres. In addition, we observed POEs for 13 genes overlapping between our CEU and YRI sets, including *TJP1* (15q13) and *DPYD* (1p22) which obtained high genesniffer scores further suggesting that their expression is regulated by specific POE. Further replication of findings from the meta-analysis and the CEU results will be carried out in a larger Northern European cohort. These results constitute a potentially novel set of imprinted genes for which expression may be mediated via methylation mechanisms.

**Improved Multiplex Ligation-dependent Probe Amplification Analysis (MLPA) with BioNumerics®.** *K. Janssens[1], D. Michielsen[1], B. Pot[1], J. Goris[1], B. West[2], P. Vauterin[1], L. Vauterin[1].* 1) Applied Maths NV, Sint-Martens-Latem, East-Flanders, Belgium; 2) Applied Maths Inc., Austin, TX.

Copy number variations in genomic DNA have been linked with pathogenic mutations in many diseases. These variations are usually not detected by PCR-based sequence analysis because a normal copy is still present. Traditionally, techniques as Southern blot hybridization or FISH are used to detect these types of mutations, with the disadvantage that these are both time-consuming and require a high amount of DNA. Multiplex ligation-dependent probe amplification (MLPA) is a relatively simple method that allows relative copy number estimation of up to 45 nucleic acid sequences in one single reaction. Introduced by MRC-Holland, MLPA has become a promising technique for the rapid detection of copy number variations in genomic DNA, mRNA profiling and for identification of microbial communities. The BioNumerics database and analysis platform was extended with a novel iterative normalization algorithm with subsequent scoring, embedded in the existing scripting environment. Sequencer data coming from different hardware manufacturers can be imported in batch as peak-tables or as raw curve files. Due to the variations of PCR efficiencies within and between samples and probes, traditional normalization methods do not perform very well. We developed a unique rapid iterative normalization method that uses both the control probes peaks as well as the peak intensities. The use of this iterative approach improves the accuracy and lowers the false positive rates, compared to traditional normalization techniques. Once the automated normalization step is completed, each probe peak is scored according to adjustable thresholds. The scoring is subsequently stored in the database. Extensive statistics and reports possibilities are embedded in the tool for individual patient reports as well as overall data mining on results obtained from MLPA combined with data from other techniques or information fields about the patients. The use of the MLPA-plugin in BioNumerics allows the user to easily and rapidly detect large genomic rearrangements in new samples and perform meta-analysis on the results. The general BioNumerics platform allows overall data management and advanced data mining. Reports for each gene or region of interest can be generated for rapid detection of candidate samples with copy number changes. The analysis can be set up with a high degree of automation, making a high throughput approach feasible.

**Insertion of small pyrosequencing reads into a core tree using parsimonious insertion.** *D. Knox[1], A. Gonzalez-Peña[1], K. Ramirez[2].* 1) Computer Science, University of Colorado at Boulder, Boulder, CO; 2) Ecology and Evolutionary Biology, University of Colorado at Boulder, Boulder, CO.

Understanding the full breadth and depth of microbial diversity between different communities provides valuable insight into global processes ranging from biogeochemical processes to human health. With the advent of high throughput sequencing technology, there has been a flood of sequence data. Successfully handling and analyzing this data has proved difficult and has hindered the ability of researchers to fully synthesize results. One goal of analyzing unknown sequences is to align and classify each sequence into a taxonomic group, and then find a relationship between sequences using phylogenic analyses. There are many tactics available to classify unknown sequences. One method, the use of parsimony insertion into a core tree, has proven successful and accurate, but difficult and time consuming on a large number of sequences. The goal of this research was to create a program to insert unknown 16S ribosomal RNA sequences into a “core” phylogenetic tree using parsimony insertion. This research was approached in two steps: (1) an alignment model was created to align sequences and prepare them for insertion into a core tree. The alignment model was created using the program Infernal and representative sequences chosen from the well-annotated Greengenes database. Using a gapping method short read sequences were aligned to representative sequences, and then rapidly ungapped for parsimonious insertion into the core tree. (2) A parsimony algorithm was created to insert sequences into the core tree. This algorithm has been tested on both short and full-length sequences. In tests, the algorithm has a ~95% accuracy for placing both short and full length sequences into the core tree. Further when sequences are designated by percent similarity, the algorithm has up to 75% accuracy when ≥ 85% sequence similarity is used. The benefit of efficiently inserting sequences into a core tree is two fold. First, it aids in the organization and visualization of sequence data. Second, and more importantly, parsimony insertion gives a highly accurate method of classifying sequences and determining phylogenetic relatedness.

**Investigation of the patterns of Linkage Disequilibrium in the human genome by comparing HapMap and genome-wide association scans.** *W. Lau, N. Maniatis.* Research Department of Genetics, Evolution & Environment, University College London, London, United Kingdom.

Over the recent years, association mapping of disease genes has developed into one of the most dynamic research areas of human genetics. Establishing the Linkage Disequilibrium (LD) structure of the Human Genome was extremely important for the effective application of association mapping. It was also instrumental for the advancement of Genome Wide Association (GWA) mapping. Metric LD maps in LD units are analogous to linkage maps in that map distances are additive but for disease association mapping they provide a much higher resolution. From the International HapMap Project and other sources, millions of SNP genotypes are now available for constructing such high resolution maps. Here we compare the LDU maps that were constructed from the 60 CEU individuals of the Phase II HapMap data and the combined 17,000 individuals from the Welcome Trust Case Control Consortium (WTCCC). We investigate the patterns of LD in HapMap and WTCCC and their relationship to the second generation linkage map. We finally examine the use of LD maps as a tool in identifying disease genes.
