The Center for Inherited Disease Research provides high quality genotyping services and statistical genetics consultation to investigators working to discover genes that contribute to common disease. The CIDR Affymetrix Analysis Pipeline, a Java application tightly integrated with the CIDR Affymetrix LIMS, is a completely automated analysis pipeline built around the Affymetrix Power Tools (APT) software suite provided by Affymetrix. Multiple Affymetrix scanners output GeneChip data to a single, multi-terabyte, network-attached storage location. The pipeline monitors the network location and, upon determining when each GeneChip’s scan is complete, archives that GeneChip’s data. The archiving process organizes the data by project, and also creates file redundancy for disaster recovery purposes. After file archiving, data concerning the scanner and the fluidics station are extracted from the AUDIT file and stored to CIDR’s Affymetrix LIMS database. Next, an eight-node Apple XServe compute cluster simultaneously analyzes the CEL file using three APT programs: apt-geno-qc, apt-copynumber-workflow, and apt-probeset-genotype. Each compute node has 32GB RAM, 350GB disk space, and dual quad-core Intel® Xeon® processors. Up to 64 APT jobs can be executed concurrently. When each of these jobs finishes, the pipeline software parses the resulting output files and stores these data into the database: quality control metrics and gender estimates from apt-geno-qc, copynumber metrics from apt-copynumber-workflow, and birdseed analysis results from apt-probeset-genotype for quality control purposes. In addition, the apt-geno-qc DM SNP genotypes are stored to aid in sample tracking and identification, and HapMap concordance is calculated for CIDR control samples from the apt-probeset-genotype output and is also stored. All of these data are then available via several user-customizable reporting applications. To date, CIDR’s pipeline has analyzed over 4.2 billion genotypes across more than 4,600 GeneChips, providing real-time quality control metrics on each of these. This has allowed lab managers to make quick, informed decisions regarding lab processing in a high-throughput environment.

**Interrogation of SNPs in duplicated gene loci: true polymorphisms or false identities.** *W. Lin[1,2], M. Ho[1,2].* 1) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 2) Institute of Biomedical Informatics, National Yang-Ming University, Taipei, Taiwan.

In our previous study, we have established a concise gene oriented ortholog database in order to improve gene transcript complexity examination and orthologous gene assignment. Due to the complex alternative splicing transcripts in human genome, the use of traditional protein primary sequence similarity best-hit search methods could have difficulties in resolving complicated orthologous relationships between many alternative spliced isoforms. By clustering transcripts with the origin of all biological mechanismsthe genomewe will be able to better decipher gene locus information as well as summarize gene isoform information. Compared with other ortholog databases, gene-oriented ortholog database provides about 80% coverage of reference sequences and yields higher accuracy. Intriguingly, around 15% of human reference genes, that could not assigned by our pipeline, are mapped to multiple genomic regions. These duplicated gene loci (DGL) might be generated from an error in homologous recombination, a retrotransposition event, or from duplication of a large chromosomal segment. Many of these multiple location DGLs are putative genes with copy number variations (CNVs) in their duplicated regions. Due to the extremely high sequence similarity between the DGL gene loci, it is likely that any given mismatch between DGLs could be mistakenly annotated as SNPs. In fact, they are merely sequence differences among various genomic copies. This provides possible explanations for numbers of SNPs with multiple genomic locations. In order to further understand the expression of these DGL or CNV genes, we tried to use dbSNP dataset (17,804,034 rsSNPs) to map and distinguish different genomic loci of DGL genes. In this study, we interrogated 2,090 DGL genes of high sequence similarity (95%) with multiple genomic locations (distributed at 7,160 genomic loci). After mapping rsSNPs to these genomic locations, we found 148,897 rsSNPs located within the boundaries of these DGL or CNV gene regions. Further examination reveals that most of these single nucleotide sequence variation sites should not be annotated as single nucleotide polymorphism. Utilization of these SNPs in genotyping practices could generate inaccurate information and impair anticipated genotyping calculations. Therefore, our study suggests that in-depth characterizations and re-annotation of these DGL or CNV associated SNP records should be performed to improve the SNP based genome-wide association studies.

**ALFRED: A resource for research and teaching.** *H. Rajeevan[1], K.-H. Cheung[2], U. Soundararajan[1], S. Stein[1], A.J. Pakstis[1], J.R. Kidd[1], K.K. Kidd[1].* 1) Dept Genetics, Sch Med, Yale U, New Haven, CT; 2) Center for Medical Informatics, Sch Med, Yale U., New Haven, CT.

ALFRED (the ALlele FREquency Database, http://alfred.med.yale.edu), has been accumulating gene frequency data on human populations from published literature, collaborators, high throughput data sources such as HGDP-CEPH website and Human Genome Diversity Project at Stanford University, and the host laboratory. ALFRED currently has nearly 500,000 tables (one population sample typed for one site) of allele frequencies involving over 18,000 polymorphisms with data on nearly 700 distinct populations from around the world. 23 polymorphisms in ALFRED have allele frequency data on more than 100 population samples. 58 population samples in ALFRED have allele frequency data on more than 4000 polymorphisms. There are several complete data sets in ALFRED, some with partial overlap. They include uploads from the host lab (638 SNPs on 40 population samples), and from published literature; 2810 SNPs on 51 HGDP populations (PMID: 18513279), 11,555 SNPs on 12 diverse populations (PMID: 16004724). Another 77 populations (combination of host lab and HGDP populations) in ALFRED, all have data on at least 791 SNPs that are a subset of the Illumina HumanHap 650Y Beadchip array panel. The remaining tables from the panel are being uploaded into ALFRED. In addition to existing downloading formats, tools to select and extract specific complete data sets in different formats are also being developed. Among multiple graphical display modes for allele frequencies for a polymorphism, pie-charts can be viewed on Google Map and Google Earth. These display modes allow users to utilize all the functions available from the Google Map, Google Earth applications. Fst and average heterozygosity values for bi-allelic SNPs displayed in tabular format and organized by chromosomes can now be sorted by locus, Fst, average heterozygosity and number of populations typed. A table mapping dbSNP's unique identifier, "rs-number" and ALFRED's unique identifier has facilitated ways to have reciprocal URL links with dbSNP, PharmGKB and Genopedia HuGE Navigator. To involve the community in collaborative authoring and curation tasks we created ALFREDWiki (http://alfred.med.yale.edu:8080/wiki/index.php/About_ALFRED). The application includes pages to edit population description and a feedback section. ALFRED is supported by U.S. NSF BCS0840570.

## 2694/F/Poster Board #242

**e-GenoType: A Rapid and Accurate Method for *in silico* Genotype Characterization.** *J. Reid, M. Bainbridge, D. Deiros, L. Nazareth, D. Muzny, R. Gibbs.* Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX.

With the rapid increase in density and read-length on NexGen sequencing platforms there has also been a significant increase in the run-time required for the analysis necessary to map reads and produce variant calls. To address this we have developed a method (available at http://www.e-genotype.com/) of rapidly screening read data using in silico probes designed to provide genotyping information on any sample almost immediately after base-calling is complete. Because of the simplicity of generating in silico probes, as the list of known variants rapidly grows (as with the 40 million new variants identified by the thousand genomes project) so will the probe list used for screening. With this method genotype calls can be produced from raw read data in minutes or hours instead of days or weeks, an essential feature necessary for addressing time-sensitive problems such as sample verification and contamination screening.

Based on analysis of HapMap deep-coverage sample data generated at the HGSC for the thousand genomes deep-sequencing pilot project, we have demonstrated that e-GenoType can rapidly produce genotype calls at over 700,000 known polymorphic sites with a miscall rate of less than 2%. We will also show that high-coverage miscalls can be improved by screening probe sets for non-specific probes, discuss an approach to e-GenoTyping in/dels and structural variants of any size, and show how rapid identification of putative somatic alleles can be found in tumor/normal pairs.

## 2695/F/Poster Board #243

**Combination of genotyping platforms to develop a haplotype map in Mexican Mestizo and Amerindian populations.** *G. Richard[1,2], C. Rangel-Escareno[1], J.C. Fernandez-Lopez[1], I. Silva-Zolezzi[1], G. Jimenez-Sanchez[1].* 1) National Institute of Genomic Medicine (INMEGEN), Mexico City, Mexico; 2) National Institute of Applied Sciences (INSA) of Lyon, Villeurbanne, France.

The aim of the Mexican Genome Diversity Project (MGDP) is to characterize genetic diversity and linkage disequilibrium structure to generate a ~1.5 million SNP haplotype map. This will allow the implementation of efficient tagging and imputation strategies for association studies in Mexicans. To increase SNP density and hence genome coverage, we merged genotype data of same individuals from the following platforms: Affymetrix 500K, Illumina HumanHap550 and Illumina HumanExon510S. We analyzed genotypes generated for the MGDP from 300 Mexican Mestizos and 150 Amerindians from three populations (Mayas, Tepehuanes and Zapotecas). Combined raw data provided a total of 1,427,627 SNPs. We evaluated genotyping assignment consistency between all platforms on the 139,033 overlapping SNPs representing 9.4%; of the total. Of these, 25.3%; were consistently reported across platforms, the rest (103,832) had either one of the following problems: strand inversion 25%;, allele differences but same strand 24.7&%;, strand differences same alleles 25%;, and allele mismatch 0.00072%;. To evaluate genotype concordance in all samples across platforms, we first solved these problems by allele or strand re-assignation for each SNP, achieving complete consistency. SNP genotype frequencies were used in a principal component analysis (PCA). Objects relative to the first two principal components were plotted as clusters using the Partitioning Around Medoids algorithm, based on the search for representative clusters among the data that minimize dissimilarities. Resulting clusters were drawn based on the average and covariance matrix of each of them. Observed clustering patterns in Mestizos and Amerindians were consistent with those obtained from our previous Affymetrix 100K analysis in the same populations (Silva-Zolezzi I. et al., PNAS 2009). However, it also showed clear platform-related differences. Affymetrix 500K includes random evenly-distributed markers, whereas Illumina 510K has a trend related to the selection of gene-centered tagSNPs and coding SNPs. Our results describe the feasibility of combining SNP panels from different platforms, a necessary step towards the construction of a haplotype map, which will be relevant for population genetics studies in Mexicans.

## 2696/F/Poster Board #244

**Predicting heart transcription enhancers in the human genome.** *N.J. Sakabe[1], L. Narlikar[2], M.A. Nobrega[1], I. Ovcharenko[2].* 1) Human Genetics Department, University of Chicago, Chicago, IL; 2) NCBI, NLM, NIH, Bethesda, MD.

Regulation of gene expression during heart development involves promoters and distal regulatory elements spread across the genome up to megabase-long distances from genes. To identify these elements based solely on their genomic sequence, we developed a classifier that learns features from an experimentally validated set of embryonic heart regulatory elements and scans the human genome for regions with similar features. Our training set was composed by 50 validated enhancers and promoters from the literature and other sources. The classifier was built to learn enrichment of known and de novo motifs. We then employed a linear regression method (LASSO) that selects features that are important in the training set and learns a linear formula comprising the selected features with different weights. As a negative set, we generated a random set of 1000 sequences with matching GC content and length. Among the features selected as important, MEF2, SRF and other 18 motifs are known to play an important role in heart development. Our method outperformed others on both sensitivity and specificity, with an area under the ROC curve of 0.92 versus 0.77 of the best competing method. We then used the trained classifier to score non-coding elements in the human genome conserved in mouse (CNE) in windows of 250 bp. Out of a total of 363,765 CNEs, 6,097 were scored as putative heart enhancers. The majority (93%) of the putative heart enhancers lie at least 2kb away from the nearest TSS. The predicted enhancers are associated with genes highly expressed in the heart and significantly correlate with chromatin modifications and DNase I hypersensitive sites, indicative of active regulatory elements. Finally, about half of the 20 putative enhancers tested in zebrafish reporter assays were validated as heart enhancers. We also tested 2 sequences on transgenic mice and both were positively validated.

## 2697/F/Poster Board #245

**A Computational System to facilitate efficient discovery of disease genes.** *T.E. Scheetz[1,2], K. Cribben[2], T.L. Casavant[1,2,3], T.A. Braun[1,2], J.H. Fingert[1], E.M. Stone[1,4], V.C. Sheffield[1,4,5].* 1) Dept Ophthalmology, University of Iowa, Iowa City, IA; 2) Dept Biomedical Engineering, University of Iowa, Iowa City, IA; 3) Department of Electrical and Computer Engineering, University of Iowa, Iowa City, IA; 4) Howard Hughes Medical Institute, Iowa City, Iowa; 5) Department of Pediatrics, University of Iowa, Iowa City, IA.

We have developed and successfully utilized a system biology strategy for disease gene prioritization. This system utilizes multiple networks of correlated gene expression to prioritize candidate disease genes. This system extended the original NPCE algorithm (Non-Positional Correlation of Expression; Scheetz et al. 2006) by: (1) incorporating a network-based analysis strategy, (2) supporting the integration of multiple expression data sets, and (3) utilizing comparative methods to integrated data among multiple species. The performance of the system was assessed using the traditional area under the curve (AROC) measurement. For genes known to cause retinitis pigmentosa, we achieved an AROC of 0.896. Of interest, just over half of the RP genes are prioritized very well, falling in the top few percent in a prioritization of all genes. The remaining genes are less specifically prioritized, although the "worst" prioritization was in the top half of all prioritized genes. In contrast the genes known to cause Bardet-Biedl syndrome were all prioritized very well with this enhanced system, with an AROC of 0.954. All of the BBS genes are prioritized in the best 15%, with most in the best 1% of all prioritized genes. We are currently pursuing mutation discovery in prioritized candidate retinal degeneration genes in previously mapped intervals in which the gene has not been identified. Scheetz et al. (2006) Regulation of Gene Expression in the Mammalian Eye and its Relevance to Eye Disease. Proc Natl Acad Sci USA, 103(39):14429-34.

## 2698/F/Poster Board #246

**Which Comes First - Lab or LIMS? The Tandem Implementation of a Laboratory Process and a Laboratory Information Management System (LIMS).** *M. Singleton[1], T. Tait[2], C. Hull[3].* 1) Laboratory Management, Axial Biotech, Salt Lake City, UT; 2) Information Technology, Axial Biotech, Salt Lake City, UT; 3) Administration, UNIConnect, Sandy, UT.

Axial Biotech was founded by top spine surgeons and geneticists focused on developing genetic tests and treatments for spinal disorders. The research developed into a clinical genetic test providing a prognosis for the advancement of Adolescent Idiopathic Scoliosis, ScoliScore. This test required a software system to track and regulate the lab and maintain quality control. Axial faced an issue similar to most labs: Do they develop the lab around LIMS, or LIMS around the lab? Axial elected to implement a LIMS early in the process that enabled a focus on customization in tandem with the development of lab processes. The UNIFlow platform was selected for its rapid adaptability. UNIFlow also offered the ability to be configured by non-programmers at Axial. An Axial team comprised of the VP of Clinical Operations, the IT Director, and the Lab Scientist attended a 3 day training session to understand the system's potential. As the ScoliScore test got closer to a launch, the VP created the LIMS vision, the Scientist outlined the process, and the IT Director configured it. With the addition of new equipment or a new assay, LIMS was configured to adapt to new processes including quality control, and physicality of performing the assay. The process of design-create-test continued over the next 9 months culminating in a LIMS that tracked the complete process. In Sept. of '08, the lab was inspected under CLIA/CAP guidelines as part of funding requirements. The auditors found very few issues surrounding the testing process that were not controlled or tracked by the LIMS. In time, the LIMS became an exact reflection of their processes, having been designed and built by Axial personnel, those who perform the lab processes on a daily basis, all built within the UNIFlow platform. In Jan. of '09, Axial went through a CAP inspection. The auditors were impressed with LIMS management and accounting for the lab processes and the inspection resulted in zero deficiencies. Conclusion: Which came first - Lab or LIMS? In the case of Axial, both. The development of a process specific LIMS greatly impacted the quality of the lab. The success of the lab in terms of daily sample processing, regulatory audits, and overall quality has been driven by the use of a customizable and flexible LIMS without having to bend and shape the lab processes to fit a preexisting mold. UNIFlow put the power to improve the system in the hands of the technician, rather than a hired programmer.

## 2699/F/Poster Board #247

**Comparision of Next Gen sequencing technologies and bioinformatic analysis tools - Case studies on different projects.** *K. Stangier.* GATC Biotech AG, Konstanz, Germany.

Objectives: Next Generation sequencers, e.g. Roche GS FLX and Illumina Genome Analyzer II, have been on the market for quite some time. A variety of different projects now reveal the pros and cons of each technology. The projects performed by GATC show that the use of one technology alone does not deliver the best results for all projects. Rather a combination of two or three technologies provides a more complete, cost-effective analysis. In addition to sequencing, bioinformatic analysis is critically important for gaining an in-depth understanding of the biological significance of the sequence data. The combination, analysis and visualisation of these data are key challenges to the successful application of the Next Generation sequencing technologies. Methods and results: Having performed many projects, each with a different set of questions and goals. GATC presents sequencing data using single and paired end sequencing methods on different systems. Sequencing of mate pairs, especially using libraries with large inserts, helps tremendously to improve assemblies and alignments. GATC uses a wide range of bioinformatic solutions for genome assembly and alignment, transcriptome analysis and other studies. We will present data comparing different bioinformatic tools which are available on the market. Conclusion: To ensure a successful sequencing project and to maximise the information obtained, it is necessary to choose the best Next Generation technology or combination of technologies followed by bioinformatic analysis using a pipeline consisting of state-of-the-art analysis tools.

## 2700/F/Poster Board #248

**The role of microRNA in the development of oxLDL-induced atherosclerosis.** *Y. Wang, S. Juo.* Graduate Institute of Medical Genetics, Kaohsiung Medical University, Kaohsiung, Taiwan.

Background: The migration and the proliferation of vascular smooth muscle cells (VSMCs) are critical to the initiation and development of atherosclerosis. Evidence suggests that microRNAs (miRNAs) might be involved in atherosclerosis. The aim of the present study is to investigate the role miRNAs in oxidized low density lipoprotein (ox-LDL) induced atherosclerotic responses in human VSMC and the differential expression after an anti-atherosclerotic chemical compound, saponin. Methods: VSMCs were treated with ox-LDL with and without saponin for 4 hrs and total RNA was extracted. miRNAs expression profiling was measured using the TaqMan Array Human MicroRNA. Expression level of each miRNA was determined with $\Delta$CT by subtracting CT of endogenous control RNU48. Differentially expressed miRNAs were calculated by StatMiner software. Results: After treating VSMC with ox-LDL, we found that 85 miRNAs decreased expression levels by at least 2-fold. Treating VSMC with saponin in the presence of ox-LDL, the cell proliferation was reduced compared with the cells only treated by ox-LDL. In addition, we found 7 miRNAs increased expression by at least 2-fold in the saponin treated group compared with the group with oxLDL. Three of the seven miRNAs with increased expression were in the miR-15 family. miRNAs in this family have been speculated to be involved in cell progression, inflammation, cell death and angiogenesis according to the information from the Sanger miRBase. Conclusions: Our results show miRNAs are involved in ox-LDL induced atherosclerosis, and some of these miRNAs may account for anti-atherosclerotic drug effect.

## 2701/F/Poster Board #281

**Data Storage & Archiving for High-Throughput Genotyping.** *L. Watkins, G. Lowe, E. Hsu, K. Roberts, J. Goldstein, M. Barnhart, D. Leary, K. Hetrick, B. Craig, E. Pugh, C. Ongaco, M. Zilka, J. Romm, K. Doheny.* Center for Inherited Disease Research, Johns Hopkins University, Baltimore, MD.

The Center for Inherited Disease Research (CIDR) began offering GWAS services in 2006, ramping up to full-scale production in 2007, expanding in 2008 to include both Affymetrix® and Illumina® platforms. A major consequence has been a vast increase in the rate and volume of data production. This requires a flexible and rapidly-evolving strategy for data storage and archiving. Starting with a few Illumina BeadArray® Readers, existing CIDR informatics infrastructure was initially able to handle all data produced. Scanner raw data was written to a network folder on a Windows fileserver connected to a Storage Area Network System (SANS), which also stored all downstream data. All of this data was retained and manually curated within a highly structured Windows/SANS filesystem. The advent of large-scale GWAS required several adaptations as more data was produced much faster. So we developed a combined genotype calling & data archiving pipeline to address these issues. Analytical data and QC metrics were automatically moved into project-specific SANS folders, with raw data files compressed on disk and copied to tape. By mid-2007 archiving was re-directed to 4TB Linux-based storage appliances. Soon even this solution became inadequate, unreliable and difficult to manage. For archival storage we then adopted CAStor, an easy to manage, highly reliable but arbitrarily large global filesystem. Still, active analytical data often exceeded the 2TB Windows/SANS limit. So in 2008 we added a large Isilon network-attached storage cluster for both raw and analytical data. By fall 2008 higher-capacity scanners and multi-sample chips pushed data production up to 12TB/week - unsustainable by almost any measure. Thus, in early 2009 we began intensive consultation among CIDR staff and external experts to redesign our storage/archiving scheme. We concluded that raw images (TIFF files) could be deleted if bead-level intensity files were preserved, bringing data output back down around 2-3TB/week. We also developed a data triage protocol whereby classes of files are archived and/or deleted at each production phase, thereby reducing the net rate of data growth. We continue to pursue every avenue to meet the data storage & archiving challenge, including 10-gigabit networking; data compression and de-duplication; filesystem virtualization to separate physical from logical storage, allowing change and growth without disruption; and ever-increasing storage density and efficiency.

## 2702/F/Poster Board #282

**Snipper: a research tool for extracting and searching biological annotations on genes near SNPs.** *R.P. Welch[1], C.J. Willer[2], L.J. Scott[2], M. Boehnke[2].* 1) Bioinformatics Program, University of Michigan, Ann Arbor, MI; 2) Department of Biostatistics, University of Michigan, Ann Arbor, MI.

Genome-wide association studies (GWAS) have provided a flurry of disease-associated loci, many of which span or are located near multiple genes. It is often unclear which of these genes may be influencing the disease or trait of interest. Functional studies can shed some light on the problem, however only a small number of genes can be interrogated as the cost and time for such studies are typically high. Therefore, prioritizing genes for functional follow-up work is an important task. To this end, we present Snipper, a command-line software utility for locating genes near associated SNPs, downloading their biological annotations from NCBI databases, and searching these annotations for information relevant to the disease or phenotype under study. Snipper is able to perform these functions simultaneously on all associated SNPs from a GWAS study, typically in a matter of minutes. The program then sorts the genes by various criteria, such as the distance to the associated SNP, the number of PubMed articles linked to the gene matching search terms, and the number of biological annotations from NCBI Entrez Gene that match search terms. This information is then exported to a formatted report file. The researcher can use this wealth of information when considering genes for future study. In contrast, collecting this information by manually navigating the NCBI databases takes hours, and searching it requires considerably more time. We present examples of Snipper's usage, including analysis of novel loci discovered by a recent meta-analysis of type 2 diabetes genome-wide association studies as part of the DIAGRAM consortium. We also discuss future additions to Snipper, including searching public eQTL, gene/protein and protein/protein interaction databases. Snipper is open-source and freely available software, written in Python and able to run on Windows, Mac OS X 10+, and most variants of Unix and Linux.

## 2703/F/Poster Board #283

**Integration of gene expression and SNP data in pathway based analyses.** *Q. Xiong, S. Mukherjee, T.S. Furey.* IGSP, Duke University, Durham, NC.

We propose a framework to integrate gene expression and genotype assays for pathway based association analysis. The central idea is to extend increasingly popular pathway based gene expression analysis, also known as gene set analysis, to incorporate genotype or SNP data. Pathway based analysis using gene expression data aims to find concerted differential expression between case and control samples over a set of a priori defined gene sets. We extend this approach to identify pathways associated with clinical phenotypes in terms of gene expression, SNP variation, or both genomic assays. The integration of biological evidence both across genes in defined pathways as well as across genomic assays can result in the inference of associations that are more robust and comprehensive. In addition, significant variation associated with a phenotype for both genetic and gene expression variation provides greater information on the possible mechanism underlying a disease. This integrative analysis may also suggest whether cis-regulation or trans-regulation is more relevant for the disregulation of a particular pathway. We apply this method to simulated genotypic and expression data to illustrate the modeling principles and interpretation of the data. We further validate the method on gene expression data and genotype data from 14 cancer cell lines with sensitivity/resistance to docetaxel as phenotypes. The 379 gene sets in the molecular signatures database (MSigDB) were used as the pathway database. Three differential pathway enrichment analyses were evaluated: differential enrichment of expression data alone (GSEA); differential association with respect to SNPs mapped to the genes defining these gene sets (GSEA_SNP); and integrative analysis of evidence for differential association in expression and with respect to SNPs (GSAA). We found that a large number of phenotype-associated genes were enriched in the top-ranked pathways. We also can identify two important genes, AKT1 and PIK3CA in the phosphatidylinositol 3-kinase(PI3K)-AKT pathway, which has been proved to play an important role in the resistance to docetaxel or other chemotherapeutic agents. These analyses required the development of a novel gene set enrichment methodology we call gene set association analysis (GSAA) that integrates expression and SNP data in a gene set framework. These analyses also involved the adaptation of gene set enrichment analysis (GSEA) to genotype data that we call GSEA_SNP.

## 2704/F/Poster Board #284

**GenePipe: A high performance bioinformatics pipeline for large-scale human genomic variation studies.** *A. Yao[1,2], C.K. Liu[2], Y.H. Chen[2], Y.J. Lin[2], C.Y. Tang[2], Y.C. Cheng[2], M.F. Tsai[2], Y.T. Chen[1,2].* 1) Biomedical Sciences, Academia Sinica, Taipei, Taiwan, Taiwan; 2) National Genotyping Center, Academia Sinica, Taipei, Taiwan, Taiwan.

With the flood of information generated by the new generation of sequencing technologies, there is a great need for more efficient bioinformatics tools with which to organize and analyze the tremendous amount of information regarding genetic variations. As a result, we have developed GenePipe 3.0 (http://genepipe.ngc.sinica.edu.tw/ngwelcome.do), a tool capable of processing hundreds of candidate markers (or regions) and thousands of neighboring variations in a matter of minutes to facilitate genome-wide association studies as well as studies of other diseases involving novel variations, such as cancer. GenePipe has three major components: VarioWatch, PrimerZ, and QualiSeq. VarioWatch not only integrates important information from various databases such as dbSNP, UniProt, KEGG, Gene Ontology, etc. for browsing but also incorporates in-depth functional analysis information on both known and novel variations. For greater user convenience, VarioWatch accepts four common query types such as gene name, SNP ID, and physical position in either single or batch query mode. Returned results are classified into four specially designed Views. The first of these, Genome View, shows an overview of the positions of queried markers on chromosomes and their possible functional impacts. Clicking on an interesting variation will lead to Gene View, which displays genes and associated variations close to the marker. In addition, annotations for each gene of gene function, tissue-specific expression, diseases, sub-cellular location, pathway, and Gene Ontology are also included here. At the gene transcript level, Transcript View shows gene structure and SNP distribution. Clicking on SNP directs one to Variation View which provides very detailed information of the variation such as risk type, risk level, allele change, amino acid change, codon position, amino acid position and describes the functional impact analysis flow. If interesting genes or variations are found, their primers can be easily designed by the second component, PrimerZ. Moreover, their flanking sequences can be directly downloaded by the third component, QauliSeq, for further bioinformatics analysis. The use of GenePipe as a high performance bioinformatics pipeline provides a very efficient tool for large-scale genomic variation studies. Currently, GenePipe mainly covers point variations but will be extended to cover copy number variations and micro RNAs by the end of 2009.

## 2705/F/Poster Board #285

**The Global Problem of Mapping Gene Identifiers to HUGO Gene Symbols and Responsibility for Dissemination of Errors.** *N. MacLennan, A. Presson, E.R.B. McCabe.* University of California, Los Angeles, Los Angeles, CA.

Background: Genetic databases contain a variety of annotation errors that often go unnoticed, especially in microarray analysis with large data sets where investigators are removed from the raw data by algorithms that are not always accurate. Correct mapping of identifiers (IDs) such as microarray probe (PIDs), genbank (GB), and entrez gene (EG) IDs to HUGO gene symbols (GS) is an important but reputedly trivial task. We show that third party pathway analysis software contributes to the annotation problem by not mapping probe sets to GS according to the chip manufacturer's recommendation. Objective: To study annotations and assess whether this is a more global problem. Methods: We compared the Affymetrix (Affy) GS annotations for 678 Mouse 430 v.2.0 PIDs to Ingenuity Pathways Analysis (IPA) software annotations for four IPA releases (2008 to 2009). We analyzed the full Affy mouse 430 2.0 array using IPA, GeneGO and Pathway Studio and compared PID, GS, GB, and EG ID annotations. Results: There were notable mapping changes among the four IPA releases. In March 2008, 25/678 probes were not annotated by Affy (Mouse430_2.na24.annot.csv), 24/678 were not annotated by IPA (v6.0) and 13 were not mapped by either. In October 2008, about the same number of PIDs were unmapped (24/678) by Affy (Mouse430_2.na25.annot.csv), but the number unmapped by IPA (v6.5) more than tripled (90/678). A comparison of IPA, GeneGO and PathwayStudio for the Affy mouse 430 v2.0 showed that all programs mapped different numbers of the four identifier types (PID, GS, GB, EG), and these differed from the corresponding Affy annotation numbers. Conclusions: Researchers must be aware of potential annotation errors that can occur when identifiers are translated or mapped to other identifier types. We provide suggestions to mitigate this problem. Recommendation: Companies should inform their customers of mapping discrepancies and any annotation errors in the software. However to this date, nothing has been disseminated about the mapping issues we experienced in 2008 and 2009. Therefore, we propose a web site dedicated to sharing and discussing experiences with scientific software and databases. This web site would centralize information on experiences with software tools and alert others to scientific issues, problems encountered in biological research, troubleshooting websites and recommendations for corporate responsibility to prevent propagation of errors.

## 2706/F/Poster Board #286

**Spectral error correction and de novo assembly for bacterial genomes from short mate pair reads.** *E. Spier, D. Brinza, Z. Zhang, H. Tu, N. Mullaken, C. Cummings.* Bioinformatics R&D, Applied Biosystems, Foster City, CA.

It is generally considered impossible to generate de novo assembly from short reads if the error rate is > 3% [1]. Spectral error correction was previously used for short sequencing reads to decrease error rates prior to assembly [1]. We describe spectral error correction method for two base encoded (2-BE, aka color-space) SOLiD reads and show that it decreases error rate for 50-mers from 3-4% to less than 1%. We use color-call (phred-like) quality values (QVs) to build the spectrum: a list of k-mers (we found that k=17 works the best for bacterial genomes) that frequently occur in reads. We implemented a dynamic programming algorithm to correct color-calls in reads based on their QVs and the spectrum. One of the challenges for base-based error correction is that it is prone to overcorrection in duplicated regions. A single base difference show as two adjacent color call changes in 2-BE reads and we implemented a rule not to correct adjacent "errors" thus dramatically decreasing the risk of overcorrection. Decreased errors enable meaningful de novo assembly for both 2x25 and 2x50 long mate pairs: We used velvet_de [2] to assemble 98% of the Listeria (2.7 Mb) genome into 8 scaffolds (N50=1.4 MB for scaffolds and 6Kb for contigs) from 140x coverage 2x25 long mate pair data set. 200x coverage for a 2x50 long reads from E.coli produced assembly of similar quality. 2-BE enables error correction in diploid data because two SNP alleles differ by two color calls and therefore we cannot overcorrect from one allele into another. We demonstrate that spectral error correction decreases false positive and false negative SNP calls in human targeted resequencing data. We think that spectral error correction will be an integral part for next generation sequencing data analysis pipelines for both de novo and resequencing applications.

**SCAN: SNP and Copy number Annotation.** *E. Gamazon[1], S. Duan[1], A. Konkashbaev[1], W. Zhang[1], E. Kistner[4], D. Nicolae[1,2], M.E. Dolan[1], N. Cox[1,3].* 1) Department of Medicine, University of Chicago, Chicago, IL; 2) Department of Statistics, University of Chicago, Chicago, IL; 3) Department of Human Genetics, University of Chicago, Chicago, IL; 4) Department of Health Studies, University of Chicago, Chicago, IL.

The large-scale genotype data available in the HapMap project has revolutionized our ability to understand human genetic variation, including patterns of linkage disequilibrium (LD). Lymphoblastoid cell lines (LCLs) from the individuals included in the HapMap project have been used extensively in gene expression studies, and the combination of the large-scale genotype and transcript level information in the same set of individuals has facilitated genome-wide association of expression phenotypes. The SCAN database leverages these dual successes of the HapMap project in order to facilitate a novel approach to annotating genetic variation with information useful in prioritizing follow up studies at the level of SNPs, CNVs and genes. SCAN encompasses a large-scale extensible database with a web interface and a set of methods and algorithms; it includes not only physical and functional annotations currently distributed across several public databases, but also summary data not available elsewhere, including multilocus linkage disequilibrium annotations as well as annotations showing association of a variant to gene expression at a user-specified threshold. For each SNP, SCAN is intended to provide: 1. summary information from analyses conducted to characterize HapMap SNP associations to gene expression in the full set of HapMap LCLs derived from individuals of European (CEU) and African (YRI) ancestry for over 13,000 transcript clusters evaluated using the Affymetrix GeneChip ® Human Exon 1.0 ST Array 2. LD information, including what genes have variation in strong LD (pairwise or multilocus) with the variant, and how well the SNP is interrogated (i.e. multilocus LD measure) by SNPs on each of the high-throughput genotyping platforms. For each gene, SCAN provides annotations on: 1. all expression quantitative trait loci (eQTLs) that predict the expression of the gene (at user-specified thresholds for cis- and trans-regulators) 2. how well all variants in the HapMap at the gene are interrogated on each high-throughput platform (using several multilocus LD coefficients for each SNP within and up to 2 kb from the gene). For each region, SCAN provides: 1. physical and functional annotations of all SNPs, genes, and known CNVs within the region 2. all genes regulated by eQTLs within the region at a user-specified threshold.

## 2708/F/Poster Board #288

**Type 2 Diabetes Mellitus Genetic Association Database.** *J.E. Lim[1], H-S. Jin[1], K-W. Hong[1], J.T. Woo[2], H.K. Park[1], B. Oh[1].* 1) Department of Biomedical Engineering, School of Medicine, Kyung Hee University, Seoul, Korea; 2) Endocrinology and Metabolism, School of Medicine, Kyung Hee University, Seoul, Korea.

The prevalence of type 2 diabetes mellitus has been epidemic worldwide with the greatest increase in Asia, Africa, and South America. The life-threatening complications of diabetes sometimes devastate patients from the retinopathy, nephropathy, lower-limb amputation caused by the continued exposure of tissue to the high glucose. Since the hyperglycemia could be prevented and reversed greatly by changing the life style including the exercise and nutrition, the diabetes risk tests, such as one provided by American Diabetes Association, have been used to alarm the high risk group. However, the increase of diabetes incidence has not been stopped for the last decade, demanding new approaches. Following the growth of genomics, the disease susceptibility of human genetic variations has successfully been explored to provide the better understanding for the development of diabetes mellitus. Since the discovery of TCF7L2 gene in 2006, more than 15 genes have been confirmed to be replicated from diverse populations. "Type 2 Diabetes Mellitus Genetic Association Database" has been constructed to collect published results of genetic association studies related to type 2 diabetes mellitus. HuGE Navigator (version1.3, http://hugenavigator.net) was used to ascertain the publications for the database. The information of the database was extracted from 572 publications of diabetes association studies. Each entry of a gene contains 12 attributes, such as gene, rs number, PubMed ID, population, sample size, odds ratio, p-value, association study result etc. The data was graphically displayed to provide the association results better to researchers. Eventually, the diabetes genetic association database will be utilized to make a computer program which provides health care providers with the individual susceptibility to diabetes for the personalized medicine, and could be expanded for the selection of high risk group for the preventive medicine.

**On design of deep-sequencing experiments.** *A. Bashir[1], V. Bansal[2], V. Bafna[1].* 1) Computer Science, University of California, San Diego, La Jolla, CA; 2) Scripps Genomic Medicine - Scripps Translational Science Institute, The Scripps Research Institute, La Jolla, CA.

New technologies have made it possible to sequence populations of individuals. The abundance of technologies and applications of sequencing pose a number of design challenges, regarding the technology to be used and the depth of sequencing. Here we describe a number of analytical and empirical results to address these questions. Specifically, we focus on detection of structural variations, transcript abundance and haplotype assembly. Our results provide explicit trade-offs between detection and resolution of rearrangement breakpoints, and the optimal mix of paired-read insert lengths. Specifically, we prove that optimal detection and resolution of breakpoints is achieved using a mix of exactly two insert library lengths. Furthermore, we derive explicit formulae to determine these insert length combinations, enabling a 15% improvement in breakpoint detection at the same experimental cost. On empirical short read data, these predictions show good concordance with Illumina 200bp and 2kb insert length libraries. For transcript sequencing, we determine the sequencing depth needed to detect rare transcripts from a small pilot study. With only 500,000 reads, we can derive corrections that enable nearly perfect prediction of the underlying expression pdf, and use this to to predict the sequencing depth required to detect low expressed genes with greater than 95% probability. For haplotype assembly, we empirically estimate the N50 haplotype lengths for a range of sequence read lengths and insert library lengths. We demonstrate how paired-end sequencing with a mix of insert sizes currently available for the Roche 454 platform can enable the reconstruction of long haplotypes with modest sequencing depth. For very short reads, using an appropriate mix of insert sizes, we can obtain N50 lengths of 200 kb at ~ 50x sequence coverage. Our results provide platform independent guidelines for designing sequencing experiments (amount of sequencing, choice of insert length, library mixtures) that will continue to be applicable as sequencing technology rapidly evolves. They also reveal interesting trade-offs; structural variation is best detected with low variance in insert lengths, but the reverse is true for haplotype assembly. Additionally, the transcriptomic results help direct the number of different samples to pursue in a large-scale sequencing survey. Together, these form a generic framework for many design considerations related to high-throughput sequencing.

## 2710/F/Poster Board #290

**Accurate Follow-up SNP Selection.** *E. Kostem[1], J. Lozano[3], E. Eskin[1,2].* 1) Computer Sci Dept, UCLA, Los Angeles, CA; 2) Human Genetics Dept, UCLA, Los Angeles, CA; 3) Computer Sci Dept, University of the Basque Country.

Genome-Wide association studies aim to identify regions associated with complex human diseases by collecting genetic variation data, such as SNPs, from case and control individuals. An informative subset of SNPs, called tagSNPs, are selected to serve as proxies for the rest of the SNPs. Once these tagSNPs are genotyped, an association statistic is calculated for each. Significantly associated tagSNPs indicate a potential causal variant in their linkage disequilibrium block. Once these regions are detected, there is substantial interest in identifying all of the associated SNPs in these regions so that the causal variant can be determined. A cost effective approach is to perform a follow-up study which collects additional SNPs, called follow-up SNPs, and genotypes them in the same case/control individuals. In this work, we address the problem of selecting the follow-up SNPs which are more likely to be associated based on the information available from observed tagSNPs and reference data on human genetic variation such the HapMap. We analyze the problem in a statistical framework based on the causal relationship between SNPs, evaluate the performance of the traditional SNP selection approach is in terms of its accuracy and statistical power. A selection method is proposed that is optimal in accuracy and benchmark results on simulated data from the ENCODE region are presented.

## 2711/F/Poster Board #291

**Computational identification of transcription factors involved in obesity identifies variation in SPI1 affecting body mass index.** *J.M. Lane[1], L.D. Parnell[1], J.P. Fortin[2], A.S. Kopin[2], J.M. Ordovas[1].* 1) Jean Mayer US Department of Agriculture Human Nutrition Research Center on Aging at Tufts University, Boston, MA; 2) Molecular Pharmacology Research Center, Molecular Cardiology Research Institute, Tufts University School of Medicine, Boston, MA.

Obesity is a complex disease that involves multiple tissues. Research in human populations is especially difficult because of gene-by-environment interactions. Here, we show that starting with data from a fat storage candidate gene screen in *C.elegans*, a novel bioinformatics approach can be used to generate candidate transcription factors (TFs) involved in obesity. In brief, human homologs of worm fat storage genes were identified. The human homologs were grouped according to function and biological process as evidence suggests that TFs control groups of genes with similar function. Then, to determine if the genes in each functional group are coordinately regulated, the upstream region of each gene in the group was scanned for putative common transcription factor binding sites (TFBS). TFBS motifs that occurred in genes within a group but not in random sets of genes were of interest. The TFs that bound to the TFBS of interest then became candidate TFs for involvement in obesity. Computationally identified TFs were validated by microarray expression analysis of differentiating preadipocytes. Our novel method identified SPI1 as a candidate TF involved in obesity. In addition, we identified variants of SPI1 that associate with obesity related traits. The single nucleotide polymorphism (SNP) rs4752829 associates with BMI in a White population. Recently, it has been demonstrated that SPI1 is expressed in white adipose tissue (Wang F et al. 2008) and that overexpression of SPI1 inhibits adipogenesis. Our studies confirm these findings in OP9 preadipocyte cells. We are currently examining the effects of SPI1 depletion on adipogenesis. Overall, this approach demonstrates the value of utilizing publicly available data and model organisms in order to gain insight into a complex human condition.

## 2712/F/Poster Board #292

**Characterizing Gene-Gene Interaction by Transitional Dynamics in Times Series Microarray Data.** *P. Song[1], X. Gao[2], Q. Pu[2].* 1) Biostatistics, Univ Michigan, Ann Arbor, MI; 2) Mathematics and Statistics, York University, Toronto, Ontario, Canada.

Gene-Gene dependency plays a very important role in system biology as it pertains to the crucial understanding of different biological mechanisms. Time-course microarray data provides a new platform useful to reveal the dynamic mechanism of gene-gene dependencies. Existing interaction measures are mostly based on association measures, such as Pearson or Spearman correlations. However, it is well known that such interaction measure can only capture linear or monotonic dependency relationships but not for nonlinear combinatorial dependency relationships. Further, when computing correlation measures, the observations across different time points have to be considered as independent replications, which ignores the dependencies across time points. With the invocation of hidden Markov models, we propose a new measure of pairwise dependency based on transition probabilities. The new dynamic interaction measure essentially checks whether or not the joint transition kernel of the bivariate state variables is the product of two marginal transition kernels of each of two state variables. This new measure enables us not only to evaluate the strength, but also to infer the details of gene dependencies. It reveals nonlinear combinatorial dependency structure in two aspects: between two genes and across adjacent time points. We conduct a bootstrap-based chisquare square test for presence/absence of the dependency between every pair of genes. Simulation studies and real biological data analysis demonstrate the application of the proposed method.

**Genome-Wide Noncoding RNAs Discovery and Characterization.** *J. Li[1], H. Tseng[2], B. Zhang[1], X. Zhang[1], J. Hansen[3], W. Ruzzo[2], L. Zhao[1].* 1) Quantitative Gen Epidem, Fred Hutchinson Cancer Research Center, Seattle, WA; 2) Computer science and Engineering , University of Washington, Seattle, WA; 3) Clinical division, Fred Hutchinson Cancer Research Center, Seattle, WA.

The recent waves of genome wide association studies (GWAS) on complex human diseases such as heart diseases, cancers and mental disorders have led to many discoveries of genetic markers, many of which fall in poorly annotated noncoding regions triggering great interests in functional annotation of noncoding RNAs (ncRNAs). While several methods have been used to discover and annotate ncRNA, we propose a two-stage approach to systematically screen for ncRNAs throughout the human genome. The first stage is to screen for all the ncRNA candidates, based on Watson-Crick base-pairing principle that has been shown to be a universal characteristic for all experimentally studied miRNAs and siRNAs. The second stage involves secondary structure prediction and statistical analyses with Hidden Markov Model (HMM) and logistic regression model to determine the candidacy of ncRNAs and their annotations. As a proof-of-principle, we have applied this strategy to our recent GWAS results, and have identified ncRNAs, their targets and associated signaling pathway which may be associated with acute graft-versus-host disease. In this presentation, we will report the genome-wide ncRNAs discovery and characterization results, results from which will be made available to public via QGE web site at Fred Hutchinson Cancer Research Center (http://qge.fhcrc.org/).

## 2714/F/Poster Board #294

**A Bayesian approach to significant analysis of dual channel RNAi data with replications.** *C.Y. Chen[1], I.S. Chang[1,2], C.H. Chen[1], C.A. Hsiung[1].* 1) Division of Biostatistics and Bioinformatics, National Health Research Institues, Miaoli, Taiwan; 2) Institute of Cancer Research, National Health Research Institues, Miaoli, Taiwan.

RNAi (RNA interference) is a conserved biological mechanism to silence gene expression on the level of individual transcripts. Cell-based RNAi screens can be used to identify genes whose mutation leads to an altered phenotype relevant to a specific pathway. Rapid reverse genetics by RNAi allows the systematic screening of a whole genome whereby every single transcript is depleted by siRNAs, dsRNAs or shRNAs. Genes with unknown functions can then be classified according to their phenotype. However, issues such as interferon response and off-targeting effect on essential genes induced by RNAi vectors justify the incorporation of viability into the analysis. We therefore consider an RNAi high throughput screening experiment in which two phenotypes are monitored; one measures cell viability and the other measures the phenotypic value representing the activity of a particular pathway. We are interested in genes that do not affect the cell viability but are involved in this particular pathway. For each shRNA, the experiment is replicated in 2J wells in which J of them are used to measure the cell viability and the other J replicates are used to measure the activity of the pathway. We propose a Bayesian data analysis method that utilizes this data duplication. Both simulation studies and validation studies are carried out to indicate its usefulness and performance. Simulation studies indicate that this Bayesian approach is capable to utilize the duplication to take care of both false discovery rate and false negative rate in identifying the interested genes. In an RNAi experiment having 6552 RNAi wells and 426 controls wells, using 281 of these controls for normalization purposes, we find none of the remaining 145 controls in the top 900 shRNAs showing significant phenotypic effects.

## 2715/F/Poster Board #295

**Genome-wide characterization of genetic variants using SIFT web server.** *P. Kumar[1], P. Ng[1,2].* 1) Department of Genomic Medicine, J. Craig Venter Institute, San Diego, CA; 2) Fred Hutchinson Cancer Research Center, Seattle, WA.

Human genetic variation data will increase in size as a result of high-throughput next-generation sequencing platforms that enable whole genome sequencing, exome sequencing and targeted gene re-sequencing for multiple individuals. The 1000 Genomes Project for example, aims to sequence the genomes of at least one thousand individuals from different ethnic groups over the next three years. Therefore, there is an increasing need to characterize and predict the effects of coding genetic variants on protein function and potentially on the phenotype of an individual.

Non-synonymous single nucleotide polymorphisms (nsSNPs) are the types of genetic variants that cause an amino acid substitution (AAS) in the corresponding protein. “Sorting Tolerant From Intolerant” (SIFT) is an algorithm that uses sequence homology and evolutionary conservation of amino acids in a protein to predict the effects of AASs on protein function. Recognizing researchers’ need for high throughput analysis of genetic variants, we have improved SIFT by adding new ‘Batch Tools that characterize and provide predictions for variants occurring at multiple genomic coordinates or in multiple proteins. SIFT can perform high throughput genome-wide variant analysis within a short time, enabling researchers to prioritize their variants for further analysis. SIFT is available as a web-tool at http://sift.jcvi.org.

## 2716/F/Poster Board #296

**Bioinformatic scoring of structural genomic variations on a universal scale of allele-specific functional difference.** *J.L. Rodriguez-flores[1], T. Gaasterland[2].* 1) Bioinformatics Graduate Program, Univ California, San Diego, La Jolla, CA; 2) Laboratory of Computational Genomics, Univ California, San Diego, La Jolla, CA.

Guame (phonetic goo-ah-meh) is Puertorrican slang for an easy task. Bioinformatically predicting genetic polymorphism function is NOT a guame because: (1) Most GWAS associated SNPs have unknown function, (2) recently discovered structural variations and epigenetic modifications expand the list of functional possibilities, (3) no universal scoring method exists. Functional prediction methods for SNPs such as SIFT (Ng02) and RAVEN (Andersen08) construct a PSSM from experimentally-verified homologous sequences to represent the probability distribution of amino acids or nucleotides at each position in a sequence or motif. We construct PSSMs for copy number variations using hundreds of CNV hotspots in 20 chimpanzees (Perry06) and 100 humans (Wong07), and integrate PSSM-based scoring for polymorphism classes (nonsynonymous, regulatory and structural) into a universal scoring method and webserver called Guame (http://snp.ucsd.edu/guame). This work demonstrates that any polymorphism can be represented using a PSSM and scored (including microRNAs, splicing, and CpG methylation) in a three-step process: (1) Classification of the polymorphism based on the molecular genomic change (SNP, indel, CNV), (2) selection of the appropriate PSSM library based on the known cellular function of the affected genomic sector (coding, regulatory, intronic), and (3) sub-class by functional change (amino acid substitution, premature stop codon, motif destruction, CNV doseage, alternative splicing). In addition to presenting the method and webserver, we demonstrate how the method works using polymorphisms, including a Gly->Ser nonsynonymous amino acid substitution in catestatin, a G->A SNP in the PNMT promoter which disrupts a mammalian-conserved G-rich Sp1 binding site, and a CNV hotspot in CCL3L1 correlated with HIV-1 infection.

## 2717/F/Poster Board #329

**How should orthologous sequences be used to predict the impact of amino acid substitutions on protein function? An experimental test of substitutions in human MTHFR.** *N. Marini[1], P. Thomas[2], J. Rine[1].* 1) California Institute for Quantitative Biosciences, University of California, Berkeley, CA; 2) Evolutionary Systems Biology Group, SRI International, Menlo Park, CA.

Comparative sequence data can potentially provide two types of information useful for predicting the effect of a nonsynonymous coding variant in a human gene. Evolutionary conservation of an amino acid is indicative of negative selection against impaired variants. Conversely, the presence of a divergent amino acid at a homologous site in an orthologous protein is generally taken to be indicative of a functional variant fixed by neutral drift or positive selection. In practice, most sites in a group of related proteins are both partially conserved and partially divergent, yet little is known about how these two signals should be balanced in predictions. We examined this question by evaluating nonsynonymous substitutions in a prototypical enzyme, human methylenetetrahydrofolate reductase (MTHFR), in a cell-based assay based on yeast complementation. The results demonstrated that, as expected, substitutions in human MTHFR at sites that are conserved in orthologs from all domains of life result in an impaired enzyme, while fixed substitutions in very recently diverged sequencesincluding a five-site mutant that "resurrects" the human-chimp common ancestorresult in a functional enzyme. Assays of a number of substitutions at sites conserved for varying lengths of time indicated that, whenever conservation is observed among all known deuterostome orthologs (most recent common ancestor ~500 million years) amino acid substitutions are nearly always impairing, even though these substitutions have been fixed at that site in a more distant ortholog. When conservation is observed for shorter periods, nearly all substitutions we tested were functional, suggesting that at these sites amino acid conservation may be due not only to strict negative selection, but also insufficient opportunity to fix other functional variants. We conclude that for human MTHFR, orthologous genes from other deuterostome species are consistently informative for predicting the effects of amino acid substitutions, while more distant orthologs are not.

## 2718/F/Poster Board #330

**Transposases phylogeny outlying clasic taxonomy.** *J.A. Morales[1], E. Borrayo-Carbajal[2], S.E. Lopez-Ruiz[1].* 1) Computer Sciences, Universidad de Guadalajara, Mexico; 2) Molecular Medicine Division, CIBO, CMNO-IMSS, Mexico.

Background: Transposases have been extensively studied ever since Barbara McClintock described the transposition phenomena more than half a century ago. Transposases are proteins related with horizontal transport, where one domain recognizes its transposon sequence, another motif homodimerizes with other transposase bound to its palindrome, and the third domain cuts the sequence and "paste" it somewhere else on the same DNA chain, on other chain on the cell or even another cell or organism. Even though it has been discovered a great deal about transposition, many details still remain unknown. Traditional phylogenetic trees are built by main branching the different central conserved domain and posterior measurement of the distances between the rest of the protein or gene sequence. These trees usually rely upon taxonomy to evidence where those sequences are biasing or misinterpreted. In this work we present the preliminary results of the analysis for transposases phylogeny. Methods: Transposase nucleotide sequences were downloaded from KEGG database. Since this database is already curated and annotated, sequences were aligned and compared as is. Jukes-Cantor algorithm was applied for distance measuring and the phylogenetic tree was assembled by average method. Data mining and statistics were done using Matlab® (v7.7). Results: 27'152 sequences were downloaded from KEGG database from 612 bacterial organisms. To evaluate the relationship between any given member of the reported families we selected a sample of random entries from each organism. The resulting phylogenetic tree shows seven distinct branches clustering four different classes of *proteobacteria* (average distance: 0.52), two of *firmicutes* (avg. dist. 0.78), and *actinobacterias* (avg. dist. 0.64) respectively. When the distances for transposase protein family members were measured, there were no statistical significance for any specific branch distribution along the tree. Conclusion: Traditionally, protein families are clustered upon single main conserved domains, however when several different conserved domains occur in a protein, modularity combination may occur which shall be considered for the classification; and given the possibility of transposases for horizontal transport even between species, the resulting tree does not match the classic taxonomy.

## 2719/F/Poster Board #331

**MetaBioME: Exploring Commercially Useful Enzymes in Metagenomic Datasets.** *T.D. Taylor, V.K. Sharma, N. Kumar, T. Prakash.* MetaSystems Res Team, RIKEN Adv Sci Inst, Yokohama, Kanagawa, Japan.

Microbial enzymes have well known applications as biocatalysts in several industries like biotechnology, agriculture, medical, etc. However, only a few enzymes are currently employed for such commercial applications due to the limited number of sequenced microbes. In this scenario, metagenomic data provide a unique resource for discovering commercially useful enzymes (CUEs) from yet unidentified microbes belonging to complex microbial communities from diverse ecosystems. Therefore, the onslaught of metagenomic data from several worldwide projects provides a new unexplored ocean of genomic wealth which cannot only enhance the enzyme repertoire by the discovery of novel CUEs, but can also reveal better functional variants of the existing CUEs.

We curated a catalogue of ~500 CUEs using text mining of PubMed abstracts and publicly available information. We classified these CUEs into nine broad application categories based on their function. Further, in order to identify novel homologs of these CUEs, we used our in-house metagenomic analysis pipeline 'iMetaSys' to identify potential ORFs in all publicly available metagenomic datasets. We then developed the comprehensive Metagenomic BioMining Engine (MetaBioME) to bring all of this information together.

Using MetaBioME, we have already successfully identified several novel homologs to the known CUEs which can serve as leads for further experimental verification. MetaBioME is an intuitive search engine for accessing the manually curated data on CUEs stored in a relational database system, along with several options for identifying their homologs from metagenomic dataset and for validating the results. Further analysis of these potential CUEs may lead to the discovery of more efficient, less costly, and environmentally friendly alternatives to the current repertoire of medical and other important biocatalysts.

## 2720/F/Poster Board #332

**Genetic variation in Matrix Metalloproteinase-2, 9 in Patients with Osteonecrosis.** *C. Cho[1,2], H. Kim[1,2], K. Kim[3], K. Yoon[1,2].* 1) Department of Biochemistry and Molecular Biology (BK21 project); 2) Medical Research Center for Bioreaction to Reactive Oxygen Species and Biomedical Science Institute; 3) Department of OrthopaedicSurgery East-West Neo Medical Center, School of Medicine, Kyung Hee University, Seoul, Korea.

Osteonecrosis is a disease caused by reduced blood flow to bones in the joints. It is resulting from the temporary or permanent loss of the blood supply to an area of bone. With too little blood, the bone starts to die and may break down and bone collapses. If avascular necrosis involves the bones of a joint, it often leads to destruction of the joint articular surfaces. The disorder is characterized by progressive pain in the groin, mechanical failure of the subchondral bone, and degeneration of the hip joint. Matrix metalloproteinase (MMP) family are involved in the breakdown of extracellular matrix in normal physiological processes, such as bone remodeling, resorption as well as osteoclast recruitment. Among them, MMP-2,-9 are assumed the development of osteonecrosis. In previous reports, the variations of MMP2 and MMP9 promoter have been researched. Interestingly, the -1306T and -735T haplotype displays an even lower promoter activity and mRNA expression compared with the haplotype consisting of only one T allele at the -1306 or -735 site, indicating an interactive effect of these two SNPs on MMP2 transcriptional function. We investigated that a genetic variant of the MMP-2,-9 determines the risk of osteonecrosis in Korean patients, using PCR, sequencing and TaqMan 5' allelic discrimination assay. Genomic DNA from 218 patients with nontraumatic FHON and 221 control subjects was analyzed for MMP-2(-1306C/T; rs243865, -735C/T; rs2285053) and MMP-9(-1562C/T; rs3918242, -90(CA)n; rs3222264) SNPs. The allele distribution of the -1306C/T in the patients (C=91.3%, T=8.7%), controls (C=89.8%, A=10.2%) and the -735C/T in the patients (C=71.6%, T=28.4%), controls (C=73.5%, T=26.5%) was detected. These findings suggest that MMP polymorphism may be a genetic risk factor in osteonecrosis.

## 2721/F/Poster Board #333

**Relationship Between Femoral Head Osteonecrosis and Gene Polymorphism related to the Coagulation and Fibrinolytic Systmes.** *H. Kim[1,2], K. Kim[3], K. Yoon[1,2].* 1) Department of Biochemistry and Molecular Biology (BK21 project); 2) Medical Research Center for Bioreaction to Reactive Oxygen Species and Biomedical Science Institute; 3) Department of OrthopaedicSurgery East-West Neo Medical Center, School of Medicine, Kyung Hee University, Seoul, Korea.

Femoral head osteonecrosis (FHON) frequently leads to progressive collapse of the femoral head followed by a degenerative arthritis of the hip joint. Besides an increased bone marrow pressure with reduced blood supply, an enhanced coagulation has been considered. Plasminogen activator inhibitor type 1 (PAI-1) is the primary inhibitor of both tissue- and urinary-type plasminogen activators. A reduced plasma fibrinolytic activity, mainly attributable to increased plasma levels of PAI-1, has been associated with osteonecrosis. The human PAI-1 gene is mapped on chromosome 7q21.3-q22 and contains nine exons and eight introns. It has been reported that there are several variations within the PAI-1 gene. We investigated that a genetic variant of the PAI-1 determines the risk of osteonecrosis in Korean patients, using PCR, sequencing and TaqMan 5' allelic discrimination assay. Genomic DNA from 218 patients with nontraumatic FHON and 221 control subjects was analyzed for four SNPs (rs2227631, rs1799889, rs6092, rs11178) located at promoter, exon2 and 3'flanking region. The femoral head osteonecrosis patients had higher frequency of rs2227631 A allele and rs11178 C allele than controls (43.8% versus 36.7%, P=0.031; 55% versus 46.2%, P=0.008). We found that rs2227631 and rs11178 polymorphism in the PAI-1 was associated with an increased susceptibility of FHON in the Korean population. The results of this study suggest that coagulation abnormalities in the forms of PAI-1 polymorphism might play a role in FHON.

**Distinct Regulatory Architectures Controlling Gene Expression in Embryogenesis and Post-natally.** *I. Aneas, F. Arimura, A. Blanski, M.A. Nobrega.* Department of Human Genetics, University of Chicago, Chicago, IL.

Developmental genes often rely on multiple widespread regulatory elements to regulate their fine spatial-temporal expression. While these genes are also expressed post-natally, nothing is known about the regulatory architecture coordinating their expression in adulthood. To address this, we characterized the regulatory architecture of TBX20, a gene involved in heart development, during embryogenesis and post-natally. Using a combination of bioinformatics, mouse and fish transgenic assays, we scanned 1,200,000 bp of genomic sequence that spans the Tbx20 locus and its intergenic regions. We identified 10 embryonic enhancers that, together, recapitulate TBX20 endogenous expression. Six of these tissue-specific enhancers drive expression in discrete and overlapping domains within the developing heart. In order to assay these enhancers in their endogenous genomic context, we engineered a 278-kb human BAC harboring all heart enhancers by recombining LacZ onto the TBX20 translation start site. BAC-transgenic mouse embryos showed LacZ expression corresponding to a sum of all individual enhancers identified. LacZ activity in the heart was also observed postnatally (P0) and 21 days after birth (P21). Deletion of the 6 enhancers from the BAC resulted in abrogation of LacZ expression in the embryonic heart, showing that those sequences are essential and sufficient to control TBX20 expression during development. Interestingly, a longitudinal analysis of mice harboring this enhancer-deletion BAC shows that by 21 days after birth lacZ expression is restored to the heart, indicating the presence of a different set of enhancers within this BAC control TBX20 expression in the adult heart. We scanned to saturation the 500 kb TBX20 locus using a reporter system in primary cardiomyocytes to uncover these adult-specific regulatory sequences. Our findings suggest that developmental genes are endowed with distinct sets of regulatory elements to orchestrate their embryonic and post-natal expression. Mutations in these elements may lead to vastly different phenotypic consequences, ranging from developmental defects to adult, late-onset diseases. These insights will be of importance in the follow-up of GWAS that have repeatedly pointed at noncoding sequences surrounding developmental genes as harboring variations associated with adult-onset diseases.

## 2723/F/Poster Board #335

**Comparative Genomics of the Primate Subtelomeric regions.** *Y. Kuroki[1], A. Toyoda[2], A. Fujiyama[1,2,3].* 1) Computational Systems Biology Research Group, RIKEN Advanced Science Institute, Yokohama, Kanagawa, Japan; 2) Comparative Genomics Laboratory, National Institute of Genetics, Mishima, Shizuoka, Japan; 3) Principles of Informatics Research Division, National Institute of Informatic, Chiyoda-ku, Tokyo, Japan.

Human subtelomeric regions have unique character as for the genome structure, in other words, these regions are curious that the subtelomeric region-specific repeats are highly duplicated among the most of human chromosomes and form a complex patchwork structure. It is known that some genes or gene families have identified in the human subtelomeres, however the functional and systematic analyses of the genes have not yet conducted. In addition, the characteristics of the genome structure, such as the gene contents, components of DNA elements, and copy number of the duplicated subtelomeric region-specific repeats, have not fully analyzed. To clarify the structural characterization of the primate subtelomeres, we carried out genome sequencing and comparative analysis of the human and chimpanzee subtelomeric regions. High quality genome sequence data provided us the exact aspect including the number of the subtelomere genes, the duplicated segments, and the repeat contents for the two chromosomes, chromosome 19 and 21. The genomic structure of subtelomere was highly diverged between the closely related two species, human and chimpanzee. We will present the systematic genome analysis of primate subtelomeres, and discuss about the biological meaning and evolutionary aspects of this regions.

**Analysis of phylogenetically reconstructed mutational spectrum in human mitochondrial DNA.** *N. Volodko, N. Eltsov.* Dept Molecular and Cell Biology, Institute of Chemical Biology and Fundamental Medicine, Novosibirsk, Russian Federation.

Mutations in mtDNA are extremely important in studies of human evolution. They play significant role in forensic investigations and are responsible for various clinical phenotypes. Therefore, analysis of mitochondrial genomes from patients and normal controls becomes increasingly common, which leads to rapid accumulation of complete mtDNA nucleotide sequences. In this study we analyzed distribution of mtDNA mutations in global phylogeny. All complete nucleotide sequences of human mtDNA (5475 mtDNAs) currently available in GenBank were extracted and their global mtDNA phylogeny was reconstructed using recently developed software tool mtPhyl v.2.010 (http://www.eltsov.org/mtphyl.aspx). As a result hotspots and "cold" regions were revealed. A total of 5740 segregating sites were identified of which 703 were in control region, 4168 in protein-coding genes and 869 in RNA genes. In the group of protein-coding mutations 2753 synonymous, 1406 nonsynonimous and 9 nonsense mutations were detected. The total number of homoplasic mutations (i.e. which occurred more than once in phylogeny) among the 5475 mtDNAs was 2958 (54% of segregating sites). This is greatly exceeds previous estimates (17%). The most common homoplasmic mutation in coding region was 709 in the 12S rRNA gene. It occurred 102 times in human mtDNA evolution. The most common nonsynonimous mutation was 5460 in the ND2 gene which occurred 52 times. We furthermore analyzed the relation between the number of homoplastic mutations and the number of DNA sequences studied. The distribution of mutations within protein-coding genes was explored and possible role of selection is discussed.

**Discovery and Reconstruction of Copy Number Variations.** *N. Furlotte[1], D. He[1], E. Eskin[1,2].* 1) Department of Computer Science, University of California Los Angeles, Los Angeles, CA; 2) Department of Human Genetics, University of California Los Angeles, Los Angeles, CA.

Structural variations such as copy number variations (CNVs) account for a large portion of human genetic variance. The accurate discovery and reconstruction of the genomic regions containing CNVs is important for the understanding of phenotypic variation. There exist array-based methods for discovering CNVs, but these methods are unable to determine the regions in copy number with high resolution. The rapidly decreasing cost associated with next generation sequencing technologies offers an alternative for finding CNVs. In this project, we describe a computational method that utilizes the properties of paired-end read sequences to identify CNVs. Our method first determines the genomic regions that likely contain CNVs by clustering discordant paired-end reads. Each potential CNV is assigned a confidence score and probabilities corresponding to the number of copies in the region. Once an estimate of the region has been obtained, we are then able to reconstruct the exact sequences making up the CNV using un-mapped reads, namely reads that span the junctions between copies and that do not match anywhere in the reference genome. Given the high coverage of next generation sequencing technologies, all junctions are covered by un-mapped reads with high probability. Copies that differ from the original reference region will do so by having different starting and ending positions, which will result in different prefixes and suffixes for these copies. Therefore, by using un-mapped reads we are able to recover the exact start and end positions of each copy within the original CNV region by mapping their prefixes and suffixes back to the reference sequence. Candidate positions can be identified when both prefix and suffix match the CNV region in the reference sequence. SNPs in different copies can then be used to recover the order of these copies. For experimental evaluation, we tested our method on both simulated random sequences and real genomic sequences. Specifically, we generate real genomic sequences by randomly sampling and concatenating large sub-sequences from an actual chromosome. This process maintains the repeat structure found in real genomes, which does not exist in completely random sequence. CNVs of differing lengths were inserted at various spacings then simulated reads are created and mapped with a widely used mapping program. The results indicate that our method is able to re-construct the CNVs accurately for both datasets.

## 2726/F/Poster Board #338

**CNV analysis of systemic-onset juvenile idiopathic arthritis.** *H. Tadaki[1,2], T. Saistu[2], H. Sakai[2], N. Miyake[2], S. Yokota[1], N. Mastumoto[2].* 1) Pediatrics, Yokohama City University, Yokohama, Japan; 2) Human Genetics, Yokohama City University, Yokohama, Japan.

Background: Systemic-onset juvenile idiopathic arthritis (JIA) is a subtype of chronic childhood arthritis, manifested by spiking fever, erythematous skin rash, pericarditis, and hepatosplenomegaly. Approximately 7% of these children are fatal because of the disease transition to macrophage activation syndrome (MAF). However, the cause of systemic JIA remains poorly defined. Although IL-6 and MIF polymorphism are reported to be associated with JIA, there are no studies analyzing copy number variations (CNVs) in systemic JIA. Method: A total of 50 patients with systemic JIA who had disease refractory to conventional treatment and were given tocilizumab were studied. We used two different commercially available SNP array platforms, the Affymetrix Genechip Human Mapping 500K array (23 patients) and the Genome-wide Human SNP array 6.0 (27 patients) , to detect CNVs. When chromosomal structural abnormalities were detected, further analysis was done using quantitative PCR, and/or fluorescence *in situ* hybridization (FISH). Result: We found 6 deletions: 2 larger than 1 Mb in size, 2 from 100 kb to 500 kb, and 2 smaller than 100 kb. The largest deletion detected was 5.5 Mb. FISH demonstrated that the mother also carried the 5.5-Mb deletion. Thus the deletion containing approximately 50 genes is unlikely to be pathogenic. Six duplications were also detected within the size from 100 kb to 1 Mb. All of the duplications were inherited from either of the parents. Conclusion: Although we have performed CNVs analysis using high density microarrays in systemic JIA, no significant pathogenic CNVs have been detected so far. Further study is absolutely necessary to identify the gene for systemic JIA.

## 2727/F/Poster Board #339

**Copy number variation in candidate regions in extended families with autism spectrum disorder.** *D. Salyakina, H. Cukier, D.Q. Ma, A. Griswold, I. Konidari, J. Jaworski, P. Whitehead, H.H. Wright, R. Abramson, M.L. Cuccaro, J.R. Gilbert, M.A. Pericak-Vance.* MIHG, Univ Miami Miller Sch Med, Miami, FL.

Recent studies have identified several copy number variations (CNVs) that are associated with increased risk of autism spectrum disorder (ASD). Most of these findings describe rare CNVs and have not been replicated by other research groups. Recently Glessner et al.(Nature, 2009) reported novel and known CNV candidate regions for ASD. Their positive findings were validated in an independent cohort of 1336 ASD cases and 1110 controls and of European ancestry. We have conducted analysis of these validated candidate regions in a cohort of 69 extended ASD families (3-6 affected ASD individuals per family) with 117 individuals diagnosed with ASD and 354 healthy relatives. We examined if any of these CNVs can account for any of the familial ASD. We tested the hypothesis that a consistent CNV contributing to ASD risk is shared in the affecteds in the family. Samples were genotyped using the Illumina Human 1M Beadchip. We used the PennCNV algorithm for CNV calling in our cohort. For the 26 candidate regions listed in the paper, we identified CNVs in 16 of these regions. 14 of them were inherited and two could be de novo: one individual had a deletion on chromosome 16p11.2 and another had a duplication on chromosome 4q31.21. Both individuals were diagnosed with ASD. Both CNVs did not segregate among relative individuals with ASD in these two families. The most CNV rich region was on chromosome 15q11-13. 80 individuals (healthy and affected) had various deletions and duplications with different breakpoints in this locus; however, no segregation in affected individuals within families could be shown. One locus on chromosome 3q26.31, including the neuroligin 1 (NLGN1) gene, had a duplication overrepresented in ASD affecteds. In total, there were 10 individuals with ASD (8.5%) and 19 healthy relatives (5.3%) that have the duplication. 15 of 19 healthy carriers of this duplication were female and 8 of 10 affected individuals with the duplication were male. Most affected relatives (62%) of the carriers of the CNV on chromosome 3q26.31 were not carriers, suggesting that this CNV probably does not contribute to ASD risk. CNVs in remaining candidate regions also did not show segregation in affecteds with ASD. In conclusion, no one candidate region mentioned by Glessner et al.(Nature, 2009) showed segregation in multiple affected individuals within our families. These CNVs probably do not contribute to risk of ASD.

## 2728/F/Poster Board #340

**Utilisation of a Whole-Genome Approach to Characterize a Novel Immunodeficiency Disorder and Implicate IL25.** *L.R. Griffiths[1,2], M.R. Green[1,2], M.K. Gandhi[2,3], J. Peake[4].* 1) Genomics Res Centre, Griffith Institute for Health and Medical Research, Griffith University Gold Coast, Southport, Australia; 2) Griffith Medical Research College, GU-Queensland Institute of Medical Research, Herston, Brisbane, Australia; 3) Queensland Institute of Medical Research (QIMR), Clinical Immunohaematology Laboratory, Herston, Brisbane, Australia; 4) Queensland Pediatic Immunology and Allergy Service, Royal Children's Hospital, Herston, Brisbane, Australia.

Primary immunodeficiency disorders (PIDs) affect ~2 people in 100,000 and predispose affected individuals to recurrent infections and the development of other disorders such as lymphoma. Diagnosis of PIDs uses case history information, immunological interrogation of cellular repertoires and immunoglobulin isotypes, as well as genetic tests to detect mutations. However, when an individual does not fit the immunological characteristics of defined disorders, and genetic tests for common immunodeficiency syndromes yield no diagnosis, there is no protocol for characterization of the disorder. In this study, we have used genome-wide SNP and gene expression microarrays to provide insight into the etiology of one such disorder. DNA copy number analysis using Affymetrix 250K Sty SNP arrays revealed quadraploidy of chromosome 14q11.2 mapping over an area of approximately 280Kbp. This amplification was confirmed by MassArray-based DNA copy number analysis of SNPs within the candidate region. The genetic locus harbouring the copy number alteration is rich in coding sequences but only two of these genes had a role in lymphocyte signalling - T-cell Receptor Delta-Alpha (TRD$\alpha$) and Interleukin-25 (IL25). From microarray data, TRD$\alpha$ showed down-regulation, however IL25 showed increased expression. Using qPCR analysis, IL25 exhibited a 2.49 fold increased expression compared to control lymphocytes following anti-CD3 T-cell activation. Microarray data supported the hypothesis of an aberrant Th2 switch resulting from the IL25 over-expression, with down regulation of expression of TBX21 (0.24 fold) and IRF2 (0.28 fold) which induce the expression of Th1-associated genes. There was also significant up-regulation of genes associated with a Th2 phenotype, as well as down-regulation of genes associated with a Th1 phenotype. Overall our results thus identified hyperploidy of a genetic region centromeric to 14q11.2, which causes over-production of IL25 in response to T-cell stimulation, and is associated with a gene expression pattern indicative of a Th2 switch. Recurrent infections associated with this disorder may therefore be associated with the inadequate clearance of pathogens that are normally addressed with Th1 responses. This disorder may provide further insight into the function of IL25 and the regulation of Th1 and Th2 responses. In conclusion, we have used a whole-genome approach to characterize the molecular etiology of a novel immunodeficiency disorder.

## 2729/F/Poster Board #341

**Detection of copy number events in patients with eye development disorders using SNP arrays and multiple detection algorithms.** *I. Ragoussis[1], L. Winchester[1], S. Ugur[2], N. Ragge[2].* 1) Genomics, Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, OX3 7BN, UK; 2) Dept of Physiology, Anatomy and Genetics, Le Gros Clark Building, South Parks Rd, University of Oxford, Oxford, OX1 3QX, UK.

Human developmental eye anomalies, including anophthalmia, microphthalmia and coloboma are responsible for around 25% of all childhood blindness. Our recent research has demonstrated that these abnormalities can be caused by disruption to single genes not only through mutations, but also through whole gene or exon deletions, detected through techniques such as MLPA (e.g. SOX2 OTX2). Surprisingly, we found the prevalence of whole gene deletions was almost as great as mutations. Here we used Illumina 1M Duo arrays to assay 40 patient trios with developmental eye disorders, mainly anophthalmia and microphthalmia. We investigated multiple analysis methods for using SNP data to detect copy number (CN) events and describe the use of several statistical models for CN detection in germline samples. We examined a number of algorithms designed to detect CN changes through the use of signal intensity data and consider methods to evaluate the changes found. We applied these algorithms to a set of well characterised CEPH samples to give an indication of detection accuracy and success of CN change prediction on Affymetrix and Illumina data. We found an overlap of between 20-49% between events detected by algorithm and previously published data covering both copy number variations and polymorphisms. We applied the QuantiSNP and PennCNV algorithms to the patient dataset. From our QuantiSNP dataset we found a total of 18,229 events, 48.7% of these were in genes found in the RefSeq sequence collection. We included a patient with a known 6p deletion in the TFAP2A gene as a control which was successfully identified by both PennCNV and QuantiSNP detection algorithms. We checked our data for events in genes known to be related to eye developmental disorders and found events in 26 genes of interest, including deletions of MAF and PAX2. We found a large novel deletion on the X chromosome in a child, disrupting 35 genes including HCCS which has been linked to microphthalmia. After filtering of our detected event list, we found a series of 52 novel events in genes not previously linked to eye developmental disorders, but some of which are expressed in retina or implicated in axon guidance. The latter provide excellent candidate genes for further investigation. We used the secondary set of detected events from PennCNV to confirm events of interest and clarify breakpoints. Finally coding SNPs were analysed for the prevalence of rare alleles in candidate genes.

## 2730/F/Poster Board #342

**CNstream: A method for the identification and genotyping of copy number polymorphisms using Illumina microarrays.** *A. Alonso, S. Marsal, A. Julià.* Grup Recerca Reumatologia, Institut de Recerca Hospital Vall d'Hebron, Barcelona, Barcelona, Spain.

Background: Copy Number Polymorphisms (copy number variants with a prevalence >1%), are actually drawing much interest as new genetic variations associated to disease risk. For this reason, Illumina Beadchip arrays, originally designed for SNP genotyping, are now starting to be used to extract copy number information. However, one of the present challenges is to develop algorithms that are able to deal with the reduced sensibility of this type of technology. Current methods available for Illumina CNP discovery and quantification are based on either a per-sample analysis of LogRatio and B-Allele Frequency parameters (i.e. PennCNV) or on a multiple-sample analysis of the two channel intensities (i.e. SCIMM - only deletions). Methods: We propose a new method specific for Illumina arrays that can identify deletions as well as amplifications using a multiple-sample approach. CNstream uses Illumina two-channel intensities as input data and the markers are successively analyzed starting with a genotyping step. This genotype information is used to robustly initialize an algorithm that indepently analyzes each intensity channel and assigns to each sample two scores that are proportional to the number of copies. In this algorithm, a Gaussian Mixture Model is fitted to the intensity data and the final scores are computed based on the likelihood of the data with respect to each GMM component. Finally, in order to avoid false positives, CNstream applies a filtering step over the scores of each sample that takes into account the distance between markers. Another strength of CNstream is that it includes two normalization steps (per-plate and per-genotype) which highly contribute to reduce the technical variability of the data and standardize the distribution of all the markers. Results: We have compared CNstream against PennCNV over a set of 488 samples genotyped with Illumina HumanHap300. PennCNV identified a total of 73 CNP regions from which 55 (75%) were also found by CNstream. Importantly, CNstream was able to identify 30 CNP regions with frequencies up to 9% that PennCNV was not able to detect, and that are located in previously described CNV regions (Database of Genomic Variants). We propose CNstream as a useful and powerful method for the identification and quantification of CNPs in Genome Wide Association Studies. CNstream will be available as an open-source R package.

## 2731/F/Poster Board #343

**Copy Number Variations (CNVs) in Biliary Atresia.** *M.J. Braskett[1], R.S. Venick[1], S.V. McDiarmid[1, 2], J.H. Vargas[1], D.G. Farmer[2], R.W. Busuttil[2], E.R.B. McCabe[1, 3, 4], S.A. McGhee[1].* 1) Pediatrics, David Geffen School of Medicine at UCLA, Los Angeles, CA; 2) Surgery, Dumont-UCLA Transplant Center, Los Angeles, CA; 3) Human Genetics, David Geffen School of Medicine at UCLA, Los Angeles, CA; 4) Bioengineering, Henry Samueli School of Engineering and Applied Science, Los Angeles, CA.

Rationale: Biliary atresia, the leading cause for pediatric liver transplantation, usually presents as an isolated finding, although up to 10% of affected individuals have a constellation of other anomalies. Reported observations describe copy number variations (CNVs) in a small subset of patients with multiple congenital anomalies. Specifically, karyotype analysis has been used to identify duplications at 22q11 associated with cat eye syndrome and 10q11.2q22.3 associated with multiple congenital anomalies, der (22) t(11; 22)(q23; q11) associated with the supernumerary der (22) syndrome, as well as full trisomies of 18 and 21. We hypothesized that microarray analysis may increase the detection of CNVs at these regions in individuals with isolated biliary atresia. However, as CNVs are also found in healthy individuals, controlled studies are warranted to investigate this hypothesis. Methods: A trio was analyzed as an index case study. Subsequently, five case subjects with biliary atresia were genotyped using the 6.0 Affymetrix platform, and data for 10 control subjects was obtained from the HapMap project. Cases did not have clinical manifestations suggestive of chromosomal abnormalities. Analysis was performed using R with the Oligo and DNAcopy packages. CRLMM was used to normalize array data and calculate intensity ratios. We modified the CRLMM algorithm to permit estimates of CNVs. Results: No shared CNVs were noted among cases except for 4 polymorphisms on chromosomes 1, 14 and 22. The index case demonstrated a de novo 791kb duplication at 10q11.22 consistent with a description in the literature, but this finding was not reproduced in the other cases. Moreover, other CNVs found in case subjects did not correspond to regions described in reported cases. Data for case subjects did not demonstrate an increased prevalence of CNVs on 10, 11, 18, 21 and/or 22. Conclusion: The role of CNVs in the pathology of biliary atresia remains unclear. One patient was identified that shared duplication on 10q11.22 with a previously described case. Of note, unlike the reported case, this individual lacks syndromic features. This suggests that high density oligonucleotide mapping array data may identify CNVs associated with biliary atresia in non-syndromic patients. These findings may indicate considerable genetic heterogeneity for biliary atresia.

## 2732/F/Poster Board #344

**Differential Detection of Copy Number Variation of Complement Component C4 Family Using TaqMan Copy Number Assays.** *I.R.L. Casuga[1], A.J. Broomer[1], F. Wang[1], N. Majumdar[1], Y. Wang[1], R. Charlab[1], T.H. Karlsen[2], A. Franke[3], C. Chen[1], K. Li[1].* 1) Applied Biosystems part of Life Technologies, Foster City, CA; 2) Medical Department, Rikshospitalet University Hospital, Oslo, Norway; 3) Institute for Clinical Molecular Biology, Kiel, Germany.

Copy number variation (CNV) is a widespread phenomenon in the human genome. CNVs are part of the normal variability among healthy individuals, but some CNVs may also increase disease susceptibility. For instance, CCL3L1 CNVs are associated with susceptibility of HIV infection. The ability to detect accurate copy number changes is important in copy number analysis, and is especially critical for isoforms within a gene family such as the complement system component C4. Located within the MHC at chromosome 6p21, the C4 gene family is part of this highly polymorphic region associated with numerous autoimmune diseases. Although they differ in only 5 nucleotides, C4A copy number but not C4B is associated with the susceptibility of systemic lupus erythematosus (SLE). In addition, the C4 gene has 2 isoforms (C4L and C4S) of different length due to the insertion of the retrovirus HERV-K(C4). Differential detection of copy number for different C4 isoforms is especially challenging but critical in understanding their association to diseases. To differentially detect copy number differences among C4 isoforms, we designed TaqMan Copy Number Assays to specifically target each isoform (C4A, C4B, C4L, & C4S). The assays were tested first on an internal panel of 94 gDNA samples from African American and Caucasian populations. Distinct copy number profiles and population differences were observed. To test accuracy of the assays, positive samples of known copy number were also tested; the results show TaqMan assays are 100% consistent with the expected copy number. To measure C4 copy number frequency and further examine the population differences, we tested the assays on the HapMap panel of 270 individuals from 4 different populations. The copy number profiles among the HapMap population are strikingly different for each C4 isoform, and copy number frequency in different populations is statistically significant. This is the first time copy number profile population differences in C4 isoforms on HapMap samples have been reported. This study indicates population difference in copy number profiles for C4 isoforms should be considered in any disease association studies and understanding the difference may help explain the population difference in disease susceptibility. The study also demonstrates that TaqMan Copy Number Assays can differentially detect challenging targets like closely related gene family members.

## 2733/F/Poster Board #377

**Segmental copy number variation shapes tissue transcriptomes.** *E. Chaignat[1], C.N. Henrichsen[1], E. Ait Yahya-Graison[1], N. Vinckenbosch[1], S. Zollner[2], F. Schutz[1], M. Ruedi[3], H. Kaessmann[1], A. Reymond[1].* 1) CIG, University of Lausanne, Lausanne, Vaud, Switzerland; 2) University of Michigan, Ann Arbor, MI; 3) Natural History Museum, Geneva, Switzerland.

Copy number variation (CNV) of DNA segments has recently been identified as a major source of genetic diversity, but a comprehensive understanding of the phenotypic effect of this type of variation is only beginning to emerge. We have generated an extensive map of CNV in wild mice and classical inbred strains. Copy number variable regions cover a total of ~340 megabases (~11%) of their autosomal genome. Genome-wide expression data from 6 major organs and 4 developmental times in six different strains reveal that expression levels of genes within CNVs positively or negatively correlate with copy number changes in approximatively 35 and 15% of the cases, respectively. Consistently, CNV genes are significantly overrepresented amongst the genes that differ in their spatiotemporal pattern of expression between strains. Our experiments also show that CNVs influence the expression of genes in their vicinity - an effect that extends up to half a megabase. These controls over expression are effective throughout mouse development, however some genes appear to be under compensatory loops at specific time point. Interestingly, genes within CNVs show lower expression levels and more specific spatial expression patterns than genes mapping elsewhere in the genome. Furthermore, genes expressed in the brain are significantly underrepresented in CNVs compared to genes with expression in other tissues, suggesting differential selective constraint on copy number changes of genes expressed in different tissues. Our study provides initial evidence that CNVs shape tissue transcriptomes on a global scale and thus represent a significant source for within-species phenotypic variation.

## 2734/F/Poster Board #378

**Genome-wide array scan identified several Copy Number Variants loci associated with adolescent idiopathic scoliosis (AIS).** *R. Chettier, L. Nelson, J.W. Ogilvie, R.A. Macina, K. Ward.* Axial Biotech, Salt Lake City, UT.

Developmental disorders are often associated with genetic variants. Copy number variations (CNVs) are recently documented micro DNA insertions and deletions that may be ten times more frequent than point mutations. Many believe that CNVs may be more likely to cause disease that point to frequently benign mutations. We performed a genome wide scan to find CNVs associated with Adolescent Idiopathic Scoliosis (AIS). A total of 879 Caucasian individuals with severe AIS and 1486 Caucasian controls were evaluated for CNVs using the Affymetrix 6.0 HUSNP array. After the implementation of quality filters the data were quantile normalized. Copy Number analysis was performed using Helix Tree (Golden Helix, Bozeman, MT). The copy number segments were determined using the Golden Helix's Univariate Segmentation Algorithm. Statistically different segments were extracted using mean Log2 ratio intensity for that segment to highlight deletions, neutrals and duplications. We then performed association analysis on those segments. A p-value of <10-7 was considered evidence of significance. We found 143 significant segments/regions associated with idiopathic scoliosis. 94 of those regions showed gains of copy while 49 had deletions. Sixty-three of these significant regions map to known genes. Biological functions of the genes identified reveal complex groups associated to embryonic development, nervous system development and function, and tissue development. These groups present an extensive overlap with the gene biological function groups that were generated using associated Single Nucleotide Polymorphism (SNP) data from the same set of individuals. For the first time we show significant copy number loss or gain in several genomic regions associated to severe scoliosis patients as compared to a control population. We are testing CNVs in mild patients to determine whether they further improve the performance of the current AIS prognostic Test (AIS-PT).The identification of novel/rare CNVs in severe cases of AIS could not only lead to the enhancement of the current AIS-PT but could also help us identify specific biological pathways that cause AIS and/or accelerate AIS progression.

## 2735/F/Poster Board #379

**Whole genome distribution and ethnic differentiation of copy number variation in Caucasian and Asian populations.** *H. Deng[1,2,3,4], J. Li[1], T. Yang[1,2], L. Wang[1,2], H. Yan[1,2], Y. Zhang[2], Y. Guo[2], F. Pan[2], Z. Zhang[1,2], Y. Peng[2], Q. Zhou[2], L. He[2], X. Zhu[2], H. Deng[1], S. Levy[5], C. Papasian[1], B. Drees[1], J. Hamilton[1], R. Recker[6], J. Cheng[7].* 1) School of Medicine, Univ Missouri, Kansas City, Kansas City, MO; 2) The Key Laboratory of Biomedical Information Engineering of Ministry of Education and Institute of Molecular Genetics, School of Life Science and Technology, Xi'an Jiaotong University, Xi'an, Shanxi 710049, P R China; 3) Laboratory of Molecular and Statistical Genetics, College of Life Sciences, Hunan Normal University, Changsha, Hunan 410081, P R China; 4) College of Life Sciences and Bioengineering, Beijing Jiaotong University, Haidian District, Beijing 100044, P R China; 5) Vanderbilt Microarray Shared Resource, Vanderbilt University, Nashville, TN 37232, USA; 6) Osteoporosis Research Center, Creighton University, Omaha, NE 68131, USA; 7) National Engineering Research Center for Beijing Biochip Technology, 18 life Science Parkway, Changping District, Beijing 102206, P.R.China.

Although copy number variation (CNV) has recently received much attention as a form of structure variation within the human genome, knowledge is still inadequate on fundamental CNV characteristics such as occurrence rate, genomic distribution and ethnic differentiation. In the present study, we used the Affymetrix GeneChip® Mapping 500K Array to discover and characterize CNVs in the human genome and to study ethnic differences of CNVs between Caucasians and Asians. Three thousand and nineteen CNVs, including 2381 CNVs in autosomes and 638 CNVs in X chromosome, from 985 Caucasian and 692 Asian individuals were identified, with a mean length of 296 kb. Among these CNVs, 190 had frequencies greater than 1% in at least one ethnic group, and 109 showed significant ethnic differences in frequencies ($p<0.01$). After merging overlapping CNVs, 1135 copy number variation regions (CNVRs), covering approximately 439 Mb (14.3%) of the human genome, were obtained. Our findings of ethnic differentiation of CNVs, along with the newly constructed CNV genomic map, extend our knowledge on the structural variation in the human genome and may furnish a basis for understanding the genomic differentiation of complex traits across ethnic groups.

**Characterization of CNV Detection in Autism Genomes Using Next-Generation Sequencing, Oligo aCGH, and SNP Microarrays.** *B. Doan[1], C. Stewart[2], A. O'Connor[1], T. Turner[1], G. Marth[2], A. Chakravarti[1].* 1) Inst Gen Med, Johns Hopkins Med, Baltimore, MD; 2) Dept of Biology, Boston College, Boston, MD.

To improve our ability to identify genomic regions sensitive to dosage, we have focused on the study of 2 Autism genomes across multiple technological platforms. Two probands were selected with validated regions of duplication (SNRPN) or deletion (16p11.2). Whole genome sequencing data was generated using AB SOLiD technology. To assess the CNV data quality of next-generation sequencing compared to existing technologies, we generated data on the probands and their parents on three additional platforms: NimbleGen 2.1M (N2m) and Agilent 1M (A1m) oligo aCGH arrays, and Affymetrix SNP 6.0 (Affy6) microarrays. Data for each individual were processed for CNV discovery by: existing technology-provided software, Bioconductor tools, and newly developed algorithms. AB pair-end reads were analyzed with our CNV detection tool, Spanner. Because such reads are susceptible to false negatives in regions of genomic repeats, a complementary algorithm focusing on read depth was also developed. Segmentation algorithms and hidden Markov models were applied to the oligo aCGH and SNP microarray based data, respectively. As expected, sequencing data identified the most variants, with a total of ~1400 identified in both probands, compared to only 429 (A1m), 552 (N2m), and 550 (Affy6) on the arrays. Only 75 of the regions, including SNRPN and 16p11.2, were found with all technologies, and ~20% of the variants identified by sequencing overlapped the 372 CNVs previously identified (ASRD) for autism spectrum disorders. One heterozygous deletion of ~1kb (at position 51.08Mb) on chromosome 2 was identified in both sequenced genomes, overlapping NRXN1. This deletion was further validated and replicated by PCR, and found to have a frequency of 10.8% in the parents of 419 autistic trios. Although none of the array probes overlapped this deletion, a heterozygous deletion was found nearby in only one individual across the array data (at position 52.6Mb, with a deletion of size ~25kb in Affy6, ~32kb in A1m, and ~1kb in N1m). Such preliminary results suggest that the overlap among all the technologies is small, and that sequencing is able to identify additional CNVs at a greater resolution than the existing technologies. With a more detailed comparison, we hope to provide a useful map of the level of genomic variation that can characterize diseased individuals and better understand the limits of technologies to discover such variations.

## 2737/F/Poster Board #381

**A multilevel hidden Markov model of DNA copy number variation.** *S.W. Erickson[1,2].* 1) Department of Pediatrics, University of Arkansas for Medical Sciences, Little Rock, AR; 2) Department of Biostatistics, University of Arkansas for Medical Sciences, Little Rock, AR.

DNA copy number variation (CNV) has received increasing attention over the past several years, and multiple studies have revealed both common inherited variants and unique de novo variants in healthy, as well as diseased, subjects. CNVs have been associated with several disease phenotypes, as well as with expression quantitative trait loci (eQTLs). Most existing methodologies for inferring copy number from microarray data have focused on analyzing arrays one at a time or, if analyzing multiple arrays, on a post-hoc basis. A multilevel hidden Markov model (mHMM) of CNV, however, simultaneously accounts for both the correlation of CNV state at different loci within an individual (i.e. along chromosomes) as well as between individuals. This is accomplished by distinguishing between common, or shared, variants and de novo, or unique, variants. Common variants are usually shared by multiple, but not all, subjects. Modeling common variants across multiple subjects allows for flexible and coherent inferential results, such as heritibility or association with case/control status. I will introduce a general inferential framework, examine computational and inferential challenges, and present results on simulated and actual data.

**Neuronal Calcium Ras Signaling in Schizophrenia Impacted by Copy Number Variation.** *J.T. Glessner[1], K. Wang[1], C.E. Kim[1], C. Hou[1], J.P. Bradfield[1], H. Zhang[1], P.M.A. Sleiman[1], M. Imielinski[1], E.C. Frackelton[1], R. Chiavacci[1], K. Annaiah[1], K. Thomas[1], F.G. Otieno[1], J. Doran[1], M. Garris[1], J.H. Flory[1], S.F.A. Grant[1], R.E. Gur[2], H. Hakonarson[1,3].* 1) Center for Applied Genomics, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Psychiatry, University of Pennsylvania, Philadelphia, PA; 3) Pediatrics/Genetics, Children's Hospital of Philadelphia, Philadelphia, PA.

Schizophrenia is a late adolescence onset psychiatric disease typically characterized by delusions, hallucinations and thought disturbances. To identify CNVs increasing risk of schizophrenia, we performed a whole-genome CNV study on a cohort of 912 schizophrenia cases and 2,000 healthy children of European ancestry who were genotyped with 800,000 SNP probes and 800,000 CN probes. Positive findings were evaluated in an independent cohort of 644 schizophrenia cases and 1,684 controls of European ancestry. *KCNMB4* and *CACNA1B*, calcium signaling genes responsible for neuronal excitation, were deleted in 20 cases in our discovery cohort and 7 cases in the replication cohort which was overrepresented in comparison to controls ($P=2.74x10^{-4}$). In addition, *RET* and *RIT2*, ras related genes important for neural crest development, were found significantly impacted by CNV. RET deletion was exclusive to 8 cases ($P=1.46x10^{-3}$) and RIT2 deletions were overrepresented common variant CNVs in cases ($P=2.61x10^{-4}$). Although these variants may be individually rare, they target genes involved in calcium dependent cascades and Ras neuronal signaling which is involved in most aspects of normal brain function. Our results indicate that variations involving calcium Ras gene networks of the brain contribute to the genetic susceptibility of schizophrenia.

## 2739/F/Poster Board #383

**Genome-wide analysis of copy number alterations in colorectal cancer.**
*M. Gornick[1], J. Xu[1], J. Li[1], S. Gruber[1,2,3].* 1) Human Gen, University of Michigan, Ann Arbor, MI; 2) Department of Internal Medicine, Universtiy of Michigan, Ann Arbor, MI; 3) Department of Epidemiology, University of Michigan, Ann Arbor, MI.

Genomic alterations such as amplifications and deletions play important roles in the pathogenesis of human cancer. In the current study we performed a genome-wide analysis of copy number alterations (CNAs) in colon tumors using two different single nucleotide polymorphism (SNP) genotyping platforms, the Affymetrix Genome-Wide Human SNP Array 6.0 and the Illumina Human 1M-Duo BeadChip. DNA derived from 19 frozen colon tumors were analyzed by Affymetrix arrays containing 1.8 million probes, including 906,600 SNP probes and more than 946,000 invariant probes for detection of copy number changes, and 8 tumors were analyzed by Illumina arrays containing 1.1 million SNPs. Eight of the samples were run on both platforms. To determine whether the detected alterations were somatic or constitutional, we analyzed 8 matched genomic DNA samples from normal tissues of the same patients. Copy number changes were identified using PennCNV software. We compared our results with those from two previous studies of genome-wide copy number changes in colon tumors using less dense arrays (Leary et al. 2008, Ji et al. 2006), and found many CNAs in regions previously reported, including amplifications in regions containing the genes *MYC*, *EGFR*, and *IRS2*, as well as deletions in regions containing the genes *MAP2K4*, *SMAD2*, and *SMAD3*. We identified 8,037 alterations (total CNA size 1.9 Gb) in the tumor samples (7460 amplifications and 577 deletions) compared to 224 alterations (total CNA size 11.2 Mb) in the matched genomic DNA samples (103 amplifications and 121 deletions). The mean number of CNAs per tumor sample was 1,010 (median = 696). The average CNA size was significantly larger in tumor samples (mean=245,036 kb, median= 119,785 kb) than genomic controls (mean=50,342 kb, median= 15,634 kb, p = 0.0000018). Additionally, we detected alterations as small as 173 kb in tumors. Tumor samples had a greater number of amplified copies (more than 3 copies, n=20) as well as homozygous deletions (zero copies, n=30) than genomic controls (more than 3 copies, n=4 and zero copies, n=8). We identified several previously unreported CNAs that contain genes with known oncogenic properties such as *CDK8* and *PIK3CA*, as well as amplification of a region harboring *KRAS* in a single tumor without a *KRAS* mutation. Our study demonstrates that SNP arrays can detect chromosomal alterations at a high resolution and that these CNAs point towards candidate genes for further study.

## 2740/F/Poster Board #384

**Screening for gene deletions using the GenomeLab GeXP technology.**
*C. Haag[1], E. Schulze[1], M. Souquet[2], F. Raue[1].* 1) Endocrine Practice, Heidelberg, Germany; 2) Beckman Coulter Inc., Germany.

Large genomic duplications and deletions have been recognized as pathogenic mutations for many years. These types of mutations are thought to represent about 5% of all reported mutations. Therefore the determination of gene dosage becomes very important in clinical medicine. One well established method for the detection of deletions in single genes is the multiplex ligation-dependent probe amplification (MLPA). However there are a lot of genes with clinical relevance where no MLPA-Kit is available for testing or the kits are not detecting all exons. In this study we adopted the GenomeLab Gene Expression Profiling (GeXP) technology for the detection of copy number variations in the human genome. The GeXP technology was originally developed for gene expression analysis and can now also be used for the detection of deletions and duplications at genomic DNA level. The GeXP method uses a universal priming strategy to overcome potential bias in amplified targets that are typically associated with other types of multiplexed assays. For validation of the GeXP method 20 patients where tested, of which 6 were known to have copy number variations of the low-density lipoprotein receptor (LDLR) due to MLPA analysis. Validation samples included deletions and duplications of several exons of the LDL receptor as well as deletions of single exons. The results showed that the GeXP method is a highly efficient technique to detect copy number variations of genes or of single exons. All deletions or duplications found with an MLPA analysis could also be detected with the GeXP method. In contrast to MLPA, the setup for a GeXP assay can be easily performed in any molecular genetics laboratory and all exons of the target gene can be included with no limitations. Data presented here demonstrate that the GeXP method is a new technique for copy number quantification at genomic DNA level.

**Genome Wide Copy Number Variation Study Associates Metabotropic Glutamate Receptor Genes with Attention Deficit Hyperactivity Disorder.**
*H. Hakonarson[1,2], J.T. Glessner[1], K. Wang[1], X. Gai[3], N. Takahashi[4], P.M.A. Sleiman[1], J.H. Flory[1], H. Zhang[1], C.E. Kim[1], J.P. Bradfield[1], M. Imielinski[1], C. Rabin[5], P. Shaw[5], T.H. Shaikh[6,7], S.F.A. Grant[1,6,7], J.D. Buxbaum[4], J.L. Rapoport[5], M. Devoto[6,7,8,9], P.S. White[3,7,10], J. Elia[11,12].* 1) Center for Applied Genomics, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Pediatrics/Genetics, Children's Hospital of Philadelphia, Philadelphia, PA; 3) Center for Biomedical Informatics, The Children's Hospital of Philadelphia, Philadelphia, PA; 4) Laboratory of Molecular Neuropsychiatry, Department of Psychiatry, Mount Sinai School of Medicine, New York, NY; 5) Child Psychiatry Branch, National Institute of Mental Health, Bethesda, MD; 6) Division of Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA; 7) Department of Pediatrics, University of Pennsylvania School of Medicine, Philadelphia, PA; 8) Dipartimento di Medicina Sperimentale, University La Sapienza, Rome, Italy; 9) Department of Biostatistics and Epidemiology, University of Pennsylvania School of Medicine, Philadelphia, PA; 10) Division of Oncology, The Children's Hospital of Philadelphia, Philadelphia, PA; 11) Department of Psychiatry, University of Pennsylvania School of Medicine, Philadelphia, PA; 12) Department of Child and Adolescent Psychiatry, The Children's Hospital of Philadelphia, Philadelphia, PA.

Attention-Deficit, Hyperactivity Disorder (ADHD) is a common, heritable neuropsychiatric disorder of unknown etiology. Recently, we identified an enrichment of rare variants in genes involved in learning, behavior, synaptic transmission and central nervous system development in autism, suggesting that rare inherited structural variants play an important role in the etiology of ADHD. In an attempt to comprehensively identify CNVs conferring susceptibility to ADHD, we performed a whole-genome CNV study on a cohort of 556 ADHD cases and 2,118 healthy children of European ancestry who were genotyped with 550,000 SNP markers. Positive findings were evaluated in an independent cohort of 770 ADHD cases and 1,987 controls of European ancestry. GRM5 (glutamate receptor, metabotropic 5) was deleted in eight cases total and deletions were not observed in controls (p=1.24x10-5). In addition, DPP6 was duplicated in five cases and GRM7 was deleted in 3 cases, both with a control frequency of zero. All variants were experimentally validated using quantitative PCR. Although these variants may be individually rare, they target genes involved in glutamatergic neurotransmission which is an important mediator for the developing brain and normal brain function. Our results indicate that variations involving glutamatergic gene networks of the brain may contribute to the genetic susceptibility of ADHD.

**Combining next-generation sequencing, arrays and population genetics to characterize genome structural variation in human populations.**
*R.E. Handsaker[1], J. Nemesh[1], J.M. Korn[1], S.A. McCarroll[1,2].* 1) Broad Institute, Cambridge, MA; 2) Department of Genetics, Harvard Medical School, Boston, MA.

Next-generation sequencing technologies provide new opportunities for characterizing human genomic variation. In deeply sequenced individual genomes, structural variation has been revealed by analysis of end-sequence pairs (Tuzun et al.; Korbel et al.) and read depth (Chiang et al.). A more common application of next-generation sequencing in the coming years may be to perform shallower sequencing (0.5-4x) on much larger numbers of individuals, as planned by the 1000 Genomes Project and contemplated in other disease-focused resequencing projects.

We describe a set of statistical approaches for discovering and characterizing structural variation from population-based resequencing data and genotyping array data, which exploit many additional relationships and properties of structural variation in populations, including: (1) population-genetic observations that a large fraction of structural variation arises from common, segregating structural alleles; (2) the observation that many such polymorphisms are in linkage disequilibrium with SNPs; (3) additional, orthogonal information provided by array-based copy-number analysis in the same samples; (4) additional population-statistical footprints that segregating polymorphisms are predicted to leave in next-generation sequencing data.

We show that an integrated, population-genetics-based approach that incorporates array data can yield clear improvements (relative to the use of sequencing data on its own and in one individual at a time) in detecting and characterizing structural polymorphisms, in estimating their breakpoints, and in precisely measuring their integer copy number each of the genomes in a population. We will present a detailed characterization of segregating structural polymorphisms on chromosome 5 based on roughly 4X sequencing coverage of 132 unrelated individuals from the 1000 Genomes Project.

Precise characterization of structural polymorphisms in a reference population, including breakpoint locations and relationships to other markers, will help enable the creation of an integrated reference map of structural variations and SNPs that can be used as a resource for imputation in future studies.

## 2743/F/Poster Board #387

**Comparative analysis of CNV detection performance of the Affymetrix 6.0 and NimbleGen HD2 platforms.** *R.R. Haraksingh[1], A.E. Urban[1,2], M. O'Huallachain[1], S. Weissman[2], M. Snyder[1]*. 1) MCDB, Yale University, New Haven , CT; 2) Genetics, Yale University, New Haven , CT.

Determining the functional consequences of CNV in the human genome requires genome-wide, high resolution mapping of the locations of these events. Current methods for mapping CNVs include SNP genotyping, array CGH and sequencing based methods. One of the most popular and successful high-resolution platforms for detecting CNVs is the Affymetrix SNP 6.0 array. An alternative high-performance platform for genome-wide CNV analysis that is now becoming available is the NimbleGen HD2 whole genome tiling array. Here we report a systematic comparison of CNV detection performance of the two platforms. The Affymetrix array simultaneously measures 906,600 SNPs and copy number at 1.8 million genomic loci. The copy number probes are spaced densely in regions of known CNV but are at low density in other regions, especially segmental duplications. While the NimbleGen array does not detect SNP genotype at all it measures copy number at 2.1 million loci spaced evenly ~1kb apart throughout the non-repetitive genome, including in areas of segmental duplication where CNV have been shown to be enriched (Korbel et al., Science 2007b). Other potential advantages of the HD2 platform could include the ability of 60mer probes to perform with less cross-hybridization and hence result in more accurate CNV detection, and the NimbleGen 2-channel protocol, which has been optimized for CGH whereas the Affymetrix protocol is adjusted to allow for both SNP and CNV detection. The expectation is that the NimbleGen platform can detect even novel CNV evenly and at high resolution throughout the genome and not just in regions previously known to contain CNVs. Conversely, one main advantage of the Affymetrix platform might become apparent when integer CNV genotypes are to be obtained. The relative performance of these two CNV detection methods is unknown. We compare the array's performances by their abilities to detect, at high resolution, a set of 1000 CNVs which are known to occur in HapMap genome NA12878, based on independent sequence-based prediction and validation using PCR and custom array CGH. We will present a comparison, against this 'gold standard', of NA12878 CNV calls from the Affymetrix SNP 6.0 array (McCarroll et al., Nat. Genet. 2008c) and NimbleGen HD2 high confidence CNV calls observed in multiple technical replicates of NA12878 hybridized against a pool of seven females and analyzed with several different algorithms and parameters.

## 2744/F/Poster Board #388

**Definitive SNP/CNV haplotyping of Asian genomes using DNAs derived from complete hydatidiform moles.** *K. Hayashi[1], Y. Kukita[2], T. Tahira[1], K. Yahara[3], K. Yamamoto[4], K. Kato[5], N. Wake[5]*. 1) Div. Genome Analysis, Med Inst Bioreg, Kyushu University, Fukuoka, Japan; 2) Research Institute, Osaka Medical Center for Cancer and Cardiovascular Diseases, Osaka, Japan; 3) Life Science System, Fujitsu Kyushu Systems, Fukuoka, Japan; 4) Division of Molecular Populatin Genetics, Medical Institute of Bioregulation, Kyushu University, Fukuoka, Japan; 5) Department of Gynecology and Obstetrics, Graduate School of Medical Sciences, Kyushu University, Fukuoka, Japan.

Segmental copy number variations (CNVSs) in the human genome can confer various phenotypic variations such as risk to complex disease. Because there is an abundance of CNVSs with possible population differentiation, cataloging CNV regions for each ethnic group is important. Available CNV data is far from complete, due to the limitations of detection methods and samples used. We determined a genome-wide high resolution SNP/CNV map, using a collection of 100 Japanese complete hydatidiform moles (CHMs) as samples, and analysing by high-density DNA array hybridization. CHM has duplicated haploid genome, and is the material advantageous in CNV detection, because the relative difference of the hybridization signal caused by the change of unit copy number is expected to be two-fold larger than when diploid samples are analyzed (larger S/N ratio). Another advantage of using CHMs in CNV detection is that it is free from the complication of resolving overlapped CNVSs when they appear as heterozygote in diploid materials. The array platforms we used were Affymetrix SNP Array 6.0 and Illumina 1M-duo, and combined numbers of markers were 1.8 million for SNP detection and 3 million for CNV detection (before q.c. filtering). The data analysis is in progress, and tentative results suggested that there may be more common CNVSs than registered in public databases such as Database of Genomic Variants (Toronto), and many so-called CNPs are likely to be divided into different ancestral CNV events. Our data also reveals definitive linkage disequilibrium structure of SNPs and CNV regions, because the materials are haploid, and the genotypes are always genome-wide definitive haplotypes.

## 2745/F/Poster Board #389

**Using Mouse models for Smith-Magenis and Potocki-Lupski syndromes to study the impact of CNV on weight and metabolism.** *M. Heney[1], W. Gu[1], J. Yan[1], W. Bi[1], P.K. Saha[2], L. Chan[2], J.R. Lupski[1,3,4]*. 1) Dept of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Dept of Molecular and Cellular Biology, Baylor College of Medicine, Houston, TX; 3) Dept of Pediatrics, Baylor College of Medicine, Houston, TX; 4) Texas Children's Hospital, Houston, TX.

Potocki-Lupski syndrome (PTLS; MIM #610883) is associated with microduplication in chromosome 17p11.2, and it is characterized by congenital and neurobehavioral abnormalities, developmental delay, low muscle tone, poor feeding, and failure to thrive. The reciprocal 17p11.2 microdeletion is associated with Smith-Magenis Syndrome (SMS; MIM #182290), a well-characterized multiple congenital anomaly disorder with features of metabolic syndrome, including obesity and hypercholesterolemia. We have generated mouse models for PTLS, *Dp(11)17/+,* and SMS, *Df(11)17/+*, that harbor either a duplication or deletion of a ~2 Mb region syntenic to the PTLS/SMS region. These mouse models recapitulate some of the physical and neurobehavioral phenotypes seen in patients, including metabolic phenotypes. This unique mouse model system allows the study of copy number variation (CNV) in relation to specific physical, neurobehavioral, and metabolic phenotypes, because *Df(11)17/+, Df(11)17/Dp(11)17, Dp(11)17/+,* and *Dp(11)17/Dp(11)17*, mice can be analyzed to evaluate the effect of one, two, three, and four copies, respectively, of the dosage-sensitive SMS critical region. The metabolic phenotypes of these mice were studied to determine if CNV of the SMS critical region can be linked to metabolic deregulation. *Dp(11)17/+* mice are significantly underweight at the time of weaning, and throughout their lifespanIn contrast, Df(11)17/+ mice are obese. Histology of adipocytes & liver, plasma chemistries, food intake, glucose tolerance, and body composition were also studied both early and later in the lifespan, and indicate a general failure to thrive in these mice. Copy number normalization in *Df(11)17Dp(11)17* mice is able to partially correct this phenotype; these results indicate that dosage imbalance in the SMS region leads to errors in metabolism, suggesting presence of gene(s) functioning in the regulation of metabolic pathways in this region. Our mouse model thus provides an opportunity to study not only the molecular mechanisms for the multiple features in SMS and PTLS, but also common traits such as obesity and metabolic disorder.

## 2746/F/Poster Board #390

**The Normal and Tumour spectrum of Copy Number Variation: Copy Number alterations correlate with changes in gene expression in tumour transcriptome.** *F.C.L. Hyland[1], X. Xu[1], R. Gottimukkala[1], B.B. Tuch[1], M. Muller[1], C. Barbacioru[1], C. Bormann-Chung[1], C. Monighetti[1], J. Brockman[2], J. Schageman[2], J. Gu[2], S. Kuersten[2], R. Setterquist[2], H. Peckham[3], Y. Fu[3], A. Siddiqui[1], D.I. Smith[4], F.M. De La Vega[1]*. 1) Applied Biosystems, Foster City, CA; 2) Applied Biosystems, Austin, TX; 3) Applied Biosystems, Beverly, MA; 4) Mayo Clinic, Rochester, MN.

Copy number variations (CNVs) have been widely observed in normal humans and in tumor genomes, and are increasingly implicated in common disease (for example, mental retardation and autism), and in cancer progression. Massively parallel sequencing allows powerful, unbiased genome-wide interrogation of CNVs. In contrast to array methods, sequencing data allows measurement of genomic coverage at single base resolution, allowing more precise breakpoint resolution. We sequenced genomic DNA from matched tumor/ normal samples of three patients with tongue/tonsillar cancer using the SOLiDTM System. Using a modified version of the SegSeq algorithm and controlling the false discovery rate, we compared the numbers of sequence reads from tumor samples to those from normal samples in 100kb windows; we identified at least 300 significant copy number changes (ranging from 1 kb to 71,000 kb and from 0 to 9 copies) per genome. Genome-wide discovery of CNVs is robust at low coverage (1x). Using a new total RNA-based protocol, we performed SOLiD sequencing of the whole transcriptome of the tumor and normal samples, and examined the correlation between genomic copy number variation and changes in gene expression between tumor and normal samples. We found a significantly positive correlation (0.76) between CNV and gene expression in a patient. Some genomic segments with big increases in copy numbers in the tumor genome also show significantly elevated expression levels in the tumor transcriptome. These CNV segments offer insight into genes associated with the initiation or progression of cancer. In parallel, we developed an algorithm to detect copy number variation in a single sample. We calculate coverage in variable-sized genomic windows that are selected to contain a constant number of mappable positions. Within these windows, we normalize coverage based on predicted mappability and GC content. We then use a Hidden Markov Model for segmentation, and we apply empirically derived filters to the contiguous segments to call copy number variants. Of CNVs above 5kb, 89% are in the Toronto CNV database, suggesting a very high true positive rate. When we compare to an orthogonal data set, we detect 72% of predicted CNVs above 2kb in the same sample. These results are robust even at 5x coverage. Hypothesis-free genome-wide CNV detection at low coverage opens the way for CNV genotyping of many samples to elucidate the role of CNVs in complex disease.

## 2747/F/Poster Board #391

**High Resolution X-Chromosome Copy Number Variation in Autism.** *M. Ikeda[1], S. Warren[1, 2].* 1) Human Gen, Emory Univ, Atlanta, GA; 2) Pediatrics, Emory Univ, Atlanta, GA.

Autism spectrum disorder (ASD) is a broadly defined developmental disorder with impairments in reciprocal social interaction and communication and stereotyped behaviors and interests. Twin and family studies demonstrate a substantial genetic component underlying ASD. Although some rare Mendelian forms of ASD exist, most cases have a complex etiology of both genetic and environmental factors. A 4- to 10-fold male preponderance of ASD suggests the existence of sex-specific risk alleles and raises the possibility of a recessive susceptibility locus on the X-chromosome. Recently, copy number variation (CNV) has been appreciated as a rich source of both inherited and de novo human genomic variation. We have exhaustively surveyed CNV of the entire X-chromosome in a series of 100 ASD males from the AGRE collection, utilizing high-density arrays consisting of 2.1 million oligonucleotide probes specific to the X-chromosome at a resolution of one probe per 50 bp of non-repetitive sequence. We identified 200 variant loci of which 90 were deleted, 102 were duplicated, and 8 were deleted or duplicated in different individuals. The median size of the deletions was 1,550 bp, 2,063 bp for duplications, and 4,807 bp for loci with both deletion and duplication calls. Over half of these loci involve genes, including 10 genes previously identified to cause X-linked mental retardation (XLMR). When resulting in XLMR, the mutations are predicted to be severe, often null mutations. In contrast, our CNV of these loci suggest more subtle effects, affecting promoters regions or other non-coding genic regions. Our hypothesis is that loci capable of causing MR with highly penetrant alleles may also be ASD susceptibility loci when the allelic variation is more subtle. On validated CNV involving genes, we are assessing functional changes conferred by the CNV allele.

## 2748/F/Poster Board #392

**An accurate genome-wide map of copy number variants of NA10851, a widely used reference sample for array CGH.** *Y. Ju[1,2], H. Park[2,3], J. Kim[1,2,4], J. Seo[1,2].* 1) Department of Biochemistry, College of Medicine, Seoul National Univ, Seoul, Korea; 2) Genomic Medicine Institute, Medical Research Center, Seoul National Univ, Seoul, Korea; 3) Brigham and Women's Hospital, Boston, MA, USA; 4) Psoma Therapeutics Inc, Seoul, Korea.

Identifying copy number variants (CNVs), including deletions, insertions and duplications, has been actively pursued over the past couple of years using a variety of different technology platforms. Amongst these, array comparative genome hybridization (aCGH) represents one of the most powerful methodologies for detecting CNVs which requires a 'reference' sample for comparative analysis. However, owing to this need for reference, it is impossible to distinguish a loss in the test sample from a gain in the reference sample, or vice versa. In order to elucidate the direct relationship between CNVs and susceptibility to disease, and also to enable utilization of CNV information in the personalized medicine, it is necessary that the absolute copy number state of certain genomic regions (rather than relative value) to the reference sample be known. Here we report the first accurate genome-wide CNVs map of NA10851, which has been widely used as a reference for aCGH experiments in the past. Three differing strategies were systematically applied to accurately identify CNVs of the reference sample in the current study. Firstly, experiments utilizing high resolution custom-designed 24 million probe set aCGHs (Agilent Inc.) and 42 million probe set aCGHs (Nimblegen Inc.) were performed on the test sample (AK1) and NA10851. Secondly, the whole genome shotgun sequencing data obtained by Illumina Genome Analyzer for both AK1 and NA10851 genome were analyzed to an average depth of 24.8x and 5.7x, respectively, and subsequently cross-compared with the data obtained through aCGH. Lastly, we reexamined the CNV regions previously reported on the Database of Genomic Variants utilizing the massively parallel sequencing data of NA10851. Through these combined approaches, we were able to elucidate 446 copy number losses and 213 copy number gains, totaling 5.76 Mb and 8.84 Mb, respectively, on NA10851 genome. Moreover, our preliminary data suggests the majority of copy number gains identified were overestimated due to copy number losses of NA10851. Overall, about 340 genes were on CNV regions of NA10851 genome. Our CNV map from NA10851 will enable unbiased and more accurate interpretation of future CNV results using aCGH. Absolute copy number of genes for test sample will also be made available. Findings from present study will help us uncover the direct relationship between the CNVs and the phenotypes, and move us one step closer to the era of personalized medicine.

**Databases for copy number variations in Japanese Integrated Database Project.** *A. Koike[1], N. Nishida[2], D. Yamashita[2], I. Inoue[3], S. Tsuji[4], K. Tokunaga[2].* 1) Cent Res Lab, Hitachi, Ltd, Kokubunji, Japan; 2) Dept Human Genetics, Univ. Tokyo; 3) Dept. of Mol. Life Sci. and Mol. Med., Tokai Univ. Sch. Med; 4) Dept Neurology, Univ. Tokyo,.

Recent advances in measurement technologies for copy number variations (CNVs) on a genome-wide scale have gradually revealed disease-associated CNVs. Especially microarray-based CNV analyses have enabled us to detect CNVs in a high-throughput manner. So far, our organization has created the repository database for genome wide association study (GWAS) (https://gwas.lifesciencedb.jp/) to achieve continuous and intensive management of GWAS data and data sharing among researchers and has widely called for data submission. In this study, we have newly constructed a repository CNV database for normal samples and a repository CNV-GWAS database for CNV association studies in addition to extending the GWAS DB function to call up CNV-case control results with SNP case control analysis results. The CNV control DB and CNV-GWAS DB provide hierarchical view of CNV regions, CNVs, CNV frequencies, and genotype patterns consisting CNVs by tables and graphs. The CNV-GWAS DB also accumulates case control statistical analysis results for duplication, deletion, and alteration of genomic segments. The comparison among studies and that among different analysis results and the superposition with DGV (Database of Genomic Variants) data and gene structures are also available.

In this presentation, in addition to the introduction of these CNV databases' structures, the analysis results of currently registered CNVs of Japanese normal individuals (Affymetrix 6.0: 150 individuals, Affymetrix 500K: 150 individuals) are reported. These CNVs were detected by multiple methods such as Circular Binary Segmentation (Olshen et al. 2004), Gaussian process with adaptive criteria (Picard et al. 2004), Hidden markov model based method (Korn et al. 2008), and were carefully selected based on the thresholds, which were determined using HapMap data (Affymetrix 6.0 and 500K ) and their CNV data validated by other experiments. The comparisons of these CNVs with known CNVs in inter- and intra-populations and the characteristics of CNV-located gene functions and the bias of CNV-locations on the genome are also discussed.

## 2750/F/Poster Board #426

**Population Genetics of Rare Copy Number Variants, and Implications for Studies of Phenotype Association.** *J.M. Korn[1,2,3,4,5], J. Nemesh[3], M.J. Daly[3,5], S.A. McCarroll[3,4], D. Altshuler[3,4,5].* 1) Dept Biophysics, Harvard Univ, Boston, MA; 2) Bioinformatics and Integrative Genomics, HST, Cambridge, MA; 3) Broad Institute, Cambridge, MA; 4) Dept Genetics, Harvard Medical School, Boston, MA; 5) Center for Human Genetic Research, MGH, Boston, MA.

Copy number variation (CNV) is increasingly analyzed alongside SNPs in whole genome association studies for association to phenotypes. A fundamental question in interpreting such data is the extent to which rare CNVs (<1% MAF) observed at the same locus in different individuals arise from a shared ancestral mutation, rather than a collection of mutations occurring at the same site (and are private or *de novo* CNVs in each individual). A more general question, relevant to association studies for both rare CNVs and rare sequence variants, involves whether ancestry matching using common variants correctly controls for association of rare variants, which as a class may be more sensitive to population substructure.

Using data from several thousand individuals whose genomes were analyzed using the Affymetrix SNP 6.0 array, we first demonstrate that the majority of rare CNVs are of the type that have a shared ancestral origin. Such CNVs have coherent breakpoints and tend to lie on long shared haplotypes (as expected of recent mutations); we use phasing and imputation algorithms to define such haplotypes. Since most rare CNVs in the general population arose from a common ancestor, the demonstration that a rare CNV arose multiple times in affected individuals carries implications for both the association statistic and the interpretation of the results. Multiple mutation events can indicate negative selection at the locus and increase confidence in an association. Furthermore, the lack of a shared haplotype implies the CNV itself is likely the causal mutation.

The tendency towards shared origin of rare CNVs ascertained in the general population is common regardless of other features of the CNV, such as size, local sequence context, and allele frequency. We demonstrate that rare CNVs can have shared haplotypes even across continental populations, although haplotype length varies both within and across populations. We show that the typical correction for ancestry as determined by common variants may not address population substructure as effectively as is required to assess the disease association of low-frequency segregating polymorphisms without inflation of association statistics. Finally, we revisit several published associations of phenotypes to rare CNVs to determine which are likely arising from an ancestral mutation (and thus potentially confounded by population substructure), and which are not.

**Genome-wide analysis of structural variations in different ethnic groups.** *V. Kumar, AM. Hilmer, P. Nuwantha, C. Lee, JHH. Tan, Y. Zhu, F. Yao, SWK. Ken, Y. Ruan, M. Seielstad.* Genome Institute of Singapore, Singapore.

Abstract: Structural variation (SV) can be defined as all genomic alterations other than single base-pair substitutions. A number of studies have shown that SV is abundant in human populations. Systematic analysis of this variation will provide fundamental knowledge to understand human diversity and to distinguish from pathogenic alterations. However, identifying them comprehensively with high resolution remains a technical challenge. We have taken a multi-pronged strategy, including Paired-end Mapping (PEM), SNP-Chip (Illumina IM and Affymetrix 6.0) and aCGH (Nimblegen 2.1M and Agilent 1M) to characterize SVs. We have applied these methods to 8 individuals comprising 2 trios of African and European descent and, 2 Asians. For PEM we fragmented genomic DNA extracted from lymphoblastoid cell lines to a size of 10 kb. This was followed by 25 base-pair sequencing of the fragment-ends using the ABI SOLiD, and mapping of these paired-ends to the reference assembly hg18 to identify SVs. The SNP and CGH microarray platforms were used to identify copy number variation (CNV). To maximize the resolution of the SNP chips we combined the Illumina and Affymetrix datasets and normalized the log-ratios. Based on the analysis of the data generated by PEM and the various microarrays we are able to accurately identify a large number of SVs, both novel and reported, as well as precisely map the break points.

**An Optimization Framework for Unsupervised Identification of Rare Copy Number Variation from SNP Array Data.** *T. LaFramboise[1,2,3], G. Yavaş[3], M. Koyutürk[3], M. Özsoyoğlu[3], M. Gould[1].* 1) Genetics, Case Western Reserve University, Cleveland, OH; 2) Genomic Medicine Institute, Lerner Research Institute, Cleveland Clinic Foundation, Cleveland, OH; 3) Electrical Engineering & Computer Science, Case Western Reserve University, Cleveland, OH.

Until fairly recently, it was believed that essentially all human cells harbor two copies of each locus in the autosomal genome. However, studies have now shown that there are segments of the genome that are polymorphic with regard to genomic copy number. These copy number variations (CNVs) have a role in various diseases such as Alzheimer disease, Crohn's disease, autism schizophrenia, and others. In the effort to scan the entire genome for these gains and losses of DNA, single nucleotide polymorphism (SNP) arrays have emerged as an important tool. As such, CNV identification from SNP array data is attracting considerable attention as an algorithmic problem, and many methods have been published over the last few years. In this work, we address the problem from a novel perspective. We frame CNV identification as an objective function optimization problem. The objective function is ideally designed so that its optimal solution is the most accurate set of CNV calls. Our method, termed ÇOKGEN, finds the best solution using a variant of the well-known heuristic simulated annealing. We apply ÇOKGEN to data from hundreds of samples, and demonstrate its ability to detect known CNVs at a high level of sensitivity without sacrificing specificity. Furthermore, we show that it performs better than other publicly-available methods. ÇOKGEN is implemented in an R package, freely available from the authors, that converts raw Affymetrix 6.0 SNP array .CEL files into CNV inferences.

## 2753/F/Poster Board #429

**Identification of Copy Number Variation in high-risk African-American men with prostate cancer.** *E. Ledet[1], X. Hu[2], M. Li[2], D. Mandal[1].* 1) Dept Genetics, Louisiana State Univ HSC, New Orleans, LA; 2) Hayward Genetics Center, Tulane University School of Medicine, New Orleans, LA.

Prostate cancer is a complex multi-allelic disease and the most common malignancy in men throughout the world. In the United States, a lifetime risk of mortality from prostate cancer is 3% for white men and 4% for African-American men. Thus far, disease susceptibility loci have been identified for this cancer but no definite locus-specific information is established due to the tremendous amount of genetic heterogeneity. Genomic copy number variations (CNVs), the most prevalent form of structural variation in the human genome, has been detected in prostate tumors and several other cancers, but changes in copy number have not been studied in germ-line DNA from hereditary African-American prostate cancer cases. In order to identify prostate cancer associated CNVs, we have identified ten high-risk African-American families with at least 3 affected individuals. From these families, 30 individuals, including 21 affected males and 9 unaffected males, were selected for CNV analysis. Array comparative genomic hybridization (aCGH) technology was used to determine the common or case specific CNVs that may predispose African-American men with family history to prostate cancer. We have used a combined targeted/whole-genome array system using the Agilent 4 X44 K format. Fifty percent of the probes were selected from the Agilent eArray system that targets more than three hundred fifty oncogenes, tumor-suppressor genes, and known cancer-associated chromosome regions, including over thirty reported prostate cancer associated genomic regions. Intervals between above genes or regions were filled relatively evenly with the remaining 50% probes to cover the whole genome. DNA extracted from the patients was co-hybridized with DNA from pooled normal individuals to the arrays. Scanned data from aCGH experiments were analyzed using CGH Analytics 3.5 software (Agilent Technologies) and genomic copy number changes were identified using aberration detection method 1. All CNVs were compared with the standard reference database to rule out known polymorphisms. Novel CNVs were identified on chromosomes 1, 13, and 20 in prostate cancer cases. These CNVs may represent a component of genetic variability which contributes to the high prevalence and high mortality of prostate cancer in African American men. Detailed analysis of our array CGH data and validation study will be presented.

**Validation of High-resolution Copy Number Variation Discovery by TaqMan Assays.** *K. Li, F. Wang, I. Casuga, A. Broomer, B. Ching, X. You, N. Majumdar, C. Chen.* Applied Biosystems, Foster City, CA.

Copy number variation is a recently appreciated, widespread form of polymorphism in the human genome and can be associated with genomic disorders and complex diseases. Array-based comparative genome hybridization (aCGH) has been a commonly used methodology for CNV discovery. The Structural Genomic Variation Consortium (http://www.sanger.ac.uk/humgen/cnv/) published a first generation, genome-wide copy number variant (CNV) map in 2006 (Nature 444:444-454, 2006) and reported that the copy number variation regions (CNVRs) cover as much as ~12% of the human reference genome. This study suggested that thousands of CNVs existed in the human genome, but technological limitations precluded the discovery of more CNVs. In 2007, the consortium launched its phase II CNV discovery to develop a more comprehensive, higher resolution CNV map for the human genome - at a level of 100-fold finer than reported previously. A 42- million probe set that tiled across the human genome was designed for NimbleGen's 2.1 million probe (HD2) arrays. Forty HapMap samples (20 CEU and 20 YRI) were then analyzed. The study was designed to capture common CNVs in these individuals that were 500 bp and larger, with a frequency of at least 2.5 percent. To validate the CNV calls made on the NimbleGen's arrays, orthogonal technologies were employed. Here, we report the TaqMan validation results of ~100 randomly chosen CNVR from this project. TaqMan assays were selected for each target from a set of ~1.7 million, pre-designed TaqMan Copy Number Assays. The same 40 HapMap samples were run on both arrays and TaqMan assays. We observed very similar copy number profiles between array and TaqMan across the tested targets and the samples and high concordance between the two platforms. This validation study showed that the CNV calls made with this array platform had a relatively low false positive rate. The validation study also demonstrated that these TaqMan assays were a useful and reliable tool for validating array-based CNV discoveries. The detailed observations and analyses will be presented and discussed. Acknowledgements: Drs. Matthew Hurles and Nigel Carter (Sanger Center, UK), Charles Lee (Harvard Medical School / Brigham and Women's Hospital, Boston, USA), Stephen Scherer (Sick Kids Hospital, Toronto, Canada).

## 2755/F/Poster Board #431

**Copy Number Variants in Myopia of Singapore Chinese Schoolchildren.** *Y.J. Li[1,2], A.E. Dellinger[1], M. Yu[1], T.L. Young[1,3], S.M. Saw[4,5].* 1) Ctr for Human Genetics, Duke Univ Med Ctr, Durham, NC; 2) Dept. of Biostatistics and Bioinformatics, Duke Univ Med Ctr, Durham, NC; 3) 3Duke - National University of Singapore Graduate Medical School; 4) Dept. of Epidemiology and Public Health, National University of Singapore, Singapore; 5) Singapore Eye Research Institute, Singapore.

Copy number variants (CNVs), duplications or deletions of chromosomal segments, are common in the human genome and can be used as genetic markers for disease studies. CNV data can be generated by multiple platforms, including genome wide single nucleotide polymorphism (SNP) arrays. We examined the characteristics of SNP array derived CNVs among multiple myopia phenotypes. A total of 1116 Chinese participant DNA samples from the Singapore Cohort study Of the Risk factors for Myopia (SCORM) were genotyped using Illumina HumanHap 550 Beadchips. CNVs were detected by Nexus CGH™ and QuantiSNP. A CNV is defined as at least five SNPs within the detected CNV region. Phenotypes examined are quantiative spherical equivalent (SE, n=912) and the binary states of any myopia (SE < -0.50 diopter (D), n=699) and high myopia (SE < -6.00D, n=97). CNVs were excluded if the CNV presented in only one sample for QuantiSNP, or in less than seven samples for Nexus. Linear regression and logistic regression were use to examine the average CNV size per sample and individual CNV size in the three phenotypes. The Fisher exact test was used to test the association of the presence of CNVs (CNV events) with any myopia and high myopia. The average participant age at the final eye examination was 13.35 years (SD=1.9). Nexus generally detected longer and fewer CNVs than QuantiSNP (0.52±1.6MB vs. 0.09±0.37MB). The average CNV length per individual was found to significantly associate with SE ($P=4.19x10^{-8}$ for Nexus, P=0.01 for QuantiSNP) and high myopia ($P=1.38\ x10^{-8}$ ) for Nexus, P=0.03 for QuantiSNP), but not any myopia. CNVs detected by both programs in chromosomes 1, 9, 11, and 16 were significantly associated with at least one phenotype (P<0.05) and map to known gene regions. The top association result was chromosome 3 (from 163,613,386 to 163,796,731) , which shows significant association between CNV sizes and SE in both programs (minimal $P=8.23x10^{-9}$ by Nexus) as well as significant association between the CNV event and SE (minimal P=0.01 by Nexus). Fisher exact test also detected two SNPs in this CNV with significant association to high myopia (P=0.004). However, this region does not map to a gene but a transcription factor binding site Cart-1 could be potentially interesting. In conclusion, our data show that CNV sizes vary among phenotypic groups. CNV size can be a useful surrogate for CNV events for identifying susceptibility genes for myopia.

## 2756/F/Poster Board #432

**Genomic copy number variants in East Asian populations.** *S. Li[1], S. Xu[2], Y. Wang[1], X. Zhang[1], X. Gong[1], Y. Shen[3], Y. Yang[1], H. Wang[1], B. Wu[1,3], J. li[1,2].* 1) MOE Key Laboratory of Contemporary Anthropology and Center for Evolutionary Biology, Institutes of Biomedical Science and School of Life Science, Fudan University, Shanghai, China 200433; 2) CAS-MPG Partner Institute for Computational Biology, Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, Shanghai, China; 3) Children's Hospital Boston and Harvard Medical School, Harvard University, Boston MA, USA.

Genomic diversity between human individuals is more extensive than previously realized. The existence of prevalent genomic copy number variants (CNV), along with single nucleotide polymorphism (SNP), has important implications in understanding human diversity, evolution and disease susceptibility. Characterization of CNV and SNP in the DNA of representative health individual from East Asian populations is the first important effort toward genome-wide association studies in this area. We used Affymetrix SNP 6.0 array for simultaneous interrogation of CNV and SNP. Here we report the initial findings from 100 Han Chinese, 50 Tibetan and 40 other ethnic groups. While many CNVs in East Asian populations could be found in other world populations, novel CNVs were also observed in the samples studied. Some novel CNVs were further confirmed by an independent analysis. We further studied some of the novel CNVs and found that they may reflect not only the mutational history as well as the local adaptation of East Asians. We believe this is the first step towards understanding the unique structural genomic variation of East Asians and their potential functional consequences related to susceptibility to diseases.

## 2757/F/Poster Board #433

**A mutational mechanism for copy number variation.** *L. Liang, L. Deng, O.F. Hashmi, C. Shao, J.A. Tischfield.* Department of Genetics, Rutgers University, Piscataway, NJ.

Discovery of copy number variation (CNV) in the human genome has provided new opportunities to examine the range of genetic variants associated with human diseases. CNVs are changes in copy number of DNA segments ranging from 1 kb to several Mb in size, and can be copy number gains (duplications or insertions), losses (deletions), or complex multi-site rearrangements. The mechanisms underlying the origin of CNV are not known. Several models that were proposed to explain how CNV arises have not been subjected to rigorous test. Nevertheless, molecular analysis of genomic segment alterations either associated with human clinical phenotypes or occurring in healthy individuals has revealed that many CNV events occur at microhomology (2-10 bp) sites. For instance, some deletions spanned one of the two microhomology (2 to 4 nucleotides) sequences and the intervening sequence. The pattern of these deletions resembles genetic consequence of microhomology-mediated end joining (MHEJ), an error-prone repair pathway of DNA double strand breaks (DSBs) that exists in many organisms, including humans. By using a cell-based reporter system for MHEJ, we demonstrated that MHEJ is one of major mutational mechanisms of CNV. Therefore, environmental insults that can induce DSBs can increase the risk for microhomology-mediated CNV, and factors modulating MHEJ can play roles in origin of CNV.

## 2758/F/Poster Board #434

**A genome-wide scan of copy number variation in Moebius syndrome.** *A.C. Lionel[1,2], C.R. Marshall[1,2], I.E. Drmic[3], W.S. Roberts[3,4], S.W. Scherer[1,2].* 1) The Centre for Applied Genomics and Program in Genetics and Genomic Biology, The Hospital for Sick Children, Toronto, ON, Canada; 2) Department of Molecular Genetics, University of Toronto, Toronto, ON, Canada; 3) Autism Research Unit, The Hospital for Sick Children, Toronto, ON, Canada; 4) Child Development Program, Bloorview Kids Rehab, Toronto, ON, Canada.

**Background:** Moebius syndrome, a rare, congenital facial palsy prevalent in 0.002 % of births, is characterized by abnormalities of the abducens (cranial nerve VI) and facial (cranial nerve VII) cranial nerves. In addition to facial paralysis and impaired ocular movement, this syndrome is also associated with a heterogeneous phenotypic spectrum including the increased incidence of limb anomalies, autism spectrum disorder and mental retardation. Familial inheritance of Moebius syndrome has been reported, although a majority of cases are sporadic. Case reports have described several cytogenetic abnormalities such as translocations and inversions as being potentially causal. The purpose of this study is to assess the possible role of copy number variants (CNVs) in the etiology of Moebius syndrome and its co-morbid phenotypes. **Methods:** We conducted a genome-wide CNV scan in 24 unrelated Moebius Syndrome patients using the Affymetrix Human SNP Array 6.0. For CNV detection, we used a multi-algorithm approach incorporating Birdsuite, Partek Genomics Suite, Affymetrix Genotyping Console and iPattern (a novel clustering-based method developed in our lab). High confidence CNVs detected by this approach in the Moebius cases were compared with CNVs found in 2,115 population based controls using the same microarray platform and CNV calling strategy. **Results:** We identified CNVs overlapping genes in the Moebius dataset which were not present in control samples. These included variants which encompassed exons of genes involved in neuronal development and function such as *GRM5*, *PTPRD* and *NRXN1*. The finding of the deletion overlapping exons of *NRXN1*, in a Moebius syndrome patient with autism spectrum disorder, is particularly intriguing, given the previous reports of CNVs at the *NRXN1* locus being associated with autism. We are currently collecting samples from the parents of the Moebius cases in order to study the inheritance patterns of the CNVs of interest and their potential segregation with elements of phenotype. **Acknowledgement:** We thank the children and families who participated and the International Moebius Syndrome Foundation for supporting this work.

## 2759/F/Poster Board #435

**Data Quality Control in Detecting Copy Number Variations using Illumina SNP arrays.** *E. Lu, Y. Xu, C. Amos.* Epidemiology, UT MD Anderson Cancer Center, Houston, TX.

SNP genotyping arrays have been developed to type DNA copy number variations (CNVs). The quality of the inferences about copy number can be affected by many factors including batch effects, DNA sample preparation, signal processing, and analytical approach. As a part of a genome-wide association analysis of lung cancer susceptibility, we obtained data from the Center of Inherited Disease Research that included 53 CEPH control cell line samples that had been genotyped in duplicate using Illumina Human Map v1.1 BeadChips. These duplicated controls allowed us to evaluate the performance of copy number variation assessments using different analytical algorithms and allowing for intraindividual variability. We analyzed these data using i) QuantiSNP and ii) Penn CNV, both algorithms that use both the log R intensity as well as the B-allele frequencies. Results show that when no constraint is made on inclusion of results from sample reads according to log R intensity, that concordance of CNV calling was higher for QuantiSNP (60% samples have at least 50% identical CNV finding when the Bayes factor was restricted to be >5 for existence of a CNV), and a little bit lower for Penn CNV (50% samples have at least 50% identical CNV findings). When only samples that showed within-subject variability in log R intensity <90% of the entire sample, the repeatability of inferences improved greatly, yielding r=? for Penn CNV. These results show higher repeatibility for the Penn CNV algorithms and the importance of restricting analyses to those samples with tighter variability in log intensities.

## 2760/F/Poster Board #436

**High resolution map of canine copy number variation.** *E.M. Nevalainen[1,2], C. Hitte[3], P. Jokinen[1,2], C. Andre[3], K. Lindblad-Toh[4,5], H. Lohi[1,2], LUPA Consortium.* 1) Department of Medical genetics and Department of Basic Veterinary Sciences, University of Helsinki, Finland; 2) Department of Molecular Genetics, Folkhälsan Institute of Genetics, Finland; 3) Institute of Genetics and Development of Rennes, CNRS-umr6061, University of Rennes, France; 4) Department of Medical Biochemistry and Microbiology, Uppsala University, Sweden; 5) Broad Institute of Harvard and Massachusetts Institute of Technology.

Copy number variations (CNVs) are an important form of structural variation in mammalian genomes. Substantial amount of phenotypic differences between healthy individuals have been attributed to CNVs and they also contribute to disease risk in several human disorders including autism spectrum disorders, schizophrenia and epilepsy. Dog breeds as genetic isolates have recently emerged as a new model for gene mapping of comparative interest for human inherited diseases. Over 400 genetic diseases have been identified in dogs, many of which are similar to human diseases and are likely to have a similar genetic background. CNVs are expected to play a role in several disorders in dogs and contribute to breed-specific characters. This study aimed to catalogue CNVs in 62 dogs from 17 dog breeds (2-10 dogs/breed) and 3 wolves using Nimblegen's comparative genome hybridization (aCGH) arrays with 2.1 million probes. This density gives a high resolution of ≈1 kb median probe spacing across the dog genome. A Finnish Boxer DNA was used as a reference for other breeds. We identified a total of 2665 high confidence CNVs (log2 ratio ≥±0.45, 10 probe coverage) with an average of 72 CNVs per dog. The analysis with less stringent criteria doubled the number of potential CNVs. The size of the CNVs varied from ≈10 kb to 1.9 Mb with an average size of ≈60 kb. X chromosome was excluded from the analysis. The results of this high resolution analysis of the CNVs in a large number of breeds provide important discoveries likely to contribute to disease risk and other phenotypes in dogs and are being followed up in many disease cohorts available in the European canine genomics effort, LUPA consortium.

## 2761/F/Poster Board #437

**High resolution CNV map of Asian population.** *H. Park[1,2], J. Kim[3,4], Y. Ju[2,3], H. Kim[3], C. Lee[1], J. Seo[2,3].* 1) Brigham & Womens Hospital, Harvard medical school, Boston, MA; 2) Genomic Medicine Institute, Medical Research Center, Seoul National University, Seoul, Korea; 3) Department of Biochemistry and Molecular Biology, Seoul National University College of Medicine, Seoul, Korea; 4) Psoma Therapeutics Inc., Seoul, Korea.

The structural genomic copy number changes involve deletions and insertions of segments of genomic DNA spanning from 1 Kb to megabases in length and are present in all individuals. About 12% of the human genome is copy number variable with the CNVs contributing 0.12% to genomic variability seen within humans. Copy number variation (CNV) of DNA sequences is functionally significant but CNV map has yet to be fully established. The specific hypothesis is there remains a need to identify CNV that is smaller than 1Kb. We have constructed a high resolution of CNV map of the human genome through the study of 30 individuals from 3 populations with ancestry in Asia (Korean, Chinese and Japanese of the HapMap collection). We designed twenty four custom 1M feature 60mer in situ synthesized oligonucleotide arrays. Our design consisted of ~23.5M probes with ~100 bp between-probe resolution spaced uniformly across the entire human genome (whole genome tiling array). This high resolution array-based comparative genomic hybridization (aCGH) array set will allow us to interrogate the samples at a level not previously achieved, and will facilitate the identification of smaller CNV events which are often missed in lower resolution aCGH array. High resolution aCGH arrays will be used to identify complete CNV regions including common and different CNV regions from the genomic DNAs of 30 individuals from 3 populations. Approximately, 1,500 copy number variable regions (CNVRs), which can encompass overlapping or adjacent gains or losses, covering 20 megabases were identified in each individual. These CNVRs contained hundreds of genes, disease loci, functional elements and segmental duplications. In conclusion, this strategy will offer insights into the molecular basis and elucidate the role of CNVs.

## 2762/F/Poster Board #438

**Calling and Scoring Copy Number Variants.** *G.A. Satten[1], A.S. Allen[2], M. Ikeda[3], J.G. Mulle[3], S.T. Warren[3].* 1) National Center for Chronic Disease Prevention and Health Promotion, CDC, Atlanta, GA; 2) Dept. of Biostatistics and Bioinformatics, Duke University, Durham NC; 3) Dept. of Human Genetics, Emory University, Atlanta GA.

**Background:** Copy number variation is an exciting new class of genetic diversity currently under intensive investigation. Many platforms and algorithms exist to detect these variants. However, regardless of the technology used, many CNVs detected are false positives. Distinguishing true from false signals requires laborious experimental validation.

**Methods:** We have developed a CNV detection algorithm that addresses the false positive CNV call rate, with a simple score that can be easily calculated for each possible CNV. We show that this score is predictive of the chance that a CNV is experimentally validated. Based on this score, we have developed a new and simple backward elimination algorithm for calling CNVs: starting with a possible jump in log-intensity ratio (LIR) at each probe (where a jump is a putative CNV breakpoint), we remove jumps one at a time (while combining the intensities between jumps) until all remaining called CNVs have a score larger than a user-specified cutoff. To make our algorithm more robust, we use medians rather than means of adjacent probe intensities when combining LIRs. Information on genomic covariates such as GC content could easily be added to our scoring and CNV-calling algorithms if desired. Our approach can also be easily extended to case-parent trio data to only call CNVs that appear in the offspring and at least one parent.

**Results:** We validated our score using samples from males with autism from the Autism Genetic Resource Exchange that were analyzed with a Nimblegen array CGH approach having approximately 2 million probes on the X chromosome. We experimentally validated 91 CNVs called in 41 individuals, of which 43 were validated and 48 were not. The mean score for validated CNVs was 4.5 with standard deviation 2.9. The mean score for non-validated CNVs was 2.3 with standard deviation 1.6.

**Novel Copy Number Variation Detection in the Asian Population Using a High-Density Array CGH Platform.** *C.J. Shaw, K. O'Moore, K. Hogan, J. Geoghegan, A. Larsen, N. Jiang, T.A. Richmond, V.L. Ott, R.R. Selzer, R. Seibl.* Roche NimbleGen, Inc, Madison, WI.

Array CGH methods have been widely used to investigate genome-wide DNA copy number variation associated with complex disorders. Disease association studies have become increasingly focused on CNVs, and several recent reports show links between CNVs and schizophrenia (Stefansson 2008; Stone 2008), autism (Sebat 2007; Marshall 2008; Glessner 2009), and cancer, among others. CNV frequencies are known to differ among populations, resulting in variable risk factors for individuals of different ethnicities. However, the majority of disease association studies with CNVs have focused on the European and Yoruban populations, while the Asian populations have been under-represented (Kang 2008; Lin 2008). Thus, the currently available databases containing CNV information and the microarray designs used to detect them are somewhat skewed toward the European and Yoruban populations. We sought to discover novel, Asian-specific CNVs using the Roche NimbleGen CNV-focused 3x720K v1.0 CGH array. We studied several individuals from the Chinese, Japanese, and Korean populations, and compared the CNV discovery to that of European and Yoruban individuals. Utilization of the CNV-focused array enabled detection of hundreds of CNVs per individual. When the frequency of CNV detection was compared across the Asian and non-Asian populations, we identified hundreds of novel CNVs that were present in Asian individuals, but absent in non-Asian individuals. Further, when the Database of Genomic Variants was searched for these Asian-specific CNVs, only a fraction were located. Competitive array platforms were also investigated to determine the detection rate of the Asian-specific CNVs we identified. The number of CNVs detected in Asian individuals varied depending on the platform, with the Roche NimbleGen array detecting more Asian-specific CNVs than the other platforms tested. We demonstrate here the variability in CNV detection in Asian individuals based on the platform utilized, and the paucity of Asian-specific CNVs contained in public databases relative to that of the European and Yoruban populations.

**Detecting Copy Number Variations from Whole Genome Resequencing Data at Low Coverage.** *Y. Shen[1,2], I. Pe'er[1,2].* 1) Computer Science, Columbia Univ, New York, NY; 2) Center for Computational Biology and Bioinformatics, New York, NY.

Copy Number Variations (CNVs) are genetic factors crucial for studying human traits and diseases. Whole genome resequencing provides multiple lines of evidence for detecting CNVs. Most obviously, depth-coverage positively correlates with the copy number, therefore can be incorporated in a Hidden Markov Model (HMM) for calculating the emission probabilities of hidden states that represent copy numbers. However, theoretical calculation and practical experience show that at low coverage, methods based solely on depth-coverage lack power to detect small- to medium-size CNVs. Using mate pair information helps to improve the power in such scenarios. Abnormality in mate pair distance, order, or orientation suggests breakpoints, and the distance reflects the size of a deletion or tandem duplication. Additionally, intra-read breakpoints are direct evidence of breakpoints. Conventional CNV detection methods generate and then filter a list of candidate CNVs by ad hoc cutoffs for abnormality of mate pairs and other information. We propose an approach that infers the likelihood of CNVs jointly from multiple mate pairs by a HMM that integrates depth-coverage, mate-pair relationship and intra-read breakpoints. There are two challenges in modeling mate pairs through a HMM: (1) The duration of a state follows exponential distribution whereas the inferred CNV size from a mate pair should follow Gaussian-like distribution; (2) A 1st order Markov chain does not remember inferred CNV size once the path goes beyond break points. To address these issues, we designed a grid of specialized CNV states. Specifically, each row states on the grid represent same copy number. The transition to states representing other copy numbers can only occur at the end of a row. Although the duration of each state still follows exponential distribution, the duration of the row as a whole approximately follows Gaussian distribution based on the central limit theorem. In addition, different rows of states have different transition probabilities designed to accommodate different ranges of CNV size. Intra-read breakpoints increase the emission probabilities of first and last CNV states in each row. By integrating all useful information in such comprehensive model, our method is aimed for projects at low to medium depth-coverage (0.1x to 10x per sample). We apply it to simulated and public-domain individual genomes and demonstrate the accuracy and power with different levels of depth-coverage.

**Functioanl Annotation of copy number variation related genes in Caucasians and Asians.** *H. Shen[1], J. Li[1], L.S. Zhang[1], X.H. Xu[2], F. Chen[2], H.Y. Deng[1], S. Levy[3], C.J. Papasian[1], B.M. Drees[1], J.J Hamilton[1], R.R. Recker[4], H.W. Deng[1,2,5].* 1) Basic Medical Sciences, University of Missouri-Kansas City, Kansas City, MO; 2) The Key Laboratory of Biomedical Information Engineering of Ministry of Education and Institute of Molecular Genetics, School of Life Science and Technology, Xi'an Jiaotong University, Xi'an, Shanxi, China; 3) Vanderbilt Microarray Shared Resource, Vanderbilt University, Nashville, TN; 4) Osteoporosis Research Center, Creighton University, Omaha, NE; 5) Laboratory of Molecular and Statistical Genetics, College of Life Sciences, Hunan Normal University, Changsha, Hunan, China.

Copy number variation (CNV) may affect the gene dosage and expression levels of corresponding genes. Previous studies have suggested that genes with certain biological functions tend to be enriched in CNV regions, such as cell adhesion, chemical stimuli and sensory receptor. In this study, we reported a genome-wide functional annotation of genes overlapping with CNVs in Caucasians and Chinese. CNV genes were examined for biological functions, relation to human genetic disorders and potential effects on human ethnic diversity.

A total of 2796 genes were identified to contain CNVs. These CNV genes are found to be significantly enriched in 29 GO (gene ontology) functional categories, such as multicellular organismal process (P = 6.47E-24, 492 CNV genes), developmental process (P = 2.17E-15, 400 CNV genes), neurological system process (P = 2.09E-09, 172 CNV genes) and reproduction (P = 7.72E-06, 84 CNV genes). In terms of biological pathways, CNV genes were enriched in several neurological pathways, such as neuroactive ligand-receptor interaction pathway and axon guidance pathway, as well as in some cancer related pathways, such as colorectal cancer, melanoma and renal cell carcinoma pathways. In addition, MAPK signaling pathway, calcium signaling pathway, Wnt pathway and insulin signaling pathway also enriched with CNV genes. A total of 317 CNV genes were involved in 392 human genetic disorders. Thirteen CNV genes were related to mental retardation and 6 CNV genes related to obesity. Other diseases, such as schizophrenia, autism, and leukemia, may also be affected by CNV genes.

Further analysis revealed 261 CNV genes showing significant difference in CNV occurrence rates between Caucasians and Chinese. These ethnic differentiate CNV genes are involved in developmental process, response to stimulus, immune system process, reproduction, and growth. A number of human genetic disorders, such as deafness, mental retardation, Cohen syndrome, leukemia, obesity and Parkinson disease, are related to these ethnic differentiate CNV genes, suggesting that CNVs may contribute to the ethnic difference of disease occurrence.

## 2766/F/Poster Board #474

**Association of DUF1220 domain copy number with brain size in human evolution and disease.** *J. Sikela[1], L. Dumas[1], J. Davis[1], M. Sikela[1], S.W. Cheung[2], P. Stankiewicz[2], T. Fingerlin[1].* 1) Dept of Pharmacology, Human Medical Genetics and Neuroscience Programs, Univ Colorado Hlth Sci Ctr, Aurora, CO; 2) Molecular and Human Genetics, Baylor College of Medicine, Houston, Texas 77030, USA.

We have previously reported that sequences encoding DUF1220 protein domains are increasingly amplified generally as a function of a species evolutionary proximity to humans, where the greatest number of copies (212) is found. Human DUF1220 domains also show signs of positive selection and are highly expressed in human brain regions thought to be involved in higher cognitive function. These findings suggest that the extreme amplification of DUF1220 domains in the human lineage may contribute to the unique brain-related characteristics, such as increased size, that distinguish the human brain from that of other species. Recent reports found copy number variations (CNVs) in chromosome 1q21.1 present in individuals with microcephaly and macrocephaly, as well as in individuals with schizophrenia (SZ) and autism spectrum disorders (ASD). Compared to unaffected individuals, brain sizes and 1q21.1 copy number in affected individuals with microcephaly and with SZ tend to decrease, or increase in those with macrocephaly and with ASD. Because the majority of DUF1220 domains map to this same region, we tested whether, and to what degree, DUF1220 copy number correlated with brain size differences in a subset of these patients. To accomplish this, QPCR analyses were carried out on genomic DNA from micro- and macrocephalic individuals with 1q21.1 rearrangements (n=33) using primer sets specific for DUF1220 domains and several other 1q21.1 target sequences. Analysis of resulting data indicate that DUF1220 domain copy number and that of a BAC clone flanked by DUF1220-encoding sequences, showed the highest correlation with head circumference (FOC Z-score) ($p<0.0001$), with FOC Z-score increasing on average 0.13 for each one-copy increase in DUF1220 ($p<0.0001$). These data 1) provide support for the view that changes in DUF1220 domain copy number not only may influence evolutionary differences in brain size, but also may influence brain size differences within the human population and underlie some forms of microcephaly and macrocephaly, and 2) suggest that the evolutionary advantage of increasing DUF1220 copy number may have favored retention of the high genomic instability of the 1q21.1 region which, in turn, precipitated a spectrum of human brain and developmental disorders.

**Joint CNV/SNP haplotype and missing data inference.** *S-Y. Su[1], J. Asher[2], D. Balding[1], A. Blakemore[2], P. Froguel[2], R. Sladek[3], M-R. Jarvelin[1,4], L. Coin[1].* 1) Department of Epidemiology and Public Health, Imperial College, London W2 1PG, UK; 2) Section of Genomic Medicine, Imperial College, Hammersmith Hospital, Du Cane Road, London UK; 3) Departments of Medicine and Human Genetics, McGill University and Genome Quebec Innovation Centre, 740 Ave Dr Penfield, Montreal, QC; 4) Institute of Health, University of Oulu, Oulu, Finland.

With the increasing rate of discovery of copy number variation (CNV) throughout the human genome and its potential impact on human diversity and complex diseases, there is growing interest in investigating CNVs associated with diseases and evolutionary history. Haplotype information is useful for these investigations. However, in most CNV datasets, CNV haplotype information is not directly available and must be inferred from the data. Here, we present a method for imputing missing CNV genotypes and inferring haplotypic phase from both CNV and SNP genotypes in a large-scale population-based study. Our method is based on a haploid hidden Markov model, which models the joint haplotype structure between CNVs and SNPs. Thus, haplotypic phase of CNVs and SNPs are inferred simultaneously. A sampling algorithm is employed to infer haplotypic phase and missing genotypes and to obtain a certainty measurement of each estimate. Our approach is flexible, allowing the copy number (ploidy) vary along the investigated sequence and across the individuals. In order to investigate the effectiveness of this approach, we took genotype data on genotyped male X chromosomes as well as known CNV regions on these samples (from array CGH) and randomly paired these into phased diploid CNV/SNP haplotypes. We then investigated how well we could reconstruct the phase of this data as well as infer missing CNV genotypes. The results of the simulation study suggest that our method provides accurate estimates of missing CNV genotypes and CNV haplotypic phase. With the increasing numbers of the CNV regions identified and the improving technology for genotyping CNV, our program is a very useful tool for the CNV haplotype analysis.

**Integrated study of copy number states and genotype calls using high density SNP arrays.** *W. Sun[1,2], F. Wright[1], Z. Tang[1], S. Nordgard[2,3], P. Van Loo[3,4,5], T. Yu[6], V. Kristensen[3], C. Perou[2].* 1) Department of Biostatistics, University of North Carolina, Chapel Hill, NC, USA; 2) Department of Genetics, University of North Carolina, Chapel Hill, NC, USA; 3) Department of Genetics, Institute for Cancer Research, Oslo University Hospital-Radiumhospitalet, Oslo, Norway; 4) Department of Molecular and Developmental Genetics, Vlaams Instituut voor Biotechnologie, Leuven, Belgium; 5) Department of Human Genetics, Katholieke Universiteit Leuven, Leuven, Belgium; 6) Department of Biostatistics, Emory University, Atlanta, GA, USA.

We propose a statistical framework, named genoCN, to simultaneously dissect copy number states and genotypes using high density SNP arrays. There are at least two types of genomic DNA copy number differences: Copy Number Variations (CNVs) and Copy Number Aberrations (CNAs). While CNVs are naturally occurring and inheritable, CNAs are acquired somatic alterations most often observed in tumor tissues only. CNVs tend to be short and more sparsely located in the genome compared to CNAs. GenoCN consists of two components, genoCNV and genoCNA, designed for CNV and CNA studies, respectively. In contrast to most existing methods, genoCN is more flexible in that the model parameters are estimated from the data instead of being decided a priori. GenoCNA also incorporates two important strategies for CNA studies. First, the effects of tissue contamination are explicitly modeled. Second, if SNP arrays are performed for both tumor and normal tissues of one individual, the genotype calls from normal tissue are used to study CNAs in tumor tissue. We evaluated genoCN by applications to 162 HapMap individuals and a brain tumor (Glioblastoma) dataset and showed that our method can successfully identify both types of CN differences and produce high quality genotype calls.

**Copy number calling in novel human genomic sequences and selected CNV regions by array CGH.** *A. Tsalenko[1], N. Sampas[1], J. Kidd[2], P. Anderson[1], P. Tsang[1], E. Eichler[2,3], L. Bruhn[1].* 1) Agilent Laboratories, Santa Clara, CA; 2) Department of Genome Sciences, University of Washington, Seattle WA; 3) 3Howard Hughes Medical Institute, University of Washington, Seattle WA.

Copy Number Variation (CNV) is now recognized as a prevalent form of structural variation in the genome contributing to human genetic variability. Methods for accurate CNV measurements over a wide dynamic range are needed to fully explore association of CNVs to various Mendelian and complex diseases. We are developing microarray-based methods and data analysis tools to determine absolute copy number states in various copy number variant regions of the genome including regions of segmental duplications and novel genomic sequences discovered by fosmid end-sequencing approaches [Kidd et al. Nature, May 1 (2008)] not yet mapped to the human reference genome assembly. In this study, we designed a 244k feature oligonucleotide microarray with 55k probes targeting non-repeat-masked sections of 3403 distinct novel contigs ranging from 1kbp to 5kbp in size, and with remaining probes targeting selected known copy number variant regions of the genome, including regions of segmental duplications and selected simple deletions. We used a simple ULS-based labeling protocol to characterize 30 HapMap samples using two-color hybridizations with a common reference sample (NA15510). For the novel contig sequences, we confined our analysis to those 2515 (74%) contigs with at least three probes remaining per sequence after removing probes with signals corresponding to less than one copy across the sample set. For these contigs and profiled copy number variant regions, we estimated copy numbers in all samples using the combination of measured log2ratios and signal intensities. Of the 2515 novel sequences present in at least one copy in at least one sample, 95% are estimated to be present in at least a single copy in all 30 samples. 40% of these sequences are estimated to be polymorphic across this sample set. In simple deletion regions, we observed sharp differences in signal intensities in samples with 0, 1 or 2 copies. In addition, in regions with known higher copy numbers signal intensities were consistent with having up to 40 copies in some samples.

## 2770/F/Poster Board #478

**Single-base Pair Breakpoint Resolution Map of Small To Large Indels Using a Split Read Technique with High-throughput Mate-pair and Fragment Sequencing.** *E.F. Tsung[1], H.E. Peckham[1], Y. Fu[1], C.J. Kennedy[1], S.S. Ranade[2], C.C. Lee[1], C.R. Couser[1], J.M. Manning[1], C.L. Hendrickson[1], L. Zhang[1], E.T. Dimalanta[1], T.D. Sokolsky[1], J.K. Ichikawa[1], A.P. Blanchard[2], M.W. Laptewicz[1], J.A. Malek[3], F.C. Hyland[2], F.M. De La Vega[2], G.L. Costa[1], K.J. McKernan[1].* 1) Applied Biosystems, Beverly, MA, 01915; 2) Applied Biosystems, Foster City, CA 94404; 3) Weill Cornell Medical College in Qatar, Doha, Qata.

Insertions and deletions are often classified as small events detectable within a read and large events detectable between mate-pair reads. We demonstrate that we are now able to detect mid-size variants, previously unattainable by either approach, by using 2x50-bp mate-pair libraries with the Applied Biosystems SOLiD™ System. Specifically, we are able to detect variants of up to 500 bp in length throughout the genome with mostly single-base pair resolution using split-reads as well as variants as small as 98 bp with a novel approach for detecting indels between mate-pair reads that are smaller than the standard deviation of the insert size of the library. With modest sequence coverage of 8x for the HapMap individual NA18507, we are able to detect 1156 intra-read deletions of sizes 21 to 500 bp, of which 49.1% have been previously identified in the Venter, Watson, or YanHuang genomes. Of these 1156 variants, 193 are also identified with the 2x50-bp libraries using deviations in the average insert size between reads. We demonstrate that we are able to detect all size ranges of deletions with no gap for medium-sized variants. The 2x50 bp libraries also identified small intra-read indel events of sizes up to 19 bp. Combining this with 50-bp fragment libraries and 2x25-bp mate-pair libraries, we detect a total of 124,936 small deletions and 100,437 small insertions with a dbSNP b129 concordance of 67.2%. Overall, a high prevalence of small indels, even sized indels, and Alu sized deletions (300-350 bp) are found in this genome.

Furthermore, we have called indels in several HapMap individuals and show that we are able to detect small variants even at low sequence coverage (~2x) and others at higher coverage (~10x). We also demonstrate the detection of heterozygous indels and the genome wide frequency of different indel allele sequences, some of which may be in common with biologically significant motifs. Finally, this split-read technique was used to achieve breakpoint resolution of other large structural variations such as inversions. Given the importance of precise placement and the previously unattainable size of these variants, this technique will enable the discovery of a new class of structural variants using ultra-high throughput sequencing.

## 2771/F/Poster Board #479

**A High Resolution CNV Survey of the GABA Gene Family Candidate Genes in Autism.** *P.L. Whitehead[1], D.J. Hedges[1], H.N. Cukier[1], D. Ma[1], J.M. Jaworski[1], H.H. Wright[2], R.K. Abramson[2], L. Nathanson[1], J.P. Hussman[3], J.L. Haines[4], M.L. Cuccaro[1], J.R. Gilbert[1], M.A. Pericak-Vance[1].* 1) Miami Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 2) University of South Carolina, School of Medicine, Columbia, SC; 3) Hussman Foundation, Ellicott City, MD; 4) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, NC.

Autism is a common neurodevelopmental disorder with a significant genetic component and locus heterogeneity. Gamma-aminobutyric acid (GABA) is the major inhibitory neurotransmitter in the brain, acting primarily via the GABA receptors (GABR). Multiple lines of evidence, including alterations in levels of GABA and GABA receptors in autistic patients, indicate that the GABAergic system may be involved in the etiology of autism. Recent findings also suggest that rare copy number variants (CNVs) can play a role in autism risk. We therefore decided to examine the GABR's and genes in related pathways for CNVs that may be associated with autism. For the high resolution CNV screen we employed custom designed high density Comparative Genomic Hybridization (CGH) arrays (Agilent). These 1x244k Agilent CGH arrays covered 23 putative GABRs and 14 other genes involved in GABA metabolism or pathways and allowed the detection of small structural variants that would typically go undetected using standard whole genome CGH arrays. Collectively, our probes spanned a total of 15 Mb with a density of approximately 1 probe every 150 nucleotides allowing a theoretical resolution for detection of CNV's of 700bp or greater. 250 autism cases and 250 control individuals were analyzed for CNVs. Preliminary findings have identified CNVs affecting multiple GABA related genes. Notable results to date include a deletion removing 3 exons from the GABRB3 gene detected in one autism case and no controls and one intronic deletion within the X-linked GABRA3 gene observed in 18 cases and 3 controls. A deletion removing 2 exons from the GABRR1 gene was observed in 2 autism cases and 0 control individuals. Finally, a deletion removing 2 exons of the SLC6A1 gene was observed in 1 autism case and 0 controls. These observations provide further support for the possible role of genetic variation within GABA genes in autism. These data also demonstrate that important structural DNA variation exists at size ranges below the current resolution of standard genome-wide array CGH and SNP-based arrays.

## 2772/F/Poster Board #480

**A Quantitative Real-Time PCR Method for Detection of UGT2B17 Copy Number Variants in Studies of Bone Disease.** *S.G. Wilson[1,2,3], S. Chew[1], B.H. Mullin[1], J. Lewis[1,2], T.D. Spector[3], R.L. Prince[1,2].* 1) Endocrinology & Diabetes, Sir Charles Gairdner Hosp, Nedlands, Australia; 2) School of Medicine & Pharmacology, The University of Western Australia, Crawley, Western Australia; 3) Department of Twin Research & Genetic Epidemiology, King's College London, London, UK.

Osteoporosis is characterized by low bone mineral density (BMD) and deterioration in bone microarchitecture. Genetic variation is a major determinant of bone structure. Yang *et al.* (Am J Hum Genet 2008 83:663-7) recently reported that a DNA sequence copy number variation (CNV) including the *UGT2B17* gene, was significantly associated with the risk of osteoporotic hip fracture. This gene encodes an enzyme with a role in glucuronidation of steroid hormones, particularly testosterone and dihydrotestosterone. We developed a high-throughput quantitative real time PCR (qRT PCR) method for genotyping candidate CNV polymorphisms. Subjects were genotyped using 30ng of genomic DNA, custom primers (UGT2B17: Fwd 5'CCAGATGAGTATGGGCACTACA, Rev 5'GGTCTCAGGTAATCCTCCACCT; Control: Fwd 5'TCATCTGGGTCCTAGCCATC, Rev 5'AGGGGAGCCAGGTAGATGTT) and a QuantiFast SYBR Green PCR Kit (Qiagen). The genotype of the CNV was determined using the Pfaffl equation. This approach accounts for the respective amplification efficiencies of CNV and control primers and threshold cycle (Ct) values for test and control DNA. By this technique subjects were categorized as having zero, one or two copies of the *UGT2B17* CNV. The technique was validated by genotyping the CNV in 1347 subjects from a population-based cohort of Caucasian women aged 70 - 85 years. Multiple linear regression (MLR) was used to assess the association, with BMD regressed against age, weight and *UGT2B17* CNV. The genotype frequency and mean Ct ratio for homozygotes, heterozygotes and wild-type homozygotes was 12.0% (0.01 ± 0.01), 45.5% (0.56 ± 0.08) and 42.5% (1.00 ± 0.16; mean ± SD), respectively. Further validation was performed using gel electrophoresis of the PCR products. The CNV genotype distribution was consistent with the expected Hardy-Weinberg distribution ($\chi^2$ test, $P > 0.05$) and not different from frequencies reported by Yang *et al.* Data from MLR showed that total hip BMD was associated with weight ($P < 0.001$) and *UGT2B17* CNV genotype ($P = 0.039$). Individuals homozygous for the deletion of *UGT2B17* had higher mean total hip BMD compared with individuals with 2 copies of the gene (0.819 ± 0.01 vs 0.806 ± 0.01, mean ± SE respectively).These data suggest that qRT PCR is a rapid, high-throughput technique for determination of candidate CNVs. This technique should be useful for the determination of genotypes for *UGT2B17* CNV, and other CNVs. This study provides further evidence of association of the *UGT2B17* CNV with BMD.

## 2773/F/Poster Board #481

**Comparing CNV detection methods for SNP arrays.** *L.M. Winchester[1], C. Yau[2], J. Ragoussis[1].* 1) Genomics Laboratory, Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, OX11 8JY, UK; 2) Henry Wellcome Centre for Gene Function, Department of Statistics, University of Oxford, Oxford, UK.

Data from whole genome association studies can now be used for dual purposes, genotyping and copy number (CN) detection. We present a comparison of the methods for using SNP data to detect CN events and describe the use of several statistical models in CN detection in germline samples. We examine a number of algorithms designed to detect CN changes through the use of signal intensity data and consider methods to evaluate the changes found. We apply a selection of proprietary and academically developed algorithms on a set of well characterised CEPH samples to give an indication of detection accuracy and success of CN change prediction on Affymetrix and Illumina data. For a single HapMap sample, NA12156, we found an overlap of 20-49% between events detected by algorithm and previously published sequencing data. Algorithms in the comparison include Birdsuite, GADA, PennCNV and QuantiSNP which detect both CNVs and CNPs. We conducted a secondary comparison on a sample, NA15510, characterised by three different studies and found an overlap of below 23% between detected events and the published validated results for each algorithm. Few events were common to all three published studies (~7%, 3% and 3% respectively). We observed similar variation between different publications as between detected events in our data and published results, suggesting this is a problem in all comparisons and not unique to the algorithms we tested. Comparison of the events detected between software directly on NA10861 showed a low level of overlap between most algorithms and platforms. This ranges from 0 overlapping events (between GADA for Illumina and CNAT for Affymetrix) to 100% of detected events overlapping (between CNAT for Affymetrix and other Affymetrix targeted detection algorithms). We show the expected similarities between data generated by the same platform and also some of the striking differences between lists of detected events from the same data using different algorithms. We conclude by suggesting a number of factors for other users to consider when picking an algorithm for their own data analysis.

## 2774/F/Poster Board #482

**Copy Number Variation prediction using Bayesian Hidden Markov Model.** *Z. Zhang[1], R. John[1], C. COGA[2], C. COGEND[3], C. GENEVA[4].* 1) Dept. of Psychiatry, Washington University in St. Louis, Saint Louis, MO; 2) COGA project; 3) COGEND project; 4) GENEVA project.

Taking the Copy Number Variant (CNV) status as the hidden states and the hybridization intensity measurements from microarrays as the observed states, we applied a Bayesian Hidden Markov Model (HMM) to the Gene Environment Association (GENEVA) alcohol addiction GWAS data. The method uses the Metropolis-Hastings algorithm for sampling with the CNV considered in a time-series analysis. Compared to other existing Bayesian models, the method offers a promising approach for CNV distribution prediction. Further investigation of the model will be applied and a user-interface program will be made available.

Cheung[2], A. Geurts van Kessel[1], J.A. Veltman[1], P. Stankiewicz[2].* 1) Dept Human Genetics 855, Nijmegen Centre for Molecular Life Sciences, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, Texas, USA; 3) Department of Medical Genetics, Institute of Mother and Child, Warsaw, Poland.

Genomic copy number variation (CNV) plays a major role in various human diseases as well as in normal phenotypic variation. For some recurrent disease-causing CNVs that convey genomic disorders, the causative mechanism is meiotic non-allelic homologous recombination between breakpoint regions exhibiting extensive sequence homology (e.g. low-copy repeats). For the majority of recently identified rare pathogenic CNVs, however, the mechanism is unknown. Recently, a model for CNV formation implicated mitotic replication-based mechanisms, such as (alternative) non-homologous end joining and fork stalling and template switching, in the etiology of human pathogenic CNVs. The extent to which such mitotic mechanisms contribute to rare pathogenic CNVs remains to be determined. In addition, it is unexplored whether genomic architectural features such as repetitive elements or sequence motifs associated with DNA breakage stimulate the formation of rare pathogenic CNVs. To this end, we have sequenced breakpoint junctions of 38 rare pathogenic CNVs, representing the largest series of such CNVs examined to date in this much detail. Our results demonstrate the presence of (micro)homology ranging from 2 bp to over 75 bp, in 79% of the breakpoint junctions. This indicates that microhomology mediated repair mechanisms, including the recently reported fork stalling template switching and/or microhomology-mediated break-induced replication prevail in rare pathogenic CNVs. In addition, we found that the vast majority of breakpoints (81%) were associated with at least one of the genomic architectural features evaluated. Moreover, an additional 8% of breakpoints were associated with the presence of two novel sequence motifs, specifically enriched in duplication breakpoint regions. These data suggest that rare pathogenic CNVs do not occur at random genome sequences, but are stimulated and potentially catalyzed by various genomic architectural features.

**Comparison of copy number calling algorithms and integrated analysis of gene expression in cancer cell lines.** *A. Oudes, A. Hoover, S. Vega.* Biosoftware, Rosetta Biosoftware, Seattle, WA.

Genomic copy number variations (CNV) may play a role in modifying gene expression patterns in diseases such as cancer. Integrated analysis of gene expression and CNV data can provide insight into the relationship of gene dose and transcript level. We obtained a data set from the caBIG repository which contains 338 cancer cell lines that have been profiled for gene expression and genotype. Principal component analysis of the gene expression data revealed a separation of hematopoietic cancer cell lines from those derived from solid tumors. Comparison of copy number calls generated by PennCNV and the recommended Affymetrix Tools indicates a greater sensitivity for CNV by the PennCNV algorithm. Integrated statistical analysis of the data revealed both cis and trans-associations of gene copy number with gene expression. CNV varied with the tissue of origin for the cell line. The majority of CNV does affect expression of genes that overlap with the locus of the CNV. The data revealed similarities in copy number of genes in signaling networks which are known to be involved with cell proliferation and cancer. In this study we have identified CNV with concomitant gene expression changes which are of interest for further investigation in the context of cancer cell signaling.

## 2777/F/Poster Board #485

**Effect of Copy Number Variation Inference in Association Study with eQTLs.** *K.-Y.A. Kim.* Dept Preventive Med, Northwestern Univ, Chicago, IL.

Recent technological developments in detecting copy number variants (CNVs), coupled with the advancements in statistical methods to identify their harboring regions, have improved our ability to understand their influence on various traits. A particular trait that CNVs are shown to influence is the gene expression levels; i.e. the CNVs act as expression QTLs (eQTLs). A study on malaria has shown that CNVs in regulatory hot spots control transcriptional variation. CNVs exhibit a distinct characteristic compared to other markers in that the underlying genotypes are integer based rather than a binary class such as the SNP markers. Similar to SNPs, the raw data of CNVs are the signal intensity values which is then inferred to integer-based copy numbers. Since the assignment of the integer-based copy number is based on a statistical model, we need to scrutinize whether the raw intensity values acting as proxies to the actual copy numbers or model-based copy numbers in integers provide increased accuracy and power. The raw intensity values along with several statistical methods that assign integer copy numbers are compared to evaluate their performance in identifying eQTLs .

## 2778/F/Poster Board #486

**Identification of translocation breakpoints and large deletions in brain cancer by whole genome paired-end sequencing.** *M. Clark[1], H. Homer[2], B. O'Connor[1], B. Merriman[1], Z. Chen[1], S. Nelson[1].* 1) Department of Human Genetics, Univ California, Los Angeles, Los Angeles, CA; 2) Deparment of Computer Science, Univ California, Los Angeles, Los Angeles, CA.

Whole genome resequencing strategies can be used to directly identify genomic variations including single nucleotide variants, copy number variants, and small insertions and deletions. Here we describe our strategy for using paired-end sequence data to identify larger structural variation breakpoints by searching for significant changes in paired-end insert size. We performed two-and-a-half runs of the ABI SOLiD sequencer to completely sequence the entire genome of the U87-MG brain cancer cell line, which is known to contain a large number of structural aberrations. The raw colorspace data was aligned using the BFAST algorithm. We extracted paired-end reads with highly aberrant insert sizes (insert sizes greater than 3000 bases) from the set of uniquely aligned reads and then clustered them in this subset based on their genomic position. A number of filtering strategies were implemented to reduce false positives from the subset. First, reads within the clusters were analyzed to ensure that they had a distribution that fit given our paired end insert size. Then, reads within 1Mb of centromeres and telomeres were removed, as these regions include densely packed repetitive regions. The filtered dataset includes interchromosomal events, large intrachromosomal events, and smaller regional deletion events. Most of these events occur at positions where changes in base coverage suggest a change in copy number. Some represented complete genomic losses where base coverage between the breakpoints was zero. A few of the more interesting candidates were confirmed by PCR and dideoxy sequencing. In a separate experiment, paired-end whole genome sequencing was performed on a tumor/normal sample pair. The same analysis was run again, but this time events present in the normal and tumor were masked in order to identify novel events present in the tumor. Here we demonstrate our ability to identify the precise genomic positions of translocation, insertion and deletion breakpoints in cancer samples using paired-end whole genome sequence data generated in a small number of SOLiD sequencer runs and aligned with the BFAST algorithm.

**Identify genomic imbalance by high density whole genome microarrays in Chinese patients with neurodevelopmental disorders.** *X. Gong[1,*], X. Chen[2,*], Y. Jiang[3,*], Y. Shen[4,*], S. Li[1], Y. An[1], Y. Wang[1], X. Zhang[1], Y. Sun[1], H. Fang[4], X. Sheng[4], H. Shao[4], H. Zhu[4], A. Cheng[4], L. Jin[1], X. Wu[3], T. Zhang[2,#], H. Wang[1,#], B-L. Wu[1,4,#].* 1) Institutes of Biomedical Science and School of Life Science, Fudan University, Shanghai, China; 2) Capital Institute of Pediatrics, Capital Medical University, Beijing, China; 3) Department of Pediatrics, Peking University First Hospital, Peking University, Beijing, China; 4) Children's Hospital Boston and Harvard Medical School, Harvard University, Boston MA, USA (*contributed equally; #senior authors for each group of this collaboration study).

Genomic imbalances/rearrangements are a common cause of developmental delay, mental retardation and autism spectrum disorders, which have been demonstrated by the studies with cohorts of the western countries. We employed two most current high density whole genome microarrays (Agilent 244K CGH array and Affymetrix SNP 6.0 array) and 4 independent analytic algorisms to evaluate/compare the deletions and duplications in a Chinese cohort consisting of 350 patients. During the process, we also cross-validated the findings between the two DNA chip platforms and the results showed very high concordance rate. We detected total of 7891 copy number variants (CNVs) in the patient cohort and 608 CNVs in matched controls. The size of CNVs range from 50 kb to 15 Mb and the detection ratio is 3:1 in patients and controls. We identified two types of genomic imbalances in the Chinese cohort: deletions or duplications at 15q11.2-12, 15q13.2-13.3, 16p11.2, 16p13.3 and 17q12 are the examples of recurrent reciprocal imbalance, all of these are recently recognized genomic disorders/syndromes; unrelated cases with overlapping deletions or duplication involving 2p12, 2q33.1, 3q12.3, 7q22, 7q31.1, 13q13.1-14.1, 14q13.2, 17p12, exemplify the imbalance occurred randomly or de novo. The most frequent recurrent reciprocal imbalances (del/dup) identified in Chinese patients are at 1q21.1, 3q11.2, 9p13.1, 9q11.2, 10q11.2, 15q11.2-12, 16p11.2, 19q12, 22q13.3, Xp22.3 and Xq28. The high density whole genome arrays also detect multiple imbalance events in each patient but many are novel CNVs with unknown clinical significance. Based on current database and literature, we identified clinically relevant genomic imbalances in about 20% of total cases. Our data demonstrated the utility of whole genome array for detecting genomic imbalance. The detection of recurrent genomic imbalance events among Chinese patient further confirmed shared etiologies among patients of different ethnicities. Since developmental disorders are a broad clinical diagnosis of heterogeneous genetic etiologies, extensive clinical phenotype evaluation and further dissection of genomic rearrangement are of great importance towards better understanding of the disorder and for eventual better patient care. In addition, to our knowledge this study is the first to reveal detailed CNVs (pathogenic and polymorphic) data of the patient cohort and matched controls both from Han Chinese population.

## 2780/F/Poster Board #488

**Development of a Custom Microarray for Inherited Vascular Diseases.** *S. Mitchell[1], T. Lewis[2], P. Bayrak Toydemir[2,3].* 1) Technology Transfer, ARUP Laboratories, Salt Lake City , UT; 2) ARUP Institute for Clinical and Experimental Pathology, ARUP Laboratories, Salt Lake City, UT; 3) the Department of Pathology, University of Utah Health Sciences Center, Salt Lake City, UT.

Oligo-comparative genomic hybridization (CGH) microarray technology has become an important tool in detecting large duplications and deletions of the human genome. Multiple formats are available with different resolutions that allow for many different applications. The development of custom oligo-CGH arrays can be useful to target specific regions of the genome that are associated with disease. This can be a useful tool when clinical symptoms of multiple diseases overlap. Samples analyzed by sequencing that show no significant changes could be further interrogated using a custom oligo-CGH array. The ability to strip used microarray slides and re-hybridize can help decrease costs when used on a research basis. We present our results with a custom oligo-CGH array we developed to detect deletions and duplications in patients with inherited vascular diseases. A custom oligo-CGH array was designed to analyze 13 genes for 7 different vascular diseases including Hereditary Hemorrhagic Telangectasia, RASA1-related disorders, Loris-Dietz Syndrome, and Hereditary Glomuvenous malformations. The format chosen was a 1 by 385K array. The density was 1 probe for every 10 base pairs of all exonic and intronic regions with a 2kb extension on the 5' end and 1kb extension on the 3' end of each gene. Five patients with known aberrations verified by Multiple Ligation-Dependent Probe Amplification (MLPA), and 3 unknown samples were studied. Self/self hybridization was performed to test the probe efficiency. Five microarray slides were used and stripped multiple times to test re-hybridization efficiency. Known aberrations were confirmed for the samples that worked on the microarray. The smallest change in our cohort was a 300bp deletion, which corresponds to a single exon deletion in ACVRL1 gene. One duplication greater than 380bp was found for one unknown sample but was not reproducible by MLPA. Discrepant results could be due to criteria set for calling a true aberration. Multiple re-hybridizations (up to 4 times) of slides showed a decrease in confidence in calling true aberrations. A custom oligo-CGH array for inherited vascular diseases is beneficial in cases where sequencing shows no significant changes. It provides information about large genomic rearrangements of multiple genes simultaneously and is a cost effective tool for research applications. Further sensitivity and specificity studies need to be done to reach single exon resolution for diagnostic purposes.

## 2781/F/Poster Board #521

**Gene dosage analysis of SMN1 gene for screening carriers of spinal muscular atrophy.** *J.Y. Wang[1], C.H. Lee[2], J.S. Lee[2].* 1) BK 21 Project Medical Sci, Graduate Sch Yonsei Univ, Seoul, Korea; 2) Dept Cilinical Genetics, Yonsei Univ Col Medicine, Seoul, Korea.

Spinal muscular atrophy (SMA) is an inherited autosomal recessive disorder characterized by progressive muscle weakness resulted from degeneration and loss of the anterior horn cells in the spinal cord and the brain stem nuclei. The two genes associated with SMA are survival motor neuron 1(SMN1) and survival motor neuron 2(SMN2) on chromosome 5q13. SMN1 and SMN2 are present in two highly homologous copies. SMN1 gene is the primary disease-causing gene and about 95-98% of individuals with SMA show homozygous deletion of exon 7 and 8 of SMN1. In SMA patients, SMN2 partially compensates for the lack of SMN1. The incidence of SMA is 1 in 10,000 livebirths and carrier frequency is 1 in the range of 35 to 50. In practice, there is no effective treatment for this disease. Therefore, precise quantification of SMN1 and SMN2 gene copy numbers is essential for diagnosis and genetic counseling. The aim of our study was to establish an efficient and rapid method for prenatal diagnosis of SMA and detection of carriers for proper counseling. We developed fragment analysis with amplified exon8 of SMA1 and SMN2 genes covering each of fluorescence labeled Locked Nucleic Acid (LNA) to quantify SMN1 gene copy number using the ABI 3100 genetic analyzer. DNA samples from a total of 175 individuals including 5 patients with SMA lacking the SMN1 gene, 70 patients with developing symptoms of SMA, and 100 control individuals from the general population were analyzed. By applying this technique, we could detect SMA patients efficiently just by recognizing a SMN2 gene peak. Furthermore, for the diagnosis of carriers, we used multiplex PCR by simultaneously amplification of the human albumin gene and examined SMN1/SMN2 gene dosages by fragment analysis. It was possible to differentiate carriers from normal controls. In this study, a simple, rapid, non-gel-based method for the diagnosis of patients and carriers carrying deletion(s) of SMN 1 gene was described and the method can be useful for the diagnosis of SMA in practice.

**Determination of parental origin by SNP array of *de novo* copy number mutations identified in offspring of atomic-bomb survivors.** *Y. Satoh[1], K. Sasaki[1], I. Fukuba[2], E. Hiyama[2], M. Imanaka[1], Y. Shimoichi[1], J. Kaneko[1], M. Kodaira[1], N. Takahashi[1].* 1) Dept. Genetics, Radiation Effects Research Foundation, Hiroshima, Japan; 2) N-BARD, Hiroshima Univ., Hiroshima, Japan.

It is widely known that there are many copy number polymorphisms in the human genome and several are related to certain kinds of disease or individual differences. While most are transmitted from parent to child, a few arise *de novo*. We have investigated whether atomic-bomb radiation causes *de novo* copy number mutations in offspring of atomic-bomb survivors. In case only one of the parents was exposed to radiation, it was necessary to discriminate in which one of homologous chromosome of offspring derived from the parents the mutation occurred. In order to examine the whole human genome, we made BAC-array CGH on which about 2,500 BAC clones were printed. The study used genomic DNA from 265 offspring of atomic-bomb survivors and 40 offspring of an unexposed control group. Three mutations were identified in three offspring, that were not in their parents. One mutation was a deletion type involving a 1.4 Mb length of chromosome 1q41 and two mutations were an amplification type involving 131,290 bp of 5p15.2 and 431,737 bp of 17p13.3, respectively. In the breakpoints of the deletion mutation, segmental duplications were involved in both termini. Precise breakpoints could not be determined. There were microhomologies in the breakpoints of both two amplification mutations. Because only fathers were the atomic-bomb survivors in all three families, we needed to determine parental origin of the *de novo* mutations. We used an Affymetrix SNP array 6.0 to examine mendelian inconsistency of SNP information in the genome region involving the mutations. We examined 422 SNPs in the genome region involving the deletion mutation, of which 43 SNPs were informative for discrimination of parental origin. There were 54 and 85 SNPs in the genome regions involving the two amplification mutations, of which 15 SNPs were informative for each. Informative SNPs for each case showed that all three mutations occurred on a chromosome derived from the father. The SNP array was valuable for determination of the parental origin of *de novo* copy number mutations. We will continue and expand our study to increase the statistical power.

## 2783/F/Poster Board #523

**Mobile Element Scanning (ME-Scan): complete ascertainment and genotyping of transposons in large population samples using targeted high-throughput sequencing.** *D.J. Witherspoon[1], J. Xing[1], Y. Zhang[1], M.A. Batzer[2], L.B. Jorde[1].* 1) Dept Human Genetics, Univ of Utah; 2) Louisiana State Univ.

**Background:** Mobile elements (MEs) are diverse, common and dynamic inhabitants of nearly all genomes. Their transposition generates a steady stream of polymorphic genetic markers, deleterious and adaptive mutations, and substrates for genomic rearrangements. Research on the impacts, population dynamics, and evolution of MEs is constrained by the difficulty of ascertaining new ME insertions and genotyping them in many individuals. **Methods:** We use ME-specific primers to construct DNA libraries that contain the junctions of all ME insertions, with their flanking genomic sequences, from many individuals. Up to 50 individual libraries are pooled and sequenced on an Illumina Genome Analyzer (36 bp paired-end reads) using a ME-specific sequencing primer. All ME insertion loci of the target family in the sample are uniquely identified by their junction sequence, and all insertion junctions can be linked to their source individuals by means of an individual-specific “barcode” sequence designed into the library oligonucleotide adapters. **Results:** The large number of *AluYb8* insertions in humans (~3,000 per haploid genome) and the high background of related *Alu* elements (> 1 million) makes this subfamily a suitable challenge for our method. Initial sequencing generated ~5.5 million read pairs from seven individual libraries that were combined at various concentrations. More than 95% of read pairs represent the desired *AluYb8*-junction products and are tagged by exact matches to one of our barcode sequences. Barcode counts show that the sequenced products reflect the intended individual library pooling proportions to within 1%. We are able to detect more than 98% of the ~1,400 *AluYb8* insertions that are believed to be fixed and contain exact matches to the amplification and sequencing primer binding sites. The few failures include some insertions that are in fact polymorphic and absent in our samples. Less-perfect *AluYb8* insertions and known polymorphic insertions are also very reliably detected, as are the expected several hundred novel insertions per individual. We are currently able to reliably ascertain - in all individuals in a sample - the presence or absence of at least 80% of *AluYb8* insertion loci.

## 2784/F/Poster Board #524

**Involvement of DNA repair-based mechanism in genomic rearrangements of Pelizaeus-Merzbacher disease.** *G. Hobson[1], K. McLean[2], L. Banser[1], D. Lavoie[1], K. Clark[1], T. Alberico[3], J. Garbern[4], K. Sperle[1].* 1) Nemours Biomedical Research, Alfred I. duPont Hospital for Children, Wilmington, DE; 2) Penn State Hershey Medical School, Hershey, PA; 3) Functional Genomics Unit, National Institutes of Health, Bethesda, MD; 4) Center for Molecular Medicine and Genetics, Wayne State University, Detroit, MI.

Pelizaeus-Merzbacher disease (PMD) is a leukodystrophy most frequently caused by duplication of the proteolipid protein 1 gene (*PLP1*) at Xq22.2. It has been proposed that these genomic duplications are a result of a coupled homologous and nonhomologous DNA repair-based mechanism (CHNR) involving a double-strand DNA break and nonhomologous end-joining (NHEJ). More recently it was reported that many rearrangements in the *PLP1* region are complex and refractory to junction analysis. A replication-based mechanism termed Fork Stalling and Template Switching (FoSTeS) requiring a single-strand DNA break and microhomology for the template switch was proposed for these rearrangements. We present our analyses of genomic rearrangements in 60 PMD patients by semiquantitative PCR, array CGH, interphase FISH, and junction analysis. We report evidence for complex rearrangements in 33% of patients, including those with two duplicated regions, and with both duplicated and higher copy number regions. We amplified and sequenced a total of 37 junctions. Templated filler insertions of 14 to 112 bases that are homologous to nearby regions create 2 sequence fusion points in 14% of these junctions; the remaining junctions each have one sequence fusion point. We report that 63% of sequence fusion points in our 37 junctions are microhomologies of 1 to 7 bases, 16% are inserts of 2 or 3 bases, 11% are blunt fusions, and 9% are chimeric repeat elements (Line or Alu). Based on similarity of our junction sequences with those found after repair of experimentally induced double-stranded breaks, we argue that a DNA repair-based mechanism is likely to be involved in the formation of simple and complex rearrangements in PMD.

## 2785/F/Poster Board #525

**Association Analysis of Kinesin family member 3 A (KIF3A) polymorphisms with aspirin intolerance in asthmatics.** *J. Cha[1], J. Park[1], A. Jang[1], S. Uh[2], Y. Lee[2], M. Kim[3], I. Choi[4], S. Cho[5], B. Park[6], H. Shin[6], C. Park[1].* 1) Genome Research Center for Allergy and Respiratory Disease, Soonchunhyang University Bucheon 1174 Jung-dong, Wonmi-gu, Bucheon, Gyeonggi-do, Republic of Korea 420-767; 2) Division of Allergy and Respiratory Medicine, Soonchunhyang University Hospital, 657, Hannam-Dong, Yongsan-Gu, Seoul, Republic of Korea,140-743; 3) Department of Internal Medicine, Chungbuk National University, College of Medicine, 62 Gaesin-dong, Heungduk-gu, Cheongju, Chungcheongbuk-do, Republic of Korea 361-711; 4) Department of Allergy, Chonnam National University Medical School and Research Institute of Medical Sciences, 8 Hakdong, Dong-gu, Gwangju, Republic of Korea 501-757; 5) Institute of Allergy and Clinical Immunology, Seoul National University Medical Research Center, 28 Yongon-Dong, Chongno-Ku, Seoul, Republic of Korea 110-744; 6) Department of Genetic Epidemiology, SNP Genetics, Inc.,1407 14th Floor, Woolimrall’ey B, Gasan-dong, Geumcheon-Gu, Seoul, Korea 153-803.

Background: The Kinesin family member 3A (KIF3A) gene on chromosome 5q31, is associated with granules and organelles within the proplatelets. Platelet activation has also been reported in both patients with allergic asthma and the experimental animal models of allergic inflammation. We investigated genetic polymorphisms of the KIF3A gene, and evaluated this locus as a potential candidate for aspirin-exacerbated respiratory diseases (AERD). Methods: The asthmatics (n=470) underwent the oral aspirin challenge (OAC). OAC reactions were categorized into 3 groups as follows: 20% or greater decreases in FEV1 or 15% to 19% decreases in FEV1 with extrarbronchial reactions (naso-ocular or cutaneous) (Y), 15% to 19% decreases in FEV1 or extrarbronchial reactions(naso-ocular or cutaneous) only (I), and 15% less decreases in FEV1(N). Results: The entire KIF3A gene was sequenced. DNA sequencing in 24 Koreans of the KIF3A gene, revealed 24 sequence variants: 23 in the intron region, one in the exon region (+38148C>T) and five haplotypes were constructed. The single nucleotide polymorphisms (SNPs) and haplotypes were significantly associated with AERD. The rare allele homozygotes on +22420 A>G showed higher in Y group than in N group (P=0.005). Asthmatics who had rare alleles for +22420A>G exhibited a more pronounced decrease in FEV1% after OAC than did those who carried the common allele (P=0.007). KIF3A gene ht3 and ht5 were associated with aspirin-induced bronchospasm, as reflected in the rates of decrease in FEV1% after OAC (P=0.004 and P=0.008). In the aspirin treated BEAS2B cell, mRNA and protein levels of KIF3A were higher than those of untreated BEAS2B cell. In the nasal polyp epithelium of AIA, KIF3A proteins seems higher expression than that of ATA. Conclusions: KIF3A SNPs +2779C>G and their haplotypes (ht3 and ht5) were associated with AERD. This work was supported by a grant from the Korea Health 21 R&D Project, Ministry of Health and Welfare, Republic of Korea (A010249).

## 2786/F/Poster Board #526

**Alternative transcription of human CHM gene including LTR12C element in colorectal cancer.** *Y. Jung[1], Y. Kim[1], J. Huh[2], D. Kim[3], H. Ha[1], K. Ahn[1], H. Kim[1].* 1) Department of Biological Science, Pusan National University, Busan, Korea; 2) National Primate Research Center, KRIBB, Ochang, Chungbuk, Korea; 3) Korea Bioinformation Center, KRIBB, Daejeon, Korea.

CHM (Choroideremia) gene located on human Xq21.2 is indispensable for the posttranslational activation of retina-specific rab protein. Various mutations such as missense, nonsense, rearrangement of the CHM gene are responsible for choroideremia. Long terminal repeat (LTR) elements have potential of transcription regulatory factors by providing of promoter activity and various transcription factor binding sites and cryptic splicing sites. The CHM has two reference transcript variants (NM000390.2 and NM001145414). Transcript variant 2 (V2) is derived from LTR12C providing a cryptic splicing site. Using bioinformatic tools, we could analyze transcript variant 2 sequences, indicating that transcript variant 2 has LTR12C sequences which results in new exon and different amino acids sequences. In order to identify effects of LTR12C, we performed RT-PCR analysis in the normal and adjacent cancer tissues. The V1 was ubiquitously expressed in various tissues, whereas the V2 expressed higher in colorectal cancer than normal tissue samples with similar expression patterns in other cancer tissues (liver, lung, testes). We also confirmed high expression of colorectal cancer in patient samples, suggesting that the CHM-V2 could be used as biomarker for colorectal cancer.

## 2787/F/Poster Board #527

**Evolutionary transcript diversification of DYX1C1 gene by HERV-H LTR integration and its application to cancer biomarker.** *Y. Kim, Y. Jung, H. Ha, K. Ahn, H. Kim.* Department of Biological Science, Pusan National University, Busan, Korea.

DYX1C1 is a candidate gene for developmental dyslexia. It has three alternatively spliced transcripts (V1, V2, V3). The V1 has HERV-H LTR element providing polyadenylation signal in last exon. The HERV-H LTR element on human DYX1C1 gene seems to have been integrated into our common ancestor genome after the divergence of Old World monkeys and New World monkeys by PCR amplification. From the sequencing analysis of various primate DNA samples, we found the lineage specific tandem repeated sequences of ORF region in Old World monkeys. We examined the effect of HERV-H element on DYX1C1 gene with various alternative transcripts. RT-PCR analysis is conducted in order to detect expression of the DYX1C1 gene in various human and rhesus monkey tissues, indicating that all of the alternative transcripts are expressed ubiquitously in the human and monkey tissues. We also identified four new alternative transcripts (V1-1, V1-2, V1-3, V1-4) related to HERV-H element in human and rhesus monkey. Those alternative transcripts are examined as a biomarker to detect specific cancer. All of transcripts including four new alternative transcripts appeared in various tumors, but detected differently between normal and adjacent tumor tissue. Semi-quantitative RT-PCR analysis and Image J program showed that the transcriptional activity of V3 and V2 was higher in tumor than in normal tissue samples, especially in the colorectal tissues. Our results indicated that integration event of the HERV-H LTR element contributed to the DYX1C1 gene transcription diversification during the primate evolution and alternatively spliced transcript variants could be used as cancer biomarkers to detect colorectal cancer.

## 2788/F/Poster Board #528

**Exon-level expression profiling using small quantities of whole blood total RNA.** *J.P. Sainsbury[1], P. Lacap[1], F.A. Plummer[1,2], M. Luo[1,2].* 1) HIV & Human Genetics, National Microbiology Laboratory, Winnipeg, Manitoba, Canada; 2) Department of Medical Microbiology, University of Manitoba, Winnipeg, Manitoba, Canada.

Affymetrix® GeneChip® Human Exon 1.0 ST Arrays provide a unique opportunity to interrogate global gene expression at the exon level. However, the use of whole blood total RNA on Affymetrix® Exon Arrays is hampered by abundant globin mRNA which has been demonstrated to decrease percent present calls, decrease call concordance and increase signal variation during microarray hybridization. Moreover, the limited quantities of total RNA available from clinical research specimens is often insufficient for direct analysis with Affymetrix® Exon Arrays. The aim of this study is to present proof-of-concept data on the use of a sense RNA - specific linear amplification strategy in combination with globin mRNA hybridization capture technology to qualify 100ng of whole blood total RNA for use on Affymetrix® Exon Arrays. The efficiency of amplification was assessed using quantitative PCR (qPCR) of housekeeping genes and the efficiency of globin reduction was assessed using qPCR of globin mRNA. Microarray target hybridization of amplified, reduced samples was correlated with that of unamplified, reduced samples to assess faithful preservation of expression profiles during amplification. This study has assessed the feasibility of using a small quantity of total RNA, containing a high proportion of globin mRNA, to conduct high-resolution expression profiling with coverage of the entire transcriptome.

## 2789/F/Poster Board #529

**A novel strategy for the simultaneous detection of alternatively spliced MEF2C transcripts enables evaluation of splicing event co-variation.** *K. Sciabica[1], B. Ramachandran[2], Y. Wu[1], H. Yowanto[1], T. Gulick[2].* 1) Genetic Analysis, Beckman Coulter, Inc., Fullerton, CA; 2) Diabetes and Obesity Research Center, Burnham Institute for Medical Research, Lake Nona, FL.

Myocyte Enhancer Factor 2 (MEF2) proteins are transcription factors that exist in all metazoans and play pivotal roles in the development and differentiation of tissues. All MEF2 proteins have an amino-terminal MADS box and adjacent MEF2 signature domain that together confer sequence-specific DNA binding and dimerization activities. The carboxy-termini of MEF2 proteins are less well conserved and harbor transcriptional regulatory and nuclear localization functions. There are 4 vertebrate MEF2 genes, MEF2A, B, C and D, and these have different temporo-spacial expression patterns. MEF2A, C and D encode protein variants by virtue of alternative splicing of primary transcripts, and these genes have similar structures and alternative splicing patterns that are conserved across evolution. The alternative splicing involves mutually exclusive exons (alpha1 and alpha2), a cassette exon (beta), and alternative splice acceptors that flank a short region (gamma). The corresponding short polypeptide domains encoded by these alternative segments are nested within the MEF2 carboxy-termini and are structurally conserved across isotypes. These domains confer specific functions, including splice variant-specific functional interactions with co-activators; potent transactivation by an "acid blob" (beta); and transrepression that is mediated by SUMOylation (gamma)that is under control of various signaling events that modify MEF2 and act in cis to control steady-state MEF2 SUMOylation. As one aspect of an effort to elucidate the roles of MEF2 alternative splicing variants, we have developed an RT-PCR long fragment assay in which all 8 MEF2C mRNA isoforms can be simultaneously monitored and quantitated from cell and tissue samples. This assay is used to confirm and extend prior observations of regulated MEF2 alternative splicing among tissues, during development and during muscle differentiation. The technique is well suited for rapid quantitative evaluation of splicing variant expression, and could be effectively used for candidates with established splicing variants or for the validation of findings observed with "next generation" sequencing. In addition, our strategy uniquely allows for the evaluation of co-variations in multiple alternative splicing events for primary transcripts of a given gene. *For Research Use Only; not for use in diagnostic procedures.

**Pilot study: Pathway analysis performed on formalin-fixed, paraffin-embedded pancreatic tissue.** *N.V. Michelsen[1,2], K. Brusgaard[1], M. Thomassen[1,3], T. Qihua[1], K. Hussain[4], H.T. Christesen[2].* 1) Dept of Clinical Biochemistry, Pharmacology and Genetics, Odense University Hospital, Odense, Denmark; 2) Dept of Paediatrics, Odense University Hospital, Odense, Denmark; 3) Human Microarray Centre, University of Southern Denmark, Odense, Denmark; 4) Great Ormond Street Children's Hospital NHS Trust and Institute of Child Health, London WC1N 1EH, United Kingdom.

**Aim.***Italic Text* The aim of this pilotstudy is to show that formalin-fixed, paraffin-embedded pancreatic tissue can be used in gene expression microarray studies for pathway analysis. We have previously shown that fixed pancreatic tissue from children with congenital hyperinsulinism (CHI) still contains disease-specific information that can be retrieved by cluster analysis. **Background.***Italic Text* We have used pancreatic tissue from children with CHI. Congenital hyperinsulinism (CHI) is a disease characterized by hyperinsulinemic hypoglycemia irrespective of blood glucose levels and is associated with a high risk of developing neurological handicaps. Most cases appear neonatal, but appearances in the late infancy and adulthood are seen. It is a heterogeneous disease with respect to phenotype and genetics. So far, six genes are known to be disease-causing. Depending on the underlying genetic cause and the severity of the disease, treatment includes conservative and medical management, and alternatively pancreasresection (resection of 60-95% of the organ). Based on these pancreasresected CHI biopsies, that were routinely formalin-fixed and paraffin-embedded, the overall purpose of this project is to detect new underlying genetic causes for CHI. **Samples.***Italic Text* In all, 20 pancreases were included in the study: 17 FFPE samples and three frozen samples. FFPE pancreatic samples consist in five CHI samples, 10 control samples, and two insulinoma samples; frozen samples consist in one insulinoma sample and two CHI samples. **Methods.***Italic Text* RNA extraction using ethanol/chloroform precipitation, RNA integrity measurement with Agilent 2100 bioanalyzer, Amplification and labeling of RNA using AminoAllyl MessageAmpII, Generation of a Genome wide oligonucleotide chip (828,830 genes in duplicates), Hybridization of sample and reference with Agilent Gene expression hybridization kit, Image Analysis, Normalization and data analysis. **Results.***Italic Text* Cluster analysis show that FFPE CHI samples cluster separately from control and insulinoma samples. Bioinformatic tools such as Gene set enrichment analysis (GSEA) and GenMAPP2.0 will be used for further data analysis. Based on the cluster analysis, we know that the disease-specific information is still present in stored tissue. Our results will show whether this information can also be extracted with pathway analysis.

**A WORKBENCH FOR MEASURING TRANSCRIPTION USING NEXT-GENERATION SEQUENCING.** *M. Busby, C. Stewart, D. Barnett, M. Stromberg, G. Marth.* Biol, Boston College, Chestnut Hill, MA.

High-throughput RNA sequencing has the potential to replace microarrays as the default technology for measuring transcription. It can be used for both discovery and quantification, and does not suffer from some of the problems seen with microarrays, such as uneven hybridization.

The complexity of analyzing high-throughput RNA reads currently puts this technology beyond the reach of laboratories which do not have the support of bioinformaticians experienced in high-throughput sequencing. Existing command-line applications that provide alignment and quantification of RNA reads are often technology-specific, or are daunting in their complexity. Statistical protocols for providing quality control and measuring differential expression between samples have not yet been firmly established. Even routine tasks such as file management can be time-consuming for labs that rely on the labor of biology graduate students, many of whom have never previously used a command-line application.

To solve this problem, we have developed a workbench for analysis of RNA-based sequences. The workbench integrates several components of the our own suite of tools including the Mosaik aligner and the Gambit visualization tool, as well as new tools developed for RNA analysis.

The goal of the workbench is to provide an easy to use and statistically robust method for analyzing high-throughput RNA data. It is designed so that, at the most basic level, the user can enter the locations of read, genome, and annotation files, and come back to a list of differentially expressed genes. More advanced options allow the user to visualize gene regions in the alignment and analyze differential splicing. Tools are also provided to measure the quality of the data (e.g. the portion of reads that align or whether samples cluster appropriately), to measure the depth of transcriptome coverage, and to analyze how unique the known coding regions in a given genome are for the purposes of read alignment.

In its initial incarnation the tool supports whole-transcriptome shotgun and 5' cap trap reads, and provides basic support for the analysis of miRNA. It currently supports data from 454, AB SOLID, and Illumina/Solexa technologies.

**Disease Gene Characterization Through Large-Scale Co-expression Analysis.** *V. Funari[1,3], A. Day[2], J. Dong[2], B. Harry[2], D. Cohn[1,2,3], S. Nelson[2,4].* 1) Med Gen Inst, Cedars-Sinai Med Ctr, Los Angeles, CA; 2) Human Genetics, School of Med at UCLA, Los Angeles, CA; 3) Pediatrics, School of Medicine at UCLA, Los Angeles, CA; 4) Psychiatry, School of Medicine at UCLA, Los Angeles, CA.

**Background** In the post genome era, a major goal of biology is the identification of specific roles for individual genes. We report a new genomic tool for gene characterization, the UCLA Gene Expression Tool (UGET). **Results** Celsius, the largest co-normalized microarray dataset of Affymetrix based gene expression, was used to calculate the correlation between all possible gene pairs on all platforms, and generate stored indexes in a web searchable format. The size of Celsius makes UGET a powerful gene characterization tool. As an example, using only 14 known cartilage-selective genes as a seed list, UGET identified 78/100 genes identified previously in a large well annotated tissue survey of gene expression. In addition, UGET extended the list of known genes by identifying 32 new highly cartilage-selective genes. Of these, 7 of 10 tested were validated by qPCR including the novel cartilage-specific genes SDK2 and FLJ41170. Using only a few genes as an example, UGET easily identifies disease genes in disease-linked intervals. We retrospectively tested this first by identifying two recently published skeletal dysplasia disease genes in SEMD Mexican type and Autosomal Dominant Brachyolmia. We similarly tested UGET to identify disease-causing genes within known linkage intervals for genetically heterogeneous disorders in Joubert syndrome, microcephaly, and Type 2 limb girdle muscular dystrophy (LGMD2) and suggest novel candidate genes within a linkage region for Joubert Syndrome (JBTS1). Finally, we observed a significantly higher gene correlation shared between genes in disease networks associated with similar complex or Mendelian disorders. **Conclusion** One of the major challenges for the geneticist with the current genome is how to prioritize sequencing of genes (many of which are poorly annotated) for mutation analysis within genomic intervals linked to a disease. We report a new genomic tool for gene characterization which uses gene expression networks to help geneticist establish the candidacy of each gene in the linked interval. UGET is an invaluable resource for a geneticist that permits the rapid inclusion of expression criteria from one to hundreds of genes in genomic intervals linked to disease. As we demonstrate, this information can be critical in prioritization of candidate genes for sequence analysis.

## 2793/F/Poster Board #533

**Using Integrative Genomics to Develop Novel Diagnostic Phenotypes for Asthma Severity.** *J.A. Howrylak[1], S. Sharma[1], A.J. Murphy[1], B. Schuemann[1], S.T. Weiss[1], E. Xing[2].* 1) Pulm Crit Care Medicine, Brigham and Woman's Hospital, Boston, MA; 2) Department of Machine Learning, Carnegie Mellon University, Pittsburgh, PA.

Gene expression profiling (GEP) for disease classification in clinical practice is quickly becoming an important aspect of patient management for a variety of disorders, particularly cancer. Though several groups have studied gene expression in asthma, the potential utility of GEP for severity classification in asthma remains unknown. To address this question, GEPs were developed from peripheral blood CD4+ lymphocyte RNA in 200 young adults (ages 16-23 years) with asthma. Subjects were participants in the Childhood Asthma Management Program Continuation Study, and blood samples were drawn during a routine study visit, together with detailed phenotype information obtained via questionnaire. Responses to questions related to asthma symptoms and medication use over the prior week were used to classify asthma severity. GEPs were generated using the Illumina HumanRef8 v2 arrays, with background correction and quantile normalization in lumi. The expression data set was randomly divided into training (n=144) and validation (n=56) sets. For each of six asthma severity phenotypes, we developed asthma severity signatures in the training set using the Support Vector Machine (SVM) learning algorithm, and assessed the predictive ability of the resultant gene set to accurately classify severity in the training set (internal cross-validation) and in the independent validation data set (external validation). We found the developed GEPs had very strong predictive accuracy for asthma severity classification. For example, the predictive accuracy for the nocturnal asthma GEP was 100% in the training set, and 95% in the validation set. The nocturnal asthma GEP was enriched for genes involved in metal-ion binding, zinc-ion binding, and transition metal binding. GEPs for use of asthma controller medications also performed well (accuracy of 75-95% in validation sets) though not as reliably as for nocturnal asthma. These data suggest that the CD4+ lymphocyte transcriptome captures aspects of asthma severity. These profiles can be used to identify novel genes and pathways implicated in the pathobiology of asthma. These results should motivate prospective evaluation of these profiles in evaluating asthma control and severity in the clinical setting. Funding: NIH/NHLBI R01 HL086601A.

## 2794/F/Poster Board #534

**An integrated multivariate approach for identifying hypoxia-induced differentially expressed genes, adjusting for cell culture covariates and performing latent structure eQTL analysis.** *F. Pettersson[1], B. Mohr[1], S. Campino[1], P. Ellis[2], C. Langford[2], K. Rockett[1], C. Pugh[3], P.J Ratcliffe[3], D. Kwiatkowski[1].* 1) WTCHG, University of Oxford, UK; 2) Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK; 3) The Henry Wellcome Building of Molecular Physiology, University of Oxford, UK.

The cellular response to changing oxygen levels plays an important role in many biological processes that are potentially relevant to human disease, such as malaria or cancer. We set out to identify genetic variants of importance for the transcriptional response to hypoxia (oxygen deficiency). Yoruba HapMap lymphoblastoid cell lines were grown under both hypoxia and normal oxygen levels (normoxia) (1% and 21% oxygen). For each of the cell lines global gene expression was measured using microarray technology. Cell culture-related covariates such as growth rate and Epstein-Barr viral transcription were also measured. Applying principal component analysis (PCA) to gene expression data that were normalised using standard protocols revealed that the main structure captured by the model related to microarray scan order and biological covariates, rather than to the hypoxia stimulus. Applying a supervised approach using partial least squares discriminant analysis (PLS-DA) rendered a strong model where the effect of hypoxia was captured in the first component and could be used to identify differentially expressed genes, both up- and down-regulated. We applied two strategies for finding association between genetic variants and gene expression, where the responses in a linear regression framework were i) expression levels for individual probes or ii) the latent structures from multivariate models (a meta-gene approach). The gene expression data and latent structures from models thereof contained systematic variation correlated with the scan order and the covariates and needed to be normalised. To remove this effect we used an approach (orthogonal PLS or OPLS) which has previously been successfully applied to normalize gene expression data and remove technical artifacts. The OPLS model separates information related to the stimulus and structure that is mathematically unrelated (orthogonal) to it. This ensures that variation related to the response is not removed, but also allows investigation of the removed variation. Four components were eliminated and these were seen to be correlated to measured covariates and scan order. Using the latent structure based approach is attractive compared to exhaustive trans-eQTL testing because it focuses on the relevant response with a smaller number of tests. The OPLS normalisation procedure can also be applied to remove and estimate unwanted biological variability in studies where covariates have not been directly measured.

## 2795/F/Poster Board #535

**Effects of *NF1* haploinsufficiency on stochastic gene expression.** *D. Stewart[1], A. Pemov[1], G. Cohen[2], N. Oden[2].* 1) National Human Genome Research Institute, Bethesda, MD 20892; 2) Emmes Corp, Rockville, MD 20850.

**Background**: Using a computer model, Cook et al (*PNAS* 95: 15641-15646, 1998) predicted that haploinsufficiency syndromes may result in increased stochasticity ("noise") in gene expression. Studies of the effects of *NF1* haploinsufficiency on morphological phenotypes in keratinocytes and melanocytes were congruent with these predictions (Koivunen et al. *J Invest Dermatol* 114: 473-479, 2000 and Kemkemer et al. *PNAS* 99: 13783-13788, 2002). We investigated differences in gene expression stochasticity in NF1-haploinsufficient and control cells. **Data Set and Analyses**: Whole-genome transcriptional profiling of lymphoblastoid cell lines from 13 females affected with NF1 (A) and 10 unrelated female controls (U) was performed under similar conditions in February and June. Raw expression data was background-subtracted, quantile normalized and $\log_2$ transformed. To measure noise, we calculated the correlation between the 2 time points for each of the 10,757 expressed transcripts for both groups (A and U). We then calculated the mean of the correlation coefficients across all transcripts in A and U, as well as the difference in mean correlation between the 2 groups. We tested the latter using a permutation test. We also examined the variability of the change in expression between February and June for all 10,757 expressed transcripts in the 2 groups. **Results**: In our first analysis, the average correlation for all transcripts was significantly greater in the unaffected group than the affected group (U = 0.549; A = 0.428; difference = 0.121, P = 0.003, 1000 permutations). The differences were observed across all genes; no single transcript was identified with sufficient evidence of a difference in correlation to remain significant after multiplicity adjustment. In the analysis of variability of change over time, there were no statistically significant differences between the 2 groups. **Discussion**: In the unaffected cells, we observed a statistically significant higher average correlation between time points when compared to the *NF1*-haploinsufficient cells. To the extent that the comparison of mean correlation over 2 time points approximates expression noise, our observations are consistent with the predicted effect of haploinsufficiency. However, this effect was not observed in our analysis of variability of change in expression over time. The causes of this discrepancy and the ontology of the top transcripts from each analysis are subjects of investigation.

**Identification of Brain Transcriptional Variability Reproduced in Peripheral Blood: an Approach for Mapping Brain Expression Traits.** *A.J. Jasinska[1], S. Service[1], O.-C. Choi[1], J. DeYoung[1], O. Grujic[1], S.-Y. Kong[1], M.J. Jorgensen[2], J. Bailey[1], S. Breidenthal[1], L.A. Fairbanks[1], R.P. Woods[3], J.D. Jentsch[4], N.B. Freimer[1].* 1) Center for Neurobehavioral Genetics, University of California, Los Angeles, CA; 2) Department of Pathology, Section on Comparative Medicine, Wake Forest University Health Sciences, Winston-Salem, NC; 3) Departments of Neurology and Psychiatry and Biobehavioral Sciences, David Geffen School of Medicine, University of California, Los Angeles, CA; 4) Department of Psychology, University of California, Los Angeles, CA.

Genome-wide gene expression studies may provide substantial insight into gene activities and biological pathways differing between tissues and individuals. We investigated such gene expression variation by analyzing expression profiles in brain tissues derived from eight different brain regions and from blood in 12 monkeys from a biomedically important non-human primate model, the vervet (*Chlorocebus aethiops sabaeus*). We characterized brain regional differences in gene expression, focusing on transcripts for which inter-individual variability of expression in brain correlates well with variability in blood from the same individuals. By applying very stringent transcript selection criteria concerning the similarities in expression between brain and blood tissues, the consistency of repeat measurements in blood samples from particular individuals, the detection of transcripts in all tissue samples, and the observation of higher inter-individual than intra-individual variability, we identified 32 transcripts whose expression is measurable, stable, replicable, variable between individuals, and of interest to brain functions. Twenty-nine of these expression traits showed heritability at a significance level of p <0.05 (91%) and 25 transcripts showed heritability at p <0.001 (78%). More than 60% of the selected transcripts displayed heritability estimates of >0.4. The high heritabilities observed for levels of these transcripts in a large vervet pedigree validated our approach of focusing on transcripts that showed higher inter-individual compared to intra-individual variability. The selected stable blood expression biomarkers of brain gene expression may be investigated in the future for expression Quantitative Trait Loci (eQTLs) differentially regulating transcript levels in the brain among individuals. Given the high degree of conservation of tissue expression profiles between vervets and humans, our findings may facilitate the understanding of regional and individual transcriptional variation and its genetic mechanisms in humans. The approach employed here - utilizing higher quality tissue and more precise dissection of brain regions than is usually possible in humans - may therefore provide a powerful means to investigate variation in gene expression relevant to complex brain related traits, including human neuropsychiatric diseases.

**Genome-wide expression profiling of human blood reveals biomarkers for hemorrhage in brain arteriovenous malformation patients.** *S. Weinsheimer[1], H. Kim[1,2,3], L. Pawlikowska[1,2], C.E. McCulloch[3], H. Xu[4,5], F.R. Sharp[4,5], W.L. Young[1,6].* 1) Center For Cerebrovascular Research, Dept Anesthesia, Univ. California, San Francisco, San Francisco, CA; 2) Institute for Human Genetics, Univ. California, San Francisco, CA; 3) Dept Epidemiology and Biostatistics, Univ. California, San Francisco, CA; 4) Dept Neurology, Univ. California, Davis, CA; 5) Medical Investigation of Neurodevelopmental Disease Institute, Univ. California, Davis, CA; 6) Dept Neurology and Neurological Surgery; Univ. California, San Francisco, CA.

**Background:** Brain arteriovenous malformations (BAVMs) are a tangle of abnormal vessels directly shunting blood from the arterial to venous circulation, and are an important cause of intracranial hemorrhage (ICH) in young adults. Studies have shown that blood genomic profiling in stroke patients can identify stroke subtypes. Based on previous expression studies of AVM tissue and on genetic studies, we hypothesized that BAVM patients at high risk for ICH will display a distinct gene expression pattern in their blood that could be used to identify prognostic biomarkers to predict ICH risk. Our study compared blood genomic profiles in BAVM patients presenting with or without ICH. **Methods:** We performed Affymetrix Human Genome U133 Plus 2.0 microarray analysis on blood from 40 BAVM patients (20 ICH, 20 non-ICH). Data were preprocessed using the robust multi-array analysis (RMA) normalization method and analyzed using Genespring GX 10.0 (Agilent Technologies). Genes with a fold change >1.5 at the false discovery rate (FDR) corrected significance threshold P<0.05 were selected as differentially expressed in ICH compared to non-ICH patients. We used the WebGestalt program to evaluate whether genes differentially expressed in ICH were represented in pathways (KEGG and BioCarta) more than expected by chance, using all probes on the array as a reference (one-sided Fisher's exact P<0.05). **Results:** 125 mRNA probes representing 52 distinct genes were differentially expressed in ICH vs. non-ICH BAVM patients (>1.5 fold change, FDR P<0.05). Pathway analysis revealed an overrepresentation of differentially expressed genes in two KEGG pathways including Fc epsilon RI signaling (P=0.02) and Toll-like receptor signaling (P=0.025) and six BioCarta pathways including TNF/stress related signaling (P=0.001), IL12 and Stat4 dependent signaling in Th1 development (P= 0.001), and signal transduction through IL1R (P=0.005). The following genes in these pathways were differentially expressed in ICH vs. non-ICH BAVM patients: IL18R1 (fold change=2.03, P=0.04), TNF (fold change=1.51, P= 0.04), and MAP2K6 (fold change=1.50, P=0.04). **Conclusion:** The gene expression pattern in blood differed between BAVM patients presenting with and without ICH. Identification of differentially expressed genes in ICH may provide clues to the pathogenesis of BAVM hemorrhage and point to new pathways for investigation.

## 2798/F/Poster Board #570

**Integrative and comparative genomics analysis of early hepatocellular carcinoma differentiated from liver regeneration in young and old.** *D. Colak[1], M. Chishti[2], A. AlBakheet[3], A. Al-Qahtani[4], M. Shoukri[1], M. Goyns[5], P. Ozand[6], J. Quackenbush[7], B. Park[8], N. Kaya[3].* 1) BESC, KFSHRC, Riyadh, Saudi Arabia; 2) King Khaled University Hospital, King Saud University; 3) NeuroGenetics, KFSHRC, Riyadh, Saudi Arabia; 4) BMR, KFSHRC, Riyadh, Saudi Arabia; 5) Immorgene Concepts Ltd; 6) Duzen Labs, Istanbul, Turkey; 7) Department of Biostatistics and Computational Biology; Dana-Farber Cancer Institute, Boston, MA,; 8) The Sidney Kimmel Comprehensive Cancer Center at Johns Hopkins, Department of Oncology, Johns Hopkins University School of Medicine, Baltimore, MD.

Hepatocellular carcinoma (HCC) is third-leading cause of deaths worldwide, and often diagnosed at an advanced stage, and hence typically has poor prognosis. Though much progress has been made in understanding HCC, there is currently no molecular marker to diagnose the early HCC. To identify distinct molecular mechanisms for early HCC we developed a rat model of liver regeneration post-hepatectomy, as well as liver cells undergoing malignant transformation and compared them to normal liver using a microarray approach. As ageing is a known confounding factor embedded in the gene expression profile data from cancer tissues, we included age as a factor in our multi-factor statistical analysis, and identified age-specific differences in early HCC. Subsequently, we performed cross-species comparative analysis by re-analyzing data from two independent human early HCC microarray studies. We then performed integrative analysis of DNA genomic copy number aberration (CNA) data with gene expression profiles. We identified 35 genes that are conserved across species for early HCC, 17 of which were mapped to human genomic CNA regions. Most significantly altered pathways include apoptosis signaling, p53, p38 MAPK, ERK/MAPK, PI3K/AKT signaling, and TGF-$\beta$ pathways. Conclusion: The integrative analysis of transcriptional deregulation with the genomic copy number aberrations data together with comparative cross species analysis bring new insights into the molecular portrait of early hepatoma formation differentiated from regenerating liver, and identify potential novel biomarkers for the early detection of early HCC.

## 2799/F/Poster Board #571

**MicroRNA analysis of formalin fixed paraffin-embedded prostate cancer tissues with different stages.** *G. Xiao, Q. Xie, R. Recker.* Dept Med, ORC, Creighton Univ, Omaha, NE.

INTRODUCTION: Prostate cancer still has the highest incidence among men in the United States. Our understanding of its molecular and cellular mechanisms is limited. Recently, microRNAs have gained favorable status as upstream regulators of prostate cancer progression since then it can posttranscriptionally regulate sets of genes. It is now estimated that there are about 1000 miRNAs in the human genome, but only about 300 miRNAs have been identified in humans now. Much of miRNAs and their roles in cancer formation still await discovery. METHODS: Formalin fixed paraffin-embedded (FFPE) prostate tissues from different stages of the cancer were de-waxed before performing total RNA extraction. Three stages of prostate cancer tissue with 15 subjects on each stage (n=15) were analyzed, including benign prostate tissue, low grade, and high grade. The total RNA was extracted with acid-phenol: chloroform. MicroRNAs were isolated from total RNA. MicroRNA microarray profiling was performed using LC Sciences technology (LC Sciences, LLC). The Bioconductor implementation of Limma was used to analyze the data. RESULTS: MicroRNA profiling experiments have been performed from 45 FFPE prostate tissues of prostate cancer subjects. By comparing the endogenous miRNA level between benign to low grade, we found that numbers of miRNAs (e.g. mir-95) were significantly induced, while some of miRNAs (e.g. mir-1247) were suppressed, in low grade. In subjects with high grade, we observed some up-regulated miRNA species (e.g. mir-95) and more down-regulated miRNA species (e.g. mir-200b*), indicating that those miRNAs could be important candidate mediators that regulate progressive process of the prostate cancer. These findings were confirmed by real time microRNA RT-PCR using prostate cancer patient samples. Further functional studies are still under investigation.

## 2800/F/Poster Board #572

**Deep surveying of whole transcriptome under CNV effect.** *E. Ait Yahya Graison[1], C.N. Henrichsen[1], J. Thomas[2], S. Pradervand[2], K. Harshman[2], A. Reymond[1].* 1) Center for Integrative Genomic, University of Lausanne, Lausanne, Switzerland; 2) DAFL, Center for Integrative Genomic, Lausanne, Switzerland.

Copy number variation (CNV) of DNA segments has recently been identified as a major source of genetic diversity, but a comprehensive understanding of the phenotypic effect of these structural variations is only beginning to emerge. We have generated an extensive map of CNV in wild mice and inbred strains (Henrichsen, 2009). These variable regions cover ~11% of their autosomal genome. Tissue transcriptome data show that expression levels of genes within CNVs tend to correlate with copy number changes and that CNVs influence the expression of flanking genes. Genes within CNVs show lower expression levels and more specific spatial expression patterns than genes mapping elsewhere. These analyses reveal differential constraint on CNV genes expressed in different tissues. Dosage alterations of brain-expressed genes are less frequent than those of other genes. This study suggests that CNVs shape tissue transcriptomes on a global scale and thus represent a substantial source for within-species phenotypic variation. To unravel the effects of CNV on expression of both coding and non-coding RNA at the nucleotide rather than locus level we used RNA-seq to monitor expression changes of transcripts that map to CNV regions and their flanks in brain and liver of three mouse inbred strains (C57BL/6J, 129S2, DBA/2J). We also sequence transcriptome of F1 crosses between these three strains. This work should (i) give an unprecedent global and precise view of the mouse transcriptome; (ii) help gauge the influence of CNVs on the transcriptome and (iii) monitor allele specific expression from F1 crosses transcriptome profiling considering Copy number variants.

## 2801/F/Poster Board #573

**Genetic Effect of Single Nucleotide Polymorphisms of PPARGC1B Gene on Airway Hyperreactivity in Asthmatics.** *S. Lee[1], J. Park[1], H. Chang[1], A. Jang[1], S. Park[1], J. Park[1], Y. Kim[2], S. Uh[2], Y. Kim[3], I. Chung[4], B. Park[5], H. Shin[5,6], C. Park[1].* 1) Genome Research Center for Allergy and Respiratory Diseases, Soonchunhyang University Bucheon Hospital, 1174, Jung-Dong, Wonmi-Gu, Gyeonggi-Do,420-020, South Korea; 2) Division of Allergy and Respiratory Medicine, Soonchunhyang University Hospital, 657, Hannam-Dong,Yongsan-Gu,140-743, South Korea; 3) Divison of Allergy and Respiratory Medicine, Soonchunhyang University Cheonan Hospital, 23-20, Bongmyeong-Dong, Cheonan-Si, Chungcheongnam-DO, 330-721, South Korea; 4) Division of Molecular and Life Sciences, College of Science and Technology, Hanyang University, 1271 Sa-1-dong, Ansan, Gyeonggi-do 426-791, South Korea; 5) Department of Genetic Epidemiology, SNP-Genetics Inc., B-1407,WonLim Lion's Valley,371-28 Gasan-Dong, Geumcheon-Gu, Seoul, 153-803, South Korea; 6) Department of Life Science, Sogang University, Sinsu-Dong, Mapo-Gu, Seoul,121-742, South Korea.

Rationale; PPARGC1B, peroxisome proliferators-activated receptor-gamma coactivator 1 beta, is a co-activator for intracellular receptors such as estrogen receptor, peroxisome proliferators-activated receptor and glucocorticoid receptor which participate in asthma development. Objectives; Genetic association of PPARGC1B polymorphisms were investigated with the risk of asthma and airway hyperreactivity and the functional effect of these polymorphisms on the expression of PPARGC1B gene and protein. Methods; Direct sequencing of DNA from 24 Koreans was applied for discovery of PPARGC1B gene polymorphisms. A large-scale genotyping was done by single base extension methods in 264 normal controls and 949 asthmatics. Alternative splicing and amount of mRNA was measured using RT-PCR and Real time PCR. Luciferase assay and gel shift assay were done for functional assay of polymorphism on the promoter. Results; Eighteen single-nucleotide polymorphisms (SNPs) and one insertion/deletion polymorphism were identified and seven SNPs (-1381T>C, -427C>T, +90138T>C,+96626 G>A, +102525G>A,+102605C>A,+111883G>C) were genotyped. There was no significant difference in the distribution of each SNPs and haplotypes between asthmatics and normal control. However, the allele frequency of PPARGC1B -427C>T, +90138T>C (Exon 2 (L42L), +96626G>A (intron 3), +102525G>A (exon 5 (R265Q)) showed a significant association with log transformed PC20 methacholine values in the asthmatics (P = 0.010-0.0001). Two RT-PCR products of 602bp (wild type) and 485bp (117 bp of exon 4 deleted) were identified. Real time quantitative PCR showed higher messenger RNA levels of PPARGC1B in -427C>T CC homozygotes than those having -427C>T TT or CT allele (P = 0.028). The ratio of alternative PPARGC1B mRNA over the wild mRNA was similar between the B cell lines carrying the each allele of +102525G>A. On Luciferase reporter system, -427C caused higher promoter activity than -427T. Gel shift assay showed that -427C double-stranded oligonucleotides had stronger binding activity to a nuclear protein of 293T cells than did the -427T double-stranded oligonucleotides. Conclusions; The polymorphisms on promoter and exons of PPARGC1B gene may affect development of airway hyperreactivity via modulation of PPARGC1B gene products and the analysis for genotypes on PPARGC1B gene may be a genetic marker for airway hyperreactivity.

**Apoptosis of CD4+CD25high T Cells in Type 1 Diabetes is Partially Mediated by IL-2 Deprivation.** *P. Jailwala[1], J. Waukau[1], S. Glisic[1], S. Jana[1], S. Ehlenbach[1], M. Hessner[1], R. Alemzadeh[2], S. Matsuyama[3], P. Laud[4], X. Wang[5], S. Ghosh[1].* 1) The Max McGee National Research Center for Juvenile Diabetes and The Human and Molecular Genetics Center, Department of Pediatrics at the Medical College of Wisconsin and the Children's Research Institute of the Children's Hospital of Wisconsin, Milwaukee; 2) Children's Hospital of Wisconsin Diabetes Center, Pediatric Endocrinology and Metabolism, Medical College of Wisconsin, Milwaukee, WI, USA; 3) Department of Pharmacology, Case Western Reserve University, Cleveland, OH, USA; 4) Division of Biostatistics, Medical College of Wisconsin, Milwaukee, WI, USA; 5) Department of Physics & the Comprehensive Diabetes Center, University of Alabama at Birmingham Birmingham, AL, USA.

Type 1 diabetes (T1D) is a T-cell mediated autoimmune disease targeting the insulin-producing pancreatic β cells. Naturally occurring FOXP3+CD4+CD25high regulatory T cells ($T_{regs}$) play an important role in dominant tolerance, suppressing autoreactive CD4+ effector T cell activity. Previously, in both recent-onset T1D patients and β cell antibody-positive *at-risk* individuals, we observed increased apoptosis and decreased suppression of polyclonal $T_{regs}$ in the periphery. Our objective was to elucidate the genes and signaling pathways triggering apoptosis in $T_{regs}$ from T1D subjects. Microarray analysis was performed on unstimulated $T_{regs}$ from recent-onset T1D (n=12) and healthy control subjects (n=15). Gene expression analysis was performed using BGX, a novel bayesian approach integrating all steps of the analysis. Components of an activation profile, including cytokine/chemokine receptor genes, HLA genes, GIMAP family genes and cell adhesion genes were downregulated in $T_{regs}$ from T1D subjects, relative to control subjects. CD4+ effector T-cells from T1D subjects showed a marked reduction in IL-2 secretion. Several downstream target genes of the AKT and p53 pathways were also upregulated in T1D subjects, relative to controls. Further, expression signatures and increased apoptosis in $T_{regs}$ from T1D subjects mirrored the response of healthy $T_{regs}$ under conditions of IL-2 deprivation. This could indicate that prior to and during the onset of disease, $T_{regs}$ in T1D are caught up in a relatively deficient cytokine milieu. In summary, expression signatures in $T_{regs}$ from T1D subjects reflect a cellular response that leads to decreased activation and increased sensitivity to apoptosis, partially due to cytokine deprivation. Further characterization of these signaling cascades should enable the detection of genes that can be targeted for restoring $T_{reg}$ function in subjects predisposed to T1D.

**Association of the Genetic Polymorphisms with the Susceptibility of the Membranous Glomerulonephritis in Taiwanese Population.** *W. Chen[1,2], S. Chen[3,4], W. Lo[5,6], C. Chen[7], F. TsAI[6,8].* 1) Department of Surgery, China Medical University Hospital, Taichung, Taiwan; 2) College of Medicine, China Medical University, Taichung, Taiwan; 3) Genetics Center, Department of Medical Research, China Medical University Hospital, Taichung, Taiwan; 4) Graduate Institute of Chinese Medical Science, College of Chinese Medicine, China Medical University, Taichung, Taiwan; 5) Graduate Institute of Integrated Medicine, China Medical University, Taichung, Taiwan; 6) Department of Medical Research, China Medical University Hospital, Taichung, Taiwan; 7) Institute of Clinical Medicine, China Medical University, Taichung, Taiwan; 8) Department of Biotechnology and Bioinformatics, Asia University, Taichung, Taiwan.

Objective: Membranous glomerulonephritis (MGN) is the most common primary cause of the nephritic syndrome in adult, and 25% of cases proceed to end-stage renal disease. It is characterized by basement membrane thickening and subepithelial immune deposits without cellular proliferation or infiltration. Previous studies suggested that genetic polymorphisms play an important role in nephropathy progression. The purpose of this study was to clarify the relationship between possible genetic variants and the pathogenesis of MGN in Taiwanese population. Methods: Individuals were divided into two groups: (1) normal controls; (2) MGN patients. Polymorphisms of the 45 genetic variants were genotyped in 106 MGN cases and 265 unrelated healthy adult in Taiwanese cohort which matched for sex and age with the study patients using PCR system with TaqMan® allelic discrimination assay. Genotypes/allelic frequencies and haplotypes for these polymorphisms in each group were compared. Results: Five single-nucleotide polymorphisms (SNPs) were associated with the occurrence of MGN. Genotype distribution and allele frequency of rs12749808, rs7523521, rs7532635, rs2070744, IL-6 -572 polymorphisms in both groups were significantly different. The frequency of C allele in the IL-6 -572 polymorphism was significantly higher in the patient group (88.7%) than in the control group (76.4%; p = 0.032, odds ratio [OR] = 0.68; 95% confidence interval [CI] = 0.47-0.97). Therefore, persons in the IL-6 -572 polymorphism with the C allele may have higher risk of developing MGN.

## 2804/F/Poster Board #576

**Gene Expression Profiling of Human Whole Blood Samples with the Illumina DASL Assay.** *M.E. Winn[1,2], M. Shaw[2], C. April[5], B. Klotzle[5], J.B. Fan[5], C.S. Bloss[2,3], S.S. Murray[2,3,4], E.J. Topol[2,3,4], N.J. Schork[2,3,4].* 1) University of California San Diego, La Jolla, CA; 2) Scripps Genomic Medicine, Scripps Translational Science Institute, La Jolla, CA; 3) Scripps Health, La Jolla, CA; 4) Dept of Molecular and Experimental Medicine, The Scripps Research Institute, La Jolla, CA; 5) Illumina Inc., San Diego, CA.

Peripheral whole blood is quickly becoming a commonly assayed tissue for the development of clinically relevant biomarker panels for a variety of human diseases. Despite a number of studies focusing on technical factors surrounding the handling and processing of whole blood, there remain a number of important biological and technical issues to resolve before blood-based gene expression biomarker panels can reach their full potential. One issue is decreased sensitivity and reliability of whole blood gene expression profiles due to the effects of high hemoglobin levels. Globin reduction assays have been shown to overcome such effects when used in conjunction with Affymetrix microarrays and the standard Illumina direct hybridization assay but never with the new Illumina DASL® assay. We compared whole blood and globin-reduced blood from eight Parkinson's disease blood samples on three Illumina assays: the IVT-based direct hybridization assay and the new DASL assay with and without globin probes. We found that whole blood hybridized on the DASL globin-probe negative assay results in higher levels of gene expression sensitivity and reproducibility than the DASL globin-probe positive and direct hybridization assays with and without globin reduction. Transcript detection is significantly increased with the use of DASL compared to IVT-based direct hybridization, while globin reduction appears to have little to no positive effect on transcript detection and raw intensity correlations.

## 2805/F/Poster Board #577

**Alternative Splicing and Differential Gene expression in Human Hematopoiesis During In Vitro Lineage Specific Cell Differentiation.** *P. Liu[1], J. Barb[2], X. Xu[1], P. Munson[2], N. Raghavachari[1].* 1) Genomic Core, NHLBI/NIH, Bethesda, MD; 2) CIT/NIH, Bethesda, MD.

Alternative splicing is a prevalent mode of posttranscriptional regulation, and occurs in approximately one half of all mammalian genes. Hematopoietic differentiation is strictly regulated by several exogenous factors and the frequency and functional impact of alternative splicing in stem cell differentiation process are yet to be determined. Disruptions of the intricate sequences of transcriptional activation and suppression of multiple genes can cause hematological diseases, such as leukemias, myelodysplastic syndromes (MDS), or myeloproliferative syndromes (MPS). Elucidating the pattern and sequence of gene expression during normal hematopoietic cell development may help to unravel the disease-specific mechanisms in hematopoietic malignancies. In this study using an vitro hematopoietic model system, CD34+ human stems cells isolated from healthy individuals were selectively induced in vitro with the lineage-specific cytokines, such as erythropoietin (EPO), granulocyte colony-stimulating factors (G-CSF), granulocyte macrophage colony-stimulating factors (GM-CSF) and thrombopoietin (TPO). Cells from each of the lineages were harvested after 11 days of culture for total RNA isolation. Gene chip analysis was performed using affymetrix human U133 plus expression arrays and human genome 1.0 ST exon arrays to delineate the changes in gene expression and associated alternative splicing events during lineage-specific hematopoietic cell differentiation. Data Analysis on the U133 plus expression chips indicated that during cell differentiation 943 genes were significantly up-regulated and 381 genes were found to be down-regulated. Gene level analysis on the Human 1.0 ST exon arrays showed good correlation (0.7) with the expression chip analysis. Analysis of the exon arrays for alternatively spliced genes during erythropoiesis, granulopoiesis and megakaryopoiesis, identified genes such as CLMN3, FBN24, FCN1, PDE34D, PDE34DIP, RGS3, BAX, SF1, THBS, NT5C2, HDAC5, ITGA2B, PTPRA, RTN4 and SLC4A2 to be significantly spliced during cell differentiation. RT-PCR analysis corroborated with the gene chip data on few selected genes. Our data thereby provides several new insights into understanding differentiation and proliferation of human stem and progenitor cells. This knowledge on the nature of stem cells and the molecular process by which these cells acquire their specific cell fate shows great promise to the success of cell-based therapies.

## 2806/F/Poster Board #578

**Single Molecule and Paired Read Sequencing of the Human Transcriptome: Exons, Splice Junctions and Fusions.** *D. Lipson, T. Raz, P. Kapranov, J. Reifenberger, J. Thompson, S. Letovsky, P. Milos.* Bioinformatics, Helicos BioSciences, Cambridge, MA.

Full transcriptome sequencing (RNA Seq) enables the study of variations in biological samples, providing new insights into basic biology. Deep sequencing now provides a means to carry out a complete comparison of gene expression across tissues, time, development, and tumor status. In addition to sequence variation, RNA Seq can be used for quantification of alternative splice variants and identification of novel DNA fusion events. Single molecule sequencing can be carried out for single reads or paired reads with the simple sample preparation methods required for either mode including only reverse transcription of RNA followed by tailing of the first strand cDNA with terminal transferase. No ligations or amplifications are necessary, avoiding artifacts introduced by those methods. Each HeliScope run can generate 50 channels (for up to 50 different samples) with more than 10 million usable reads in each channel. This provides exhaustive coverage of exons as well as splice junctions and fusion transcripts often found in tumors. Highly reproducible profiles for a variety of tissues and species will be shown. To augment the single read data, we have used short paired reads generated by a HeliScope single-molecule sequencer for de novo discovery of fusion transcripts. Generation of single-molecule paired-reads involves no additional sample preparation steps and therefore greatly reduces the risk of false positives. In addition, a single run generates paired reads of different lengths as well as a large number of single reads. The combination of these different data types allows de novo discovery of putative fusion events using the longer pairs (e.g. 25+25bp or longer), validation of these events using the shorter pairs (e.g. 20+10bp or longer), and mapping of the exact breakpoints using single reads. We demonstrate the application of this approach for confirmation of known fusion events in well-characterized cell lines as well as identification of novel fusion events. A similar analytical approach may be used to identify unannotated transcript isoforms and local fusion events such as gene-skipping, demonstrating the significant utility of single-molecule paired-reads for transcriptome analysis.

## 2807/F/Poster Board #579

**Genetic control of the transcriptional landscape in humans.** *J.K. Pickrell[1], A.A. Pai[1], J.C. Marioni[1], J.F. Degner[1], E. Nkadori[1], M. Stephens[1], Y. Gilad[1], J.K. Pritchard[1,2].* 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Howard Hughes Medical Institute.

Understanding how genetic variation in human populations influences transcription is an important step towards understanding the mechanisms by which regulatory polymorphisms influence disease risk. Recently, studies of expression quantitative trait loci (eQTLs) have become an important tool for connecting variation in gene expression levels to individual genetic loci. Additionally, next-generation sequencing technologies now allow for rapid quantification of the RNA content of a tissue. To take advantage of these tools, we have performed RNA-sequencing on 76 lymphoblastoid cell lines derived from Nigerian individuals that have been extensively genotyped by the International HapMap Project. We identify thousands of unannotated transcribed regions, hundreds of which are predicted to be novel protein-coding exons. Using the genotypes from the HapMap, we confirm the majority of eQTLs previously identified using microarrays, as well as identify novel ones. Turning to transcriptional processing, we identify hundreds of loci that impact the inclusion of individual exons, likely through influences on splicing. We discuss these results both in the context of disease mapping efforts and the evolution of gene structure.

## 2808/F/Poster Board #580

**A Comparison of Next Generation Sequencing and Microarrays for Transcriptome Expression Profiling.** *P. Whitley, A. Lemire, C. San Jose, N. Hernandez, J. Gu, K. Bramlett, D. Ilsley, J. Schageman, J. Brockman, K. Lea, R. Setterquist, S. Kuersten, S. Heater, L. Qu.* Life Technologies, Molecular Biology Systems Division, R&D, Austin, TX.

Microarray based expression profiling has been remarkably successful at elucidating the spatio-temporal patterns of mRNA transcripts within cells and tissues, however there are a number of shortcomings to the existing technology. Both sensitivity and specificity can be low with microarrays. Accuracy can also be negatively affected by the low dynamic range of existing microarray technology. Perhaps more importantly, microarrays restrict the expression profiling data to specific annotations and content that are present. Digital expression profiling using RNAseq and next generation sequencing (NGS) promises to reduce or in some cases eliminate these weaknesses. In order to evaluate the merits of RNAseq for expression profiling, we have performed an extensive comparison of data generated with the ABI SOLiD NGS platform and the Affymetrix U133Plus 2.0 and Human Exon 1.0 ST GeneChip platforms. Using the Microarray Quality Control Consortium RNA control samples as a model system we have demonstrated increased sensitivity, specificity and accuracy of the SoliD RNAseq data relative to the microarray platforms. Both microarray platforms showed similar levels of concordance with the RNAseq data, but the exon arrays provided additional information about exon usage and transcript diversity that were verified by the NGS data. TaqMan PCR was used as a third platform technology to assess relative performance of the NGS and array data and validate the findings for both systems. We also discuss some of the potential weaknesses of NGS, including transcript length bias. We have also compared the results of RNAseq using either polyA RNA fractions or total RNA that has been depleted of rRNA. While the results are highly concordant, the two sample types offer unique advantages and disadvantages for RNAseq. Using total RNA for RNAseq gives a fuller picture of the transcriptome, including non-coding RNAs and non-polyadenylated transcripts, but may require more sequencing depth to attain the same level of sensitivity. RNAseq with polyA selected RNA results in high sensitivity and accuracy for expression profiling, but does not survey the entire transcriptome sequence space. Applications, such as, novel transcript discovery, splice variant discovery, allele specific expression and traditional gene expression profiling may require the use of one or both RNA sample types.

## 2809/F/Poster Board #581

**Testing the predictive power of regulatory annotations using expression quantitative trait loci.** *D. Gaffney, J-B. Veyrieras, M. Stephens, Y. Gilad, J. Pritchard.* Human Genetics, University of Chicago, Chicago, IL.

The vast majority of regulatory sites in the human genome remain undiscovered. Computational prediction of regulatory regions typically suffers from a high false-positive rate while experimental approaches, such as ChIP-seq, can only examine a limited subset of transcription factors, cells and tissue types. Furthermore, although previous annotation efforts have frequently predicted tens of thousands of functional regulatory regions, experimental validation of these predictions is typically laborious and low-throughput. We propose a novel approach to complement traditional experimental validation. Our method rests on the assumption that true regulatory regions will also be enriched in expression quantitative trait loci (eQTLs). Using the Bayesian regression framework outlined in Servin & Stephens (2007), we infer putative eQTLs using gene expression data from HapMap cell lines and SNP data from HapMap and the 1000 genomes project. We then use the hierarchical model introduced in Veyrieras et al (2008) which enables a formal test for eQTL enrichment in any annotation. Using this approach we can test multiple, genome-wide annotations simultaneously while accounting for known predictors of eQTLs such as distance from the transcription start site. We test the level of eQTL enrichment in a diverse of array of regulatory annotations, both experimentally and computationally-predicted. We find that evolutionarily-conserved transcription factor binding sites as well as sites associated with histone modification and polyadenylation, are significantly enriched in eQTLs. We also demonstrate that this approach can provide functional information on the link between changes in the DNA sequence and changes in transcription. Our method provides a reliable test bed for future regulatory annotation efforts and will gain in power as increasing quantities of large scale genotyping and high-throughput gene expression data become available.

## 2810/F/Poster Board #582

**From gene evolution to gene function: characterization of a newly identified SERPINA2.** *Z. Ferreira[1, 2], J. Figueiredo[1], J. Correia[1], J. Rocha[1, 2], S. Seixas[1].* 1) Biological Sciences, IPATIMUP, Porto, Porto, Portugal; 2) Faculty of Sciences of the University of Porto, Porto, Portugal.

Serine protease inhibitors (SERPINs) are a superfamily of highly conserved proteins that play a key role in controlling the activity of proteases in diverse biological processes. Alfa-1-antitrypsin (*SERPINA1*), the most studied member of this family, is encoded by a gene located within the proximal 14q32.1 *SERPIN* subcluster, together with its highly homologous sequence, SERPINA2, which has been thought to be a pseudogene. Previously, we have found that a polymorphic 2 kb deletion in *SERPINA2* was associated with a signature of positive selection in Africa, possibly through a role in fertility or in host-pathogen interactions. To understand the selective forces driving *SERPINA2* evolution, we initiated the functional characterization of *SERPINA2* non-deleted alleles, possibly encoding functional protein isoforms with unknown inhibitory activity. To achieve this goal we first amplified *SERPINA2* gene from a human testis cDNA library and cloned it into a pLenti6/V5 vector. Then, we co-transfected 293FT cells with *SERPINA2* plasmids and ViraPower Packaging Mix and collected the cell media containing the corresponding lentivirus particles, 48 to 72 hours later. This media was used to transduce two mammalian cell lines (HeLa and CHO). Stable cell lines were obtained by Blasticidin selection of transduced cells and the evaluation of SERPINA2 expression was done by performing Real-Time PCR, western blotting and immunoflurescence assays. We efficiently transduced both cell lines with three SERPINA2 variants (L308-E320, P308-E320 and P308-K320) and with an empty vector. For each variant, we identified a single protein band of approximately 50 kDa which is the expected size for a regular SERPIN. SERPINA2 was localized inside the cells in contrast with its close homologue, SERPINA1, which is secreted and only found within the cell in cases of misfolded variants. However, the higher SERPINA2 content, and the absence of aggregates after treatment with proteasome inhibitors, rather suggest that SERPIN2 expression is differently regulated by a post-translational mechanism, dependent on the proteasome. In summary, we provide the first evidence of SERPINA2 expression in vitro and propose that its expression and activity probably differs from SERPINA1. Our preliminary work favors the hypothesis of a polymorphic gene/pseudogene whose loss of function might be advantageous in human evolution.

## 2811/F/Poster Board #583

**A high-resolution anatomical atlas of the murine transcriptome at embryonic stage E14.5.** *G. Diez-Roux[1], S. Banfi[1], M. Sultan[8], L. Geffers[7], L. Kumar[4], P. Sarmientos[2], A. Reymond[3], D.R. Davidson[4], P. Dolle[5], S.E. Antonarakis[6,10], M.L. Yaspo[8], S. Martinez[9], R.A. Baldock[4], G. Eichele[7], A. Ballabio[1,11], EURExpress consortium.* 1) Fondazione Telethon, Telethon Inst Gen & Medicine, Naples, Italy; 2) PRIMM srl, Milan, Italy; 3) Center for Integrative Genomics, Genopode building, University of Lausanne, Switzerland; 4) MRC Human Genetics Unit, Western General Hospital, Edinburgh, UK; 5) Institut de Génétique et de Biologie Moléculaire et Cellulaire, Inserm, U 964, CNRS, Faculté de Médecine, Université de Strasbourg, France; 6) Department of Genetic Medicine and Development University of Geneva Medical School, Switzerland; 7) Genes and Behavior Department, Max Planck Institute of Biophysical Chemistry, Goettingen, Germany; 8) Max Planck Institute for Molecular Genetics, Berlin, Germany; 9) Experimental Embryology Lab, Instituto de Neurociencias UMH-CSIC, Univ. Miguel Hernandez , San Juan de Alicante, Spain; 10) University Hospitals of Geneva, Geneva, Switzerland; 11) Medical Genetics, Department of Pediatrics, Federico II University, Naples, Italy.

Ascertaining when and where genes are expressed is of crucial importance for the understanding of their physiological role. RNA in situ hybridization (ISH) provides an accurate spatio-temporal description, panoramic view and cellular resolution of the expression of individual transcripts. Digital anatomical atlases of gene expression can be built based on large-scale ISH. In a previous large-scale ISH study we described the transcriptome atlas of all paralogs of human chromosome 21 genes in the mouse embryo. We have now generated the first genome-wide digital transcriptome atlas by RNA ISH of an entire mammalian organism, the developing mouse at embryonic stage 14.5 (E14.5). The expression patterns of approximately 18,000 genes were generated, curated manually and textually annotated in a highly informative database freely available to the scientific community (www.eurexpress.org), which contains over 1400 hierarchically organized anatomical terms. The global analysis of gene expression annotation determined that 39% of genes displayed a regional or restricted expression pattern at this stage. We found that about 950 genes, 16% of which are of unknown function, display exclusive expression to particular anatomical structures. These represent an important source of novel tissue-specific markers for 37 different anatomical structures, which can be used for high-resolution histological analyses of complex organs and for pathology studies. The ISH data generated and the accompanying textual annotation allowed detecting synexpression gene clusters. Finally, the quality and the resolution of the data allowed us to perform high-resolution molecular regionalization, revealing novel molecular domains for several developing structures. This genome-wide digital transcriptome atlas represents a unique resource to investigate gene function and to identify novel ontogenetic and functional associations between genes relevant to development and disease.

## 2812/F/Poster Board #584

**Geographical genetics of expression variation in southern Morocco.** *Y. Idaghdour[1], W. Czika[2], H. Martin[3], R. Wolfinger[2], G. Gibson[3,4].* 1) Department of Genetics, North Carolina State University, Raleigh, NC; 2) SAS Institute, Cary, NC; 3) School of Biological Science, University of Queensland, Brisbane, QLD, Australia; 4) Center for Integrative Genomics, Georgia Tech, Atlanta, GA.

We describe a genome-wide association study for gene expression variation in peripheral blood samples from 194 residents of southern Morocco in which we jointly estimate the effects of ethnicity, relatedness, geographical location, gender and genotype on the transcriptome. Arab and Amazigh villagers differ from one another and from residents of Agadir for up to half of all expressed transcripts, with significant enrichment of ribosomal biosynthesis and oxidative phosphorylation as well as differential expression of numerous genes involved in disease. We also provide evidence for regional differences in particular transcript classes within genes, though many of these are not obviously due to annotated alternate splice forms. Despite the global effects of the environment, genome-wide significant genotype-transcript associations are detected involving 371 and 12 unique cis and trans autosomal target transcripts after genomewide Bonferroni adjustment (P<10E-8 or <10E-12, respectively). There is no evidence for genotype by environment interactions influencing these strong associations, but a clear tendency for derived alleles to have increased frequency in Moroccan and European relative to Yoruban samples was observed. Furthermore, we confirmed numerous cases of SNPs reported in other gene expression GWAS association studies, several of which are also associated with diseases or traits, and discovered several novel notable instances of this. Finally, we document the genetic population structure in the Souss region of Morocco and discuss the effect of jointly controlling for geograohic and genetic influences on the partitioning of sources of transcriptional variation, concluding that cultural factors influence human peripheral blood gene expression.

## 2813/F/Poster Board #617

**Post-transcriptional profile of human transcripts using polyribosomal fractionation.** *S. Nikolaev[1], S. Deutsch[1], R. Genolet[2], C. Borel[1], L. Parand[1], C. Ucla[1], F. Schütz[3], G. Duriaux Sail[1], Y. Dupré[1], P. Jaquier-Gubler[2], T. Araud[2], B. Conne[1], P. Descombes[4], J-D. Vassalli[1], J. Curran[2], SE. Antonarakis[1].* 1) Department of Genetic Medicine and Development, University of Geneva Medical School, 1 Rue Michel Servet, CH-1211, Geneva Switzerland; 2) Department of Microbiology and Molecular Medicine, University of Geneva Medical School, 1 Rue Michel Servet, CH-1211, Geneva Switzerland; 3) Swiss Bioinformatics Institute, Genopode Builiding, CH-1015, Lausanne; 4) Genomics Platform, University of Geneva Medical School, 1 Rue Michel Servet, CH-1211, Geneva Switzerland.

Recent studies have demonstrated extensive transcriptional activity across the human genome, a substantial fraction of which is not associated with any functional annotation. However, the post-transcriptional processes that operate within the different classes of RNA molecules are largely unknown. To characterize the post-transcriptional properties of expressed genomic sequences we separated RNA molecules from 3 cell lines (GM06990, HeLa S3 and SK-N-AS) according to their ribosome content by sucrose gradient fractionation. Polyribosomal associated RNA (a proxy for translation) and total RNA were subsequently hybridized to HSA21 genomic tiling arrays. We found that approximately 50% of the transcriptional signals were located outside annotated exons and were considered as TARs (Transcriptionally Active Regions). However, RT-PCR and RACE experiments revealed that approximately 40% of TARs were likely to represent non-specific cross-hybridization artifacts. Bioinformatic analysis of TARs according to conservation and sequence complexity identified a set of high confidence TARs. This set of TARs was significantly depleted in the polysomes suggesting that they are not likely to be translated. Analysis of polysome representation of Refseq exons showed that at least 15% of RefSeq transcripts undergo significant post-transcriptional regulation in at least 2 of the 3 cell lines tested. Among the regulated transcripts, enrichment analysis revealed an overrepresentation of genes involved in Alzheimer's disease (AD), including APP, and the BACE1 protease that cleaves APP to produce the pathogenic beta 42 peptide. High throughput sequencing of polyribosomal associated RNA is in progress to better estimate the genome-wide posttranscriptional regulation of transcripts. These studies provide a characterization of the intermediate step between transcription and protein levels, and establish the translation potential of numerous annotated genes and TARs.

## 2814/F/Poster Board #618

**A Machine-learning Approach to Predict Genes that are Related to Gemcitabine Cytotoxicity.** *K. Kalari[1], L. Li[2], C. High Seng[1], JP. Kocher[1], R. Weinshilboum[2], L. Wang[2].* 1) Division of Biostatistics and Informatics Department of Health Sciences Research Mayo Clinic 200 First Street SW Rochester, MN, 55905; 2) Health Sciences Research Division of Clinical Pharmacology Department of Molecular Pharmacology and Experimental Therapeutics Mayo Clinic 200 First Street SW Rochester, MN, 55905.

**Motivation:** The cytidine analogue, gemcitabine shows significant therapeutic effect in a variety of cancers. However, response to this drug varies widely. Despite recent improvements in high-throughput approaches, it still remains to be a challenge to identify an informative subset of genes that influence drug response. In this study, we investigated the ability of several machine learning methods to identify the most informative markers for gemcitabine cytotoxicity using lympoblastoid cell lines from normal and pancreatic cancer patients. **Methods:** Affymetrix U133 Plus 2.0 expression data and IC50 (dose at which 50% growth is inhibited) drug cytotoxicity phenotypes were obtained for 197 Human Variation Panel lymphoblastoid cell lines (Epstein-Barr virus transformed) and 60 Mayo clinic pancreatic patient lymphoblastoid samples. Genome wide expression correlation with gemcitabine IC50 value was computed for both datasets. Common significant probeset correlations in the Human Variation Panel cell lines and Mayo patient samples were selected as features for data mining. All informative probesets, together with other covariates, were trained using a wide variety of machine learning methods on the cell-based model system and were tested using the patient samples. **Results:** Machine learning algorithms such as decision trees, logistic model tree, linear regression, random forest, artificial neural networks, support vector machines, and logistic regression were explored to identify genes that might contribute to variation in gemcitabine cytotoxicity. Sensitivity of the models varied from 51% to 80% and specificity from 58% to 80%, depending on the machine learning model used. The logistic regression method yielded the best results; five candidate genes identified by this method were further considered to perform functional validation. Knock down experiments of one candidate gene, *GSTM3*, increased tumor cell sensitivity to gemcitabine, which is consistent with our *in silico* analysis. Functional studies of the remaining candidate genes are being performed. **Conclusions:** Our results suggest that the application of machine-learning methods with high-throughput datasets, when combined with complementary functional validation of candidate genes, may help to identify biomarkers in response to gemcitabine therapy.

## 2815/F/Poster Board #619

**Mapping regulators of the transcriptional response to hypoxia in human cells.** *A.J. Mohr[1], F. Pettersson[1], S. Campino[1,2], P. Ellis[2], Y.Y. Teo[1], H. Lockstone[1], R. Andrews[2], C. Langford[2], K. Rockett[1], C. Pugh[3], P. Ratcliffe[3], D. Kwiatkowski[1,2].* 1) Wellcome Trust Centre for Human Genetics, Oxford, United Kingdom; 2) Wellcome Trust Sanger Institute, Hinxton, Cambridge, United Kingdom; 3) The Henry Wellcome Building of Molecular Physiology, Oxford, United Kingdom.

To identify genetic regulators of the response to hypoxia (oxygen deficiency), we study whether variation in the hypoxic transcriptional response is associated with DNA variation. Lymphoblastoid cell lines of 56 unrelated individuals from the HapMap Yoruba (Nigeria) panel were subjected to standardized culture at 1% oxygen (hypoxia) vs. 21% oxygen (normoxia) for 16 hrs, and RNA extracted (6-800,000 cells/ml). WG-expression was measured on Illumina WG-6 v.3 beadchips. Expression intensities were scaled by variance-stabilizing transform, quantile-normalized across arrays, and linear regression-normalized across days of array processing. Expression of the Epstein-Barr viral transcript LMP1 was qPCR-quantified. Of 15,000 expressed genes, 25% are differentially expressed (40% up-regulated; 60% down-regulated under hypoxia; 1% FDR). Up-regulated processes include glycolysis, biosynthesis of cholesterol and steroids; those down-regulated include the proteasome, TCA cycle, basal transcription factors, RNA processing, splicing, and translation. Growth rate explains significant (>10%) variation in expression for 10% of genes; pH for 8%; viral activity for 6%. Genotype is known for 2.5 million SNPs. We test for association between each gene's expression and SNPs within 500kb of the gene (cis; additive linear models). Significance is permutation-based (5% FDR). We find significant associations in both normoxia and hypoxia for ~400 genes; in only normoxia for 200 genes; and in only hypoxia for 200 genes. Significant SNPs cluster close to the gene (median SNP-probe-distance, 13 kb). Analysis of covariate-corrected datasets (growth rate, pH, viral activity) shows 85% overlap with above. When mapping differential expression (DE; log-fold-change) as cis-phenotype, we find only 50 associations (median SNP-probe-dist, 150 kb), 25% of which are also detected in normoxia or hypoxia analyses, above. Less cis-eQTLs with the DE phenotype may be due to variation in the normoxic baseline, reducing the accuracy of quantifying hypoxic change; or could indicate a large fraction of false-positives in normoxia and hypoxia datasets due to SNPs under probes, as DE analysis is internally controlled. To uncover master-regulators of the global hypoxic response, we derive a meta-variable of hypoxia-responsiveness per cell line, using principal components analysis of expression values over DE genes, and perform GW-association for this phenotype. Results from this approach will be presented.

**Global gene expression in human primary leukocytes - effect of stimulations and potential for eQTL mapping.** *P. Saavalainen[1], E. Dukes[1], M. Zucchelli[2,3], J. Vendelin[1,4], E. Einarsdottir[1], J. Kere[1,2,3,4].* 1) Dept Medical Genetics, University of Helsinki, Helsinki, Finland; 2) Dept Biosciences and Nutrition, Karolinska Institutet, Huddinge, Sweden; 3) Clinical Research Centre, Karolinska University Hospital, Huddinge, Sweden; 4) Folkhalsan Institute of Genetics, Helsinki, Finland.

BACKGROUND: Expression quantitative trait loci (eQTLs) are genetic variants that can control the expression level of genes - either by proximal (cis) or by distal (trans) effects. eQTLs are of increasing interest in the context of complex genetic diseases which are associated with a number of intronic or intergenic risk variants common in populations and with relatively low risk effects. Studies on the eQTL nature of these variants and their role in disease pathogenesis are needed. Several systematic genome wide eQTL studies have been recently carried out using lymphoblastoid cell lines. These studies are, however, limited by the cell type, as EBV-transformed B cells cannot truly reflect the transcriptome of other cell populations and tissues, nor unmanipulated cells. MATERIALS AND METHODS: We have developed an expression tool to identify eQTLs potentially relevant in immune mediated diseases and other complex traits. We created Agilent whole human genome (44K) expression data from unmanipulated primary human peripheral blood mononuclear cells (PBMCs) from 41 blood donors. Since PBMCs are a heterogeneous mix of various leukocyte populations, we further studied a single cell type, CD4+ T cells, from the same donors. In addition to unmanipulated cells, we studied also cells exposed in vitro to inflammatory stimuli (LPS for PBMCs and anti-CD3/CD28 for CD4+ T cells). To replicate previously identified eQTL effects, we genotyped SNPs in IRF5, ERAP2 and ORMDL3 genes. RESULTS AND CONCLUSIONS: Principal components analysis showed specific expression signatures of the two types of stimulations. PBMC stimulation with LPS was characterized by 607 unique upregulated and 408 downregulated probes, whereas T-cell receptor stimulation showed instead 762 unique upregulated and 283 downregulated probes. In addition, 300 probes were upregulated and 45 downregulated in both cell types. 15 probes were downregulated in PBMCs but upregulated in CD4+ T cells. The three well known eQTLs showed clear genotype vs expression association in both cell types, demonstrating the power of our sample size to detect common eQTLs and the usefulness of even the heterogeneous PBMC population in eQTL studies. For functional studies of any target gene, our database provides useful information on general expression levels of any gene in PBMCs and CD4+T cells, on the stability or variability of their expression between individuals and effects of immunological stimuli on them.

**Genetic identification, replication, and functional fine-mapping of expression quantitative trait loci in primary human liver tissue.** *G.M. Cooper[1,2], C.D. Brown[1,3], S. Mirkov[4], J. Ramirez[4], J.D. Smith[2], I.B. Stanaway[2], E. Heinz[3], M.H. Domanus[3], N.D. Trinklein[5], D.A. Nickerson[2], A.E. Rettie[6], M.J. Rieder[2], M.J. Ratain[4,7,8], K.P. White[3], F. Innocenti[4,7,8].* 1) equal contributors; 2) Dept of Genome Sciences, University of Washington, Seattle, WA; 3) Institute for Genomics and Systems Biology and the Depts of Human Genetics and Ecology and Evolution, University of Chicago, Chicago, IL; 4) Dept of Medicine, University of Chicago, Chicago, IL; 5) SwitchGear Genomics, Menlo Park, CA; 6) Dept of Medicinal Chemistry, University of Washington, Seattle, WA; 7) Committee on Clinical Pharmacology and Pharmacogenomics, University of Chicago, Chicago, IL; 8) Cancer Research Center, University of Chicago, Chicago, IL.

Most loci identified in genome wide association studies of complex traits reside in non-coding DNA and may contribute to phenotype via changes in gene regulation. The discovery of expression quantitative trait loci ('eQTLs') can thus be used to more precisely identify modest but real genetic associations and provide insights into the underlying molecular mechanisms. This is particularly true for expression studies in non-transformed cells from tissues relevant to the complex traits of interest. We have conducted two independent studies to identify genetic, including both SNPs and CNVs, and environmental determinants of human liver gene expression variation. We analyzed two sets of primary livers (n=220 and n=60) using Agilent and Illumina expression arrays, respectively, and Illumina SNP genotyping (550K). At least 30% of genetic and non-genetic factors that are significant ($p < 1 \times 10^{-9}$) in one study fail to replicate in the second study, suggesting that artifacts, like unknown SNPs that affect RNA-probe hybridization or hidden confounding variables, often result in statistically significant but biologically irrelevant correlations. This illustrates the value of independent replication to enrich for truly predictive eQTLs, and given our study design we identify hundreds of reproducible correlations. We show that these data can provide insights into disease-relevant phenotypes, with examples including eQTLs related to cardiovascular disease (e.g. LDL cholesterol), immune system function, and drug response (e.g. warfarin). Furthermore, we hypothesized that promoters and 3'UTRs are enriched for causal eQTL variants. Therefore, we re-sequenced the promoters and 3'UTRs of 25 eQTL genes, cloned each discovered haplotype, and quantified their effect on transcription using a luciferase-based assay. We find multiple examples of robust, haplotype-specific in vitro functional differences that correlate directly with in vivo expression levels. This suggests that many eQTLs can be fine-mapped to one or a few single-nucleotide variants and mechanistically characterized using such assays. To our knowledge, these are the first analyses of primary liver eQTLs to include both independent statistical replication and functional characterization. Our data suggest that integration of functional assays with eQTL discovery, and eQTLs with complex trait associations, is a powerful means to improve biological interpretability of genotype-phenotype correlations.

## 2818/F/Poster Board #622

**Cis-association mapping of expression trait loci underlying the transcriptional response induced by TLR7 activation in lymphoblastoid cell lines.** *S. Biswas[1], J. Strout[2], J.D. Smith[1], J.M. Akey[1], M.M. Wurfel[2].* 1) Department of Genome Sciences, University of Washington, Seattle, WA; 2) Division of Pulmonary and Critical Care Medicine, Harborview Medical Center, University of Washington, Seattle, WA.

Recognition of single-stranded RNA present in viruses such as influenza and HIV is mediated by Toll-like receptors 7 and 8 (TLR7/8), and leads to activation of an innate immune response. Genetic variation that modulates this response could play a role in host susceptibility to infection. We hypothesized that the transcriptional response to a TLR7-specific agonist in B-lymphoblastoid cell lines (B-LCLs) is heritable and that loci controlling these responses can be identified. We used B-lymphoblastoid cell lines from the HapMap Project and publicly available SNP genotype and copy number polymorphism data to map cis-eQTLs that are associated with variation in the innate immune response. Gene expression profiles of ~24000 transcripts in 82 and 87 individuals with CEPH and Yoruban ancestry, respectively, were determined in resting and CL097-treated cells using Illumina Human Ref-8 arrays. At a conservative FDR threshold (FDR=0.01), 2470 transcripts were differentially expressed between the two conditions. The most significantly differentially expressed gene ZC3H12A ($p=1.4x10^{-47}$) confirms a recent finding describing its role as an IL6 regulator. In addition, the result includes several genes like SLC43A3 ($p=1.1x10^{-16}$), INSIG1 ($p=1.6x10^{-16}$) that are not known to play a role in TLR7 mediated response. Using a more stringent estimate of differential expression, 15% of the transcripts were found to have significantly heritable transcriptional variation ($p < 0.05$, $h^2$= 0.3) including PHF11, ALOX5AP, and HVCN1. We performed population-specific tests of association at cis-acting variants (SNPs and CNV clones within 1Mb of transcript) to map expression trait loci. At a bonferroni-corrected p-value of 0.05, significant cis-SNP associations were obtained for 19 and 38 transcripts in the CEPH and Yoruban samples respectively, while 9 and 11 significant ($p < 0.001$) cis-CNV associations were found in the respective samples. We also performed family-based tests of association using SNPs to confirm our findings. These analyses demonstrate that TLR7-mediated activation of B-LCLs induces a widespread transcriptional response, that a portion of this transcriptional response is heritable, and identifies sequence polymorphisms that underlie this heritability component.

**Reference genes in LPS-stimulated monocytes.** *R.M. Grimholt, R. Øvstebø, M.K. Kringen, J.P. Berg, A.P. Piehler.* Department of Medical Biochemistry and Clinical Pharmacology, Oslo University Hospital, Ullevål, Oslo, Norway.

**Background:** Stimulation of monocytic cells with bacterial lipopolysaccharide (LPS) is a frequently used model system to study pathophysiological processes of inflammation and infection. For the investigation of gene expression, quantitative real-time reverse transcription PCR (RT-qPCR) is the method of choice. Internal reference genes, previously called housekeeping genes, are often used for normalization of mRNA transcription levels between different samples. The selection of suitable reference genes is essential as several studies have shown that expression of traditional reference genes may vary substantially under certain conditions. In this study, we sought to identify and validate stably expressed reference genes in the frequently used model system of LPS-stimulated monocytes. **Methods:** Elutriated, purified human monocytes from six consenting, healthy donors were stimulated with LPS from E. coli and N. meningitidis, respectively, for three hours. Expression of twelve potential reference genes were assessed in stimulated and control monocytes using RT-qPCR. The most stably expressed genes and the recommended number of reference genes required for RT-qPCR normalization were calculated using the software package geNorm. **Results:** In monocytes stimulated with LPS from E. coli, the genes B2M (Beta-2-microglobulin), TMBIM4 (Transmembrane BAX inhibitor motif containing 4), PPIB (Cyclophilin B), PPIA (Cyclophilin A) and TBP (TATA-box binding protein) were the most stably expressed genes. Stimulation of monocytes with LPS from N. meningitidis exhibited least variation of the genes B2M, TMBIM4, PPIB, PPIA and UBC (Ubiquitin C). In both models, the three most stable reference genes (B2M, TMBIM4 and PPIB) were calculated to be sufficient to obtain satisfactory normalization of mRNA expression levels. Notably, the genes ACTB (beta-actin) and GAPDH (Glyceraldehyde-3-phosphate dehydrogenase), which are frequently used for gene expression normalization, were among the genes with the highest variability in monocytes stimulated with LPS from E. coli and N. meningitidis, respectively. **Conclusion:** Validation of stable reference gene expression is mandatory for normalization of RTqPCR results as genes traditionally used for normalization may vary significantly depending on experimental conditions. Employment of the reference genes B2M, TMBIM4 and PPIB is suitable to normalize gene expression in monocytes stimulated with bacterial LPS.

**Multiplexed Single Cells mRNA-Seq: Expression Lineage of Blastomeres during Early Mouse Development.** *C. Barbacioru[1], F. Tang[2], E. Nordman[1], J. Bodeau[1], K. Lao[1], A. Surani[2].* 1) Life Technologies, Foster City, CA; 2) Wellcome Trust/Cancer Research UK Gurdon Institute of Cancer and Developmental Biology, University of Cambridge, Cambridge,.

We developed a barcode-based multiplexed single cells mRNA-Seq method to obtain whole transcriptome landscape for 32 single mouse blastomeres at their different development stages on the next generation sequencing technique, SOLiD System [1]. While the expression difference between two blastomeres at the 2-cell embryo stage is not significant, there are more than one thousand genes up/down regulated with a more than 4-fold difference between two blastomeres at 4-cell and 8-cell embryo stages. The expression profiles between two blastomeres within the same 2-cell embryo are similar to each other but they are not identical. We have observed differences in coverage obtained from different blastomeres suggesting variation of the transcribed regions. Comparing the differentially expressed genes between blastomeres from the same 2-cell embryo to the oocytes, we found that the differentially expressed genes between blastomeres from a 2-cell embryo were mainly associated with the up/down regulated genes from oocytes to 2-cell embryos. The newly expressed genes of the 2-cell embryo are clearly associated with differentially expressed genes between two blastomeres. A similar result is obtained when comparing 2-cell to 4-cell embryos. We also compared the differentially expressed genes between blastomeres in the same 2-cell embryo with E3.5 TE and ICM and we found that the differentially expressed genes between blastomeres in the same 2-cell embryo match to the differentially expressed genes between E3.5 TE and ICM. These genes may lead to the final lineage diversification. We also found that the differentially expressed genes between blastomeres in the same embryos match to the differentially expressed genes between E3.5 TE and ICM. For this study, changes in gene expression are complemented with structural changes. We used de novo assembly tool [2] for each individual cell stage development, to generate transcript assemblies. Although the vast majority of the contigs represent known transcripts, which prove the accuracy of our de novo transcript assembly method, we were able to identify alternative splicing events and new fusion transcripts.

## 2821/F/Poster Board #625

**Use of biological and technical replicates for expression analysis of spotted microarrays.** *C.T. Ekstrøm[1], S. Bak[2], M. Rudemo[1].* 1) Dept. Basic Sciences and Environment, University of Copenhagen, Frederiksberg, Denmark; 2) Dept. Plant Biology, University of Copenhagen, Frederiksberg, Denmark.

Dye swap designs and duplicate or triplicate printing are often used for spotted microarrays. The combination of dye swaps and multiple prints makes it possible to partition the variance in both within-array variation (due to multiple printing) and within biological sample variation (due to dye swaps) as well as the normal biological variation. However, the number of biological and technical replicates are often small for microarray experiments so the precision of these variance estimates will be low for a single gene. We extend the idea from the LIMMA package of having a single common within-array correlation for all genes to accommodate both multiple sources of technical replicates and biological replicates. The extended method either assumes that only the within-array variation is identical for all genes or alternatively that also the within biological sample variation is shared between all genes. The proposed method is applied to a dataset from a study of *Arabidopsis* and the results are compared to the traditional method of analysis. We conclude that substantial differences in gene expression levels can be found when variation from several sources is taken into account.

**Role of Trichothiodystrophy DNA Repair and Transcription Genes in Human Placental and Fetal Development.** *A.H. Dzutsev[1], A. Morgun[2], C. Signore[3], J.L. Mills[3], J. Troendle[3], R. Moslehi[1,4].* 1) National Cancer Institute (NCI), NIH, Bethesda, MD; 2) National Institute of Allergy and Infectious Diseases (NIAID), NIH, Bethesda, MD; 3) National Institute of Child Health and Human Development (NICHD), NIH, Bethesda, MD; 4) Epidemiology and Biostatistics, School of Public Health, and Center for Excellence in Cancer Genomics, State University of New York (SUNY) at Albany, Rensselaer, NY.

**Background** Effects of abnormalities in DNA repair and transcription genes in human prenatal life have never been studied. Trichothiodystrophy (TTD) is a rare (affected frequency of $10^{-6}$) recessive disorder caused by mutations in genes involved in the nucleotide excision repair (NER) pathway and in transcription. Mutations in *XPD* (*ERCC2*), *XPB* (*ERCC3*) and *TTDA* (*GFT2H5*) which code for subunits of transcription factor TFIIH can cause TTD. Mutations in *TTDN1* (*C7ORF11*), a gene of unknown function, have also been associated with TTD. **Methods** Based on clinical observations, we conducted a genetic epidemiologic investigation of the role of TTD genes in human fetal development. We compared pregnancies resulting in TTD-affected offspring (N=24) with respect to gestational complications to population reference values. **Results** Highly significant increased risk of hemolysis, elevated liver enzymes, and low platelets (HELLP) syndrome (RR=35.7,P=0.0002), elevated mid-trimester maternal serum human chorionic gonadotropin (hCG) levels (RR=14.3,P<0.0001), Small for gestational age (SGA<3rd percentile) (RR=13.9,P<0.0001), preterm delivery (<32 weeks) (RR=12.0,P<0.0001), pre-eclampsia (RR=4.0,P=0.006) and decreased fetal movement (RR=3.3,P=0.0018) were noted in TTD-affected pregnancies. Abnormal placental development may explain constellation of observed complications. Thus, we hypothesize that TTD genes play an important role in normal human placental development. We investigated this hypothesis by analyzing the expression patterns of the four TTD genes identified to date. Using EST Profile Viewer (NCBI), we determined expression of all four genes in human placenta. Using microarray dataset GDS596 containing expression data for *XPD*, *XPB* and *TTDA* in different human tissues/organs, we found high expression of all three genes in placenta, above the mean of their expression in all organs. All three genes appeared to be in the higher range of their expression in placenta than in skin. Analyzing dataset GDS2528 containing normal placentas collected at different periods during gestation from 14 to 40 weeks indicated expression of all four genes throughout this period. Expression of *TTDA* was strongly negatively correlated (r=-0.7,P<0.0001) with gestational age, while *XPD*, *XPB* and *TTDN1* were consistently expressed throughout this period. **Conclusion** Our results indicate an important role for *XPD*, *XPB*, *TTDA* and *TTDN1* gene products during normal human placental and fetal development.

## 2823/F/Poster Board #627

**Characterization of Transformed Lymphoblastoid Cell Lines for use in Gene Expression and CNV Studies: An Alternative to Nucleic Acid from Whole Blood.** *G.A. Heiman[1], D. Fugman[1], P. Van Hummelen[2], J. Sypula[2], K. Arora[2], J.A. Tischfield[1], A.I. Brooks[1,2].* 1) Rutgers University Cell and DNA Repository, Human Genetics Institute of New Jersey, Department of Genetics, Rutgers University, Piscataway, NJ; 2) Environmental and Occupational Health Science Center, Bionomics Research and Technology Center, RWJMS-UMDNJ, Rutgers University, Piscataway, NJ.

Epstein Barr virus (EBV)-transformed lymphoblastoid cell lines (LCLs) made from blood lymphoblasts are the major renewable resource for both DNA and RNA in genetic studies. We compared LCLs, whole blood and fresh small lymphocytes for both gene expression and copy number to better understand their utility in constructing models of gene expression. Samples from 20 subjects were subjected to the following processing: A) PaxGene tube RNA isolation from whole blood, B) RNA isolation from Ficol-fractionated fresh lymphocytes, C) RNA isolation from EBV-transformed lymphocytes cultured for 30 days. In parallel, DNA was isolated from each subject for CNV analysis. Total RNA was processed in parallel for all samples and hybridized to Affymetrix U133 2.0 Plus expression arrays with labeled cDNA prepared with the NuGEN Whole Transcriptome Ovation protocol, which yields cDNA suitable for array analysis and QPCR with no directional bias from reverse transcription. Preliminary analyses of gene expression demonstrate significant differences between whole blood, fractionated fresh lymphocytes and LCLs. Cluster analysis revealed that lymphocytes from different subjects are relatively similar to each other but distinct from EBV-transformed cell lines. Differences in expression of specific genes between whole blood, fresh lymphocytes and LCLs will be reported in depth with regard to known cellular functions. It may be possible to identify and statistically “isolate” those parts of the transcriptome that are significantly affected by EBV transformation, thereby allowing a correction in LCL gene expression studies leading to the enhanced effectiveness of LCLs as models for gene expression. Our goal is to evaluate the utility of LCLs vs. fresh blood or lymphocytes for the interrogation of differences in gene function that arise through epigenomic or DNA sequence variation. Ongoing studies will generate CNV profiles of different cellular ontogenies for all subjects. LCLs from genetics research subjects are the most available surrogate tissues for gene expression and CNV profiling, but their utility revolves around specific gene expression similarity between whole blood, fresh lymphocytes, LCLs and specific tissues of interest in disease (e.g., brain or liver).

## 2824/F/Poster Board #628

**Myostatin inhibition gene expression profiling.** *F. Rahimov[1], O.D. King[3], L.C. Warsing[4], K.R. Wagner[4,5], L.M. Kunkel[1,2].* 1) Program in Genomics, Children’s Hospital Boston and Harvard Medical School, Boston, MA; 2) Howard Hughes Medical Institute; 3) Boston Biomedical Research Institute, Watertown, MA; 4) The Johns Hopkins University, School of Medicine, Baltimore, MD; 5) Kennedy Krieger Institute, Baltimore, MD.

Myostatin is a potent negative regulator of skeletal muscle mass and consequently it has widely been considered as a potential therapeutic target for neuromuscular disorders. The putative myostatin receptor is activin receptor type IIB (ActRIIB). In order to evaluate the molecular effects of a biotherapeutic that mimics the myostatin binding site of the receptor and identify potential downstream target genes of the myostatin signaling pathway, we compared gene expression patterns in two different muscle types from mice treated with a soluble ActRIIB with those deficient for the myostatin gene. We assessed global gene expression profiling in quadriceps and soleus muscles obtained from mice treated with ActRIIB.Fc over one and two weeks, from $Mstn^{-/-}$ and control mice using the Affymetrix GeneChip® 1.0 ST arrays. There was a significant overlap in up and downregulated genes in both muscle types between mice treated for two weeks with ActRIIB.Fc and $Mstn^{-/-}$ mice ($P$<0.0001). Consistent with previous reports, we observed an overrepresentation of Type IIa muscle fiber genes of the slow-twitch muscles among the downregulated genes in both the knock-out and inhibitor treated mice, although we did not detect a concomitant upregulation of Type IIb fiber genes encoding fast-twitch muscle fibers. Furthermore, we validated expression of 30 genes that showed the most significant up and downregulation on arrays with quantitative real-time PCR using TaqMan gene expression assays on Fluidigm’s BioMark microfluidic dynamic arrays. There was a strong correlation between microarray results and quantitative real-time PCR with a correlation coefficient of over 0.9. Our results demonstrate that intervening in the myostatin signaling pathway using exogenous drugs gives gene expression signatures that are comparable to those of myostatin knock-out mice.

## 2825/F/Poster Board #629

**The impact of racial differences in epidemiologic studies of gene expression.** *S. Sharma[1, 2], A. Murphy[1], B. Himes[1,3,4], J. Chu[1], M. Cho[1,2], B. Klandermann[1], J. Sylvia[1], V. Carey[1], S. Weiss[1,4], B. Raby[1,2].* 1) Dept Respiratory Epidemiology, Channing Lab, Boston, MA; 2) Division of Pulmonary and Critical Care, Brigham and Women's Hospital, Boston, MA; 3) Harvard-MIT Division of Health Sciences and Technology, Cambridge, MA; 4) Partners Center for Personalized Genetic Medicine, Boston, MA.

Although population differences in gene expression have been established, the impact of these differences on epidemiologic studies of gene expression is not well understood. We describe the effect of race on a gene expression study of impaired lung function in asthma. We generated Illumina HumanRef8(v2)gene expression profiles for 254 young adults(205 non-Hispanic whites; 49 African American)with mild- to moderate persistent asthma participating in the Childhood Asthma Management Program (CAMP) on whom concurrent total RNA derived from peripheral blood CD4+ lymphocytes and spirometry was obtained. After quantile normalization and log2 transformation of the raw expression data was performed, 18,373 autosomal probes were analyzed for association with lung function measures. Principal component analysis (PCA) as implemented in the *pcaMethods* package in Bioconductor was performed on all subjects to identify smaller clusters of genes that accounted for overall differences in gene expression. PCA identified three principal components that explained 57% of variance in gene expression. Using regularized t-tests with multiple comparison adjustments as implemented in the Bioconductor *siggenes* package, we identified 9,460 genes that were differentially expressed between self-identified non-Hispanic whites and African Americans. The effect of race was highly correlated with the first PCA principal component, which explains approximately 30% of the variance in gene expression across subjects. The impact of these racial differences in gene expression was also observed when attempting to model the relationship between gene expression and lung function. Using linear models with and without adjustment for race, we tested whether gene expression was associated with post-bronchodilator FEV1 percent predicted, a spirometric value that incorporates an adjustment for race. Although unadjusted linear models of post-bronchodilator FEV1 percent predicted identified genes that were correlated with lung function, after adjusting for race this correlation was no longer statistically significant, indicating confounding of gene expression by race. These results suggest that race is a critical covariate in epidemiologic studies of gene expression and that as in genetic studies, consideration of race in gene expression profiling studies is needed to avoid spurious association. Funding: NIH K12 HL089990 and R01 HL086601.

## 2826/F/Poster Board #630

**Global analysis of adipose tissue gene expression in response to insulin among insulin-resistant and insulin-sensitive women.** *J.M. Soronen[1,2], P-P. Laurila[1,2], J. Naukkarinen[1,2], J. Westerbacka[3], M. Jauhiainen[2], V. Olkkonen[2], H. Yki-Järvinen[3], L. Peltonen[1,2,4,5].* 1) Institution for Molecular Medicine Finland (FIMM), Helsinki, Finland; 2) National Institute for Health and Welfare/ Public Health Genomic Unit, Helsinki, Finland; 3) Department od Medicine, Division of Diabetes, Helsinki, Finland; 4) The Broad Institut, Massachusetts Institute of Technology, Cambridge, Massachusetts, USA; 5) Wellcome Trust Sanger Institute Wellcome Trust Genome Campus, Hinxton, Cambridge, UK.

The development of insulin resistance is tightly connected to the metabolic status of adipose tissue and its endocrine functions. To gain a better understanding of the transcriptional changes in fat that develop along with increasing insulin resistance, we compared transcriptional profiles of 5 insulin-resistant and 5 insulin-sensitive women before and after a hyperinsulinemic euglycemic clamp. Subcutaneous adipose tissue biopsies were obtained after overnight fasting and after 3 hours of intravenously maintained euglycaemic hyperinsulinaemia and they were analyzed for transcript profiles using Affymetrix HG U133 Plus 2 microarrays. Data analysis and pathway analysis were performed with GeneSpring 10 and by using an in-house developed nonparametric pathway analysis. We observed extensive up-regulation of inflammatory pathways in the insulin-resistant subjects including antigen processing (GO:0002504), complement activation (GO:0050778) and chemotaxis (GO:0006935). The most prominent difference in gene expression during the hyperinsulinemic euglycemic clamp between insulin-resistant and insulin-sensitive group was observed in lipid biosynthesis pathways associated with steroid, sterol and cholesterol biosynthesis (GO: 0016126, GO:0006694, GO:0006695) as well as in several mitochondrial pathways. This study demonstrates that insulin resistance alters markedly the insulin reactivity of several lipid biosynthesis pathways and pathways associated with mitochondrial function in human adipose tissue.

## 2827/F/Poster Board #631

**Genome-wide microRNA profiles in peripheral blood as potential biomarkers for schizophrenia.** *C.Y. Lai[1,6], H.Y. Chen[2,6], Y.H. Huang[1], S.L. Yu[3,6], P.C. Hsiao[6], C.C. Wen[4], C.K Hsiao[1], C.M. Liu[4], P.C. Yang[5,6], H.G. Hwu[1,4], W.J. Chen[1,4,6].* 1) Department of Public Health, Institute of Epidemiology, National Taiwan University, Taipei, Taiwan; 2) Institute of Statistical Science, Academia Sinica, Taipei, Taiwan; 3) Department of Clinical Laboratory Sciences and Medical Biotechnology, College of Medicine, National Taiwan University, Taipei, Taiwan; 4) Department of Psychiatry, College of Medicine and National Taiwan University Hospital, National Taiwan University, Taipei, Taiwan; 5) Department of Internal Medicine, College of Medicine and National Taiwan University Hospital, National Taiwan University, Taipei, Taiwan; 6) Division of Genomic Medicine Research Center for Medical Excellence Taipei, Taiwan.

Several recent studies have demonstrated the potential utility of the blood-based gene expression profiling as a diagnostic tool for schizophrenia, though these studies were limited to the expression of protein-coding genes. The expressions of non-coding genes such as microRNAs (miRNAs) are now considered to play a significant role for the regulation of gene expression by means of inhibiting the translation of messenger RNAs (mRNAs), indicating that the miRNAs profiling in the peripheral blood might be potential biomarkers for schizophrenia. This study aimed to identify blood-based miRNA signature and evaluate its potential as biomarkers for schizophrenia. This study enrolled 60 schizophrenia patients at National Taiwan University Hospital and 60 age- and gender-matched normal controls, and the paired sample was randomly separated into the learning sample and the validation sample. In the learning sample (n = 30 pairs), the expression levels of genome-wide 368 human miRNAs from peripheral blood were measured using ABI PRISM 7900 Real Time PCR system. Supervised classification with internal cross-validation method was used to identify miRNAs that might be useful as biomarkers for schizophrenia. Possible biological mechanisms implicated in the target genes involved by the miRNAs were explored using bioinformatics methods. We identified a blood-based nine-miRNA signature (miR-34a, miR-449, miR-564, miR-548d, miR-652, miR-659, miR-185, miR-4095p, and miR-501) that could discriminate schizophrenia patients from normal controls with an accuracy ranging from 78.5% to 90%. Bioinformatic analyses using the software Ingenuity Pathway Analysis indicated that the top networks associated with dysregulation of these miRNAs were those involved in neurological diseases, lipid metabolism, and respiratory system development and function. These nine candidate miRNAs are being evaluated in the validation sample (n = 30 pairs) using real-time RT-PCR. These results, although preliminary, indicate that genome-wide miRNA profiling is a feasible way for the identification of biomarkers for schizophrenia and the nine-miRNA signature identified in this study warrants further investigation.

**From miRNomics to pathway analysis in Parkinson's Disease (PD).** *S.A. Oliveira[1,2], M. Martins[1,2], A. Rosa[3,2], B.V. Fonseca[1,2], S. Violante[2], L.C. Guedes[1], T. Mestre[1], M. Coelho[1], M.M. Rosa[1], J.M. Vance[4], J.J. Ferreira[1].* 1) Unidade Neurológica de Investigação Clínica, Instituto de Medicina Molecular, Lisboa, Portugal; 2) Instituto Gulbenkian de Ciência, Oeiras, Portugal; 3) Departamento de Ciências da Saúde, Universidade da Madeira, Portugal; 4) Miami Institute for Human Genomics, University of Miami, USA.

PD is the second most prevalent neurodegenerative disorder after Alzheimer disease. The main pathological hallmark of PD is the loss of dopaminergic neurons within the substantia nigra, leading to insufficient formation and action of dopamine in the basal ganglia circuitry. The cardinal clinical signs are muscle rigidity, resting tremor, bradykinesia and, in more advanced cases, postural instability. Although much has been learned in recent years about the genetic aetiology of Mendelian-inherited PD, far less is known about the molecular mechanisms underlying the vast majority of cases. MicroRNAs (miRNAs) are short, endogenous non-protein coding RNAs that post-transcriptionaly modulate gene expression by base-pairing to target mRNAs. miRNAs are abundant in the brain, are essential for efficient brain function, and increasing evidence implicates miRNA dysfunction in PD pathogenesis. To further investigate the role of miRNAs in PD etiology, we conducted miRNA expression profiling in peripheral blood mononuclear cells (PBMCs) of 19 PD patients and 13 controls, using Exiqon microarrays spotted with probes for 733 human miRNAs. Out of the 275 miRNAs expressed in PBMCs, 24 miRNAs were differentially expressed. All of these miRNAs are under-expressed in patients relative to controls. The chip results were validated by quantitative RT-PCR for selected miRNAs. 745 genes are predicted by at least six programs using different algorithms in miRecords to be target genes of the differentially expressed miRNAs, and pathway analysis using Ingenuity revealed that the top canonical pathways in which these genes are involved are novel pathways including hypoxia signaling in the cardiovascular system and retinoic acid receptor activation, and the previously implicated protein ubiquitination pathway. These findings are currently being further explored.

**Discovering biomarkers in dystrophinopathies.** *A. Ferlini, M. Bovolenta, P. Rimessi, C. Scotton, S. Brioschi, L. Merlini, F. Gualandi.* Dept Med Gen, Univ Ferrara, Ferrara, FE, Italy.

The DMD gene is the largest in the human genome, it spans 2.4 Mb and is made of 79 exons and 7 isoforms, all finely regulated and expressed in specific tissues. Mutations in this gene lead to three distinct phenotypes depending on the genomic variation: Duchenne Muscular Dystrophy (DMD), Becker Muscular Dystrophy and X-linked dilated cardiomyopathy. Therapeutic approaches are now becoming reality in DMD, nevertheless, clinical outcome measures may not always be sensitive enough to detect small changes in disease progression/regression and after short treatment periods. It is therefore imperative to identify enrichment endpoints, as biomarkers, able to document benefits of the treatment at the individual level. Recently, genome-wide approaches to monitor transcription have revealed a notable number of non coding RNAs (ncRNAs) with many regulatory functions. We designed a new gene-specific Gene Expression tiling array focused on the DMD gene and used it to detect non-coding transcripts in brain, heart, skeletal muscle and skin normal human tissues. We identified 35 sense transcripts from total RNA and 15 sense and 2 antisense transcripts from polyA+ RNA preferentially associated with heart and muscle tissues. The 35 transcribed units, clustered preferentially within the introns surrounding the isoforms first exons and ranging in size from 120 to 1205 nucleotides, were identified in the DMD gene introns and in its same sense of transcription after total RNA hybridization using the 90th percentile analysis. By aligning the transcribed units (TUs) with all the ESTs in UCSC Genome Browser we found that about 35% correspond to previously annotated ESTs; the remaining are transcribed sequences never identified before. We validated through Northern blotting and Real-time PCR all 15 polyA+ sense transcripts and fully characterised by RACE 3 polyA+ transcripts close to 7 isoforms' promoter regions. We are monitoring the transcription behaviour of the polyA+ transcripts in DMD patients myogenic cells before and after treatment with antisense oligoribonucleotides in order to identify if any of these ncRNAs may change its profile as well its effect on the cell phenotype (in terms of dystrophin isoforms representation). The aim is to evaluate if these ncRNAs might be employed as biomarkers of dystrophinopathic phenotype progression or regression.

**Non-coding RNA: Using TaqMan® Assays to Quantitate the Expression Level of Long Non-coding RNAs.** *K. Lee, Y. Wang, B. Kong, P. Brzoska, F. Hu, C. Chen, M. Augustine.* Applied Biosystems, Foster City, CA. 94404.

It has been shown that the vast majority of the eukaryotic genome is transcribed and that a large proportion of the transcriptome includes non-protein coding RNAs (ncRNA). These noncoding transcripts are derived from intronic, intergenic and overlapping coding gene sequences that are arranged in complex networks where expression may come from the sense or antisense strand. The study of these sequences has emerged as an important area of investigation and recent studies have shown that ncRNAs play a role in chromatin modification, transcription and post transcriptional gene regulation. Deep sequencing has identified tens of thousands of short ncRNAs as well as long ncRNAs (>200 nts). In addition microarrays and genomic tiling arrays have been used to identify and study the expression pattern of long ncRNAs. For accurate and reproducible quantitation, we have developed human, mouse, and rat TaqMan® Assays that target specific long ncRNA sequences. Using Applied Biosystems genomic assay design pipeline and an enhanced set of selection criteria, we have designed TaqMan® Assays to the majority of the annotated noncoding RNA sequences listed in NCBI (RefSeq, NR_) as well as from the literature curated noncoding RNA database, RNAdb (http://research.imb.uq.edu.au/rnadb/) which contains a large collection of biologically relevant ncRNAs. The performance of the TaqMan® Assays was evaluated using assays designed to target >150 known ncRNAs. For high expressing transcripts, linearity across 4 logs was >0.96. In addition we found that there was no significant detection of gDNA for assays designed to cross known exon-exon junctions, indicating that these multi-exon assays are transcript specific.

## 2831/F/Poster Board #699

**Expression pattern of ABC transporter pseudogenes in 44 human tissues.** *A.P. Piehler, R.M. Grimholt, J.P. Berg.* Clinical chemistry, Oslo University Hospital, Ulleval, Oslo, Norway.

Background: Recently, our group has identified all ABC transporter pseudogenes in the human genome. We found that 45% of these pseudogenes are transcribed and accumulated evidence that a regulatory interdependency exists between a transcribed pseudogene (ABCC6P1) and its parental, protein coding gene (ABCC6). In this study, we sought to assess the expression pattern of other transcribed ABC transporter pseudogenes in a broad variety of human tissues. Methods: RNA pools (at least 3 donors) from 44 different healthy human tissues were reverse transcribed. Expression stability of twelve potential reference genes in these tissues and the sufficient number of reference genes for normalization were assessed by RT-qPCR and the program geNorm. Based on the five most stable reference genes, RNA levels of five transcribed ABC transporter pseudogenes and their parental, protein coding genes were determined. Results: Except for the pseudogene homologous to the rodent ABC transporter ABCA15, which is predominantly expressed in testis and blood vessels, all transcribed pseudogenes are expressed in a wide variety of healthy human tissues. The pseudogene ABCC6P1 shows a similar expression pattern like its parental gene ABCC6 with highest expression in kidney and adult and fetal liver. The other transcribed pseudogenes do not follow the expression pattern of their parental genes. For the pseudogene ABCA11P, highest RNA levels can be found in whole adult and fetal brain and in artery blood vessels, whereas the parental gene, ABCA10, is mainly expressed in ovary, heart and bladder tissue. The surfactant deficiency causing gene, ABCA3, exhibits highest mRNA levels in lung and adult and fetal brain, whereas its pseudogene, ABCA17P, is predominantly expressed in the salivary gland, fetal brain and testis. The gene encoding the multidrug resistance protein 2 (MRP2, ABCC2) is mainly expressed in the kidney and the adult and fetal liver. Its homologous pseudogene ABCC13 shows highest RNA levels in peripheral blood leukocytes, bone marrow and fetal liver. Conclusions: Transcription of pseudogenes in the human ABC transporter superfamily is a common phenomenon. Together with the expression of pseudogenes into several alternatively spliced variants and the evidence of gene-pseudogene interference, differential expression of ABC transporter pseudogenes in a broad variety of human tissues suggests distinct physiological functions of these genes.

## 2832/F/Poster Board #700

**Association of ALOX5 gene polymorphisms with asthma and functional validation.** *S. Park[1], H. Chang[1], H. Song[1], J. Park[2], A. Jang[2], Y. Lee[3], S. Uh[3], M. Kim[4], I. Choi[5], S. Cho[6], C. Hong[6], Y. Lee[6], J. Lee[7], B. Park[8], H. Cheong[8], H. Shin[8,9], C. Park[1,2].* 1) Genome Research Center, Soonchunhyang Univ. Hosp., Bucheon, Korea; 2) Division of Allergy and Respiratory Medicine, Department of Internal Medicine, Soonchunhyang University Hosp., Bucheon; 3) Division of Allergy and Respiratory Medicine, Department of Internal Medicine, Soonchunhyang University Hosp.,Seoul; 4) Department of Internal Medicine, Chungbuk National University; 5) Department of Allergy, Chonnam National University Medical School and Research Institute of Medical Sciences; 6) Department of Internal Medicine and Institute of Allergy, Yonsei Univ; 7) Department of Interanal Medicine, College of Medicine, Hallym Univ; 8) Department of Genetic Epidemiology, SNP Genetics, Inc; 9) Department of Life Sciences, Sogang Univ.

Background: CysLTs exert important roles in airway inflammation of asthma. ALOX5 is the first committed enzyme in the biosynthetic pathway leading to the production of the LTs. Methods: We genotyped five SNPs of ALOX5 gene in a Korean asthma cohort (n=1189) and association analysis was done using logistic regression analysis. Promoter activity was measured by luciferase reporter assays. mRNA levels of B cell lines were measured by real-time PCR. Urinary concentrations of lipoxin A4 (LXA4) and LTE4 were measured by EIA. Results: The ratio of major allele homozygote of -754C>G on promoter region and +21757G>A on intron 3 were higher in asthmatics than those in normal subjects (dominant model, -754CC; 89.7 vs 83.1%, +21757GG; 39.4 vs 29.3%, p = 0.001 - 0.041). The quantitative mRNA expression levels and promoter activity were significantly higher in B cell lines having G allele on -754 than that possessing C allele (p=0.007, 0.003). RT-PCR demonstrated an alternatively-spliced variant of ALOX5. This variant lacked an exon 3 of the previously-reported full length sequence, resulting that produces a pre-mature stop codon. A variant form lack the lipoxygenase domain. The ratio of quantitative mRNA levels for alternatively spliced variant to wild form were significantly lower in B cell lines having G allele on +21757 than that possessing A allele. The basal urinary concentration of LTE4 and LXA4 was significantly higher in asthmatic patients with the -754 C allele than those who were homozygous for the G allele (p=0.031). The +21757 G>A was not associated with the basal urinary concentration of LTE4 and LXA4. Conclusion: The ALOX5 gene polymorphisms may be associated with the development of asthma via modulation of the ALOX5-gene expression and/or alternative splicing.

## 2833/F/Poster Board #701

**Extensive cell type specificity of common regulatory variation.** *A.S. Dimas[1], S. Deutsch[2], B.E. Stranger[3], S.B. Montgomery[1], C. Borel[2], H. Attar-Cohen[2], C. Ingle[1], C. Beazley[1], M. Gutierrez-Arcelus[1], M. Sekowska[1], M. Gagnebin[2], J. Nisbett[1], P. Deloukas[1], E.T. Dermitzakis[1,2], S.E. Antonarakis[2].* 1) Wellcome Trust Sanger Institute, Hinxton, United Kingdom; 2) Department of Genetic Medicine and Development, University of Geneva Medical School, Geneva, Switzerland; 3) Division of Genetics, Department of Medicine, Harvard Medical School and Brigham and Women's Hospital, Boston, MA.

Studies correlating genetic variation to gene expression provide information for the interpretation of common human phenotypes and disease. To date most studies have examined the genetic basis of gene expression variation either in large collections of EBV-transformed B-cells (lymphoblastoid cell lines or LCLs) or in single cell types. However, the cell type-dependence of genetic variants associated with gene expression (eQTLs) still remains largely unexplored. To address this we performed gene expression profiling and association with genetic variants (SNPs) on three cell types (LCLs, primary fibroblasts and T-cells) for 75 individuals. eQTLs in LCLs are well-replicated between previous studies and the present analysis, with over 80% of identical SNP-probe pairs passing stringent significance thresholds. This highlights the value of large collections of LCLs from different cohorts for studies of gene expression. We detected extensive cell type-specific genetic effects with only 10% of gene associations shared in all three tissues and 69 - 80% of regulatory variants operating in a cell type-specific manner. After controlling for the correlation structure between SNPs in the genome, we found that at least 7% of genes had more than one independent eQTL and the abundance of these eQTLs was positively correlated with the number of transcripts per gene. Cell type-specific eQTLs were found at larger distances from genes and had lower effect size similar to known enhancers. Furthermore, a number of eQTLs were found to overlap with well-documented variants from genome-wide association studies including SNPs associated with Crohn's disease, bipolar disorder, triglycerides, HDL cholesterol, BMI and height, thus suggesting a regulatory role for these variants. Overall, our study suggests that the complete regulatory and functional repertoire of variants can only be uncovered in the context of tissue and cell type specificity.

**Enhancing the Power of eQTL Mapping: A Catalog of 6,000 cis eQTLs in Lymphocytes.** *L. Liang[1], A.L. Dixon[2,3], M.F. Moffatt[2], W. Chen[1], S. Heath[4], G.M. Lathrop[4], W.O.C. Cookson[2], G.R. Abecasis[1].* 1) Center for Statistical Genetics, Dept. of Biostatistics, SPH II, Ann Arbor, MI 48109, USA; 2) National Heart and Lung Institute, Imperial College London, SW3 6LY, England; 3) Wellcome Trust Centre for Human Genetics, University of Oxford, OX3 7BN, England; 4) Centre National de Genotypage, 91057 Evry Cedex, France.

Genome-wide expression quantitative loci (eQTL) mapping has been widely used in recent years to provide biological insights about the regulation of gene expression, to further understanding of the differences in gene expression profiles and regulation among populations and tissues, and to aid in the interpretation of disease associated loci from many genome-wide association studies. Appropriately powered analyses of mRNA transcript levels have the power to detect hundreds of genome-wide significant cis association signals, but in previous reports only ~14% transcripts with high heritability have been mapped with genome-wide significance. Here, we reanalyze previously published eQTL datasets with newly available statistical methods and show that the number of eQTLs mapped in cis increases from 2,175 to 6,162 when (a) better statistical models are used to describe shared correlation between different gene expression measurements and (b) data from the 1000 Genomes Project is used to drive genotype imputation and augment the list of genotyped SNPs. Specifically, we show that principal component analysis (PCA) can be used to capture non-genetic contributions to many different gene expression levels and that the resulting information can be used to adjusted observed expression values generating a phenotype that is more mappable (because it results in a greater number of cis eQTL that reach genomewide significance, without increasing background false positive rates). Similarly, we show that genotype imputation using the 1000 Genomes haplotypes as templates can increase the number of markers available for testing to >8 million and increases the number of cis eQTL, even after adjusting statistical significance thresholds to account for the greater number of markers tested.

## 2835/F/Poster Board #703

**Measurement of Allelic Expression in postmortem brain samples using Illumina Goldengate assay.** *K.K. Mantripragada, L.C. Carroll, M.C. O'Donovan, M.J. Owen, N.M. Williams.* Psychological Medicine, Cardiff University, Cardiff, United Kingdom.

Differential allelic expression has been implicated in many human diseases including complex disorders. The importance of cis-acting regulatory polmorphisms on gene expression has been well documented. However, currently there are no high throughput methods that allow assessment of differential allelic expression under cis-acting influences. We utilised Illumina's Goldengate methodology and the Cancer SNP panel for validating the allelic expression in 14 postmortem brain samples obtained from the Stanley foundation. We also spiked in varying proportions of Human and Chimpanzee DNA samples in order to validate the performance of Goldengate protocol in differential copy number measurement. Preliminary results demonstrate that the approach can detect quantitative differences in allelic expression and further work is required to optimise the protocol for robust performance.

## 2836/F/Poster Board #704

**Causal regulatory variants for complex trait associations.** *A.C. NICA[1,2], S.B. MONTGOMERY[1,2], B.E. STRANGER[1,3], A.S. DIMAS[1,2], C. BEAZLEY[1], I. BARROSO[1], E.T. DERMITZAKIS[1,2].* 1) Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, Cambridge CB10 1HH, UK; 2) Department of Genetic Medicine and Development, University of Geneva Medical School, Geneva, Switzerland; 3) Harvard Medical School/Brigham and Women's Hospital, Boston MA, USA.

The recent success of genome-wide association studies (GWAS) is now followed by the challenge to determine how the reported susceptibility variants mediate the manifestation of complex traits and diseases. Expression quantitative trait loci (eQTLs) have been implicated in disease associations through overlaps between eQTLs and GWAS signals. However, the high abundance of eQTLs and the strong correlation structure of variants in the genome make it likely that some of these overlaps are coincidental and not driven by the same functional variants. In order to distinguish accidental colocalizations from causal regulatory variants, we propose an empirical methodology that directly combines eQTL and GWAS data while accounting for the correlation structure (linkage disequilibrium - LD) of the region harbouring the GWAS SNP. By assessing the impact on the expression phenotype of the removal of the GWAS SNP effect, we discover causal regulatory variants and their affected candidate genes in *cis* and *trans*. To test this, we use gene expression measured in lymphoblastoid cell lines derived from 109 Phase 3 HapMap CEU individuals and focus on the subset of 976 GWAS single nucleotide polymorphisms (SNPs) catalogued by NHGRI and genotyped in the HapMap 3 CEU samples. We observe a significant abundance of regulatory signals for the analyzed GWAS loci, prominently in *cis*. We further dissect this signal and detect potential disease causing regulatory effects for a number of traits, with a strong enrichment for immunity-related conditions, consistent with the nature of the cell lines tested. Furthermore, we present an extension of the method in *trans*, where the primary biological effect of the disease variant is not necessarily *cis*-regulatory. As such, we discover multiple genes throughout the genome with equally convincing evidence for disease relevance and we indicate that these are likely to act downstream of the causal variant. Finally, we also show that the correlation strength ($R^2$) between the GWAS SNP and the eQTL is not, as generally assumed, a sufficient predictor of regulatory mediated disease effects.

## 2837/F/Poster Board #705

**Direct RNA Sequencing.** *P. Milos, A. Platt, D. Jones, J. Reifenberger, P. McInerney, J. Thompson, J. Bowers, M. Jarosz, F. Ozsolak.* Helicos BioSciences Corp, Cambridge, MA.

Methods for in-depth characterization of transcriptomes and quantification of transcript levels have emerged as valuable tools for understanding cellular physiology and human disease biology. Current methods, however, typically require RNA to be converted to complementary DNA (cDNA) prior to measurements and sequencing. cDNA synthesis has been shown to introduce biases and artifacts. We have developed a single molecule RNA sequencing technology, in which RNA is sequenced directly without prior conversion to cDNA. As a proof-of-concept experiment, we applied this technology to sequence attomole quantities of poly-A+ Saccharomyces cerevisiae RNA and human small RNAs utilizing a surface coated with poly(dT) oligonucleotides to capture the RNA and serve as primers for sequencing by synthesis. We observed 3' end RNA heterogeneity and poly-adenylated short RNA species. This novel technology paves the way towards high-throughput and low-cost direct RNA sequencing, with the ultimate goal of understanding transcriptomes in a comprehensive and bias-free manner.

## 2838/F/Poster Board #706

**Integrating large-scale genetic and monocyte expression data reveals major *trans* regulators of biological processes.** *M. Rotival[1,2], T. Zeller[3], P. Wild[3], S. Szymczak[4], A. Schillert[4], T. Munzel[3], F. Cambien[1,2], A. Ziegler[4], L. Tiret[1,2], S. Blankenberg[3].* 1) INSERM UMRS 937, Paris, France; 2) Université Pierre et Marie Curie, Paris, France; 3) II. Medizinische Klinik und Poliklinik, Johannes-Gutenberg Universität Mainz, Mainz, Germany; 4) Institut für Medizinische Biometrie und Statistik, Universität zu Lübeck, Lübeck, Germany.

The simultaneous assessment of gene expression and genetic variation on a genome-wide basis provides a powerful tool for unravelling the mechanisms by which genes might contribute to disease. While *cis* expression SNPs (eSNPs) have ubiquitous effects that can be easily mapped with high-throughput technologies, identification of *trans* eSNPs is more challenging because they are more context- and tissue-dependent and prone to spurious findings. Yet, *trans* eSNPs are of considerable interest because they constitute the ground of systems genetics by their capacity to control transcriptional modules, ie sets of highly co-regulated genes. Since *trans* eSNPs are expected to have pleiotropic effects on a large number of genes, each being modestly affected, mapping these SNPs may be facilitated by prior recognition of subsets of co-regulated genes. In a large population-based cohort (n=1,490), we have analyzed 12,808 well characterized genes expressed in circulating monocytes - a key player in the development of atherosclerosis and the immune response - in relation to genome-wide variability (675,350 SNPs). We applied first a method of extraction of expression patterns - Independent Component Analysis - allowing us to identify 91 transcriptional modules of co-regulated genes, several of them being significantly enriched in functional pathways. These patterns were then related to SNPs. At a study-wise significance threshold of $8.14 \times 10^{-10}$, we found 8 blocks of SNPs associated with expression patterns. One block mapped to the *ERBB3* gene previously identified as a susceptibility gene for type 1 diabetes (T1D). As the associated pattern did not contain *ERBB3*, an effect via *ERBB3* expression could be excluded. The associated pattern suggested *MADCAM1*, an endothelial adhesion cell molecule, as the most plausible mediator linking *ERBB3* to T1D. Another block mapped to the *ARHGEF3* gene which is involved in RhoGTPase activation. The associated pattern was strongly enriched in genes involved in cell adhesion and platelet activation, including several integrins. *ARHGEF3* is known to undergo alternative splicing and one explanation for the association might be that the splicing leads to a less efficient interaction of *ARHGEF3* with RhoGTPases, with subsequent repercussions on the activation of the Rho signaling pathway. This study demonstrates how coupling genome-wide expression and genetic variability in large cohorts may help to identify major *trans* regulators.

## 2839/F/Poster Board #707

**Genome-wide prediction and expression analysis of common SNPs affecting mRNA splicing.** *P.K Rogan[1,2], T. Whitehead[3], E.J. Mucaki[1].* 1) Biochemistry; 2) Computer Science; 3) SHARCNET, University of Western Ontario, London, ON, Canada.

Non-coding, incompletely penetrant mutations can be difficult to detect, but are of significant interest due to their likely contributions to complex genetic disorders. Genome-wide prediction of common SNPs with subtle effects on mRNA splicing was undertaken followed by targeted assessment of differences in gene expression between the major and minor alleles. Software was developed in the Haskell language to compute information changes of constitutive splice sites ($\Delta R_i$, in bits) for all validated SNPs across the genome. Genome-wide, 963 natural donor and 2134 natural acceptor sites exhibited significant alterations (≥1 bit or ≥2 fold) in strength. ($\Delta R_i$ values were compared with allele-specific differences in expression based on exon microarray data from Phase II HapMap individuals (GEO Accession GSE7851). Splicing indices for each exon (the ratio of the exon to core probeset intensities; SI) were determined for each SNP genotype. 9997 SNPs were predicted to alter splice site strength of natural or cryptic splice sites within the sequences defining splice site intervals (-26 to +2 and -3 to +7). Of 987 SNPs which are associated with significant changes in SI values, 573 SNPs have minor alleles with reduced $R_i$ values and SI's < 1. Natural acceptor splice sites were weakened or abolished for ~20% (n=2008) of minor SNP alleles; most were associated with exons with significant allele-specific differences in SI (83%). Minor alleles weakened or abolished donor sites in ~5% (n=453) of SNPs, and most were associated with allele-specific differences in SI (75%). Many minor alleles were predicted to activate cryptic acceptor (838 of 2065) or donor (161 of 405) sites and 40% had altered SI values. The exon boundaries of published expressed sequence tags corroborated predictions of strengthened SNP-induced cryptic splice forms for 60 different acceptor sites and 43 different donor sites. SNPs predicted to result in leaky splicing mutations are much less likely to result in exon skipping. This class of mutations ($\Delta R_i < 4$ bits for donors and <7 bits for acceptors, $R_i \geq R_{i,minimum}$) comprise 40-60% of the total and also exhibits reduced SI values. At least 16 of these SNPs are found in 15 genes (*LILRA2*, *EGF*, *FGF1*, *IGFBP3*, *COL2A1*, *DOCK9*, *CALCA*, *MAD2L2*, *CSMD1*, *TRPV1*, *GNAL*, *PDE11A*, *LAMA2*, *CRYZ*, and *ABCA1*) previously documented in genome-wide association studies. Several of these are in LD with SNPs known to exhibit significant associations.

## 2840/F/Poster Board #708

**Gene expression profile of human multipotent mesenchymal stromal cells derived from bone marrow during osteoblast differentiation.** *C. Kaneto[1], P. Lima[2], W. Silva-Jr.[1].* 1) Dept Genetics, Faculdade de Medicina de Ribeirão Preto, Sao Paulo, Brazil; 2) Natural Science Dept, Universidade Estadual do Sudoeste da Bahia, Vitória da Conquista, BA, Brasil.

Mesenchymal stem cells (MSCs) are multipotent precursors present in adult bone marrow that differentiate into osteoblasts, adipocytes and myoblasts. However, their low frequency in bone marrow requires ex vivo expansion for clinical application. We examined gene expression of these cells by serial analysis of gene expression during differentiation into osteoblasts. SAGE analysis of MSC during osteogenic differentiation identified three candidate genes for further examination and functional analysis: CRYAB, TNFRSF11B and ID3. These genes showed differential expression in the early phases of osteoblastic differentiation, providing evidence that they exhibit specific roles during this process. Additionally, we were able to identify cancer-related pathways represented in our data, suggesting that mesenchymal stem cell and cancer can share some particularities. This study reports the profile of gene expression in MSCs during differentiation and identifies the important contribution of extracellular protein products, adhesion molecules and growth factor molecules as part of their transcriptome. Finally, we were able to illustrate the different phases of osteogenic development in a human model and could associate gene clusters to four distinct phases of the development of osteoblast phenotype.

## 2841/F/Poster Board #709

**Genetic genomics of Parkinson Disease: an association-based method for detecting modules of co-expressing genes in disease.** *E. Kenny[1,2], R. Melchiotti[2], O. Litvin[3], M. Kedmi[4], A. Bar-Shira[4], N. Giladi[5,6], D. Pe'er[3], I. Pe'er[2], A. Orr-Urtreger[4,6].* 1) Rockefeller Univ, New York, NY; 2) Department of Computer Science, Columbia University, New York, USA; 3) Department of Biological Sciences, Columbia University, New York, USA; 4) Genetic Institute Unit, Parkinson Center, Department of Neurology, Tel-Aviv Sourasky Medical Center, Israel; 5) Movement Disorders Unit, Parkinson Center, Department of Neurology, Tel-Aviv Sourasky Medical Center, Israel; 6) Sackler Faculty of Medicine, Tel-Aviv University, Israel.

Gene expression phenotypes have proven uniquely useful for association mapping. Not only are genetic effects stronger and more isolated at the molecular level, but also the inherent modularity in expression space and the functional interpretation of such associations is more informative. We consider modules in transcription profiles as the link between genotypes and disease. We have adapted a framework, originally presented in yeast genomics, to search for association between SNPs and transcription modules. We apply our method to a unique dataset including genomewide SNP and transcription data in Parkinson disease patients and matched controls from an Ashkenazi population. This data is enriched for carriers of disease mutations, providing a useful genetic handle on disease mechanisms. The scale of this problem, involving association mapping of a million SNPs by 20,000 transcripts poses a challenge for traditional methods. Furthermore, mapping is complicated by the multiple correlations due to linkage disequilibrium in the SNP data on the one hand and co-expression on the other. We thus implement a rapid and extensive permutation system to select statistically significant associations in a computationally feasible manner - 30,000 hours or 12.5 days on a 100 CPU core (3.0Ghz) cluster. Our methodology exposes 2,142 SNPs that map to modules of 5 or more co-expressed transcripts, where the nominal p-value for each transcript in the module exceeds the permutation threshold. The modules range in size from 5 to over 1,000 co-expressed transcripts and are enriched for functional annotations. Motivated by these initial findings, we next seek to assess whether any of these associated modules influence Parkinson disease. Current work seeks to implement a likelihood based scoring function for disease status given both genotype and expression data.

## 2842/F/Poster Board #710

**Investigation of gene expression levels and XCI patterns in female carries of *MECP2* microduplications.** *K. Ravn[1], RS. Møller[2], B. Bertelsen[1], W. Reardon[3], Z. Tümer[1], LB. Møller[1].* 1) Kennedy Center, Glostrup, Denmark; 2) Danish Epilepsy Centre, Dianalund, Denmark; 3) Our Lady's Hospital for Sick Children, Crumlin, Dublin 12, Ireland.

Microduplications at Xq28, which include the dosage-sensitive methyl-CPG binding protein gene (*MECP2*), cause severe X-linked mental retardation in males. Other phenotypic characteristics are absent or limited speech, progressive neurological problems (such as spasticity and seizures), axial and facial hypotonia, mild and non-specific facial dysmorphism, and severe recurrent respiratory infections. The typical size of these microduplications varies between 0.2 to 2 Mb. The male patients often inherit the duplication from their phenotypically normal mothers. X chromosome inactivation (XCI) studies using peripheral blood lymphocytes from the phenotypically normal female carriers show a complete skewing of one of the X chromosomes, probably favouring the normal X chromosome. Here we report two families with overlapping Xq28 duplications, involving *MECP2*. In both families the duplications segregate for three generations involving three affected males and five female carriers. One of the female carriers displays neurological symptoms. In this study we investigated the gene expression levels of *MECP2*, *IRAK1* and *L1CAM*, which all are located within the duplicated regions, in cultured fibroblasts of the involved affected males and female carriers. Furthermore we determined the local inactivation pattern of the female carriers using several differentially methylated polymorphic loci scattered on the long arm of the X chromosome. This study may give clues to the phenotype-genotype correlation of the duplications observed in this region.

## 2843/F/Poster Board #711

**Establishment of a whole transcriptome data analysis workflow and cognate modules for quality control and quantitation using the SOLiD 3 system.** *J.J. Schageman[1], J. Brockman[1], C. Mueller[1], D. Ilsley[1], P. Whitley[1], A. Lemire[1], K. Bramlett[1], S. Heater[1], J. Gu[1], S. Kuersten[1], C. Barbacioru[2], A. Siddiqui[2], B. Tuch[2], M. Muller[2], R. Setterquist[1].* 1) Research and Development, Life Technologies Corp., Austin, TX; 2) Life Technologies Corp., Foster City, CA.

Ultra high-throughput sequencing of RNA (RNA-Seq) has shown great promise for the measurement of transcriptional activity at a single nucleotide resolution. The tradeoff for such a powerful technology is management of the voluminous resultant data and what analysis workflows are appropriate for answering specific biological questions. We will present an analysis workflow for assessing quantitation and characterization of millions of RNA sequence reads generated by the SOLiD 3 system. We have established logical bioinformatics workflow consisting of a combination of read mapping to a reference genome after specific filtering of overrepresented RNA species combined with several summarization modules. Included are modules that effectively report QC information in the form of reproducibility measures, filter mapping statistics as well as quantitation and per base coverage of well known spike in controls and housekeeping genes. Downstream modules report a per nucleotide transcriptional index across each chromosome which may be used for comparing run to run reproducibility and serve as an estimator of differential expression for annotated segments of the genome. In addition, saturation reports describe the fraction of annotated RNAs that are detected per sample per million reads in common reference RNA sequence databases including RefSeq and the more comprehensive AceView. This workflow has allowed for facile interpretation and faster turnaround when evaluating transcriptional activity and QC information from a given sample RNA.

## 2844/F/Poster Board #712

**Three individual human genome sequences.** *J. van Velkinburgh[1], J. Kim[2], Y. Ju[2], H. Park[2], S. Kim[3], S. Lee[3], J. Yi[2], J. Mudge[1], N. Miller[1], D. Hong[2], R. Kim[1], H. Kim[2], G. Schroth[6], G. Church[5], C. Lee[4], J. Oksenberg[7], S. Baranzini[7], S. Hauser[7], S. Kingsmore[1], J. Seo[2].* 1) NCGR, Santa Fe, NM; 2) ILCHUN Genomic Medicine Institute, Medical Research Center, Seoul National University, Seoul 110-799, Korea; 3) Macrogen Inc., Seoul 153-023, Korea; 4) Department of Pathology, Brigham and Women's Hospital and Harvard Medical School, Boston, MA, 02115, USA; 5) Department of Genetics, Harvard Medical School, Boston, MA 02115; 6) Illumina Inc., Hayward, CA 94545, USA; 7) Department of Neurology, School of Medicine, University of California San Francisco, 513 Parnassus Ave. Room S-256, San Francisco, CA 94143-0435, USA.

Recent advances in sequencing technologies have initiated an era of personal genome sequences. To date, human genome sequences have been reported for male individuals with ancestry in four distinct geographical regions: a Yoruba African, two individuals of Northwest European origin, a person from China and a Korean. Here, we provide highly annotated, whole genome sequences for a Korean male (AK1) and two Northwest European females. The genome of AK1 was determined by a combined approach that included whole genome shotgun sequencing (27.8x coverage), targeted bacterial artificial chromosome (BAC) sequencing, and high-resolution comparative genomic hybridization (CGH) using custom microarrays featuring over 24 million probes to provide the most detailed analysis of an individual human genome to date. The two female genomes were determined by whole genome shotgun sequencing (approximately 18x coverage of each). Alignment to the NCBI reference disclosed approximately 3.5 million single nucleotide polymorphisms (SNPs) and approximately 200,000 deletion or insertion polymorphisms (indels) in each genome. SNP and indel densities were strongly correlated genome-wide. Applying very conservative criteria yielded highly reliable copy number variants (CNVs) for clinical considerations. Potential medical phenotypes were annotated for nsSNPs, coding domain indels, and structural variants. Integration of human whole genome sequences, particularly from groups of individuals with minimal ethnic admixture, will assist in understanding genetic ancestry, migration patterns, and population bottlenecks.

## 2845/F/Poster Board #745

**Fine mapping of association signals with haplotype association analysis in CGEMS when a functional variant is known.** *J. Gonzalez Bosquet[1], M. Yeager[1], L. Amundadottir[1], P. Kraft[1], K.B. Jacobs[1,3], S. Wacholder[1], R.N. Hoover[1], G. Thomas[1], D.J. Hunter[1,2], S.J. Chanock[1].* 1) Division of Cancer Epidemiology and Genetics, NCI, Bethesda, MD; 2) Department of Epidemiology, Harvard School of Public Health, Boston, MA; 3) SAIC-Frederick, NCI-Frederick Cancer Research and Development Center, Frederick, MD.

The NCI Cancer Genetic Markers of Susceptibility (CGEMS) initiative has conducted multi-stage GWAS in both breast and prostate cancer with the discovery of new loci highly associated with both cancer risks. In an attempt to fine map these associations, we performed haplotype association analyses of regions based on the selection of tagged SNPs genotyped in two multi-stage GWAS of breast cancer and prostate cancer in the CGEMS study. The initial breast GWAS genotyped 528,173 SNPs using the Human Hap500 Infinium Assay in the Nurses' Health Study (NHS), and in a second stage over 30,000 markers with a custom Illumina iSelect panel in the additional studies, totaling 5,723 women with breast cancer and 5,598 controls (total of 11,321). The region 10q26 around locus rs1219648, within intron 2 of FGFR2, reached genome-wide significance (p-value$\leq 10^{-10}$), and functional studies were available in the same region. The initial prostate GWAS and follow up scans reported by the CGEMS initiative, followed the same study design as that in breast cancer. The locus rs10993994 in the 10q11 region, located in the promoter region of the MSMB gene, was genome-wide significant (p-value$\leq 10^{-10}$). A total of 12,223 men (6,118 cases and 6,105 controls) were genotyped for 14 tagSNPs surrounding the MSMB gene. Also, over 2,500 bp of the coding gene and its 5' region were sequenced. Functional data also was available for this region. We reconstructed haplotypes based on the regional LD structure, and tested for association with breast and prostate cancer risk using 3 different haplotype methods: 2 haplotype association analyses, the variable-sized sliding-window regularized regression approach, and the sequential haplotype scan, and a location estimation analysis, based in evolutionary clustering using Bayesian partition modeling to cluster haplotypes with similar disease risks. The most significant haplotypes for each included the most significant loci in both areas and delimited a genomic region where significant functional variation has been described. We then compared the utility of tagged SNPs based on HapMap between two regions in which a putative functional variant has been identified. We conclude that fine mapping analysis is useful to narrow the region but still requires additional genotyping based on a comprehensive resequence analysis of the region to effectively test common variants.

## 2846/F/Poster Board #746

**ERBB3 variants at 12q13 confer genetic risk for type 1 diabetes.** *K. Keene, S. Onengut-Gumuscu, P. Concannon.* Center for Public Health Genomics, University of Virginia, Charlottesville, VA.

Type 1 diabetes (T1D) is a complex autoimmune disease that involves both genetic and environmental risk factors. Genome wide association studies (GWAS) have recently provided a new list of potential T1D predisposing loci including the 12q13 locus containing the ERBB3 gene. GWAS for T1D provide evidence for association with two SNPs across the 12q13 region, rs2292239 (ERBB3, intron 7; P= $1.89 \times 10^{-14}$) and rs11171739 (intergenic RPS26-ERBB3; genotypic P= $9.71 \times 10^{-11}$). In order to fully determine a functional role for variants in the 12q13 region, in relation to T1D susceptibility, it is imperative that the causal variants are identified and characterized. Using sequencing and fine-mapping approaches, we aimed to identify and subsequently perform tests of association for variants within the 12q13 region. Using HapMap CEPH data, we identified 25 common SNPs (MAF >5%) that span a five gene region of 12q13 that included ERBB3. Seven tagging SNPs were genotyped, using the Eclipse genotyping platform, in 382 multiplex T1D families from the Type 1 Diabetes Genetics Consortium. Single SNP association was performed using Family Based Association Tests (FBAT). Four tagging SNPs (all located in ERBB3) provided evidence for association (P< 0.05) with T1D. The most significant single SNP associations were observed with rs2271189 (Exon 27; P= 0.000182) and rs705708 (Intron 15; P= 0.00113), while rs2292239, one of the significantly associated SNPs from GWAS, provided somewhat less evidence of association (P= 0.013) in this population. There are relatively few reported SNPs in this region. To further explore the associations observed in ERBB3, we re-sequenced all 28 exons and intron/exon boundaries of ERBB3 in 48 individuals, confirming nine previously identified SNPs and five novel SNPs. Three of the additional SNPs identified by sequencing were genotyped, of which two were significantly associated with T1D. Of the ten total SNPs genotyped across 12q13, six SNPs showed evidence for association with T1D. Three SNPs provided stronger evidence for association than the previously associated GWAS SNP rs2292239, suggesting that variants within the ERBB3 gene are responsible for the genetic risk for T1D observed on 12q13.

## 2847/F/Poster Board #747

**Locus heterogeneity in Hereditary Hemorrhagic Telangiectasia (HHT): Linkage and candidate gene analysis of four large HHT families.** *W. Wooderchak[1], C.J. Bukjiok[1], K. Damjanovich[1], T. Lewis[1], F. Gedge[1], J. McDonald[1,2], P. Bayrak-Toydemir[1,3].* 1) ARUP Institute for Clinical and Experimental Pathology; 2) Department of Radiology, University of Utah; 3) Department of Pathology, University of Utah.

Hereditary hemorrhagic telangiectasia (HHT) is an autosomal dominant disorder characterized by aberrant vascular development. All known genetic defects that cause HHT are found to be within the transforming growth factor-beta (TGF-$\beta$) signaling pathway. Endoglin (ENG, chromosome 9q34), activin A receptor type II-like 1 (ACVRL1, chromosome 12q13), and SMAD4 (chromosome 18q21), are known to cause HHT1, HHT2, and Juvenile Polyposis/HHT syndrome, respectively. Mutations in two unidentified genes on chromosome 5q31 and chromosome 7p14 cause HHT3 and HHT4, respectively. Four types of HHT have been identified, yet over 85 percent of patients diagnosed with HHT have mutations in ENG or ACVRL1.

We have identified four large families with HHT that do not have ENG or ACVRL1 coding region mutations. Mutation analysis of SMAD4 and other SMAD genes (SMAD1-3 and 5) revealed no mutation. In order to determine the genetic cause of HHT for each family, we performed locus specific linkage analysis using short tandem repeat markers located in the 5 known HHT loci. Interestingly, one family linked to chromosome 9q34 where ENG is located, while two families linked to chromosome 12q13 where ACVRL1 is found. These results suggest that genetic aberrations in the noncoding or regulatory regions of ENG and ACVRL1 may also cause HHT. One of the families linked to chromosome 7p14 where the causative gene has yet to be determined. A custom designed oligo-CGH array was performed on the 7p region for a 7p14-linked family, and no large deletions were detected. Several candidate genes from this 7 Mb region were sequenced including BMPER, a lead candidate gene that encodes an endothelial cell regulatory protein expressed in the earliest stage of endothelial cell lineage. No mutations have been found. Studies are underway to narrow the critical region on chromosome 7p and determine the causative gene. Our findings further support the locus heterogeneity observed in HHT.

## 2848/F/Poster Board #748

**Agilent Technologies SureSelect$^{TM}$ All Human Exon Target Enrichment Kit Development.** *C. Pabón-Peña[1], A. Giuffre[2], B. Novak[1], M. Visitacion[1], S. Joshi[2], A. Wong[1], J. Eberle[1], W. Rasmussen[2], S. Hunt[1], J. Ong[2], R. Kanemoto[1], S. Happe[2], E. LeProust[1], D. Roberts[1].* 1) Agilent Technologies, Inc., Santa Clara, CA; 2) Agilent Technolgies, Inc., Cedar Creek, TX.

Next-generation sequencing technology has dramatically increased the ability to sequence DNA in a massively parallel manner. This improvement in throughput can be further augmented by targeting only the specific regions of the genome under study. Agilent Technologies has leveraged its ability to efficiently manufacture high fidelity long oligonucleotides to develop the SureSelectTM Target Enrichment System platform, a portfolio of sample-preparation products to enable next-generation sequencing users to sequence only their regions of interest. Here we describe development and validation of the SureSelect$^{TM}$ Target Enrichment System. The design covers human exonic regions corresponding to the ~37Mb of the NCBI Consensus CDS database (CCDS) in addition to over 1000 human non-coding RNAs. We discuss the performance of the system with respect to the efficiency, uniformity, and reproducibility of enrichment.

## 2849/F/Poster Board #749

**Functional interactions of conserved non-coding (CNC) sequences with other CNC using circular chromosome conformation capture (4C).** *D. Robyr[1], M. Friedli[1], C. Gehrig[1], M. Arcangeli[1], M. Marin[1], L. Farinelli[3], A. Quazzola[2], S. Verp[2], D. Trono[2], S.E. Antonarakis[1].* 1) Genetic Medicine/ Development, Univ Geneva Medical Sch, Geneva, Switzerland; 2) Global Health Institute, School of Life Sciences, EPFL, Lausanne Switzerland; 3) FASTERIS SA, Ch. du Pont-du-Centenaire 109, P.O. Box 28, CH-1228 Plan-les-Ouates, Switzerland.

The comparison of human chromosome 21 (Hsa21) sequences with the mouse syntenic regions led to the identification of roughly 3500 regions displaying an identity of >70% over a length of a least 100 nucleotides of ungapped alignment. About 65% (~ 2300) of these are conserved non-coding sequences (CNCs). Very little is known about the function of most CNCs, although some act as enhancers. We speculated that a functional CNC might interact with its genomic target (i.e. an enhancer would bind to its cognate gene promoter). Thus, the identification of any part of the genome that interacts directly with a CNC could provide clues on the function of the latter. We have generated libraries of CNC-interacting DpnII fragments by chromosome conformation capture (4C) whose identity is determined by subsequent high-throughput sequencing. We have identified genomic loci that interact physically with a selection of 10 CNCs from human chromosome 21. All CNCs are capable of interacting with loci in trans albeit at different levels, ranging from 0.1% to 95.9% of all sequence tags. Remarkably, there is a statistical significant enrichment of other CNCs among the interacting fragments. Moreover, we have identified two evolutionary conserved DNA elements (separated by 89kb) that have the ability to interact with the oligodendrocyte gene OLIG2 and that drive the expression of a reporter gene in the mouse embryo in regions corresponding to its native expression. This study also demonstrates the power of 4C technology to identify interactions of functional DNA elements.

## 2850/F/Poster Board #750

**Human Sequencing and Project Management in the Broad Institute Genome Sequencing Platform.** *L. Ambrogio[1], L. Aird[1], K. Ardlie[2], J. Baldwin[1], T. Bloom[1], J. Blye[1], T. Fennell[1], S. Fisher[1], R. LeVine[1], K. Ross[1], C. Sougnez[3], H. Spurling[1], J. Wilkinson[1].* 1) Genome Sequencing Platform, The Broad Institute, Cambridge MA; 2) Biological Samples Platform, The Broad Institute, Cambridge MA; 3) Genetic Analysis Platform, The Broad Institute, Cambridge MA.

One of the biggest challenges of increasing throughput across multiple sequencing platforms is managing sample receipt, project tracking and data submission. In the first five months of 2009 the Sequencing Platform at the Broad Institute received approximately 1,300 human DNA samples for sequencing and generated over 4.9 terabases of data, a significant increase from comparable time frames in prior years. Data was generated across multiple initiatives, including The Cancer Genome Atlas, The 1000 Genomes Project, and The Human Microbiome Project. To meet this challenge, we have formed a cross-platform team of Project Managers who work closely with internal and external collaborators to develop project designs, timetables and goals. In addition, we have a suite of tools for monitoring project status beginning with sample procurement and concluding with data submission. The Genome Sequencing Sample Repository (GSSR) ensures the fidelity and accuracy of all sample information entered into the project-tracking database. Work Requests link samples to sequencing workflows via the LIMs console. The Analysis pipeline interacts with Project Workbench to verify the data submission protocol. As new sequencing technologies increase the velocity at which a sequencing project can be completed, there is a continuous need to improve current project management methods and build new tools where necessary. The Broad Institute Project Management Team has worked to improve and streamline communication across multiple platforms, develop flexible tracking and reporting methodologies, and has also implemented standard procedures for managing a project through its life cycle. Combined, these efforts allow us to better manage and balance the needs of all project stakeholders.

## 2851/F/Poster Board #751

**Third-Generation Complete Human Genome Sequencing of Multiple Individuals.** *R. Drmanac.* Complete Genomics, Mountain View, CA.

We sequenced the complete human genomes of four individuals, including two parents-offspring trios, using Complete Genomics' third-generation technology to yield the first series of high quality human genome sequences at a medically relevant cost and scale. The technology employs high density nanoarrays, an unchained read chemistry, and high performance imaging to reduce overall cost and improve time to results. Our latest human genome sequencing data includes individual coverage depths ranging from 50- to 89-fold (150-270 Gb per genome), and average discordance of 0.63% in 85% of the highest quality bases. An average of over 3,000,000 SNPs were found in each of the individual sequences, of which an average of 10.7% were novel SNPs. An average of over 353,000 INDELs were identified, of which over 45% were novel INDELs. We will also discuss some implications of this rapidly expanding sequencing capability for use in other studies.

## 2852/F/Poster Board #752

**Resequencing All Unique X Choromosome Exons to Identify Genetic Variants Contributing to Autism Susceptibility.** *K. Mondal[1], D. Okou[1], K. Meltz-Steinberg[1], V. Patel[1], A.C. Shetty[1], M.E. Zwick[1,2,3].* 1) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA; 2) Graduate Program in Population Biology, Ecology and Evolution, Emory University School of Medicine, Atlanta, GA; 3) Graduate Program in Genetics and Molecular Biology, Emory University, Atlanta, GA.

Our goal is to assess the impact of X-linked genetic variants as contributing factors to autism susceptibility. We are focused on comprehensively sequencing all unique exons on the X chromosome in 300 males with autism from the Simons Simplex Collection. Recently, we have shown that microarray-based genomic selection (MGS) using custom microarrays manufactured by Roche NimbleGen Systems, Inc. can be combined with the Illumina Genome Analyzer (IGA) to successfully capture and sequence diploid genotypes in large discontiguous genomic regions. Here we report the data obtained from an 8-fold scale-up targeted towards all the exons on the X chromosome. To do this, an initial custom-design MGS array (385K oligos) was used to enrich for 7417 exons (~2.4MB) on the human X-Chromosome in 10 Male Hapmap samples. Our results suggest that MGS is a feasible strategy for resequencing most of the exons on the X chromosome, although some technical challenges remain in obtaining high quality data at all targeted sequences. A univariate analysis of the results showed that longer exons gave higher basecalling rate because they had more MGS probes. Also, MGS probes with lower GC content and Tm (melting temperature) gave higher basecalling rates. Our results suggest that MGS performance can be enhanced by both improving algorithms for probe selection and further optimizing experimental protocols. Finally, our data suggest that enrichment approaches will be prone to false positive SNP identification when probes capture paralogous sequences from other genomic regions.

## 2853/F/Poster Board #753

**The human reference genome, v 2.0.** *V.A. Schneider[1], D. Grafham[2], T. Graves[3], M. Caccamo[4], Genome Reference Consortium (GRC).* 1) NIH/NCBI, Bethesda, MD, USA; 2) The Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK; 3) The Genome Center at Washington University, St. Louis, MO, USA; 4) The European Bioinformatics Institute, Hinxton, Cambridge, UK.

The description of the essentially complete human genome sequence described by the International Human Genome Sequencing Consortium in 2004 marked a scientific milestone[1]. At the time, it was the only mammalian assembly of such high quality and coverage. While the assembly described in this publication has been the basis of much scientific discovery, such discovery has also made it clear that additional work is needed to allow the genome representation to grow as our understanding of the human genome grows. To this end, the Genome Reference Consortium (GRC) was created. Over the past two years, we have built systems and tools to facilitate the assembly and curation of clone based assemblies such as the reference human and mouse genomes. The culmination of this effort has resulted in the release of an updated human genome assembly, referred to as Genome Reference Consortium Human Build 37 (GRCh37). We will review the significant improvements in this new human reference assembly. The initial focus of the group has been to fix assembly and sequence errors identified in human Build 36. Notably, the availability of new clone resources in non-BAC vectors[2] has also allowed us to re-examine gaps previously thought to be inaccessible to cloning. We have been able to add sequence to or completely close approximately one third of the unspanned gaps in Build 36. Additionally, much of the sequence that had been considered part of the 'bottom-drawer' has now either been localized or determined to be redundant and removed from the assembly. To accommodate our growing awareness of genetic diversity, this assembly also provides alternate representations of highly divergent loci for a limited number of regions. Additionally, the GRC has increased access to the data underlying the genome assembly. Tools to review component overlaps, as well as curation decisions, are publicly available. Regions that are currently under review can be seen at both the GRC portal and Ensembl Browser. Users can also report problems and ask questions through the GRC website (http://genome-reference.org). [1]Nature (2004) 431:931-45, [2]Nature (2008) 453:56-64.

## 2854/F/Poster Board #754

**LuCAMP: Genome-wide association study of patients with the combined at-risk metabolic phenotypes through whole-exome sequencing of 2,000 individuals.** *J. Wang.* Genomics & Bioinformatics, Beijing Genomics Inst, Shenzhe, Shenzhen, China.

Genome-wide association studies (GWAS) provided evidence that common genetic variation contribute to metabolic disorders including obesity and type II diabetes. About 19 genes were identified to be associated with type II diabetes. However, these loci only explain ~10% of the genetic variation of type II diabetes, since these studies all used a genotyping approach investigating between 100~500K different known genetic variants that covered approximately 80% of the common variation in HapMap with a minor allele frequency (MAF) >5%. To identify novel variations, especially rare variations, that increase the risk of type II diabetes, we used the combination of recently developed DNA capture and next-generation sequencing technologies. Through sequencing the whole coding part of the genome (including 5'- and 3'-UTR) and highly conserved regions, we studied 1,000 Danish Caucasian patients with gender-defined visceral obesity who in addition suffer from type II diabetes and essential hypertension and 1,000 matched control individuals. The novel genetic variations with MAF as low as 0.1% were identified; the difference of allele frequency of novel and known variation between patients and controls were identified. The project also contributes with the sequence of thousands of human genomes for studying the population structure of the Danish population. In general, the method we developed and the study we performed demonstrated the feasibility and advantages of large-scale genome sequencing approach for population genetics and genome-wide association studies.

## 2855/F/Poster Board #755

**Identification and resequencing of the cis-regulatory elements surrounding Tbx5.** *S. Smemo, M.A. Nobrega.* Department of Human Genetics, University of Chicago, Chicago, IL.

Congenital heart malformations are the most common form of birth defect, affecting nearly 1% of all children. Such a high prevalence is partly due to the inherent difficulty in maintaining the complex interplay of many genes whose expression is finely-tuned spatially and temporally. A critical gene in this dynamic system is T-box 5 (Tbx5), and coding mutations in Tbx5 are known to cause Holt-Oram Syndrome (HOS), which is characterized by congenital heart and limb malformations. Interestingly, 30-70% of patients with HOS lack any such coding mutations. One hypothesis, explored here, is that the cis-regulatory elements that normally confer Tbx5 with its precise spatiotemporal expression pattern have been disrupted by mutation, resulting in defects in the heart developmental program and ultimately in heart malformations. We have used a combination of bioinformatics, comparative genomics and mouse transgenic assays to identify many of the individual elements responsible for controlling Tbx5's tissue and temporal expression specificity in the developing heart. Preliminary sequencing of a few of these short, highly conserved elements in human patients with congenital heart defects has revealed a number of mutations, the functional significance of which is being determined. This study not only has implications for identifying variation underlying congenital heart disease, but the strategy is broadly applicable to other human diseases as well.

## 2856/F/Poster Board #756

**Taybi-Linder syndrome (MOPD I/III) maps to a 3Mb interval on chromosome 2q.** *P. Edery[1,2], A. Labalme[1], R. Touraine[3], P.-S. Jouk[4], D. Sanlaville[1,2], F. Clerget-Darpoux[5,6], A.-L. Leutenegger[5,6].* 1) CHU de Lyon, Service de Cytogénétique Constitutionnelle, Bron, F-69677, France; 2) Université Lyon 1, Lyon F-69003, France; 3) CHU de Saint-Etienne, Service de Génétique, Saint-Etienne, France; 4) CHU de Grenoble, Département de Génétique et Procréation, Grenoble, France; 5) Inserm, U535, Villejuif, France; 6) UMR-S 535, Univ Paris-Sud, Villejuif, France.

Taybi-Linder syndrome, also named microcephalic osteodysplastic primordial dwarfism (MOPD) type I/III (OMIM 210710), is a rare autosomal recessive condition characterized by intrauterine growth retardation, low birth weight, dwarfism, bone dysplasia, facial anomalies, microcephaly and severe brain malformations. In 2006, we mapped the Taybi-Linder locus to a 13 cM interval on chromosome 2q14.2-q14.3, by performing homozygosity mapping in one inbred sibship (2 affected and 3 unaffected sibs) and in two unrelated inbred patients, using inbreeding coefficients estimates from the patients' genomic information (Leutenegger AL et al, Am J Hum Genet 2006). Here, we present a fine mapping study of the Taybi-Linder syndrome locus together with the genotyping of an additional Taybi-Linder family, which confirms that this syndrome maps to chromosome 2q. Altogether, our data show that the Taybi-Linder syndrome locus maps to a 3.19 Mb chromosome 2q interval, flanked by the RALB gene (centromeric boundary) and by a polyAC microsatellite marker in close vicinity to D2S347 (telomeric boundary). We also performed direct sequencing of the coding exons and flanking introns of several candidate genes, including TFCP2L1, CLASP1, MKI37IP and TSN, but no pathogenic base change was found. We are currently performing high throughput sequencing of the 3.19 Mb genomic region (capture by Agilent's Oligo Library Synthesis Technology, and, sequence by Illumina Genome Analyzer II) likely to contain the pathogenic mutations in order to identify the Taybi-Linder causative gene.

## 2857/F/Poster Board #757

**Linkage analysis and comprehensive resequencing of the whole exon-captured genomic DNAs toward identification of causative genes for hereditary neurodegenerative diseases.** *Y. Fukuda[1], K. Reginaldo[2], W. Qu[2], Y. Nakahara[1], H. Ishiura[1], K. Hara[3], Y. Suzuki[4], S. Sugano[4], S. Morishita[2], S. Tsuji[1].* 1) Dept Neurology, Univ Tokyo, Tokyo, Japan; 2) Dept Computational Biology, Univ Tokyo, Kashiwa, Japan; 3) Dept Neurology, Brain Research Institute, Niigata Univ, Niigata, Japan; 4) Dept Medical Genome Science, Univ Tokyo, Kashiwa, Japan.

Objective: Identification of causative genes for diseases with Mendelian inheritance still remains a challenging project when the size and the number of pedigrees are limited. To overcome the difficulty, we conducted comprehensive resequencing of the whole exon-captured genomic DNAs from a patient with familial multiple system atrophy (fMSA), a recently identified rare hereditary neurodegenerative disease. To facilitate the search for the causative genes, we simultaneously conducted a high-throughput linkage analysis using SNP microarrays to define the candidate regions. Methods: A genome-wide linkage analysis of a pedigree of fMSA was conducted employing a recently developed SNP microarray-based high-throughput linkage analysis system (BMC Bioinfo., 2009, 10:121). We have performed linkage analysis of a consanguineous MSA pedigree where autosomal recessive inheritance is suggested. Whole exons were enriched using NimbleGen Sequence Capture 2.1M Human Exome Array, and selective, high-throughput DNA resequencing was conducted using next generation sequencers (Solexa/Illumina). Results and Discussion: From 50 million reads, total of approximately 80K candidates of single nucleotide variations (SNVs) were detected after our fist filtering. Of those approximately 15K SNVs were located in primary target regions designed on capturing array (average read depth = ~15x). Based on the SNP array-based high-throughput linkage analysis, the candidate region was defined to be ~70Mb regions with the homozygosity shared by the affected patients. Application of these SNVs identified in the candidate regions for the search for the causative genes will be discussed.

**Profiling of small ncRNAs in psoriatic skin with microarrays and Next Gen sequencing.** *C. Joyce, A. Bowcock.* Dept Gen, Washington Univ, Saint Louis, MO.

Psoriasis is a complex, chronic inflammatory disease of the skin affecting 2-3% of the European population. While the majority of changes in mRNAs associated with protein coding genes are known, and genetic risk factors are beginning to be identified, many of the underlying mechanisms of gene expression changes in the disease are not clear. Several classes of non-coding RNAs (ncRNAs), such as microRNAs (miRNAs) and naturally occurring antisense transcripts (natRNAs), are endogenous regulators of gene expression and may account for some of these alterations. To begin to determine whether changes in ncRNA expression might contribute to altered gene expression in psoriasis, we examined global changes in miRNA levels in normal and psoriatic skin. We first used Exiqon miRCURY arrays to interrogate expression levels of miRNAs in normal versus psoriatic skin samples. Potentially differentially expressed miRNAs were then followed up with qRT-PCR analyses of eight normal, ten involved and ten uninvolved skin samples. This lead to the identification of three miRNAs- miR21, miR31, and miR133- that are misexpressed in psoriatic involved versus normal skin ($P = 0.0003$; 0.0001; 0.0001, respectively). Since the Exiqon arrays only harbor probes for 561 miRNAs, and many more are likely to exist, we are also interested in identifying additional miRNAs and other small ncRNAs. Hence, we are generating small ncRNA libraries from normal and involved psoriatic skin and sequencing them with Next Gen technologies. A first pass analysis of 4,193,899 sequences from a library derived from involved skin included known differentially expressed miRNAs, such as miR21 and miR31, and many novel sequences. Hence, this study will lead to the identification of novel ncRNAs in both normal and psoriatic skin and provide additional insights into the pathogenesis of this inflammatory skin disease.

## 2859/F/Poster Board #759

**Whole Genome Amplification and screening methods of Formalin-fixed Paraffin-embedded Tissues for Selective Hybridization Sequencing on Illumina's Genome Analyzer II Sequencer.** *M. DeFelice[1], B. Blumenstiel[1], W. Winckler[1], M. Freedman[1,2], L. Ziaugra[1], S. Gabriel[1].* 1) Broad Inst, Cambridge, MA; 2) Dana-Farber Cancer Institute, Boston, MA.

There are an estimated 300-500 million paraffin tissue blocks in the United States today and that number is growing by roughly 20 million samples per year. Formalin fixed tissue is more abundant than fresh frozen tumor tissue but presents a multitude of technical challenges for molecular profiling. Next generation sequencing technologies coupled with hybrid selection techniques are quickly making large tumor sequencing studies an affordable reality. DNA degradation, formalin modification, and total yield of extracted DNA all pose challenges to obtaining high quality sequence for mutation discovery. Using a hybrid selection panel targeting 4.4 megabases across ~20,000 exons, we observe the performance of extracted FFPE samples sequenced on the Illumina Genome AnalyzerII. With solution and array based hybrid selection methods requiring upwards of 3 and 20 ug of input DNA respectively, we tested three whole genome amplification methods to assess their suitability for amplifying FFPE DNA for library construction, hybrid selection, and sequencing. WGA methods tested include: Genomeplex, REPLI-g FFPE, and Restriction and Circularization-Aided Rolling Circle Amplification. Because of the broad spectrum of sample variation in FFPE collections there is a critical need to understand the quality of a sample for any type of genetic analysis before valuable time and money is expended. We report on the development of an up-front screening assay for predicting hybrid selection sequencing success on any given FFPE sample on the Illumina sequencing platform. Since concentration and size distribution of genomic DNA isolated from FFPE tissue are often inadequate predictors for future genomic analysis success, we used a multi-plex PCR assay coupled with the Sequenom Homologous Mass Extension (hME) assay to quantify the extent of degradation/ modification and ultimately select for FFPE extractions with optimal sequencing potential. The ability to screen for sequence-quality FFPE samples will greatly expand the available collection of tumor DNA samples, enabling well-powered studies of the cancer genome.

## 2860/F/Poster Board #760

**Genomic Approaches to Understanding PGC-1a Regulated Metabolism.** *A. Charos[1], B. Reed[1], D. Raha[1], S. Weissman[2], M. Snyder[1].* 1) MCDB, Yale University, New Haven, CT; 2) Genetics, Yale University, New Haven, CT.

PGC-1a is a transcriptional coactivator that functions as a master regulator of energy homeostasis. It becomes activated in response to a variety of metabolic stressors including physical activity, dietary conditions and temperature and mediates the proper transcriptional response through its interactions with a number of transcription factors. Although PGC-1a mediates transcriptional outputs across a range of tissue types, its role in the liver is of key interest to this study. In the liver, PGC-1a has been shown to control the fasting response by upregulating genes involved in gluconeogenesis and the oxidation of fatty acids. Polymorphisms in PGC-1a have been identified in patients with type II diabetes amongst different ethnic populations. The expression of PGC-1a is aberrantly upregulated in the livers of both type I and type II diabetics, contributing to hyperglycemia. Despite its critical role in metabolism, few PGC-1a target genes have been identified to date. Recent advances in ultra high-throughput DNA sequencing technology have made it possible to identify transcription factor binding sites across the entire genome at very high resolution compared to other technologies such as tiling array platforms. In order to identify the complete set of genomic binding sites of PGC-1a and its associated factors, we performed chromatin immunoprecipitation followed by DNA sequencing (ChIP-seq) in human hepatocarcinoma (HepG2) cells that were subjected to treatment with forskolin to mimic glucagon signaling in the fasted liver. The immunoprecipitated DNA was subjected to massively parallel DNA sequencing on the Illumina Genome Analyzer platform. Several PGC-1a binding sites were located in the promoters of known PGC-1a target genes. In addition, several novel binding sites were found. Enriched motifs were identified for each of eight different factors. An analysis of the data revealed two clusters of transcription factors with overlapping binding sites, providing evidence for new functional relationships between different factors. ChIP-Seq data were compared with Affymetrix expression data to correlate binding sites with changes in gene expression. Finally, a network determining the relationships between the factors revealed an interesting hierarchy in which some factors bind to the promoters of each other.

**Human Variome Project - Pilot projects and progress.** *R.G.H. Cotton[1,2], F. Macrae[3], Collaborators.* 1) Genomic Disorders Research Centre, & Convenor, Human Variome Project, Melbourne, Australia; 2) Faculty of Medicine, Dentistry and Health Sciences, The University of Melbourne, Parkville, Australia; 3) Colorectal Medicine and Genetics, The Royal Melbourne Hospital, Parkville, Australia.

The Human Variome Project (Axton 2007) (www.humanvariomeproject.-org) was initiated in June 2006 (Ring, Kwok et al. 2006) drawing attention to the importance of collection of variation and its phenotype and to develop programs to put this into effect. The project builds on work and concepts of the HGVS over many years (www.hgvs.org) to focus on all variation associated with disease. HVP collaborators include those discovering mutations, their effects and then collect the data making it instantly available for those who need it to inform clinical decisions and research. The HVP and InSiGHT (www.insight-group.org) has developed a major pilot study to develop procedures and systems to allow effortless flow of de-identified data from the patient/clinic/diagnostic laboratory via curated locus or gene specific databases to central databases/genome browsers such as NCBI, UCSC and EBI. The system will be easily adaptable to other genes and to multiple laboratories, states and countries worldwide. A country specific collection pilot is underway in Australia and an International Confederation of these countries has been initiated with Korea and China in the application process. Such collection will aid genetic healthcare in a country and be a second failsafe collection mechanism. Other pilot studies developed include specific ethical studies related to mutation collection, loading of LSDB content to dbSNP, funding of curation of LSDBs, a system of Microattribution/ reward for mutation submission. A high level meeting in Spain (Kaput, Cotton et al. 2009) developed plans to implement the recommendations of the HVP Melbourne meeting (Cotton, Appelbe et al. 2007). The HVP was featured recently in relation to Neurogenetic databases (Cotton, Auerbach et al. 2008). References: Axton, M. (2007). "What is the Human Variome Project?" Nat Genet 39(4): 423. Cotton, R. G., W. Appelbe, et al. (2007). "Recommendations of the 2006 Human Variome Project meeting." Nat Genet 39(4): 433-6. Cotton, R. G., A. D. Auerbach, et al. (2008). "GENETICS. **A novel deletion in HSL causes a frameshift mutation associated with high triglycerides and low HDL in the Amish.** *J.S. Albert, L.J. Reinhart, B.D. Mitchell, A.R. Shuldiner, T.I. Pollin, C.M. Damcott.* University of Maryland School of Medicine, Baltimore, MD.

Lipases are enzymes responsible for the catabolism and mobilization of stored lipids. Hormone sensitive lipase (HSL) is responsible for most of the catabolic activity in lipolysis. Regulated by norepinephrine, adrenaline, and glucagon, HSL breaks down triacylglycerol, diacylglycerol, and monoacylglycerol for energy. In the HSL knockout mouse, adipocytes are significantly enlarged, indicating dysregulation of lipid catabolism. Thus, we hypothesize that polymorphisms in HSL disrupt the lipase activity of the enzyme leading to abnormal lipid metabolism. To test this hypothesis, we sequenced the 10 exons in HSL in 12 Amish subjects with extremely high and 12 with extremely low fasting triglycerides. In our sequencing set, there was very little variation across the gene; however, we found a novel 19 base pair deletion in the coding region of exon 10. This mutation abolishes the stop codon, and lengthens the protein by 92 amino acids. We genotyped the deletion in 1,635 Amish subjects who are well-characterized for traits related to cardiovascular disease, and compared mean trait levels of fasting lipids across genotype groups adjusting for age, sex and family structure. We found that the deletion had an allele frequency of 0.02 and was significantly associated with higher fasting triglycerides (p-value = 3.9 x 10-5) and lower HDL-cholesterol (2.6 x 10-6). Median TG levels and interquartile ranges were 81 (46 - 98) in II, 111 (52 - 149) in ID and 204 (145 - 264) mg/dl in DD. Mean HDL levels were 56 +/- 15 in II, 49 +/- 14 in ID, and 36 +/- 15 mg/dl in DD (mean +/- SD). These data provide evidence that the novel 19 base pair deletion found in HSL is associated with increased fasting triglycerides and low HDL-cholesterol, suggesting a role for HSL variation in dysfunctional lipid metabolism in humans.

## 2863/F/Poster Board #795

**Sensitivity and Specificity of High Throughput Melting Curve Analysis for the Detection of Common Genome Variants and Rare Mutations in PCR Amplicons.** *H. Prucha[1], M.F. Sinner[2], S. Lindhof[1], M. Vieracker[1], B.M. Beckmann[1], D. Sibbing[3], N. Von Beckerath[3], B. Lorenz-Deperieux[1], H. Prokisch[1], S. Kääb[2], T. Meitinger[1], A. Pfeufer[1].* 1) Institut für Humangenetik, TU München und Helmholtz Zentrum München; 2) Klinikum Grosshadern, 1. Med. Klinik, LMU München; 3) Klinikum rechts der Isar, 1. Med. Klinik, TU München.

High resolution melting curve analysis (HRM or MCA) is an innovative screening method for unknown genome variants in PCR amplicons. MCA has shown convincing potential as a cost efficient high throughput method (≤10 cents per PCR product screened in 384 well plates) beyond medium throughput methods like chemical or enzymatic cleavage, SSCP, TGGE and DHPLC or more expensive methods like Sanger- or next generation resequencing. We have evaluated MCA in a series of 362 patients with autosomal dominant dilative cardiomyopathy. In a discovery set of 96 patients who had undergone complete Sanger resequencing of 18 exons we discovered overall 44 sequence variants. 17 of the variants had an allele frequency below 1%, i.e. were detected only once in the discovery set, while 27 variants were more common i.e. observed more than once in the set. Sensitivity of MCA to detect sequence variants was on average 96.5% (range: 74.2-100%) if variants were common (i.e. occurred more than once) and PCR amplicons were no longer than 350 bp. This was the case even if several common and rare variants were present within the same amplicon. Sensitivity was decreased for rare variants, for longer amplicons and for amplicons containing several variants. At the cutoffs that we used to select a PCR product for further analysis the specificity of MCA was higher (78% average) than with previously used methods in our hands, avoiding unnecessary resequencing expenses. Overall the current implementations of MCA in a 384 well format offer a good detection of private mutations and other rare variants in PCR-amplifiable short genomic regions, applicable in high throughput with a reasonable cost-efficiency ratio and bridges the technology gap between conventional mutation screening methods and next generation resequencing.

## 2864/F/Poster Board #796

**A census of LINE-1 and Alu elements expressed in human embryonic stem cells.** *J. Garcia-Perez, A. Macia, J. Cortes, S. Morell, M. Munoz, G. Lucena.* Andalusian Stem Cell Bank, Univeristy Granada, Armilla, Granada, Granada, Spain.

Almost half of the human genome has been generated by the activity of mobile DNA elements, and their activity continues to shape the genome. Long Interspersed Element-1 (LINE-1 or L1) is a family of active non-LTR retrotransposons that comprise 17% of the human genome. An active LINE-1 element code for the proteins required to mediate their mobility (known as retrotransposition), and these proteins are also used by Short Interspersed Elements (SINEs) like Alu to mediate their mobility in trans. The mobility of L1 and Alu has resulted in a diverse range of diseases and it has been estimated that 1/10 newborn may contain a de novo L1/Alu retrotransposition event. As a type of selfish DNA, L1 and Alu might ensures its evolutionary transmission to new generations trough the accumulation of new insertions in germ cells or during early embryonic development. Human Embryonic Stem Cells (hESCs) represent an excellent model to study the accumulation of L1/Alu in early human development, and we recently described that L1 is expressed in these cells and that hESCs can accommodate a low level of L1 mobilization using a cell cultured based assay. In the present study, we adapted a previously characterized L1 antisense promoter to precisely map expressed L1s in undifferentiated hESCs and a straight cloning approach to determine the bulk of Alus expressed in hESCs. We found that several subfamilies of Alu are expressed in hESCs, and that the core from these elements is active in a cell culture based assay. Surprisingly, we found that the antisense promoter is conserved trough LINE-1 evolution, and that almost half of the expressed L1s are not present in the Reference Human Genome (RHG). Furthermore, we also described several locus shared by all hESCs lines analyzed that are characterized by active L1 expression, which suggest that L1 expression in the developing embryo might be linked to defined and discretes places of the genome.

## 2865/F/Poster Board #797

**Detection of small indels from next generation sequencing data by Bayesian evaluation of alternative haplotypes.** *C. Albers[1,2], W. Ouwehand[1,2], R. Durbin[2].* 1) Dept Haematology, University of Cambridge and National Health Service Blood and Transplant, Cambridge, United Kingdom; 2) Wellcome Trust Sanger Institute, Cambridge, United Kingdom.

Small insertions and deletions are the second most abundant type of variation in the genome and play a substantial role in genetic disorders. We present a probabilistic method for inferring small indels from next generation sequencing data.

In essence the method performs a local diploid reassembly of reads around a candidate indel site. For every candidate indel identified by gapped alignment of reads to the reference we first generate a set of 16 potential haplotypes incorporating combinatorially up to 4 local variants. Next we compute the likelihood of every read given each potential haplotype using a probabilistic alignment model that takes into account base qualities, mapping qualities and indels due to sequencing errors. From these likelihoods and additional priors we then infer the pair of haplotypes with the highest a posteriori probability.

We evaluated the method on 10 replicates of 46 bp paired-end reads simulated for a 5 Mb diploid region containing ~6000 SNPs and ~600 indels. Respectively 77.3 %, 96.5 % and 97.2 % of the simulated indels at 4x, 20x, and 40x were recovered as candidate indels after alignment with BWA [Li and Durbin, Bioinformatics 2009]. Using 16 potential haplotypes of 120 bp the false-positive rate was 0.06 %, 0.14 % and 0.17 % with sensitivities (of all simulated indels) of 50.0 %, 92.4 % and 94.6 % at respectively 4x, 20x and 40x. The SAMtools program [Li et al, Bioinformatics; in press] produced indel likelihoods an order of magnitude faster, but was less accurate with false-positive rates of 0.18 %, 2.7 % and 5.9 % at sensitivities of 9.1 %, 64.9 % and 91.4 % at respectively 4x, 20x, and 40x. Considering haplotypes allows us to call linked SNPs: at 40x our method identified 93 % of the SNPs within 35 bp of the candidate indels at a false-positive rate of 0.9 %. Our analyses suggest that considering additional local variants improves accuracy of the indel calls.

We applied the new method to the ~36x Illumina data for HapMap individual NA19240 sequenced as part of the 1000 Genomes project. We inferred 531770 indels of less than 11 bp, of which 299016 had a match in dbSNP within 10 bp. We show that discordance between our SNP genotype calls and the HapMap SNP genotype calls was significantly increased in the vicinity of indels.

## 2866/F/Poster Board #798

**A Variation Database for Amyotrophic Lateral Sclerosis.** *M. Yoshida[1], Y. Takahashi[2], A. Koike[1], Y. Fukuda[2], J. Goto[2], S. Tsuji[2].* 1) Central Research Laboratory, Hitachi, Ltd., Tokyo, Japan; 2) Graduate School of Medicine, University of Tokyo.

A variation database for amyotrophic lateral sclerosis (ALS) has been constructed as a publicly accessible online resource for recording all nucleotide and amino-acid variants identified in genes associated with ALS along with corresponding clinical conditions. ALS is a common neurodegenerative disorder worldwide, which is considered as a complex disease involving many genetic factors in the pathogenesis and pathophysiology. The database currently consists of more than 600 entries, including about 200 unique variants found in 33 disease-causative or disease-related genes. All sorts of variations including mutations, variants of uncertain pathogenic significance, and polymorphisms are accumulated. In addition to published data exhaustively collected from literature, novel variants identified by microarray resequencing in our laboratory are also incorporated in the database. Every reported gene has a respective page that provides information on its variation positions with various statistics, resulting clinical characteristics, and primary references as well as gene-sequence and protein-structure information which will assist in assessing the variation effects on gene and protein functions. Through a homology search function, users are able to find variations in arbitrary sequences of interest and check if they have already been described in the database. This database is expected to fulfill the essential need for integrating comprehensive information on genetic and clinical data regarding ALS. It will become a valuable tool for epidemiological and pathophysiological research through correlating genotypes with phenotypes in patients and evaluating the clinical significance of detected variations. In addition, it is intended to be a useful resource in actual clinical practice, especially as an aid to predicting disease course and prognosis based on clinical information of patients with the same mutations. The database is designed for inclusion of new variants when discovered, both from published data and from direct submission. Data submission is open to all researchers and highly encouraged. The database is accessible at the following URL: https://reseq.lifesciencedb.jp/resequence/SearchDisease.do?targetId=1. Acknowledgements: This study was supported by the integrated database project of MEXT.

## 2867/F/Poster Board #799

**Genetic variation in the *TCF7L2* gene in Mexican Amerindian populations.** *L. Del Bosque-Plata, S.N. Cazañas-Padilla, C. Acosta-Correa, H. Miranda, S. Hernandez, G. Jimenez-Sanchez.* National Institute of Genomic Medicine (INMEGEN), Mexico City, Mexico.

Variants in the *TCF7L2* gene confer high risk to type-2 diabetes (T2D), it encodes a transcription factor in the WNT signaling pathway and has also been associated to cancer. Several links between the WNT signaling, insulin secretion, and proliferation of human beta cells have been reported. Association of this gene and T2D, have been universally replicated, but risk alleles in the *TCF7L2* vary in the populations analyzed thus far. Given the particular demographic history and the high prevalence of T2D in the Mexican population, we re-sequenced its 17 exons, and ~300 bp flanking each exon in 30 Mexican Mestizos and the following Amerindian populations: 30 Zapotecan, 60 Mazatecan, and 32 Nahua. We identified complex patterns of variation in microsatellite length in introns 7 and 14. In exons 9 and 17 we found four non previously reported SNPs. There are frequency differences of these sequence variants between analyzed Amerindian groups. Pro490His was found in 20% of the Mazatecas (Oaxaca) and 21.9% in Nahuas (Veracruz), in contrast with 3.3% in Zapotecas from Oaxaca. In Nahuas, Pro502Thr and Pro502Pro were found in 9.4% for each polymorphism. In Zapotecas Pro490His (3.3%), Pro502Thr (6.7%), Pro502Pro (6.7%) have a similar frequency that in Mestizos Pro490His (3.3%), Pro502Thr (10%), Pro502Pro (10%). We have found novel SNPs in the *TCF7L2* gene, a gene that has been associated with DT2 in most of the populations of the world, some of which show particularly high frequency in some Amerindian populations in Mexico.

## 2868/F/Poster Board #800

**High-throughput variation scanning system of responsible genes for X-linked autistic disorder spectrum, *NLGN3* and *NLGN4*, by a PCR coupled high-resolution melting curve analysis.** *K. Tanaka[1,2], T. Kaname[2,3,4], H. Maehara[1], Y. Fukushima[4,5], K. Naritomi[2,4], K. Yanagi[2].* 1) Med , Orthopedic, Ryukyu Univ, Nishihara town, Japan; 2) Dept Med Genet, Univ Ryukyus, Nishihara, Japan; 3) Okinawa Cutting-Edge Genome Project; 4) SORST, JST, Tokyo, Japan; 5) Dept Med Genet, Shinshu Univ, Matsumoto, Japan.

It is important to establish an easy and reliable system to detect mutations or variations for gene examination and genetic association study. High-resolution melting curve analysis (HRM analysis) is a method, which allows simple and rapid detection of gene variations. We constructed a sensitive system for detecting gene variations in the *NLGN3* gene and *NLGN4* gene. In those genes, disease-associated mutations were found in patients with autism or Asperger syndrome. Some reports are pointed possibilities that the gene variations are associated with autistic disorder spectrum (ADS). Since it is, however, estimated that small number of patients will be affected by variations in those genes, a scanning system is needed to investigate correlations between the gene variations and ADS patients, which allows rapid detection of variations in large scale. We set up PCR/HRM system for all exons of *NLGN3* and *NLGN4* using combination with SYTO9 fluorescent dye (Invitrogen), Ex-Taq polymerase (TAKARA), and LightCycler 480 Instrument (Roche). Then we evaluated the PCR/HRM system in the screening known SNPs of both genes in 48 controls by confirming direct sequencing of amplicons. The PCR/HRM system could detect all the known and novel variations in 48 control individuals. Besides, the PCR/HRM discriminated not only each haplotypes in the same exon, but also between heterozygous and hemizygous or homozygous of those haplotypes. The system is a valuable method for rapid and reliable scanning of the *NLGN3* or *NLGN4* gene variations to survey variations in ADS patients.

## 2869/F/Poster Board #801

**Genome-wide genotyping of pooled samples for ancestry assessment of populations of unknown origin.** *Z.K.Z. Gajdos[1,2,3], C.W.C. Chiang[1,2,3], J.M. Korn[3], F. Kuruvilla[3], J.L. Butler[1,3], R. Hackett[3], C. Guiducci[3], T. Nguyen[1,3], H.N. Lyon[1,3], K.D. Henderson[4], C. Haiman[5], L. Le Marchand[6], B. Henderson[5], M.R. Palmert[7], R. Wilks[8], T. Forrester[8], C.A. McKenzie[8], R.S. Cooper[9], X. Zhu[10], J.N. Hirschhorn[1,2,3].* 1) Children's Hospital Boston, Boston, MA; 2) Harvard Medical School Department of Genetics, Boston, MA; 3) Broad Institute, Cambridge, MA; 4) City of Hope National Medical Center, Duarte, CA; 5) University of Southern California, Los Angeles, CA; 6) University of Hawaii, Honolulu, HI; 7) Hospital for Sick Children, Toronto, Canada; 8) University of the West Indies at Mona, Mona, Jamaica; 9) Stritch School of Medicine, Loyola University of Chicago, Chicago, IL; 10) Case Western Reserve University, Cleveland, OH.

Genetic ancestry is an important covariate to include when conducting genetic association studies to reduce the possibility of spurious associations. There are two main methods currently used to estimate global genetic ancestry: genotyping a set of known ancestry informative markers (AIMs) or assessing individual-level genome-wide genotype data. However, AIMs are only useful if the ancestral populations are known with confidence and there are known AIMs, and individual-level genome-wide data are expensive to obtain for large numbers of individuals. Here we present admixture proportion estimation data from pooled genome-wide genotype data to demonstrate that pooling can be an effective method to estimate genetic ancestry when neither AIMs nor individual-level genome-wide data are available. We genotyped pooled DNA samples from four cohorts (one African-American, two Jamaican, and one Native Hawaiian) using the Affymetrix 6.0 array. After removing poorly performing SNPs, we estimated allele frequencies in the pooled samples. We used these allele frequencies and the HapMap populations as reference panels in a regression-based analysis for estimating admixture proportions relative to the HapMap references in these cohorts. The admixture proportions in the African-American cohort were estimated at ~82% YRI (West African) and ~18% CEU (European) ancestry, and the Native Hawaiian cohort was estimated at ~60% CHB+JPT (East Asian), ~32% CEU, and ~6% YRI. These estimates are very similar to those obtained using genotype data from known AIM loci that distinguish the HapMap populations. One of the Jamaican cohorts was estimated to be ~86% YRI and ~12% CEU and the other Jamaican cohort was estimated to be ~82% YRI and ~10% CEU. There appears to be a missing component of ancestry in the 2nd Jamaican cohort that remains unknown. To identify any additional components of ancestry and additional AIMs for each of our samples, we constructed corresponding "pseudopopulations" using the HapMap reference panels, weighted according to our ancestry estimates. We identified putative population-specific AIMs as those with large allele frequency differences between pooled estimates and that expected based on the pseudopopuation. A subset of putative AIMs was validated by individual genotyping in the samples that comprise the pools, demonstrating that a pooling approach can be effective for identifying markers that are highly informative for genetic ancestry.

## 2870/F/Poster Board #802

**Personal genome interpretation with the Genome Commons and the Genome Commons Navigator.** *S.E. Brenner.* University of California, Berkeley, CA.

The acquisition of individuals' genomes has long been the aspiration of the human genomics, and sequencing technologies promise to make this affordable within the next several years. Already, large-scale genotyping arrays are widely used in research and retail DNA tests of genetic markers have captured the public's imagination. Unfortunately, today one can do little of value with a personal genome, due to a variety of scientific, technical, legal, sociological, and ethical challenges.

We are constructing a Genome Commons Database and Genome Commons Navigator, open-source open-access research resources aiding the scientific interpretation of personal genomes. The Genome Commons Database will be an integration and augmentation of existing data sources of genetic variation and human disease, drawing from many locus-specific databases, as well as large public data sources such as dbSNP, dbGaP, OMIM, GeneTests, and PharmGKB. We are also developing a curators' toolkit to facilitate manually verified entry of data into the commons, so that individuals with expertise can readily submit data and improve data quality. The Genome Commons Navigator prioritizes and predict phenotypes of genetic variants within an individual genome, by applying knowledge from the Genome Commons Database and methods for assessment of novel variants. The Genome Commons Navigator will be an open framework that draws upon the Genome Commons database as well as an array of plug-in modules. These modules already exist as stand-alone tools, but the ability to assess and apply them has sharply limited by their inability to deploy them within a comprehensive analysis environment such as the Navigator will provide.

We plan for the Genome Commons and Navigator to be initially used in the research community to improve the methods to make new discoveries. However, with consumer and medical interest in personal genomics growing and sequencing costs plummeting, we our long term aim is to develop methods applicable to clinical practice. We will look towards the eventual prospect of the Genome Commons being deployed in within academic and commercial clinical laboratories with appropriate ethical and regulatory oversight. Ultimately, we envision the Commons as a repository of our common human inheritance would be a vast resource for research and medicine.

**Genome-Wide Association Study of Fractional Excretion of Sodium (FENa).** *H.S Jin[1], K.W Hong[1], J.E Lim[1], M.J Go[2], J.Y Lee[2], S.H Lee[3], C. Shin[4], H.K Park[1], B. Oh[1].* 1) Department of Biomedical Engineering, School of Medicine, Kyung-Hee University, Seoul, Korea; 2) Center for Genome Science, National Institute of Health, Seoul, Korea; 3) Department of Internal Medicine, Kyung Hee University East-West Neo Medical Center, Seoul, Korea; 4) Division of Pulmonary and Clinical Care Medicine, Department of Internal Medicine, Korea University Ansan Hospital, Ansan, Korea.

Fractional excretion of sodium (FENa) is the percentage of sodium excreted in the urine versus the sodium reabsorbed by the kidney. Resorption of sodium constantly maintains the osmotic-pressure of plasma, which ensures the appropriate exchange of electrolytes in cells and extracellular environments. To investigate genetic factors that affect FENa, genome-wide association studies were conducted in two independent cohorts, Ansung (n=1,019), and Ansan (n=1,568) in Korea. The genotypes were determined by Korea Association Resource consortium (KARE) using Affymetrix SNP array 5.0. Linear regression analyses were conducted for FENa in each cohort with controlling covariates by age, sex, body mass index, and mean arterial pressure. Also, we performed the same analysis to the combined data set of Ansung and Ansan including cohort as an additional covariate. In this study, there was no signal reaching genome-wide significant p-value criterion ($p=5 \times 10\text{-}7$). This phenomenon may be attributed to genetic effect of FENa is low or multi-locus effects, and our samples were a small number for GWAS study. All associated SNPs showed moderated signals with (p-value < 0.01). Among the moderately associated SNPs, 17 SNPs revealed repeated association in both cohorts. These SNPs located on four known gene loci, in CSMD2 (rs1536110, $p=2.25 \times 10\text{-}5$), in CIB4 (rs935172, $p= 2.65 \times 10\text{-}5$), in XKR4 (rs9298526, $p=5.39 \times 10\text{-}5$), and in ESCO1 (rs12373434, $p=6.29 \times 10\text{-}5$), and one unknown gene in KIAA1772 (rs8086339, $p=4.25 \times 10\text{-}5$). Although, significant SNPs were not satisfied GWAS basis, this study is the first genome-wide association study of FENa. This study for the association of genetic variations with FENa in cohorts of Korean population will be worth validated in the other populations and will highlight mechanisms that influence FENa.

## 2872/F/Poster Board #804

**Determination of haplotypes and estimation of haplotype frequencies by detecting homozygotes with genome-wide SNP genotypes of 3,397 individuals from the Japanese population.** *Y. Yamaguchi-Kabata[1], A. Takahashi[1], T. Tsunoda[2], N. Hosono[3], M. Kubo[3], Y. Nakamura[4,5], N. Kamatani[1].* 1) Laboratory for Statistical Analysis, Center for Genomic Medicine, RIKEN, Tokyo, Japan; 2) Laboratory for Medical Informatics, Center for Genomic Medicine, RIKEN, Yokohama, Japan; 3) Laboratory for Genotyping Development, Center for Genomic Medicine, RIKEN, Yokohama, Japan; 4) Human Genome Center, Institute of Medical Science, University of Tokyo, Tokyo, Japan; 5) Center for Genomic Medicine, RIKEN, Yokohama, Japan.

Understanding haplotype structure and haplotype frequencies is important for associating genetic polymorphisms with a given trait and for inferring genetic genealogy of alleles in a population. Haplotypes can be determined without ambiguity when an individual does not have more than one heterozygous site at the genomic region. Taking advantage of a large size of genome-wide SNP genotype data from 3,397 individuals from the Japanese population, we attempted to examine the accuracy and efficacy of the estimation of population haplotype frequencies based on the data from homozygotes for each chromosomal region. We compared the haplotype frequencies estimated by our method with the inferred haplotype frequencies estimated by two statistical methods. The comparison showed that the haplotype frequencies estimated from the proportions of homozygotes were very similar to the results obtained by the statistical methods, PHASE and SNPHAP. The haplotype frequencies were also compared to those from the 'definitive haplotypes' from 74 complete hydatidiform mole samples in D-haploDB, and the haplotype frequencies were quite similar. Determination of haplotypes from homozygotes using the genotype data from thousands of individuals appears to be useful for detecting real haplotypes that exist at relatively low frequencies. In addition, the detected haplotypes with the estimated frequencies will be a catalogue of haplotypes for the population, which is useful for study design of GWAS to search for causative variants for the trait from the most associated SNPs.

## 2873/F/Poster Board #805

**Identification of loci influencing Toll-like receptor 7-induced innate immune responses in HapMap B-lymphoblastoid cell lines.** *J.L. Strout, F. Radella, S. Stratton, M.M. Wurfel.* Division of Pulmonary and Critical Care Medicine, Harborview Medical Center, University of Washington, Seattle, WA.

**Background:** Recognition of single-stranded RNA present in viruses such as influenza and HIV is mediated by Toll-like receptors 7 and 8 (TLR7/8), and leads to activation of an innate immune response. These responses could be influenced by common genetic polymorphisms, altering susceptibility to infection. B-lymphoblastoid cell lines (B-LCL) used in the HapMap project can be stimulated to produce inflammatory cytokines via the TLR7 receptor, and therefore, are a valuable resource for the discovery of loci influencing TLR-mediated responses. **Hypothesis:** Loci affecting innate immune inflammatory responses to a TLR7 agonist can be identified using B-LCL from HapMap trios. **Methods:** We exposed Epstein-Barr Virus transformed B-LCL from 30 Caucasian (CEU), and 30 Yoruban (YRI) trios (International HapMap project populations) to CL097, an imidazoquinoline compound that is a specific agonist for TLR7. After a 24 hour incubation, we measured levels of IL6, IL10, and TNF$\alpha$ in the culture supernatants. We then used QFAM in PLINK to determine associations between genotypes present in HapMap (Release 23) and the three different TLR7-mediated inflammatory responses (TNF$\alpha$, IL6, IL10). We also evaluated the differentiation state of the B-LCLs, by measuring the expression of five cell surface markers by flow cytometry, and soluble IgG and IgM production. **Results:** We identified 29 loci in CEU and 18 loci in YRI ($p<1 \times 10\text{-}5$) that associated with TLR7-induced cytokine responses. Of these, 10 CEU, and 6 YRI loci were associated with multiple cytokine responses. While no single polymorphism was found to be significant at this level in both populations, we did identify 15 gene regions in which overlapping associations were observed. We identified only marginal (p<0.01) associations between cell surface expression of CD95 (FAS) and TLR-7-induced responses in CEU and YRI. Likewise, differentiation state, as measured by IgM production, showed only a moderate association (p<0.01) with TLR-7 induced responses, but only in CEU. **Conclusion:** HapMap B-LCLs are a valuable resource for identifying the genetic determinants of the TLR-7 mediated innate immune response.

**CFTR gene's mutational spectrum in Mexican patients diagnosed with cystic fibrosis.** *M. Chávez-Saldaña[1,2], E. Yokoyama[1], J. Lezana[3], A. Carnevale[4], M. Macias[1], R. Vigueras[1], M. López[5], L. Orozco[6].* 1) HISTOMORFOLOGIA, INSTITUTO NACIONAL DE PEDIATRIA, Mexico City, Mexico; 2) Doctorado en Ciencias Biológicas, Universidad Autónoma Metropolitana, Mexico City, Mexico; 3) Hospital Infantil de México "Federico Gómez" S.S. Mexico City, Mexico; 4) Coordinación Nacional de Medicina Genómica, ISSSTE, Mexico City, Mexico; 5) Departamento de Sistemas Biológicos. Universidad Autónoma Metropolitana, Campus Xochimilco, Mexico City, Mexico; 6) Laboratorio de Genómica de Enfermedades Multifactoriales. Instituto Nacional de Medicina Genómica, Ciudad de México, México.

Cystic fibrosis is the most common autosomal recessive disease. In Mexico, at the National Institute of Pediatrics, 20 new cases are registered annually. To date, over 1,600 mutations have been described related to the causative gene. Mutation distribution varies on the different populations world wide. In this study, we hope to establish the CFTR gene's mutational spectrum in Mexican patients diagnosed with cystic fibrosis. A total of 230 non-related patients were analyzed. The characterization of the alleles was done using a commercial kit for 36 mutations, as well as a simple chain conformational polymorphism method and DNA sequencing. With the combination of these strategies was able to characterize 77.3% of all alleles with CF and twelve different mutations were added to the 34 previously reported, making a total of 46 different mutations detected in the Mexican population. Only seven mutations showed a frequency more than 1%: DF508 (44.6%), G542X (7.4%), N1303K (2.4%), DI507 (1.52%), S549N (1.52%), R334W (1.52%), and 3849 +10 kbC -T (1.3%). The two last mutations are included in the panel of the most frequent mutations in the Mexican population, reported in this study. Is important to note that to know the ethnic and geographical distribution of CFTR mutations could improve the CF detection programs in a given population. In this way is essential to increase knowledge about of the molecular genetic and epidemiology of this disease in our country, to develop methods of diagnostic more effective and to improve the cost-benefit of studies. Support CONACYT-SALUD 2003-C01-066 and specifically CONACYT for a full scholarship number 89745.

## 2875/F/Poster Board #807

**Genomic survey of loss-of-heterozygosity status in Glioblastoma Multiforme using sequencing data.** *R. Dominguez-Vidana[1, 2], R.A. Gibbs[1], D.A. Wheeler[1], L.A. Donehower[1,3].* 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 2) Interdepartamental Program in Cell and Molecular Biology, Baylor College of Medicine, Houston, TX; 3) Department of Molecular Virology and Microbiology, Baylor College of Medicine, Houston, TX.

Glioblastoma Multiforme (GBM) is the most common and malignant of the glial tumors. It is a mixture of poorly differentiated astrocytes located preferentially in the cerebral hemispheres. GBM primarily affects adults; and manifests mostly de novo. It is estimated that the median survival time from diagnosis is approximately 14 months; and approximately only 1 in 5,000 patients survives more than 5 years. The Cancer Genome Atlas (TCGA) pilot project reported an integrative analysis of mutations, CNVs, gene expression and DNA methylation patterns in 206 GBMs. Provided insights into the roles in the disease of *ERBB2, NF1* and *TP53*, *PIK3R1*, and revealed a link between *MGMT* promoter methylation and a hypermutator phenotype, and, most importantly, provided a network view of the altered pathways. A Johns Hopkins's University project also studied GBMs, finding recurrent mutations in *IDH1*, associated with increased survival. Both of these studies established the power of unbiased genomic analyses in the characterization of brain cancer. The purpose of this study is to identify which genes show a statistically significant loss of heterozygosity (LOH). Mutation files were compiled; and unvalidated, and silent mutations were removed from the analysis. Valid mutations were split into missense mutations, and LOH. This hits were crossed with KEGG, manually curated, and other previously delimited pathways. From these analyses several genes were identified with a recurrent LOH pattern, like: *MKI67, NRAP, C10orf54, C9orf66, PRAME, IL1RL1, ABCA13, GDF15, KIAA1632, PALM2-AKAP2, PTPRR, SERPINA6, TP53, TRPM3*. Further analyses are required to elucidate their functional roles in GBMs. This type of analyses shows that combining current pathway data with SNP data can allow identifying potential new genomic alterations that can contribute to carcinogenesis.

**Genetic Control of DNA Methylation and Expression in the Human Brain.** *D.G. Hernandez[1, 2], R. Gibbs[1, 2], M. van der Brug[1, 3], B. Traynor[1], M. Nalls[1], L. Shiao-Lin[1], S. Arepalli[1], R. Zonozi[1], A. Dillman[1], J. Troncoso[4], R. Johnson[5], H. Zielke[5], L. Ferrucci[6], D. Longo[7], M. Cookson[1], A. Singleton[1].* 1) Laboratory of Neurogenetics, National Institute on Aging, National Institutes of Health, Bethesda, MD, 20892, USA; 2) Department of Molecular Neuroscience and Reta Lila Weston Laboratories, Institute of Neurology, UCL, Queen Square House, London WC1N 3BG, United Kingdom; 3) Department of Molecular and Integrative Neurosciences, The Scripps Research Institute, 130 Scripps Way, Jupiter, FL 33458, USA; 4) Division of Neuropathology, Department of Pathology, School of Medicine, Johns Hopkins University, Baltimore, Maryland 21205, USA; 5) University of Maryland Brain Bank, University of Maryland School of Medicine, Baltimore, MD 21201, USA; 6) Clinical Research Branch, National Institute on Aging, Baltimore, MD, USA; 7) Lymphocyte Cell Biology Unit, Laboratory of Immunology, National Institute on Aging, National Institutes of Health, Baltimore, MD, USA.

An important challenge in the post-genome era is to annotate and understand the effects of genetic variation, particularly within the context of human tissues. Fortunately, the technology is now in place to investigate epigenetic variation and gene expression from a whole-genome perspective. Comprehending how these multiple layers of control interact in a complex and heterogeneous tissue such as the brain is a challenge that can be addressed using high throughput technologies designed to capture large amounts of information for each level of variability. In this study, we investigated the effects of common genetic variability on DNA methylation, mRNA expression and microRNA expression in the frontal cortex and cerebellum regions of 400 normal human brains. We found an abundance of genetic cis regulation of mRNA expression and show novel quantitative trait loci for DNA CpG methylation. Integrating genetic, epigenetic and expression data not only allows an understanding of the normal regulation of DNA methylation and gene expression in the human brain, but acts as an essential first step toward understanding the pathobiological consequences of genetic variants linked to disease. These functional maps also offer the opportunity to form inferences regarding relationships between genes based on patterns of co-regulation and present an a more complete view of the multiple levels of gene regulation in the human brain.

**Buccal Cell DNA for Population Studies: Comparative analysis with corresponding blood DNA validates the use of buccal DNA for high-throughput genotyping.** *M. Karim, S. MacLeod, C. Randolph, W. Zhao, C. Hobbs.* Dept Pediatrics, Arkansas Children's Hospital Research Institute, Little Rock, AR.

Cost-effective and non-invasive methods for DNA collection are required for high-throughput genetic analysis. Peripheral blood is an excellent source of large amounts of high quality DNA, however obtaining peripheral blood samples is a costly, invasive procedure and requires well trained, skilled professionals with proper materials. In addition, the collection of blood from newborn babies and obese individuals is often very tedious, requiring multiple needle sticks. On the other hand the buccal cell collection for DNA is easier, cheaper and usually self collected by study subjects. In order to validate the use of buccal cell-derived DNA in a high throughput genotyping platform, we used DNA from a total of 96 mothers (16 to 40 years) for whom DNA derived from both blood lymphocytes and buccal cells was available. We have evaluated and compared an alternative, less invasive protocol for isolation of DNA from buccal cells with the corresponding blood derived DNA from the same individuals and tested for the outcome of genotyping 1536 single nucleotide polymorphisms (SNPs) for each individual. Whole genome amplification (WGA) was performed on all buccal DNA samples by the use of the GenomePlex® Complete Whole Genome Amplification (WGA) Kit (Sigma, St. Louis, MO). The genotyping data showed (98.2%) concordance between genotype calls for buccal and blood extracted DNA. Our results suggested the non-invasive buccal cell collection in conjunction with WGA results in sufficient DNA for large-scale high-throughput genotyping studies with high concordance of genotype calls compared to genomic DNA derived from blood cells.

## 2878/F/Poster Board #810

**The relation between the change of functional cardiac parameters and SNPs in GSTP1 and CBR3 after doxorubicin chemotherapy.** *M. Alikasifoglu[1], B. Volkan-Salanci[2], E. Tulumen[3], P.O. Kiratli[4], B. Oksuzoglu[5], N. Guler[6], L. Tokgozoglu[3], B. Erbas[4].* 1) Medical Genetics Dept, Hacettepe University Medical Faculty, Ankara, Turkey; 2) Institute of Childs Health, Genetics Unit, Hacettepe University Medical Faculty, Ankara, Turkey; 3) Cardiology Dept, Hacettepe University Medical Faculty, Ankara, Turkey; 4) Nuclear Medicine Dept, Hacettepe University Medical Faculty, Ankara, Turkey; 5) Internal Medicine Dept, Ankara Numune Egitim ve Arastirma Hastanesi, Ankara, Turkey; 6) Medical Oncology Dept, Bayindir Hastanesi,-Ankara, Turkey.

Background: Cardiotoxicity is an important adverse effect of anthracycline chemotherapy. Although it is known to have a dose dependent effect, studies have shown variances in individual response, due to genetic background. Glutathione S transferase P1 (GSTP1) is responsible for the detoxification of doxorubicin (Dox), and carbonyl reductase 3 (CRB3) converts Dox to doxorubicinole. Genetic variants of GSTP1 and CRB3 may be contributory to pharmacokinetic and pharmacodynamic variability of Dox. Aim of this study was to investigate the relationship between genetic polymorphisms of GSRP1 (A313G) and CBR3 (V244M) and cardiotoxic effect of Dox assessed by ECG-gated blood pool SPECT (SPECT) and echocardiography (E). Materials and methods: Sixty-eight (61 F, 7 M) patients, with normal baseline cardiac function, was included. Chemotherapy combinations contained either Dox or epirubicin as 1st line chemotherapy. Systolic and diastolic cardiac functions were evaluated before and after therapy (mean follow-up:10.4 months± 4.7) using E and SPECT. Left ventricular ejection fraction (EF), peak filling rate (PFR), peak ejection rate (PER), end systolic volume (ESV), end diastolic volume (EDV) values were calculated using SPECT data. GSTP1 and CBR3 polymorphisms were analyzed using TaqMan probes. Results: The mean received Dox dose was 511 ± 146 mg/m2 (210-1188). Fifteen patients (28 %) received adjuvant radiotherapy over the cardiac region. HER2 antagonists were given in 7 patients after chemotherapy. EF values were significantly decreased after Dox with both SPECT and E ($p<0.01$, $p= 0.043$). In 1 patient EF was below 40% after 7 months at 600 mg/m2 of Dox ESV ($p=0.028$) and diastolic parameters; (Mi) e wave deceleration time ($p<0.001$), Mi color propagation ($p=0.001$), and PFR ($p= 0.038$) deteriorated significantly after therapy. Patients who received HER2 antagonists and radiation to cardiac region, showed higher ESV % change ($p=0.015$, 0.013) compared to others. The difference between cardiac parameters and CBR3 genotypes were not significant. GSTP1 polymorphism's AA genotype revealed higher ESV % increase (9.4 ml ± 10) when compared to G allele carriers (GG and AG) (3.09 ml ± 10) after Dox treatment ($p=0.02$). Conclusion: This prospective clinical study showed a significant relationship between GSTP1 (A313G) polymorphism and ESV change after Dox treatment. GSTP1 genotypes may contribute to Dox cardiotoxicity and might be used in dose adjustment in the future.

## 2879/F/Poster Board #811

**Single Nucleotide and Structural Variant detection using paired end sequence data.** *S. Gopalakrishnan, Z.S. Qin.* Biostatistics, University of Michigan, Ann Arbor, MI.

The emergence of short read sequencing has brought us large datasets, which present us with opportunities to find rare disease predisposing variants. Sequence data includes variants that may occur only in the sequenced individual. The first step involved in analysis is identifying single nucleotide variants and separating them from sequencing errors. In our previous work, we presented methods for identifying single nucleotide variants (SNV) using single end data. Here, we propose a new method for identifying SNVs using paired end short read sequence data. Current methods use only the read pairs where both reads of the pair are mapped uniquely to the genome. In our data, about 25-30% of the read pairs are lost due to multiple mapping and/or the inability to map one read of the pair. Extending our previous work, we allow both read ends to be mapped to multiple locations, and choose the appropriate alignment of the reads based on our algorithm. We also allow orphaned reads that have only one read end mapped to the genome to contribute to the inference procedure. Our method is based on a Bayesian Gibbs sampling approach with a continuous prior based on the insert length of read pairs. We run an iterative procedure that chooses read alignments for the multiply mapped paired end and orphaned reads. We infer SNVs based on the final alignment given by the algorithm. Another consequence of using paired end data is the inbuilt information present about structural variants. In addition to SNVs, we also identify genomic locations that are candidate structural variants. We use a sliding window based likelihood ratio test based on insert length and depth of coverage to test for structural variants. Once candidate regions are found, one can carry re-sequence across the inferred boundary to verify the presence and type of structural variant. Preliminary results indicate that we find a lot more SNVs and structural variants by using our algorithm than using only the uniquely mapped paired end reads.

## 2880/F/Poster Board #812

**Follow-up with dense SNP genotyping in NTRK2 continues to show significant association to LOAD.** *R.T. Perry[1], H.W. Wiener[1], R.C.P. Go[1,2].* 1) Dept. Epidemiology, Res Asst Prof, Univ Alabama at Birmingham, Birmingham, AL; 2) Pacific Health Research Institute, Honolulu, HI.

Linkage scans of Alzheimer's Disease (AD) families have identified the 9q22 region as a candidate region. Next to the 19q13 peak where *APOE* is located, the 9q22 signal was the most suggestive from the linkage scan of the NIMH Alzheimer's Disease Genetic Initiative (ADGI) family cohort. Follow-up confirmation of this signal was demonstrated when we genotyped additional microsatellite markers, narrowing the 1 LOD region to 11.5 cm. Four candidate genes located adjacent to the proximal edge of this peak have been reported to be associated with AD from candidate gene and genome wide association studies. We reported a significant association of a three SNP haplotype (designated, SNPs 4, 5, 6) in one of these genes, *NTRK2*, in the NIMH-ADGI cohort. *NTRK2* belongs to the neurotrophic tyrosine receptor kinase (*NTRK*) family, which includes *NTRK1*, *NTRK2*, and *NTRK3*. The *NTRK* family encodes the receptors TRKA, TRKB, and TRKC, to which the neurotrophins, nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF) and neurotrophin-3 (NT-3) bind respectively, with high affinity. Signaling through the NTRK family of receptors appears to be compromised in AD. There are three alternatively spliced isoforms that are differentially expressed between the brain and other tissues and between the frontal cortex of AD and control brains and they involve exons located in the same area of the gene where the three SNP haplotype is located. In order to delineate this association further, we have identified and genotyped all the haplotag SNPs located in the 10 LD blocks spanning and bordering the three SNPs and additional SNPs located between the blocks (Total = 47) in LOAD families of the NIMH-ADGI cohort. Single locus results were suggestive of association around SNP 4; therefore, we performed haplotype analyses from adjacent SNPs to increase heterozygosity and genetic information. Under a dominant model, we found significant association for two SNP haplotypes adjacent to SNP 4 and upstream of SNP 5 (pvalue 0.0006, 0.0005, respectively). Similar results for SNPs in these two areas were obtained for three SNP haplotypes. We are now in the process of confirming these associations by genotyping the most significant SNPs in a separate LOAD family cohort of 899 samples in 201 families from the National Cell Repository for Alzheimer's Disease (NCRAD). Results will be presented at the meeting.

## 2881/F/Poster Board #813

**Ascertainment biases in SNP chips affect measures of population divergence.** *A. Albrechtsen[1], F. Nielsen[2], R. Nielsen[3].* 1) Dept biostatistics, Copenhagen Univ, Copenhagen, Denmark; 2) Department of Clinical Biochemistry, Rigshopitalet, Copenhagen,Denmark; 3) Department of Integrative biology and Statistics, University of California Berkeley, USA.

Chip based high throughput genotyping has facilitated genome-wide studies of genetic diversity. Many studies have utilized these large data sets to make inferences about the demographic history of human populations, using measures of genetic differentiation such as FST or principal component analyses. However, the SNP chip data suffer from ascertainment biases caused by the SNP discovery process in which a small number of individuals from selected populations are used as discovery panels. In this study, we investigate the effect of the ascertainment bias on inferences regarding genetic differentiation among populations in one of the common genome-wide genotyping platforms. We generate SNP genotyping data for individuals, that previously have been subject to partial genome-wide Sanger sequencing and compare inferences based on genotyping data to inferences based on direct sequencing. In addition we also analyze publicly available genome-wide data. We demonstrate that the ascertainment biases will distort measures of human diversity and possibly change conclusions draw from these measures in some times unexpected ways. We also show that details of the genotyping calling algorithms can have a surprisingly large effect on population genetic inferences. We present a correction of the spectrum for the widely used Affymetrix exttrademark SNP chips but also show that such corrections are difficult to generalize among studies.

## 2882/F/Poster Board #814

**Population Genomics of Human Gene Expression using Next-Generation RNA Sequencing.** *S.B. Montgomery[1,2], C. Beazley[1], C. Ingle[1], J. Nisbett[1], R. Lach[1], J. O'Brien[1], S. Searle[1], S. White[1], E.T. Dermitzakis[1,2].* 1) Population & Comparative Gen, Wellcome Trust Sanger Inst, Cambridge, United Kingdom; 2) Department of Genetic Medicine and Development, University of Geneva Medical School, Geneva, Switzerland.

Understanding the genetic basis of gene expression variability is a fundamental component in building our understanding of the etiology of complex traits. We have previously investigated the proximate causes of expression variability in natural populations genotyped as part of the HapMap project (Stranger et al. Science 2007 and Nat Genet. 2007). Recent advances in next generation RNA sequencing (RNA-seq) have enabled increased resolution of expression variability and transcriptional complexity providing access to features such as alternative splicing, isoform quantitation and allele-specific expression. We have investigated population differences in gene expression in lymphoblastoid cells from 60 HapMap CEU individuals of European descent, also sequenced in the 1000 genomes project, using 37-bp paired-end RNA-seq. Using a single lane of an illumina sequencing reaction, we have obtained 10 million reads per individual which cover ~ll,000 known genes and ~95,500 known exons. We detect high correlation of read counts across individuals and have investigated technical sources of discordance. We have investigated the potential of imputation of read counts between well-quantified exons (>50 reads) and have seen intermediate correlation (SRC: 0.4-0.5). We have detected expression quantitative trait loci (eQTLs) using the HapMap3 genotypes and compared them to those obtained from the same individuals in an array-based study. We find a significant enrichment of sharing in association between the two but have also identified specific differences which are likely due to higher resolution of the RNAseq data. RNA-seq eQTLs are distributed around the transcription start site as observed in array data but we have also seen a substantial enrichment within the gene and outside. Known splice variants also seem to have a large impact on levels of expression from different exons supporting the idea that the resolution of the RNAseq data allows for the identification of the effect of splicing variants. Finally, we will discuss our observations of de novo gene structure and allele-specific expression and eQTLs discovered by integrating the 1000 genomes low coverage genotype data.

**High-throughput Polymorphism Detection and Genotyping Using Next Generation Sequencing Technology.** *Z. Deng[1,2], M. Yeager[1,2], L. Amundadottir[2], L. Qi[1,2], J. Boland[1,2], C. Matthews[1,2], A. Hutchinson[1,2], S.J. Chanock[2].* 1) Core Genotyping Facility, Advanced Technology Program, SAIC-Frederick Inc., NCI-Frederick, Frederick, MD; 2) Division of Cancer Epidemiology and Genetics, NCI, NIH, Bethesda, MD.

Targeted re-sequencing of genomic regions associated with human diseases is required to follow-up signals conclusively identified by genome-wide association studies. Sequence-based variation discovery makes it possible to produce a comprehensive list of genetic polymorphisms and subsequent functional studies can be preformed to identify potential causal variants from the regions of interest. Recently, massively parallel sequencing technologies have become the preferred choice for targeted re-sequencing. However, the high-throughput nature of the next generation sequencing has posed new challenges to downstream data analysis. We have developed a high-throughput computational pipeline to process next generation sequence data for single nucleotide polymorphisms (SNP) and insertion/deletions (INDEL) discovery and genotyping. Briefly, sequence reads that passed QC were aligned to the target genomic region by MOSAIK software. The alignment parameters were optimized based on the repetitive nature of the target region. The resulting assembly was analyzed in a column-by-column approach and potential polymorphic sites and most likely genotypes were called based on a set of heuristic rules. Next, the completion rates were determined and loci with low completion rates were removed from further analysis. Lastly, manual inspections aided by the NextGENe software and CONSED were performed to QA the results and resolve ambiguous cases. To validate this computational pipeline, we have analyzed sequence data from three targeted re-sequencing projects covering a total of 290 kb genomic regions. Genotype calls on more than 2,500 polymorphic sites were made with high accuracy (>98% for SNP). Comparisons with dbSNP indicated that about half of the variants are novel. Minor Allele Frequencies distribution analysis and Hardy-Weinberg fitness analysis showed no major deviations for most polymorphic sites. To further validate the genotype results, concordance checks were performed on 41 HapMap samples included in the sequencing projects. The results showed near perfect concordant rates (>98%), indicating high accuracy of our approach. In summary, we have developed and validated a high-performance computational pipeline and demonstrated its utility in targeted re-sequencing projects. Funded by NCI Contract No. HHSN261200800001E.

## 2884/F/Poster Board #816

**Rapid Detection of Ashkenazi Jewish Carrier Screening Using the AutoGenomics INFINITI BioFilmChip Microarray.** *M. Procter[1], L.Z. Chou[1], A. Marchese[3], S. Moledina[3], R. Mao[1, 2].* 1) Res & Development, ARUP Lab, Salt Lake City, UT; 2) Department of Pathology, University of Utah, Salt Lake City, UT; 3) AutoGenomics, Carlsbad, CA.

Background: Jewish persons of eastern European descent, referred to as Ashkenazi Jews, are at higher carrier risk of certain genetic diseases than the general population. The American College of Obstetricians and Gynecologists (ACOG) recommends genetic testing for prospective parents of Ashkenazi Jewish descent for mutations associated with the following conditions: Tay-Sachs, Canavan, Familial Dysautonomia, and Cystic Fibrosis. Furthermore ACOG recommends that testing be offered to these same individuals for mutations associated with 5 additional diseases. These diseases are all autosomal recessive, 20-100 times more frequent in the Ashkenazi Jewish population, and associated with debilitating or life-threatening conditions. In a collaboration between ARUP and AutoGenomics, a BioFilmChip Microarray was developed to screen 30 mutations and 1 polymorphism in all these diseases except Cystic Fibrosis, which is usually a stand-alone test. We evaluated the feasibility and utility of using this assay in our molecular genetics laboratory. Methods: The polyester film-based chip consists of 240 spots contained replicates of the 30 loci. These mutations are detected using PCR followed by hybridization to a chip. Samples were hybridized, incubated and detection took place in an automated Infiniti instrument manufactured by AutoGenomics. To determine accuracy of this assay, DNA from 35 samples with various mutations for Ashkenazi Jewish diseases detected by this panel was used. We used DNA from Coriell Cell Repositories and known-positive and known-negative samples from ARUP's clinical genetics laboratory. Results and conclusion: One-hundred percent concordance was observed in the samples tested, except for one sample with 3 no-call results. Our study showed this test to be, reliable and robust in the detection of a large number of mutations associated with Ashkenazi Jewish diseases. This BioFilmChip Microarray assay can simultaneously detect many mutations in a single reaction while the automated 24-well format allows high sample throughput for a large population screening. Further testing for reproducibility and limit of detection is in progress.

## 2885/F/Poster Board #817

**Genetic Associations with Lactase Dehydrogenase, Anion Gap, and Hepatitis in the Third National Health And Nutrition Examination Survey (NHANES III).** *M.J. Rieder[1], K. Brown-Gentry[2], J. Canter[2], D.C. Crawford[2].* 1) Dept Genome Sciences, University of Washington, Seattle, WA; 2) Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

Serum lactate dehydrogenase (LDH) is a heritable (35-60%) intermediate phenotype that is associated with trauma mortality and hemolysis. LDH catalyzes the interconversion of pyruvate and lactate, and is a multimeric protein encoded by *LDHA*, *LDHB* and *LDHC*. Pyruvate production is controlled by the pyruvate dehyrodrogenase complex, encoded by *PPM2C*. One measure of anion imbalance and LDH levels is calculated anion gap ($[Na^+]+[K^+]$)-($[Cl^-]+[HCO3^-]$). We hypothesized that genetic variation in the enzymes for LDH production influences serum levels, calculated anion gap (AG), or tissue injury (e.g hepatitis infection). We selected and genotyped 13 *LDHA/B/C* and *PPM2C* tagSNPs in 7157 participants from the Third National Health and Nutrition Examination Survey (NHANES III). NHANES III is a diverse, population-based sample (2631 non-Hispanic **W**hites; 2108 non-Hispanic **B**lacks; and 2073 **M**exican-**A**mericans) linked to health and lifestyle variables, including serum LDH, cation/anion values, hepatitis. Assuming an additive genetic model, we performed linear regressions adjusted for BMI, sex, and age and stratified by race/ethnicity. For serum LDH, we had four significant associations: *PPM2C* rs911 ($\beta$=3.21; p=0.028) in **B** and *PPM2C* rs911 ($\beta$=3.61; p=0.012), *LDHC* rs2721126 ($\beta$=4.60; p= 0.020), and *LDHA* rs11601413 ($\beta$=-5.39; p=0.005) in **MA**. For calculated AG, the two significant associations were *PPM2C* rs4735258 ($\beta$=0.23; p= 0.036) and *LDHC* rs10832934 ($\beta$=-0.84; p=0.009) in **B**. Tissue injury due to acute hepatitis was quantitated from the presence/absence of hepatitis A, B, and C antibodies (Hep A/B/C), and tested using logistic regression using the same covariate adjustments. Consistent with the calculated AG results, *PPM2C* rs4735258 (OR= 1.18; 95% CI: 1.01-1.4; p = 0.038) and *LDHC* rs10832934 (OR=0.58; 95% CI: 0.36-0.93; p = 0.024) were associated with HepA in **B** (n=772 cases and 937 controls). In **MA** (n=1424 cases and 324 controls), *LHDA* rs2896526 (OR=0.77; 95% CI=0.60-0.98; p = 0.035) was associated with HepA. Furthermore, *LDHA* rs2896526 was significantly associated with HepB (OR=1.34; 95% CI: 1.1-1.8; p=0.021) in **B** (n=242 cases and 1467 controls), and *LDHA* rs2403279 was significantly associated with HepC (OR=0.61; 95% CI: 0.37-0.99; p=0.05) in **W** (n=42 cases and 2357 controls). These results suggest that genetic variation associated with serum LDH, calculated AG, and presence of hepatitis exposure may provide information on pathways and diseases associated with cell turnover.

## 2886/F/Poster Board #818

**Genome wide association study on leptin levels in the KORA study.** *H. Grallert[1], C. Gieger[1], C. Herder[2], B. Thorand[1], C. Meisinger[1], H.E. Wichmann[1,3], W. Rathmann[5], W. Koenig[4], T. Illig[1,3].* 1) Instiute of Epidemiology, Helmholtz Zentrum München, Neuherberg, Bavaria, Germany; 2) Institute for Clinical Diabetes Research, German Diabetes Centre, Leibniz Centre at Heinrich Heine University Düsseldorf, Düsseldorf, Germany; 3) Institute of Medical Informatics, Biometry and Epidemiology, Ludwig-Maximilians-Universität, Munich, Germany; 4) Department Internal Medicine II-Cardiology, University of Ulm, Medical Center, Ulm, Germany; 5) Institute of Biometrics and Epidemiology, German Diabetes Centre, Leibniz Centre at Heinrich Heine University Düsseldorf, Düsseldorf, Germany.

Leptin inhibits hungry feeling and has a major role in regulation of metabolism. Leptin levels increase with adiposity degree. In the KORA study we investigated the association between leptin levels and genetic variation in a genome wide approach. We used a sample of 1644 participants of the follow up of KORA survey 3 (F3) and a second sample of 1814 participants of KORA F4 for our analysis. Genotyping was done with the Affymetrix 500K Arrayset in KORA F3 and with the Affy 6.0 Chip in KORA F4. For better comparison of the different genotyping methods genotype data were imputed. In both surveys none of the SNPs reached genome wide significance level. However, we found 10 SNPs that were associated with leptin levels with p-values lower than 0.0009 in both surveys. These SNPs were located in three regions on chromosome 4 and 5. Two SNPs on chromosome 5 are located near genes coding for proteins that might interact with leptin (SNP1: OR=1.12 p=4.7x10-4 (F3), OR=1.11 p=6.8 x10-4 (F4)); SNP2: OR= 1.11 p=4.2x10-4 (F3), OR=1.14 p=8.3x10-5 (F4)). One SNP on chromosome 4 is located in proximity to a gene of interest (SNP3: OR=1.12 p=4.0 x10-4 (F3), OR=1.11 p=6.7 x10-4 (F4)). The other seven SNPs are located in a region on chromosome 5 far away from known genes. Thus, speculations on these SNPs are impossible up to now. In conclusion our results give evidence for two loci that are potentially associated with leptin levels and thus might be involved in leptin regulation and energy metabolism. However, the detailed mechanisms have to be elucidated in further studies.

## 2887/F/Poster Board #819

**Genome-wide Screening for Novel Alu Retrotransposons.** *D. Hedges, S. Zuchner, N. Rocco.* Miami Institute for Human Genomics, Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami, Miami, FL 33136.

Transposable elements (TEs) make up a significant fraction of primate genomes. While most of this genomic content is comprised of older elements that have lost their capacity to generate new copies, multiple lineages of TEs continue to actively propagate in extant primates, including humans. These elements generate de novo insertion events which can result in pathogenic alleles. TE activity has now been implicated in over 20 genetic disorders. The discovery of disruptive TE insertions within genes may assist in elucidating the genetic architecture of complex disorders. However, there currently exists no feasible method for high throughput screening of populations of mammalian-sized genomes for novel TE insertions. Here we describe a method for the discovery of all novel Alu insertions within a given human genome. Our approach, which combines targeted enrichment with Next-generation sequencing, will make it feasible to screen significant numbers of individuals for insertion events. We are currently validating the method by examining the transmission of detected Alu insertions within a pedigree structure.

**A High Resolution Association Mapping Panel for the Dissection of Complex Traits in Mice.** *E. Eskin[3,4], B.J. Bennett[1], C.R. Farber[8], L. Orozco[1], H.M. Kang[5], A. Ghazalpour[1], T. Kirchgessner[6], E.P. Gargalovic[6], L.W. Castellani[1], E. Kostem[4], N. Furlotte[4], T.A. Drake[7], A.J. Lusis[1,2,3].* 1) Department of Cardiology, David Geffen School of Department of Cardiology, David Geffen School of Medicine at UCLA, University of California, Los Angeles CA; 2) Department of Microbiology, Immunology and Molecular Genetics, UCLA; 3) Department of Human Genetics, David Geffen School of Medicine at UCLA, University of California, Los Angeles CA; 4) Department of Computer Science, UCLA, University of California, Los Angeles; 5) Computer Science and Engineering, University of California, San Diego; 6) Bristol Myers Squibb; 7) Department of Pathology and Laboratory Medicine, David Geffen School of Medicine at UCLA,University of California, Los Angeles CA; 8) Department of Medicine, Department of Biochemistry and Molecular Genetics and Center for Public Health Genomics, University of Virginia, Charlottesville, VA.

Linkage analysis for the identification of genes contributing to complex traits in mice has been only modestly successful due to low mapping resolution. Association analysis in mice has the potential of much better resolution but is confounded by population structure and inadequate power to map traits that explain less then 10% of the variance, typical of mouse quantitative trait loci (QTL). We report a novel strategy for association mapping that combined classic inbred strains for mapping resolution and recombinant inbred strains for mapping power. Using a mixed model algorithm to correct for population structure, we validate the approach by mapping about 3000 cis- expression SNPs with a resolution 1 to 2 orders of magnitude narrower than QTL analysis. We report the fine mapping for metabolic traits such as plasma lipids. This resource, termed the Hybrid Mouse Diversity Panel (HMDP), has sufficient power to map traits that contribute to 10% of the overall variance. Importantly, the resolution of the panel can approach up to an order of magnitude better than that achievable using linkage analysis of complex traits. In addition, each strain is renewable and, therefore, diverse molecular and phenotypic data can be collected ad infinitum. In addition to greatly increased ability to narrowly map and identify genes for complex traits, this panel should be useful for the analysis of gene-by-environment interactions where multiple individuals of the same genotype need to be studied. Moreover, the fact that the data involving clinical traits, expression traits, proteomic traits, and metabolic traits are cumulative makes this resource ideal for systems biology.

## 2889/F/Poster Board #821

**Therapeutic drug discovery in dystrophin deficient zebrafish.** *G. Kawahara[1], M. Alexander[1], J. Guyon[2], L. Kunkel[1, 3].* 1) Children's Hospital Boston, Boston, MA; 2) Alaska Fisheries Science Center, Auke Bay Laboratories, Juneau, AK; 3) Howard Hughes Medical Institute, Boston, MA.

Zebrafish animal models of human diseases are powerful tools for screening a large number of chemical compounds for therapeutic efficiency. The zebrafish *sapje* mutant has been shown to carry a nonsense mutation in exon 4 of the zebrafish dystrophin gene and *sapje like* ($sap^{c/100}$) is a second allele of dystrophin deficiency caused by exon 62 skipping. Both alleles are excellent models of human Duchenne Muscular Dystrophy (DMD) and each shows disturbed muscle structure and a severe reduction of birefringence (the ability to refract polarized light) at 3-7 days post fertilization (dpf). The birefringence is a result of dorsal skeletal muscle deterioration and weakness that ultimately results in lethality of the most *sapje* mutants at 10 dpf. To identify potential therapeutic chemicals for treating DMD, we undertook chemical screening of a small, commercial molecular library using the *sapje* fish. Embryos from mating heterozygous *sapje* fish were cultured in normal fish water containing pools of the chemical library and were incubated from 1 dpf to 4 dpf. To examine the effects of chemicals for the recovery of the muscle phenotypes, birefringence assays were examined at 4 dpf. Fish treated with some pooled chemicals in the chemical library that were genotypically confirmed as *sapje* mutants showed no defects in birefringence compared to the control, suggesting that we may have successfully identified compounds that are effective for the recovery of phenotypes caused by dystrophin gene mutation. We have identified several pools of compounds that are capable of extending the lifespan of the embryos of *sapje* fish and reduce muscle weakness. Currently the individual components of the pools are being tested and also screened against the second allele of dystrophin deficient zebrafish. Those influencing both alleles will be tested for affect on their function in myoblast fusion in primary myoblast cultures isolated from wild type and *sapje* fish. The results of this screen may lead to new candidate molecules and pathways towards better therapeutic strategies for DMD.

## 2890/F/Poster Board #822

**High-density, genome-wide profiling of over 600k single nucleotide polymorphisms (SNPs) and over 900k Copy Number Variations (CNVs) using the Affymetrix Mouse Diversity Genotyping Array.** *A.J. Williams[1], H. Yang[2], F. Pardo-Manuel de Villena[3], G.A. Churchill[2], T. Webster[1], A. Pirani[1].* 1) Informatics, Affymetrix, Inc., Santa Clara, CA; 2) The Jackson Laboratory, Bar Harbor, ME; 3) The University of North Carolina at Chapel Hill, Chapel Hill, NC.

A new Mouse genotyping array has been developed, the first tool that enables researchers to study the complexity of the mouse genome and strain diversity in terms of both SNPs and copy number variation. Previously mouse researchers had a relatively limited ability to conduct whole-genome association studies and find markers for disease. This comprehensive array will be an effective tool for scientists using the mouse as a model for human disease and as a tool for researchers looking to better understand the mouse genome.

We describe the analysis methods developed for the array, using a Gaussian mixture model named BRLMM-P to perform genotype calling. Analysis has been tuned to meet the particular needs of mouse genetic data resulting in very high call rates and accuracy. SNP-specific models have been created by analyzing a large set of training data to optimize clustering for each SNP individually. The training data consists of classic Laboratory strains as well as their crosses and crosses between them and other strains. In an assessment of a prototype form of the system, the average sample concordance is 99.65% with an average sample call rate of 98.9%. For inbred strains, the average sample heterozygous rate (which is equivalent to an error rate) is 0.34%.

Applications for the array include but are not limited to mapping the phylogenetic origin for each segment of the genome, identifying structural variation in laboratory mice, observing genetic variation among substrains and sister strains, identifying de novo mutations and studying gene conversion.

## 2891/F/Poster Board #823

**Use of Zebrafish (Danio rerio) for identification of human genes related to aging.** *J.M. Keller, J. Escara-Wilke, E.T. Keller.* Urology & Pathology, Univ Michigan, Ann Arbor, MI.

**Background:** Zebrafish (Danio rerio) are an outstanding animal model to explore vertebrate development and genetics. Systematic phylogenetic analysis has defined mammalian orthologs of mapped zebrafish genes and comparison of map positions in zebrafish and mammals identified significant conservation of synteny. Zebrafish have been primarily utilized to explore development and are underexploited for evaluation of pathophysiology of age-related diseases. We believe that evaluation of mature zebrafish will provide novel information that can link genes to a variety of disease processes in the aged-human. However, there is an extensive gap in knowledge regarding age-specific morbidity and population lifespan data of zebrafish. Accordingly, the goal of our project was to characterize zebrafish demographics and age-related disease so that genetic screens can be applied to these phenotypes to identify human gene candidates for age-related diseases.

**Methods:** We established a colony of 3500 zebrafish to evaluate the population aging and age-related diseases. These zebrafish were divided into low and high density populations which consisted of 10 and 20 fish/tank, respectively. Zebrafish were observed daily for signs of disease or death.

**Results:** Currently, the colony is on year 6, with less than 1% of the population remaining for each density group. The median lifespans are approximately 35 and 28 months of age for the low and high density groups, respectively. We found several age-related diseases in large proportions of the population. Specifically, male zebrafish developed seminoma with similar histological attributes as human seminoma. This started to occur at approximately 25 months of age. Other tumors were observed including intestinal carcinomas and spindle cell sarcomas, but at much lower frequency. Another finding in a large proportion of the age-population was the occurrence of kyphosis and osteoporosis at fish greater than 36 months of age.

**Conclusion:** These data set the groundwork for age-related diseases of zebrafish and provide phenotypes that can be targeted for genetic screening to identify zebrafish genes that regulate age-related diseases. These genes can than lead to identification of candidate human genes that impact aging and age-related diseases.

## 2892/F/Poster Board #824

**Resequencing of the whole candidate region for 16q22-linked spinocerebellar ataxia in Japanese individuals using next-generation sequencing.** *T. Kaname[1,2,4], M. Tsukahara[3,4], K. Yanagi[1,4], K. Fujimori[4,5], I. Kikuzato[4,6], M. Teruya[4,7], Y. Imada[3,4], M. Nezuo[3,4], S. Yano[3,4], Y. Sato[4,6], Y. Miwa[3,4], T. Hirano[4,5], R. Hirano[8], H. Takashima[8], K. Yoshiura[2,9], N. Niikawa[2,10], K. Naritomi[1,2].* 1) Dept Med Gen, Univ Ryukyus, Nishihara, Japan; 2) SORST, JST, Tokyo, Japan; 3) Tropical Technology Center Ltd., Okinawa, Japan; 4) Okinawa Cutting-Edge Genome Project; 5) Advanced Industrial Science and Technology, Tsukuba, Japan; 6) OSTC, Okinawa, Japan; 7) Okinawa Industrial Technology Center, Okinawa, Japan; 8) Dept Neurology and Geriatrics, Kagoshima Univ Sch Med, Kagoshima, Japan; 9) Dept Hum Genet, Nagasaki Univ Grad Sch Biomed Sci, Nagasaki, Japan; 10) RIPHS, Health Sci Univ Hokkaido, Hokkaido, Japan.

Next Generation Sequencing technologies have brought new approaches of genetic analyses for personal genome or human diseases. The technologies can accurate giga-base order of sequence within a single run, allowing for complete resequencing of whole candidate region of a genetic disease in patients, whose responsible gene is not identified. We picked one candidate region of a neurologenetic disorder, the autosomal dominant spinocerebellar ataxia linked to chromosome 16q22 (16q ADCA), as an example of the resequencing approach. The candidate region of 16q ADCA in Japanese individuals was extracted and amplified by long-range PCR or other techniques spanning the whole region. Then, a fragment library or a mate-paired library from the region was constructed and sequenced to a depth >100-fold using the SOLiD 3 system. Comparison of each sequences and the genome database allowed us to find novel variations in Japanese individuals in addition to known SNPs or variations. We compared the results of fragment library and mate-paired library as well. The approach of 'Resequencing of whole candidate region for a genetic disease' might be a powerful tool for searching mutations in patients to identify the responsible gene.

## 2893/F/Poster Board #825

**Deep clinical resequencing to detect simple and complex mutations using Next Generation Sequencing.** *E.L.H. Chin, C. Alexander, L. Bean, B. Coffee, M. Hegde.* Department of Human Genetics, Emory University, Atlanta, GA.

Full gene sequence analysis to detect mutations in disease genes is common place in clinical diagnostic laboratories. Current technology, Sanger dideoxy termination sequencing, allows rapid development and implementation of sequencing assays in the clinical laboratory, but has limited throughput and mainly because of cost constraints only allows analysis of one or a few genes in a patient. Since mutation identification is of paramount importance for diagnosis confirmation, genetic counseling, risk assessment and carrier screening, efforts must be made to perform accurate and sensitive mutation analysis. Next generation sequencers have evolved rapidly, but have mainly been used for large scale genome sequencing projects and are just beginning to be used in clinical diagnostic testing. One advantage of next generation sequencers is that many genes in a patient can easily be analyzed at the same time, allowing for mutation detection when there are many possible candidate genes for a specific phenotype. In addition, regions of a gene typically not tested for mutations, deep intronic and promoter mutations can now be analyzed routinely. In parallel with the advances in sequencing technology, bioinformatic tools have been developed to assemble sequences from short reads. The technology is now sufficiently mature to begin implementation in a clinical laboratory setting where highly accurate data is required. We describe here the application of next generation sequencing technology in clinical diagnostic testing at Emory Genetics Laboratory (EGL). EGL specializes in testing for rare disorders, sequencing over 150 genes individually or in panels using the Sanger dideoxy termination methodology. EGL recently acquired a SoLiD platform (ABI) and is currently validating twenty previously characterized positive controls in disease causing genes where nucleotide changes were detected by Sanger sequencing. The positive controls chosen for validation range from simple substitution mutations to complex deletion and insertion mutations occurring in autosomal dominant and recessive disorders. These validation studies will include sequence quality, depth, accuracy, and cost analysis. This data will serve as a model for implementation for next generation sequencing in clinical laboratories by defining the strengths and weaknesses of the methodology.

## 2894/F/Poster Board #826

**Informatic Challenges for Human Whole-Genome Next-Generation Resequencing.** *N. Homer, B. Merriman, SF. Nelson.* Dept Human Gen, Univ California, Los Angeles, Los Angeles, CA.

Next-generation sequence technology has allowed for the cost-effective resequencing of human genomes. Nevertheless, the size and complexity of data can be overwhelming when performing informatics analysis. Many recent alignment and variant calling algorithms have been developed to help analyze next-generation sequencing data. These algorithms and tools can be used together to create a complete analysis workflow that enables accurate and efficient variant calling that identifies protein coding change mutations, structural variants, and other potential differences. We present our experiences pertaining to human glioblastoma whole genome resequencing. In particular, we detail informatics challenges and their solutions to whole genome sequencing using the Applied Biosystems SOLiD sequencer. We also describe the application of these tools to the resequencing of paired tumor/normal cancer samples. The informatics challenge begins with retrieving and archiving any raw data produced by the sequencer. Next, we align the data to the human reference genome, tolerating errors as well as variants such as single base changes, insertions, and deletions. Finally, we apply various variant-calling algorithms to identify potential coding change mutations, as well as cataloguing intra and inter chromosomal translocations. Utilizing such a workflow, we are able to help reveal the mutational spectrum of human glioblastoma multiforme.

## 2895/F/Poster Board #827

**Interleukin 7 alpha receptor mutation in an infant with Severe Combined Immunodeficiency of South American decent.** *A. Shanmugham, H. SHUHAIBER HANS H., E. GUZMAN, K. ANYANE-YEBOA.* PEDIATRICS, COLUMBIA UNIVERSITY, NEW YORK, NY.

Severe Combined (SCID) is a fatal disorder if untreated, characterized by severe lymphopenia and lack of adaptive immunity. SCID occurs with an estimated incidence of 1 in 75,000 births and is considered a pediatric emergency of potentially lethal outcome due to recurrent and persistent infections. Early diagnosis is critical, since Hematopoietic stem-cell transplantation ( HSCT) results in survival rates above 90% when performed serious infections develops. A major X-linked locus and sever autosomal recessive loci have been identified for SCID. A 5 month old girl with no significant past medical history was admitted for and loose stools and weight loss of 700 grams in 1 month. She was the full term product of an uncomplicated pregnancy. She had experienced upper respiratory infections. Laboratory workup revealed a total T-cell count of 3 (normal 2500-5600), CD4: 1 (1800-4000), CD8: 2 (590-3000). B-cells were 1596 (590-3000), Natural Killer 242 (of 17-830). Her plain chest x-ray revealed prominent interstitial markings consistent with Pneumocystis jerovicii. A primary immunodeficiency was considered. The coding sequence of Interlukin 7 receptor was amplified from genomic DNA and sequenced in 9 segments. She was found to have a homozygous splice site nucleotide change, c.83(-2a>t). Subsequently, both parents were confirmed to be heterozygous for the same mutation. This mutation, similar to one previously reported by Giliani et al (2005), disrupts the required “at” splice acceptor site at the 5’ end of exon 2 of the IL7R gene,encoding the IL-7Rα receptor (also known as CD127). Several nucleotide polymorphisms have been reported in the IL7RA gene, some of which result in amino acid changes . The IL-7Rα cDNA is composed of 1379 nucleotides and encodes for an 80-kDa type I membrane glycoprotein of 440 amino acids. Following binding of IL-7 to IL-7R, one of the key events is the activation of Jak1 (that is coupled to IL-7Rα) and Jak3 (associated with γc), which can phosphorylate the IL-7Rα, thus allowing recruitment of STAT5 and PI3K. Gilani et al 2005 reported 16 novel cases of SCID due to IL7RA gene defects. Our case further identifies new splice defect mutation (splice mutations contribute 24% to total IL-7RA mutations) in an Argentinian patient with a typical presentation. Relatively few IL7R mutations have been published, and the true incidence is unknown. Many US states are considering including SCID in their newborn screening programs.

## 2896/F/Poster Board #828

**Identification of novel sequence variants in *FMR1* in developmentally delayed males.** *S.C. Collins, D.J. Cutler, J. Visootsak, M.P. Adam, B. Coffee, M.E. Zwick, S.T. Warren.* Department of Human Genetics, Emory University School of Medicine, Atlanta, GA.

Fragile X syndrome (FXS) is a common form of mental retardation resulting from the functional loss of the *FMR1* gene product. While this is most often due to transcriptional silencing triggered by trinucleotide repeat expansion, there is one report of FXS caused by a missense mutation, I304N (De Boulle et al. 1993). To determine if other sequence variants in *FMR1* associate with the more general diagnosis of developmental delay, we used the Illumina GAII to resequence pools of LPCR products covering the promoter, exons, and a portion of the introns of *FMR1* in 963 developmentally delayed males referred to our clinical laboratory for fragile X testing. The probability of the minor allele frequencies in each pool exceeding the base error rate was calculated using a binomial distribution, and the threshold for variation detection was empirically set at $p < 1x10^{-4}$. The resulting positive predictive value, as determined by Sanger sequencing confirmation, was 78.2%, with a false negative rate of 23.5%. Within the tested clinical population, we identified and verified a novel missense change in *FMR1*, R138Q, which alters a conserved residue within the nuclear localization signal of FMRP. Clinical characterization of the proband reveals severe MR, seizure disorder, and recurrent otitis media, but no striking FXS-like physical features. Family studies have been inconclusive, but do not rule out the segregation of the R138Q allele with the phenotype. In addition to the R138Q missense change, we have also identified novel synonymous changes in codons 125 and 217, a novel 5’UTR variant downstream of the CGG repeat tract, three novel variants in defined promoter elements, and hundreds of novel variants in the introns and 3’UTR of *FMR1*. Although functional characterization and control genotyping of these novel variants will be necessary to determine association with developmental delay, this study more than doubles the number of known sequence variants in *FMR1*. Furthermore, this study is the first to conclusively show that missense, nonsense, and promoter mutations in *FMR1* are rare in patients who are currently tested for FXS by repeat tract analysis, suggesting that there is limited clinical utility for *FMR1* resequencing in these patients.

## 2897/F/Poster Board #829

**Exome sequencing of patients with Kabuki syndrome.** *C. Gilissen, A. Hoischen, N. Wieskamp, P. Arts, W.A. van der Vliet, M. Buckley, B.B.A. van Bon, B. de Vries, H. Scheffer, H.G. Brunner, J.A. Veltman.* Radboud University Nijmegen Medical Centre, Nijmegen, Gelderland, Netherlands.

Up to half of all rare genetic diseases remain unexplained at the molecular level. Identification of the causative genes in these disorders has been difficult because of their low frequency (not allowing association studies), de novo occurrence (not allowing linkage analysis), and lack of frequent occurring structural genomic variants (not allowing microarray-based CNV approaches). The recent development of massive parallel sequencing technology, combined with whole exome enrichment, now for the first time allows the unbiased analysis of all coding sequences in the human genome. We apply this strategy by capturing and sequencing the exome of three patients with Kabuki syndrome. For each patient we capture 34 Mb of genomic sequence using the Roche NimbleGen Exome capture array representing ~180,000 human exons and 550 miRNAs. The captured fragments are processed by the Roche 454 FLX Titanium, resulting in up to 1Gb uniquely map-able data per patient. More than 85% of the captured sequence can be mapped near or on the target sequence, indicating efficient enrichment. We find up to 7100 exonic variations per patient compared to the reference genome including 0.2% nonsense, 34% missense mutations and 13.9% small insertions and deletions. These numbers are consistent with those reported on the sequencing of other individual genomes [1]. Array based genotyping confirms on average 98% of the SNP variations, indicating the genotyping accuracy of this novel approach. After exclusion of all known SNPs, variations are classified based upon information from splice sites, amino acid changes, evolutionary conservation, protein truncating potential, and protein structure predictions. Currently we are in the process of validating the high ranking mutations by Sanger sequencing, testing for de novo occurrence, and testing disease candidate genes in a cohort of more than 50 Kabuki patients.

**A highly annotated whole genome sequence of a Korean Individual.**
*J. Kim[1,2,4], Y.S. Ju[1,2], H. Park[2,4], S. Kim[5], S. Lee[5], J.H. Yi[2], J. Mudge[6], N.A. Miller[6], D. Hong[2], C.J. Bell[6], D. Suh[2,3], S. Lee[2,3], S.H. Seo[4], J.Y. Yun[4], R.W. Kim[6], K.S. Yang[5], H. Kim[5], C. Lee[7], S.F. Kingsmore[6], J.S. Seo[1,2,3,5].* 1) Department of Biochemistry, Seoul National University College of Medicine, Seoul, Korea; 2) ILCHUN Genomic Medicine Institute, Medical Research Center, Seoul National University, Seoul, Korea; 3) Department of Biomedical Sciences, Seoul National University Graduate School, Seoul, Korea; 4) Psoma Therapeutics, Inc., Seoul, Korea; 5) Macrogen Inc., Seoul, Korea; 6) National Center for Genome Resources, Santa Fe, NM; 7) Department of Pathology, Brigham and Women's Hospital and Harvard Medical School, Boston, MA.

Sequencing technologies have much progressed in recent years, and initiated an era of personal genome sequences. To date, human genome sequences have been reported for individuals with ancestry in three distinct geographical regions: a Yoruba African, two individuals of Northwest European origin, and a person from China. Here, we provide a highly annotated, whole genome sequence for a Korean individual (AK1). The genome of AK1 was determined by a combined approach that included whole genome shotgun sequencing (27.8x coverage), targeted bacterial artificial chromosome (BAC) sequencing, and high-resolution comparative genomic hybridization (CGH) using custom microarrays featuring over 24 million probes to provide the most detailed analysis of an individual human genome to date. Alignment to the NCBI reference, a composite of multiple ethnic clades, disclosed nearly 3.45 million single nucleotide polymorphisms (SNPs) including 10,162 non-synonymous (ns) SNPs, and 170,202 deletion or insertion polymorphisms (indels). SNP and indel densities were strongly correlated genome-wide. Applying very conservative criteria yielded highly reliable copy number variants (CNVs) for clinical considerations. Potential medical phenotypes were annotated for nsSNPs, coding domain indels, and structural variants. Integration of human whole genome sequences, particularly from groups of individuals with minimal ethnic admixture, will assist in understanding genetic ancestry, migration patterns, and population bottlenecks.

**Solution-Based Enrichment of Genomic Loci for Massively Parallel Sequencing on the SOLiD System.**
*K. Li[1], D. Roberts[2], T. Sokolsky[3], A. Antipova[3], B. Novak[2], C. Pabon[2], L. Degoricija[1], M. Visitacion[2], C. Lee[3], C. Clouser[3].* 1) Life Technologies, 850 Lincoln Centre Dr., Foster City, CA, USA; 2) Agilent Technologies, 5301 Stevens Creek Blvd., Santa Clara, CA, USA; 3) Life Technologies, 500 Cummings Center, Beverly, MA, USA.

The identification of genetic variants and mutations associated with human disease requires the development of a robust and cost-effective approach for systematic resequencing of candidate regions in the human genome. The SOLiD System acquires tens of gigabases of mappable sequence within a single run, allowing for accurate resequencing of large genomes. When combined with the Agilent SureSelect Target Enrichment System, the ultra-high throughput of the SOLiD System facilitates deep sequencing of target genomic regions of interest. The SureSelect method extracts target regions from genomic DNA by hybridization to in-solution biotinylated cRNA probes, or "baits." The target enrichment workflow is streamlined to incorporate this enrichment step after libraries are constructed. Post-enrichment material is amplified and used directly for downstream steps including emulsion PCR and sequencing on the SOLiD System. Sequence capture of a 2.7 Mb region from Yoruba DNA resulted in 700-fold enrichment with 65% of reads mapping uniquely to the target region, as compared to 0.1% for an un-enriched control. Due to the inherent scalability and potential for automation of SureSelect in-solution enrichment, the coupling of this method with the SOLiD System platform provides a useful solution for targeted resequencing applications.

## 2900/F/Poster Board #832

**Exon capture approaches for gene discovery in callosal agenesis.**
*J. Li[1], M. LEE[1], G. Da Gente[1], R. Yeh[2], E. Sherr[1].* 1) Dept Neurology, UCSF, San Francisco, CA; 2) Dept Biostatistics, UCSF, San Francisco, CA.

Resequencing of high-value genomic regions promises to accelerate the identification of disease-associated mutations. Here we present an approach that combines customized, high-density Agilent microarrays and Illumina 1G massively parallel sequencing to selectively sequence 3.5Mb of exons identified by homozygosity mapping in patients with autosomal recessive callosal agenesis. We selected exons from genomic fragments identified through homozygosity mapping. These fragments and flanking regions were analyzed using the program OligoWiz2.0 to design probes for our custom array that cover these candidate genomic regions and the unique sequences are identified by the NCBI Browser with repeats masked by Window Masker program. The full set (244K) of probe sequences was exported to Agilent's eArray platform to produce the custom array. Genomic DNA from patients was prepared according to the Illumina/Solexa sample preparation protocol. Briefly 5 ug of recently purified high quality genomic DNA suspended in TE was noninvasively sonicated (Misonix sonicator 3000) in eppendorf tubes. After fragmentation, DNA samples were ligated with 1G sequencing adaptors and the products size purified (100-400 bp) and quantified. The fragments were PCR amplified to yield 5ug of DNA using adaptor-based primers followed by hybridization to the Agilent custom arrays. Prior to hybridization to the array, to assess the genomic representation of the purified DNA, fragments were cloned into blunt end vectors before hybridization and a sample of bacterial clones selected, purified and sequenced. Hybridization to the custom designed Agilent chip, was conducted according to the Agilent CGH protocol (version 2.0) and enriched DNA was eluted from the chips and reamplified with 10-12 PCR cycles before Illumina sequencing. For data analysis, we use MAQ to align the sequence reads with the reference. Among the 14818199 reads generated, 46.09% reads mapped to the target sequences and 85.6% of the target sequences were covered with average depth of 91.58. We identified 375 candidate SNPs of which 26 are non-synonymous changes. Overall, the method we present allows a flexible, cost effective approach to disease-oriented gene discovery and resequencing projects.

## 2901/F/Poster Board #833

**High-throughput, High-accuracy Targeted Multiplex Amplification for Medical Resequencing Using Spacer Multiplex Amplification ReacTion (SMART).**
*P. Shen, S. Krishnakumar, W. Wang, C. Scharfe, M. Mindrinos, R. Davis.* Genome Technology Ctr, Stanford Univ, Palo Alto, CA.

Efficient and cost-effective targeted resequencing studies are highly dependant on the reduction in human genome complexity that can be achieved by targeted multiplex amplification. We have developed a novel, robust, and reproducible methodology to amplify human sequences in parallel for use in downstream multiplexed sequence analyses. We call the methodology SMART (Spacer Multiplex Amplification ReacTion); it is based, in part, on padlock probe technology. A significant feature of the SMART assay is the use of Long Padlock Probes (LPPs that are greater than 300 bases in length for the assay). The LPPs have sequences that hybridize to the sequences flanking a target sequence, and capture the target by extension of the probe, followed by ligation to form a circular molecule. The target sequences are then amplified using primer sequences in the probe that are common to all the circular molecules. We applied the SMART amplification to 5376 exons up to 600 bp in length in genes involved in mitochondrial function and associated clinical disease phenotypes. The multiplex PCR products were hybridized to a custom-designed Affymetrix MRS array containing the coding sequences (>0.8Mb) of 524 mitochondrial genes. Using a maximum-intensity base caller of >90% as the cutoff for the success of target amplification, we were able to sequence 93% of the exons by the MRS arrays. The failed exons mostly have higher GC content. For the 3312 exons with GC content less than 50%, the successful rate of our multiplex PCR is close to 99%. Currently we are using NGS (next-generation sequencing) platforms to test amplicon amount distribution across all exons. In comparison with other target enrichment systems such as Roche's Sequence Capture arrays and Agilent's SureSelect, we believe that our SMART technology reaches equivalent multiplex fold at higher specificity, requires less DNA, and is more flexible to run and cost-effective.

**Robustness in the Face of Complexity, Single Molecule Real Time DNA Sequencing.** *S. Turner.* Pacific Biosciences, Menlo Park, CA.

New DNA sequencing technologies are needed in order to fulfill the goals of projects like the 1000 genome project and better understand human disease. We present such a technology. Single molecule real time (SMRT) DNA sequencing is a novel high-throughput method for sequencing DNA. It harnesses the intrinsic power of DNA polymerase enzymes as sequencing engines by eavesdropping on template directed synthesis in real time. Using two technological innovations, phospholink nucleotides and ZMW confinement, this method enables fast, single molecule DNA sequencing at very long readlengths. Through the combination of these innovations, our technology allows the speed, processivity, efficiency and fidelity of the enzyme to be exploited. The accuracy in SMRT sequencing is equally good throughout a read because after each base incorporation, the labeled portion of the phospholink nucleotide is cleaved away and the system reverts completely back to its initial condition. We show application of this technology to shotgun sequencing of human and bacterial DNA resulting in high consensus accuracy and unprecedented readlength. We will present a novel sample prep concept based on DNA hairpin ligation to double-stranded DNA that facilitates whole genome shotgun sequencing directly from genomic DNA with near-Poisson limited coverage uniformity and practically no GC bias. This sample prep will be demonstrated to enable consensus sequencing based on just one DNA molecule, allowing high accuracy sequencing at the molecular limit and without amplification. This capability is applied to detect SNPs in mixed samples with fractions as low as 1%. We will present an alternative to paired-end reads called strobe-sequencing in which insert sizes are dynamically adjustable at run-time and a variable number of linked reads inside one molecule are possible. This will allow elucidation with sub-one-fold coverage of structural variations including complex tangles that with paired ends require multiple libraries with different insert sizes and high fold coverage.

## 2903/F/Poster Board #835

**Functional Significance of Novel Genetic Variants of PON1 in a Mexican-American Population.** *K. Huen, K. Harley, S. Rose, A. Bradman, B. Eskenazi, N. Holland.* Center for Children's Environmental Health, School of Public Health, University of California, Berkeley, CA, USA.

Paraoxonase 1 (PON1) is a high density lipoprotein (HDL) - associated enzyme, which can inactivate the toxic oxon derivative of organophosphate (OP) pesticides. Additionally, it can prevent oxidation of LDL. PON1 genotype frequencies vary widely between ethnic populations. Over 250 SNPs have been previously identified in the PON1 gene (mostly in Caucasians), yet studies of PON1 genetic variation and effects on PON1 phenotypes focused primarily on promoter SNPs (-108,-909 and -162) and coding SNPs at positions 192 and 55. Previously, we sequenced the PON1 gene in Mexican-American subjects (60 chromosomes) and identified over 99 genetic polymorphisms with MAF > 5%, including several novel variants (7 SNPs, 3 insertions, and 8 deletions). We genotyped the newly identified polymorphisms in addition to 37 SNPs across the PON1 gene (chosen by Tagger) and measured PON1 phenotype using three substrate-specific assays (arylesterase, chlorpyrifos-oxonase, and paraoxonase) in 339 children and 361 mothers from the Mexican-American birth cohort CHAMACOS. Single marker association tests adjusting for multiple testing (FDR) were performed in PLINK to determine the functional significance of the PON1 variants. We also tested for haplotype-based associations employing a sliding window approach. Twelve polymorphisms were significantly associated with arylesterase activity in both mothers and seven-year old children (FDR adjusted p-value <0.05). Of those, two were newly identified deletions (located in the five prime UTR region and intron 7) that were not in strong LD with the well known promoter SNP at position -108. Over 30 polymorphisms were significantly associated with POase activity, however only 10 were in weak LD with both PON1-108 and PON1192. We identified several novel PON1 genetic variants that affect enzyme activity and thus may impact its ability to protect against OP pesticides and oxidative stress. This is particularly important for minority populations with high pesticide exposures.

**Optimal Algorithm For Haplotype Assembly From Whole-Genome Sequence Data.** *D. He, E. Eskin.* Univ. of California, Los Angeles, Los Angeles, CA.

Haplotypes (the sequence of alleles present on a single chromosome) in human populations contain the complete information for DNA variation in an individual. Many studies has shown that haplotypes are very useful for whole-genome association studies and for inferring human evolutionary history. In this study, we examine how haplotypic information can be explained using DNA sequence fragments. Current sequencing technology is cost-effective enough to generate large number of DNA reads. The problem of "haplotype assembly" is a challenging problem of assembling the two haplotypes for a chromosome given the collection of such fragments, or reads. Errors in reads significantly increase the difficulty of the problem and it's been shown that the problem is NP-hard even for reads of size 2. Existing greedy and stochastic algorithms are not guaranteed to find the optimal solutions for the haplotype assembly problem. In this paper, we proposed a dynamic programming algorithm, which is able to assemble the haplotypes optimally with time complexity O(m*2^k*n), where m is the number of reads, k is the length of the longest read and n is the total number of SNPs in the haplotypes. Our experiments show that the optimal solution makes on average a 1.1% improvement over the current best-known solution.

## 2905/F/Poster Board #837

**Using next generation sequencing technologies to identify variants in the neuroligin pathway associated with autism spectrum disorder.** *K.M. Steinberg[1, 2], M. Zwick[1].* 1) Dept Human Gen, Emory Univ, Atlanta, GA; 2) Graduate Program in Population Biology, Ecology and Evolution, Emory Univ. Atlanta, GA.

Neuroligins are post-synaptic cell adhesion molecules that bind to neurexins in the pre-synaptic density. Recent studies demonstrate that mutations in the X linked genes neuroligin 3 (NLGN3) and 4X (NLGN4X) and the autosomal gene neurexin 1beta (NRXN1β) contribute to autism spectrum disorder (ASD). However other studies failed to find these associations in individuals with ASD. To comprehensively survey the common and rare variation in these regions, we are resequencing NLGN3, NLGN4X and NRXN1β in individuals from families with two or more affected male sibpairs from the Autism Genetic Resource Exchange (AGRE) using two different next generation sequencing platforms. Affected male sibpairs were chosen based upon sharing identical markers near NLGN4X (DXS9895 and 9902) with each other as well as with their mother. One male from each sibpair was selected for resequencing; data from these affected males will be presented. In the first part of our study we examined 21 affected males and 20 controls (the affected males' fathers). Target DNA was isolated using Microarray-based Genomic Selection and then hybridized to custom resequencing arrays containing all unique coding and non-coding DNA from the three genes. SNPs identified in our study are partitioned into functional classes (UTR, silent, replacement, intron, intergenic) and compared within and between these classes. We identified and validated 3 exonic variants: 2 synonymous and 1 non-synonymous; however, the non-synonymous variant was identified in a control. Validation of variants in other functional classes is ongoing. In the second part of the study we are examining 152 affected males. Target DNA was isolated using long range PCR and then sequenced using the Illumina Genome Analyzer. All variants will be examined for evolutionary conservation using the phastCon program, severity of functional mutations using the Panther program and presence or absence from dbSNP. We are currently in the process of validating variants as well as identifying the presence and/or absence of these mutations in control males.

**Discovery and analysis of short sequence variants from population resequencing of two genes in the human genome.** *V. Bansal[1], O. Harismendy[1], S.S. Murray[1], N.J. Schork[1], J. Deleuze[2], E. Topol[1], K.A. Frazer[1].* 1) Scripps Genomic Medicine - Scripps Translational Science Institute - The Scripps Research Institute, 3344 N. Torrey Pines Court, La Jolla, CA 92037; 2) Sanofi Aventis, France.

Resequencing of candidate genomic loci in large populations represents a promising approach for the discovery of low frequency DNA variants that are unlikely to be captured in genome-wide association studies. Using the Illumina GA sequencing platform, we have resequenced 200 kilobases from two genes in a sample of 289 individuals of European Ancestry (146 individuals with Body Mass Index (BMI) below 30 and 143 individuals with BMI above 40). These two genes, Fatty acid amide hydrolase (FAAH) and monoglyceride lipase (MGLL) are important genes in the endocannabinoid pathway and a polymorphism in the FAAH gene has previously been associated with drug abuse in a population of European ancestry. Using the short read analysis package MAQ, we identified 1451 single nucleotide variants in our population. We leveraged the sequence data across all individuals to filter out false variants, resulting in ~ 1350 SNVs. These include more than 800 SNVs that have a minor allele frequency below 1 percent. We evaluated the accuracy of sequencing based genotype calls by sequencing individual samples multiple times and estimate an error rate of ~ 7% for genotype calling. Comparison of sequencing based genotype calls to genotype calls using the Sequenom platform showed that the sequencing derived genotype calls are robust to the presence of neighboring variants. We also developed a pipeline to detect short insertions/deletions using paired-end mapping and de novo sequence assembly of the short reads. Using this strategy, we identified a set of 143 reliable indel variants in our population. Finally, case control association analysis identified a set of rare single nucleotide variants with moderate association with BMI (p-value < 0.01). Accordingly, population sequencing appears to be useful for identifying rare sequence variants associated with morbid obesity.

## 2907/F/Poster Board #839

**Targeted Enrichment Of Genomic Loci Using Custom Microarrays For Massively Parallel Sequencing.** *J.J. Corneveaux[1,2], H.J Friedman[1,2], A.N. Allen[1,2], S. Szelinger[1], D.W. Craig[1,2], J.V. Pearson[1,2], A. Caruso[3], A. Keller[4], A. Borries[4], J.T. Leonard[3], M.J. Huentelman[1,2].* 1) The Translational Genomics Research Institute (TGen), Neurogenomics Division, 445 N. 5th Street, Phoenix, Arizona 85004, USA; 2) Arizona Alzheimer's Consortium, 901 E. Willetta Street, Phoenix AZ 85006; 3) febit inc., 99 Hayden Avenue, Lexington MA, 02421 USA; 4) febit biomed GmbH, Im Neuenheimer Feld 519, D-69120 Heidelberg, Germany.

Massively parallel sequencing technologies have ushered in a new era of genomic research including whole genome and linkage/association peak resequencing. When coupled with "DNA bar-coding" strategies, this technology can sequence tens to hundreds of individuals across several hundred kilobases in a single sequencing run. A key milestone in achieving these multiplexed assays is the selective enrichment of the regions of interest from the genome. Long range PCR has shown to be an effective means of achieving enrichment, however this approach is often challenging to optimize and, depending on the number of individuals to be sequenced and the number of regions investigated, is not always time or cost effective. In this light, we have collaborated with febit (Heidelberg, Germany) to generate custom DNA microarrays to capture regions of interest from the genome for downstream sequencing. Using the febit Geniom One instrument to create custom capture biochips, we can synthesize microarrays with >120,000 probes overnight and selective hybridization of genomic DNA can be achieved in as little as 24 hours. The sequencing library is prepared using standard Illumina protocols prior to hybridization-capture; therefore, we can elute from the biochip, perform standard linear PCR and load directly onto the Genome Analyzer instrument for sequencing.

Using a single febit biochip and a single Illumina Genome Analyzer II flow cell, we performed a pilot study to capture genomic DNA from 7 HapMap individuals across two contiguous genetic loci on different chromosomes; one 210Kb in size (*WWC1*) and one 20Kb in size (*TP53*). An average of 8.8 million ±3.7 million paired-end reads were generated per flow cell lane following quality control for a total of 72 bases sequenced per cluster. We show across our target regions an average of 327X ±139X coverage per individual with 95.1% ±8.3% of target bases with 1X or greater coverage. 46.5% ±6.2% of total quality filtered reads align to the target loci. We further show that the majority of off-target reads map to genomic repeat regions. Our results demonstrate the utility of such an approach for target loci enrichment and we show the theoretical potential to multiplex 10 or more samples per lane on a flow cell while still achieving 20X or greater coverage per sample across a target of 230Kb. Using these data as a benchmark, we provide some estimates for calculating depth of coverage for a variety of target sizes.

## 2908/F/Poster Board #840

**Molecular barcoding schema for medical and metagenomic SOLiD sequencing applications.** *P. Gilles[1], J. Kilzer[1], J. Bodeau[2], H. Breu[2], T. Sokolsky[3], J. Johnson[1], A. Harris[1], R. Bennett[1].* 1) Genetic Systems, Life Technologies, Carlsbad, CA; 2) Genetic Systems, Life Technologies, Foster City, CA; 3) Genetic Systems, Life Technologies, Beverly, MA.

As the SOLiD sequencing platform rapidly increases its throughput to the 250GB/run range - it is essential to efficiently utilize this expanding capacity for targeted sequencing of decomplexed human samples and sequencing of a multitude of species and strains of microorganisms. To this end, a specialized set of 10bp - 96 color-space-balanced barcodes have been developed that enable clear discrimination between samples for maximum sequencing accuracy and are designed for use as a "nested" set that allows 20-plex sequencing with 5 base barcode reads and 96-plex runs with 10 base sequence reads. Importantly, validation runs have demonstrated color balance by Satay plots of sequenced DNA fragment libraries and multiple sequence tests are experimentally designed for sensitive detection of complete sequence coverage and barcode sequence accuracy. Furthermore pilot early access developments have been tailored for combined and routine use of decomplexing systems such as the Agilent SureSelect target enrichment system on the SOLiD sequencing platform. The 96-plex barcoding system for the generation of DNA fragment libraries described herein provides validated color-balanced barcodes and primers which enable obtaining optimal quality, efficiency and cost effectiveness for enhanced depth and breadth of medical resequencing and metagenomic applications.

## 2909/F/Poster Board #841

**Massive parallel sequencing of ataxia genes after array-based enrichment.** *A. Hoischen[1], C. Gilissen[1], W. van der Vliet[1], P. Arts[1], N. Wieskamp[1], S. Vermeer[1], R. Meijer[1], M. Buckley[1], B. Kremer[2], N. van Slobbe-Knoers[1], J. Veltman[1], H. Scheffer[1].* 1) Department of Human Genetics, UMCN St. Radboud, Nijmegen, Netherlands; 2) Department of Neurology, UMCN St. Radboud, Nijmegen, Netherlands.

Targeting multiple disease genes by massively parallel sequencing has tremendous diagnostic potential but requires new 'front-end' methods to enrich templates to be sequenced. Here we validated the array-based sequence capture method for medical sequencing approaches in heterogeneous genetic disorders. As a model disease we chose autosomal recessive ataxia and selected 7 patients with known mutations in ataxia genes. Genomic sequences of all known disease genes, including all intronic sequences and 5kb up- and downstream of each gene, as well as a novel ataxia candidate locus were represented on a single oligonucleotide array, comprising 2.5 Mb of genomic sequence in total. After enrichment each of the patients DNA was analyzed by one quarter of a Roche GS FLX Titanium sequencing run, resulting in up to 100 Mb sequence data per patient. This was sufficient to reach an average per base coverage of 25-fold in all targeted regions. Enrichment showed high specificity, as on average 85% of all reads mapped uniquely to the targeted regions. Very few single reads mapped to non-targeted regions. Importantly, this approach enabled an unbiased detection of known mutations in all 7 patients, deletions and point mutations, as well as known SNP variants (hetero- and homozygous). These results show that massive parallel sequencing of enriched samples enables tailor-made genetic diagnosis of heterogeneous disorders.

## 2910/F/Poster Board #842

**Comprehensive identification of SNPs, indels and structural variants by sequence capture and deep re-sequencing of large genomic regions in pooled DNA samples.** *K.A Hunt[1], L. Franke[1,2], G.A.R. Heap[1], J.H.M. Yang[3], N. Bockett[1], V. Mistry[1], C.A. Mein[4], R.J. Dobson[4], Z. Albertyn[5, 6], C. Chelala[7], C. Hercus[6], D.A. Van Heel[1].* 1) Gastroenterology, Inst Cell/ Molec Sci, Barts and the London, London, United Kingdom; 2) Department of Genetics, University Medical Centre Groningen, 9700 RB Groningen, the Netherlands; 3) Diabetes and Inflammation Laboratory, Department of Medical Genetics, Cambridge Institute for Medical Research, University of Cambridge, Addenbrooke's Hospital, Cambridge, United Kingdom; 4) The Genome Centre, Barts and The London School of Medicine and Dentistry, Charterhouse Square, London, United Kingdom; 5) Centre for Comparative Genomics, Murdoch University, Perth, Australia; 6) Novocraft Technologies Sdn Bhd, Kuala Lumpur, Malaysia; 7) Institute of Cancer & CR-UK Clinical Centre, Barts and The London School of Medicine and Dentistry, Charterhouse Square, London, United Kingdom.

Comprehensive definition of regional genetic variation in a large sample collection is essential for pharmacogenetics; deep exon resequencing for coding mutations; and fine mapping after genome wide association studies (GWAS). We assessed three genomic regions (total 1.26Mb, selected to include RGS1, IL12A, IL2, IL21 from a recent GWAS), using 10 pools of 8 human DNA samples, enriched each pool using Nimblegen sequence capture microarrays, and high-throughput Illumina sequenced DNA fragments. We developed gapped alignment (Novoalign) and variant calling algorithms, to identify: 3457 SNPs (45.8% previously known); 472 small (≤7bp) insertion-deletion variants (6.6% known); and 10 larger structural variants including a common 980bp deletion between IL2 and IL21. Excellent correlation between known genotypes in each sample and sequence called genotypes in each pool was observed. A 5.0% per-SNP false negative rate was determined using 121 genotyped HapMap SNPs. A 6.5% per-SNP false positive rate was determined using dideoxy capillary resequencing of 46 randomly selected SNPs. A subset of insertion-deletion and structural variants was validated using a second method. DNA pooling is cost-effective for both sequence capture and sequencing stages, without compromise in accuracy. We show common and rare variants of multiple types (not just SNPs) can be defined in large sample numbers from targeted genomic regions.

## 2911/F/Poster Board #843

**Multiple sample pooling and next-generation sequencing to determine *RET* sequence variation within a population.** *R.L. Margraf[1], J. Durtschi[1], S. Dames[1], D.C. Pattison[1], J. Stephens[1], R. Mao[1,2], K. Voelkerding[1,2].* 1) ARUP Institute for Clinical & Experimental Pathology®, Salt Lake City, UT; 2) Department of Pathology, University of Utah School of Medicine, Salt Lake City, UT.

Background: The determination of sequence variation within a genetic diagnostic locus is critical for molecular assay design and clinical test interpretation. Next generation sequencing (NGS) offers a new approach for characterizing sequence variation within a population by cost-effectively pooling multiple samples before re-sequencing. Using the *RET* proto-oncogene as a model; we examined multi-sample pooling coupled with NGS to determine gene sequence variation within a population. Methods: We used 10 de-identified human DNA samples with known sequence variations determined previously by Sanger sequencing *RET* exons 10, 11, and 13-16, since sequence variation within these exons can be causative of Multiple Endocrine Neoplasia type 2. Long range PCR was used to amplify the 8.8 kb fragment spanning intron 9 to intron 16. Amplicons were equimolar pooled, fragmented by sonication, and sequenced on a single flow cell lane of the Illumina Genome Analyzer to generate 36 base length reads. Alignment and data analysis employed DNAStar's SeqMan and NGen programs. Results: Although the pooled data set averaged 18,000 read coverage, there were four areas of lower coverage (<6000); two areas were immediately 36 base pairs from amplicon ends and the two internal areas of low coverage had high GC content (yet averaged approximately 250 reads per allele). Each of the 10 samples in the pool had at least one unique single nucleotide variation, each with a singleton allele frequency of 5% (1/20 alleles). Using ≥20 for the phred-like quality score criterion, all 12 unique *RET* variants in the pool were detected with an average read frequency of 4.8%. Two samples each had two unique variants; one sample had two variants immediately adjacent on the same allele (GC>TG) with frequencies of 4.4% and 4.3%, while the other sample had variants in exon 13 and exon 14 with frequencies of 4.3 and 4.6%, respectively. These read frequencies per singleton alleles were well above the average random nucleotide error of 0.09 +/- 0.14%. Conclusions: Known sequence variations in the *RET* proto-oncogene were accurately detected near expected allele frequencies of 5% in a pool of 10 samples. Based on allele frequencies, random error, and the areas of low read coverage; we predict 20 to 30 samples could be pooled to reliably detect singleton alleles by NGS. We will continue to investigate improvements in sample pooling technique, Illumina library preparation and sequencing, and data analysis.

## 2912/F/Poster Board #844

**Genome-wide survey of common variants in pre-microRNA regions in humans.** *L.M. Reynolds[1], S.H. Wu[3], M.T. McManus[2], W.C. Hsueh[3].* 1) Dept of Biopharmaceutical Sciences, UCSF, San Francisco, CA; 2) Dept of Microbiology and Immunology, UCSF, San Francisco, CA; 3) Depts of Medicine and Epidemiology & Biostatistics, UCSF, San Francisco, CA.

MicroRNAs (miRNAs) are a novel class of genes that regulate gene expression by base pairing with target mRNAs and affecting translation. Since 30% or more of human genes might be regulated by miRNAs, their involvement in human diseases could be quite common. Therefore, we set out to identify common variants (MAF ≥ 5%) in all human pre-miRNA genes, in order to evaluate their association with complex traits in humans.

We identified 461 validated and 747 predicted pre-miRNAs (candidates) from the UCSC Genome Browser (as of June 2006). Primers could be designed for 1,071 regions, and 893 were successfully sequenced using the Sanger method, in 24 CEU samples used by the HapMap project. Of these 893 sequenced regions, 342 are validated pre-miRNAs (50% reported in miRBase 11, 2009). The variant discovery results are summarized in the table below. In conclusion, we identified many novel common variants in pre-miRNA regions to be included in future miRNA association studies. Furthermore, as our sequencing study was carried out using HapMap CEU samples, our findings can be readily used by all other scientists. *P<0.001 compared to (Pre-miRNA - miRNA)

| Region | n | Mean size (range) | # snp (% novel) | snp freq/kb | # Indel (%novel) | Indel freq/kb |
|---|---|---|---|---|---|---|
| Nonpre-miRNA | 876 | 458 (411-511) | 497 (24%) | 1.26 | 32 (72%) | 0.08 |
| Pre-miRNA - miRNA | 342 | 67 (39-114) | 19 (26%) | 0.86 | 1 (100%) | 0.04 |

**Reliable recovery of mutations and CNVs (incl. all known) using array-based sequence capture of 112 MR-genes.** *R. Almomani[1], J. van der Heijden[1], Y. Ariyurek[2], J. den Dunnen[1], M.H. Breuning[1].* 1) Center for Human and Clinical Genetics, Dept. of Clinical Genetics, Leiden University Medical Center, Leiden, The Netherlands; 2) Leiden Genome Technology Center LUMC, The Netherlands.

Although sequencing of a human genome gradually becomes an option, cost remains a prohibitive factor and zooming in on the region of interest is attractive. We tested array-based sequence capture prior to massive parallel sequencing to select genes potentially involved in mental retardation (MR) and congenital malformation. Fragmented, patient-specific tagged sequence-ready DNA was hybridized to custom 385K long oligonucleotide NimbleGen arrays to enrich the protein-coding and immediate intron flanking sequences of 112 genes. After hybridization, washing, elution and PCR-enrichment, captured DNA was sequenced using Illumina's technology. Arrays were successfully re-used and hybridized with pooled samples. For data analysis we have built a pipeline automatically reporting sequence variants, checking their presence in known databases (e.g. dbSNP) and predicting the potential consequences at the level of RNA splicing and protein translation. All known variants were reliably detected, incl. the pathogenic variants from control cases and SNPs derived from array experiments. Of the new variants, 24 exonic and 93 intronic, nearly all were confirmed using Sanger sequencing; analysis of the potential pathogenic consequences is ongoing. Although overall coverage was highly variable, it was reproducible per region and facilitating the detection of large deletions and duplications (CNVs), incl. a partial deletion in the B3GALTL gene from a control sample. To improve results further, and to get a more even coverage over the targeted region, future arrays should contain probes from both DNA strands and fewer probes from densely and more probes from sparsely covered regions.

## 2914/F/Poster Board #846

**Population-Based Detection of Rare, Surfactant Associated Gene Variants Using Pooled Sample Next Generation Sequencing.** *H. Heins[1], D. Wegner[1], S. Robison[1], T. Druley[1,2], R. Mitra[2], F. Vallania[2], A. Hamvas[1], F.S. Cole[1]*. 1) Pediatrics, Washington Univ, St. Louis, MO; 2) Genetics, Washington Univ, St. Louis, MO.

**Background:** Rare mutations in the genes encoding surfactant protein C (*SFTPC*) and ATP-binding cassette family submember A3 (*ABCA3*) cause respiratory disease in infants and children. Previous technologies have prevented cost-effective estimation of the population attributable fraction of childhood respiratory disease associated with these mutations. **Objective:** To use pooled sample next generation sequencing to determine the population-based frequency of genetic variants in *SFTPC* and *ABCA3*. **Methods:** Equal amounts of DNA extracted from 1110 Guthrie cards from the Missouri newborn screening program were combined into four pools: one African American (AA) pool (n=197) and three European American (EA) pools (n=304, n=304, n=305). PCR products from each pool spanning the entire *SFTPC* (6.2 kb) and 32 exons (13.8 kb) of *ABCA3* were normalized, pooled, and sequenced using an Illumina Genome Analyzer. SNP detection was performed using an in-house software program (Splinter). Functional analyses of non-synonymous SNPs were performed with SIFT and PolyPhen. **Results:** In *SFTPC*, we found 24 novel SNPs out of a total of 67 (44 promoter, 2 splice site, 2 non-synonymous, 1 synonymous, 18 intronic). Both non-synonymous SNPs were common and predicted to be nonfunctional. In *ABCA3*, we found 69 novel SNPs out of a total of 106 in the AA cohort (6 splice site, 11 synonymous, 14 non-synonymous, and 75 intronic). Of the non-synonymous SNPs, 4 were previously found in infants with surfactant deficiency or predicted to be functionally disruptive by both programs. In the EA cohort, we found 33 novel *ABCA3* variants out of a total of 66 variants (9 splice site, 6 synonymous, 15 non-synonymous, and 36 intronic). Of the non-synonymous SNPs, 7 were previously found in infants with surfactant deficiency or were predicted to be functionally disruptive by both programs. Four of these functionally disruptive SNPs were identified in more than one individual, and four were novel. The population-based frequencies of functionally disruptive mutations were 2.5% (5/197 in AA) and 1.9% (17/913 in EA). **Conclusions:** Functionally disruptive mutations in *SFTPC* are very rare, but the overall frequency of disruptive mutations in *ABCA3* (2%) suggests that the prevalence of respiratory disease attributable to these mutations is significant. This technology will allow the identification of the population-based frequency of genetic variants in other surfactant-related genes.

## 2915/F/Poster Board #847

**WHOLE EXOME RESEQUENCING IN A MULTIGENERATIONAL PEDIGREE WITH HEREDITARY SPASTIC PARAPLEGIA.** *S. Züchner[1], J. Huang[1], C. Almonte[1], E. Powell[1], S. Young[2], D. Burges[3], M. Schmidt[1], B. Boese[3], E. Szekeres[3], X. Zhang[3], M. Pericak-Vance[1], E. Rampersaud[1], E. Martin[1], T. Harkin[3], D. Hedges[1]*. 1) Miami Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 2) Center for Computational Sciences, University of Miami Miller School of Medicine, Miami, FL; 3) Roche Inc.

Classic approaches to gene mapping in Mendelian disease require the availability of large informative pedigrees. We are studying a relatively small autosomal-dominant family with five affecteds suffering from Hereditary Spastic Paraplegia with the aim to identify the causative gene using microarray-based whole exome capture followed by next-generation sequencing. In eight individuals we were able to cover up to 98% of the 180,000 targets at a read depth of >= 3, 86% at a read depth of >=10, and over than 50% of all targets with read depth of >=20. In average we identified 8500 variants per individual, with approximately 450 of these being novel. To further reduce the number of potentially significant novel variants, we applied a novel genomic convergence strategy using linkage exclusion mapping. Currently, we are confirming the <50 remaining novel variants in unrelated cases and controls to ultimately identify the underlying genetic cause. By comparing the variant calls derived from sequencing with 1M Illumina genotyping data we estimated a false negative error rate of <4%. The three-generational pedigree structure will allow us to further explore false-positive error rates and de-novo changes per meiosis. The results enabled us to develop realistic strategies for the efficient application of whole exome capture-arrays. This is of particular interest for genetic studies of diseases with high phenotypic penetrance but also rare variant studies of complex diseases.

## 2916/F/Poster Board #848

**Approaches for targeted sequencing of genes associated with healthy aging.** *E.F. Kirkness[1], T. McIntosh[1], S. Scherbakova[1], K. Beeson[1], P.C. Ng[1], R.L. Strausberg[1], S.S. Murray[2], N.J. Schork[2], E.J. Topol[2], S. Levy[1]*. 1) The J. Craig Venter Institute, Rockville, MD; 2) Scripps Genomic Medicine, The Scripps Research Institute, La Jolla, CA.

We have initiated a project to sequence human cohorts, targeting 81 genes potentially associated with healthy aging. Two approaches have been assessed for optimal detection of sequence variants in coding exons. The first employs RainDance technology to assemble a 1,526-plex PCR reaction in microdroplets. After a single PCR reaction, the 1,526 amplicons (mean length 370 bp) were sequenced via the Roche-454 platform. The amplicon pools from different individuals were barcoded to enable sequencing of multiple samples in a single sequencing run. In order to test the completeness and accuracy of the methodologies, we initially targeted a DNA sample that had been sequenced previously (HuRef). The analysis of HuRef DNA revealed that 93% of the targeted bases (exons and flanking intronic sequence totaling 563 kb) were covered to a depth of more than 10x after sequencing of the pooled products to an average depth of 148x. Two distinct approaches identified 90% of the 211 SNPs originally identified in the targeted regions of the 81 genes via Sanger sequencing. The remaining loci were either located in regions of high GC content, and had insufficient sequence coverage for calling SNPs, or were located in homopolymeric stretches that were incorrectly aligned, or had no alternate allele. Notably, the amplicon sequence data revealed an additional 23 SNPs that had not been detected by previous analysis of the HuRef genome assembly. A majority of these were confirmed as SNPs in dbSNP. In order to assess the utility of WGA-amplified DNA, we performed RainDance amplification and Roche-454 sequencing on two WGA-amplified case samples. After sequencing to an average depth of 68x and 25x, only 5.6% and 6.5% of the target bases remained unsequenced, and at least 80% of the target bases were covered by 30% of the average coverage. Sequence analysis revealed 192 and 183 SNPs respectively. The second capture approach employed solution hybridization of probe baits (Agilent SureSelect). Sample DNA was sheared and adapters for downstream sequencing were ligated before hybridization. The captured DNA was then sequenced using the AB SOLiD platform. Targeted DNA was sequenced to an average mapped depth of 200x, with 80% of the target region covered at 20% of the normalized coverage. Finally, we have compared the ability to detect variants via targeted capture versus whole genome sequencing (Sanger and SOLiD), and compare the biases inherent in each approach.

## 2917/F/Poster Board #849

**Whole-Genome SNP Detection and Haplotype Phasing with Mate Pairs via Ligation-Based Dibase Sequencing.** *S. McLaughlin[1], H. Peckham[1], S. Ranade[2], C. Lee[1], C. Clouser[1], J. Manning[1], C. Hendrickson[1], L. Zhang[1], E. Dimalanta[1], T. Sokolsky[1], J. Ichikawa[1], J. Warner[1], M. Laptewicz[1], B. Coleman[1], F. Hyland[2], F. De La Vega[2], A. Blanchard[1], J. Malek[3], G. Costa[1], K. McKernan[1]*. 1) Applied Biosystems, Beverly, MA; 2) Applied Biosystems, Foster City CA; 3) Weill Cornell Medical College in Qatar, Doha, Qatar.

The HapMap project along with next-generation sequencing technologies provides unprecedented opportunities to fully characterize whole-genome polymorphism events comprising many individuals across multiple populations. Genetic variants such as single-nucleotide-polymorphisms (SNPs), small indels, large-scale indel events on the order of several kibobases, genomic rearrangements such as inversions and translocations, and even full-scale de novo sequencing can be characterized rapidly and at per-base cost orders of magnitude less than the original Human Genome Project. We sequenced a Yoruba HapMap sample, NA18507, using mate-pair libraries (14.9x) with various insert sizes (600bp-3.5kb) as well as several fragment libraries (3x). SNP detection was performed via a heuristic approach which considers the number of reads per allele as well as a weighted score for each base call. We found 2.33M heterozygous SNPs and 1.53M homozygous SNPs with an overall dbSNP concordance of 81% (dbSNP v129). We evaluated mate pairs which cover 6.18M distinct potential genotypes (our whole genome SNP calls and HapMap genotypes which include reference-allele homozygous loci) and we observed 4.03M potential genotypes covered by 6.77M pairs. Nearly 2/3 of the genotypes are covered by at least 1 mate pair read that is in phase with another genotyped location and 43% that we detect as heterozygous are in phase with another that we also detect as heterozygous. We compared annotated heterozygous HapMap phases to these data and found they are in 98.95% agreement. We also attempted to resolve phases for our 634,568 novel heterozygous SNP calls by interrogating mate pairs pairing to both a novel heterozygous and a HapMap phased heterozygous and found that 76,300 (8.32%) of the novel heterozygous SNPs paired to a HapMap-phased heterozygote. For the 15,946 of these SNPs that have both alleles paired to a HapMap phased heterozygous, the two alleles are in opposite phase as expected 99.52% of the time. The average size of these haplotype blocks is 1.6Kb with blocks extending to as long as 215Kb using multiple mate pairs which overlap with multiple heterozygous loci. We have demonstrated that SOLiD mate-pair data is highly amenable to resolving haplotype phases at single-base pair resolution.

**Assembly of *E. coli* using Single Molecule Sequencing™ Paired Reads.** *J. Reifenberger, C. Hart, D. Lipson, K. Steinmann, T. Raz, K. Kerouac, J. Kepler, J. Lessard, P. Wellman, S. Letovsky, J. Thompson, P. Milos.* Helicos Biosci Corp, Cambridge, MA.

Single molecule DNA sequencing provides a novel method for interrogating DNA molecules with minimal manipulation of the sample. However the short reads, typically 25 - 50 bases in length, are difficult to fully assemble into a genome. Paired reads can provide additional linkage information to aid in de novo assembly and we have developed a paired reads strategy using the Helicos Single Molecule Sequencing (tSMS)™ platform. Sample preparation for a paired reads experiment is just as it is for single pass sequencing experiments and includes only shearing and terminal tailing of template DNA molecules. To create paired reads, DNA strands are attached to a surface and sequenced-by-synthesis for a known number of cycles. A spacer is then added to the DNA strands in a controlled manner by alternating between the addition of a trio of natural dCTP, dTTP, dATP (i.e. non-fluorescing nucleotides) and dTTP, dATP, dGTP to the individual strands on the surface. The length of the spacer is sequence dependent and aids in the eventual assembly of the reads. Once the spacer has been added, sequencing by synthesis continues for as many cycles as desired. The simple sample preparation, which does not require ligation of primers or any PCR amplification, results in the pairs being free of the artifacts and biases that complicated sample preparations can introduce. In this work, we demonstrate the viability of the technique and our ability to tightly control the length of the spacer between the two reads on an individual DNA molecule. Using our paired read strategy we have produced data that has allowed us to assemble *E. coli* using single molecule paired read data. We present assembly results using third party tools, such as Velvet, and results rendered using a novel de Bruijn graph assembly strategy. We focus on extending de Bruijn assembly methods that can utilize two unique features of the Helicos paired read strategy including both variable read lengths and the additional sequence information that is contained within our spacer.

### 2919/F/Poster Board #851

**Analysis of human Dorsal Root Ganglion neurons.** *I. Belfer, K. Motoyama, M. Poddar, C. Lee, M. Gold.* Dept Anesthesiology, Univ Pittsburgh, Pittsburgh, PA.

Study: Evidence on molecular biological, biochemical and physiological properties of dorsal root ganglia (DRG) neurons, the neurons responsible for somatosensation, has been obtained through the study of lower species. Genetic studies of human pain require data on human DRG neurons properties. The purpose of the study was to determine the extent to which human tissue obtained from two sources within the University of Pittsburgh Medical Center could be used for genetic, biochemical and functional analysis. Methods: Tissue samples: Human DRG (L4-L5 bilaterally) were taken from regular autopsies and organ donors according to criteria provided by the Committee for Oversight of Research Involving the Dead (CORID). Of the four ganglia collected from each donor, one was fixed in paraformaldehyde for subsequently histological analysis, two were snap-frozen on dry ice and used for subsequent analysis of DNA, RNA and protein, and one was placed in ice-cold culture media and processed for subsequent functional analysis. This last procedure was only attempted with tissue obtained from organ donors. Results: Tissue was obtained from 10 organ donors and 35 autopsies. The maximum delay between cross clamp and the collection of donor tissue was 3 hrs with an average of 2hrs. Autopsy tissue was obtained on average 18-hour post-mortem (28 hour maximum and 5 hour minimum). As anticipated, based on the stability of DNA, the integrity of DNA was excellent in all samples. RNA was largely degraded in tissue obtained via autopsy with a post-mortem delay of 15 hour or more. RNA integrity was excellent in the organ donor samples. Western blot analysis indicated that even relatively low abundance, high molecular weight proteins such as NaV1.7 and NaV1.8 were detectable in tissue obtained via organ donation and autopsy. Finally, functional analysis of isolated DRG neurons obtained from organ donors was possible, with neurons surviving in culture for at least a week. Conclusion: 1) Quantitative analysis of mRNA expression levels is possible with tissue obtained from both autopsies and organ donors; 2) Preliminary analysis indicates that it will be possible to perform quantitative between subjects analyses of tissue obtained via organ donation and autopsy. Histological analysis will be particularly important for these experiments to confirm the protein of interest is in DRG neurons; 3) It is possible to obtain live DRG neurons from organ donors.

### 2920/F/Poster Board #852

**Linear whole genome amplification method produces templates suitable for quantitative diagnostic analyses.** *A. Brooks[1], M. Stapleton[2], I. Aranovich[1], P. Van Hummelen[1], S. Wang[2], N. Kurn[2].* 1) Rutgers Cell & DNA Repository, Rutgers Univ, Piscataway, NJ; 2) NuGEN Inc., San Carlos, CA.

DNA based diagnostics from limiting and poor quality samples continue to be a challenge for a variety of qualitative and quantitative tests. Traditional whole genome amplification (WGA) approaches have been demonstrated for a variety of DNA based applications; however, none of the current approaches amplify the DNA template in a sufficiently linear fashion to permit utilization of WGA products for clinical applications. This study describes the development and application of a linear whole genome amplification approach, whole genome-SPIA, for limiting amounts (<10ng) of genomic DNA to be used for both quantitative real time PCR (QPCR) and microarray based technologies as well as its potential use in next generation sequence analyses. We demonstrate the utility of this approach using a trisomy 21 model which is indicative of the sensitivity and linearity needed for subtle quantitative analysis. Whole-genome single primer isothermal amplification (whole-genome-SPIA) technology was used to generate linearly amplified DNA templates from 6 trisomy 21 and 6 normal fetal gDNA samples. Each amplification uses 10ng of gDNA template and yields an average of 10ug of amplified product with no positional or deletional bias. This amplification technology employs chimeric DNA-RNA primers for the random generation of substrates which are linearly amplified by the single primer isothermal amplification (SPIA). To test the reproducibility, linearity and fidelity of the amplified product both QPCR and QFPCR were performed for multiple chromosome 21 targets on all amplified samples as well as gDNA amplified with commercially available amplicon-based and multiple strand displacement WGA products. The results demonstrate that whole-genome-SPIA amplified products from all cases result in products suitable for quantitative analysis. QPCR analysis of all regions explored has demonstrated statistical segregation for all trisomy 21cases from controls in a ratio similar to unamplified templates. Additionally, QFPCR analysis has demonstrated that in all cases there is a statistical difference in peak height for all chromosome 21 markers and not for markers interrogating chromosomes 18 and 13. This data demonstrates the potential clinical utility of linear whole genome-SPIA amplification approach and the value of limiting DNA samples for genetic analyses where conservation of genomic loci (or genomic copy number) is essential.

### 2921/F/Poster Board #853

**Novel method to produce partial trisomy mice using a human artificial chromosome (HAC): an application to Down syndrome.** *J. Kudoh[1,2,3], K. Miyamoto[2], N. Suzuki[4], K. Sakai[2], S. Asakawa[2,5], T. Okazaki[4], N. Shimizu[3], M. Ikeno[2,4].* 1) Center for Bioinformatics, Keio University School of Medicine, Tokyo, Japan; 2) Department of Molecular Biology, Keio University School of Medicine, Tokyo, Japan; 3) Advanced Research Center for Genome Super Power, Keio University, Tsukuba, Japan; 4) Chromo Research Inc., Nagoya, Japan; 5) Laboratory of Aquatic Molecular Biology and Biotechnology, Graduate School of Agricultural and Life Sciences, The University of Tokyo, Tokyo, Japan.

Down syndrome (DS), or trisomy 21, is caused by the inheritance of three instead of two copies of human chromosome 21 (HC21). Individuals with DS show characteristic faces, mental retardation, congenital heart defect, increasing risk of leukemia in postnatal periods and early onset type of Alzheimer disease in adulthood. It is difficult to identify critical gene(s) for each phenotype because the number of partial trisomy 21 is limited and the phenotype is highly variable even with full trisomy 21. Therefore mouse models have been used to study phenotype-genotype correlations in DS. Here we report the development of novel method to produce mice harboring an extra copy of gene(s) on a human artificial chromosome (HAC). HAC is a recently developed cloning vector for mammalian cells and animals. As HACs are maintained extrachromosomally, the genes carried on HACs are expected to express under the authentic regulation without insertional mutagenesis of cellular chromosomes. We developed a HAC vector to insert any target genes into the fixed site of a HAC by Cre/lox recombination. Bacterial artificial chromosome (BAC) clones containing the entire target gene(s) were selected and inserted into HAC vector maintained in mouse embryonic stem (ES) cells. From ES cells containing HAC, we produced mice harboring HAC that carries human chromosome 21 gene(s). Subsequent backcrossing with C57BL/6 showed that HAC is stably transmitted to progeny mice. These novel mouse model will be useful to identify a gene(s) responsible for a phenotype(s) of DS and analyze gene-dosage effects at the levels of transcriptome, proteome and metabolome.

## 2922/F/Poster Board #854

**High-throughput DNA quality control: Allelic discrimination panel for determining sample contamination, gender and ethnicity in a biorepository setting.** *J. Tischfield[1], M. DiCola[2], Q. Wang[2], P. Van Hummelen[2], A. Brooks[1,2].* 1) Human Gen Inst, Life Sci Bldg, Rutgers Univ, Piscataway, NJ; 2) Environmental and Occupational Health Science Institute, Bionomics Research and Technology Center, RWJMS-UMDNJ, Piscataway, NJ.

The quality of genomic DNA (gDNA) is a core issue for biorepositories. Many different approaches have been used for both the quantitative and qualitative appraisal of gDNA but there is no standardization for the functional assessment of DNA quality in terms of sample identity and utility for present and future downstream applications. Most gDNA quality measurement assays provide no specific identifiers of samples. Rather, they assess the global quality of nucleic acids while yielding no information on subject gender and probable ethnicity or potential contamination with other samples, all of which are important metrics for any lab managing large numbers of samples in a repository setting. At present, most laboratories use gDNA for discovery applications that involve analysis via SNP genotyping or NextGen sequencing technologies, both of which have a PCR component in their workflow. We have implemented a rapid and cost effective means for assessing the quality of each gDNA in terms of its suitability for PCR, while capturing critical information concerning subject identity. We developed and validated a panel of 96 SNPs using the Fluidigm 96.96 dynamic array to determine gDNA subject gender and putative ethnicity as well as contamination during processing. The flexibility of the Fluidigm dynamic array allows for rapid quality control testing while retaining the relatively easy option to employ study specific supplementary panels that can be used to generate more in depth information on ethnicity (126 SNPs) or parentage (136 SNPs), as needed. There is complete correlation between the Fluidigm BioMark system and our standard QPCR validation. The correlation to SNP data from DNA microarray and capillary electrophoresis analysis is 100%. This quality control approach allows the Rutgers University Cell and DNA Repository to easily provide data for over 10,000 gDNA samples per month while reducing operating costs and generating essential information that may be used for sample utility assessment and subsequent study management. The 96 SNP database can also be used to validate GWAS data in the event of a discrepancy given that >90% of SNPs in this panel are represented on a variety of commercial array platforms. We describe the selection of SNPs for the quality control panel, standard operating procedures for sample processing and a quality assessment schema for the rapid processing and analysis of genotype data.

## 2923/F/Poster Board #855

**Diagnostic validation of an integrated DNA extraction platform for large volumes of blood.** *T. Janssens[1,2], I. Salden[1], E. Dequeker[1,2], G. Matthijs[1,2].* 1) Center for Human Genetics, University Hospital Leuven, Leuven, Belgium; 2) EuroGentest, Leuven, Belgium.

Reliable and fast DNA extraction is a prerequisite in molecular genetic testing. Automation of this process has some important benefits, including increased throughput, more consistent and reproducible processing and improved sample tracking. Several manufacturers have produced a plethora of platforms, with different extraction chemistries. However, the extraction of large blood volumes (>1 ml) is still a challenge, for which only a few systems are available. This EuroGentest project involved the validation of the Chemagic Magnetic Separation Module I extraction robot (Chemagen), integrated with a Perkin Elmer liquid handler robot. The extraction technology is based on the use of paramagnetic beads with a DNA binding coating. Using magnetic rods, these beads can be transferred from one DNA washing buffer to another when applying an electro-magnetic field. The aim of this validation was to thoroughly validate the system, through verifying the physico-chemical qualities of the extracted DNA. In addition, we wanted to compile instructions for the in-house validation, in order to avoid duplication of effort in other laboratories while warranting a uniform level of validation. Over 180 whole blood samples on EDTA (not older than two weeks) were extracted under different conditions. The DNA concentration was measured and the yield was determined. The 260/280nm ratio was calculated as a parameter for the quality of the DNA. All DNA samples were checked in a multiplex drop-out PCR. Furthermore, samples were run on agarose to detect degradation of the DNA. Stability of the DNA was evaluated by repeating the multiplex PCR and the degradation test on randomly selected samples, stored at different conditions, during several months. Finally, the performance of the DNA for downstream diagnostic tests was assessed. Our study has shown that the integrated Chemagen-Perkin Elmer DNA extraction platform is an easy-to-use, flexible system resulting in good quality DNA, high yield and satisfying performance for diagnostic purposes. A few minor adaptations had to be made to the protocol(s) to warrant optimal performance. We suggest that some of the most critical parameters are locally verified when a diagnostic laboratory implements the system under accreditation.

## 2924/F/Poster Board #856

**Association of Biomolecular Resource Facilities (ABRF): Advancing Human Genetics through Research, Communication, and Education.** *T. Hunter[1], M. Detweiler[2], G. Grills[3], K. Sol-Church[4].* 1) University of Vermont, Burlington, VT; 2) Roswell Park Cancer Institute, Buffalo, NY; 3) Cornell University, Ithaca, NY; 4) Center for Pediatric Research, NCC-Delaware.

Improvements in cutting edge and emerging technologies, such as the introduction of next generation sequencing to biomedical research, have dramatically changed the landscape of genetics and the way genetic research is performed. Today, genetic research is often a collaborative effort that is performed in association with shared resource biotechnology (core) laboratories. These cores represent centers of technological excellence that bridge discovery and translational research by integrating state-of-the-art molecular genetics and proteomics technologies into current research programs. The Association of Biomolecular Resource Facilities (ABRF) is an international society dedicated to advancing biotechnology laboratories through research, communication, and education. ABRF Research Groups conduct multi-institutional studies that focus on comparison and optimization of the state-of-the-arts biotechnologies and methodologies available to biomedical researchers and geneticists. An overview of the aims and results of ABRF Research Group (RG) studies will be presented to illustrate the challenges and opportunities of genetic technologies. For example, the results of an RG gene expression study, based on reverse transcription quantitative real time PCR, underscores the importance of sample quality, optimal priming strategies, qPCR assay location and data troubleshooting. An RG study on microRNA expression highlights the strengths and weaknesses of some of the most popular array platforms and compares data from conventional microarray platforms with Taqman Low Density Arrays (TLDA) and Illumina GAII next generation sequencing. An RG study on SNP discovery and validation provides performance comparison of two major next generation sequencing platforms (Illumina GAII and ABI SOLiD) and highlights the strengths and weaknesses of these platforms in dealing with allelic discrimination in a diploid organism. This presentation will provide a forum for discussion of cutting edge methodologies and approaches in molecular genetics and will illustrate how they can be used to facilitate human genetics research.

## 2925/F/Poster Board #857

**Single Tube Amplification of Large Sets of Genes.** *O. Ericsson[1, 2], M. Isaksson[1], H. Johansson[1], J. Stenberg[1], M. Nilsson[1].* 1) Molecular Diagnostics, Genetics and Pathology, Uppsala, Sweden; 2) Olink Genomics, Dag Hammarskölds väg 54A, Uppsala Sweden.

PCR has dominated the sample preparation for Sanger sequencing due to the advantages of 1) high specificity 2) excellent limit of detection and 3) a very simplistic reaction format. These traits have enabled analysis of highly homologous regions in the genome and sequencing of DNA from very scarce sources such as biobanks and ancient biological remnants. However, because the reaction is limited to single- or low-plex amplification, PCR is not suited for targeted re-sequencing using the new sequencing instruments. Instead, several new technologies have been developed in order to provide multiplex sample preparation of larger interesting genomic regions for the new sequencing instruments. It has proven difficult to solve the bottleneck of PCR without compromising one or several of the original advantages. The currently available solutions either lack the specificity and detection limit provided by enzymatic amplification or depend on expensive and complicated instrumentation and in some instances involve both. We present the Selector Technology, a solution phase protocol for amplification of thousands of target fragments using pools of oligonucleotides that in combination with enzymes enable amplification of target regions. Following restriction enzyme digestion of the target DNA and specific circularization of target fragments, directed by the probe library, circularized targets are amplified specifically. The protocol can be scaled up using a standard 96 or 384 well reaction format and is compatible with the Illuminja, SOLiD and 454 sequencing instruments. Each oligonucleotide can capture up to kbp regions, allowing analysis of redundant genomic elements, and repeats. The protocol enables amplification of as little as 100 ng starting material, which together with scalable single tube amplification provides a protocol suitable for parallel analysis scarce biobank samples. Sequencing data from presented probe designs, targeting exons using renewable probe pools, capturing 3000 and 1500 fragments respectively, show that in average 87% of amplification products align to amplified regions and 95% of regions are recovered. In average, first-pass designs returned targeted sequencing coverage for analysis for 84% of amplified regions of interest with a ten fold sequencing bias. The reproducibility of sequencing read distribution in targeted regions is very good ($R2 = 0.92$) providing reproducible coverage and target regions are enriched over 10.000 fold.

**Optimization of library preparation methods for next-generation sequencing.** *A.F. Scott, D.W. Mohr.* Genetic Resources Core Facility, McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins School of Medicine, Baltimore, MD.

Next-generation sequencing has great potential for medical resequencing and as a follow-up to examine candidate genes in regions identified by GWAS. Most next-gen DNA sequencing involves the creation of libraries of molecules with appropriate adapters that are captured, amplified in situ and used to create templates for sequencing. Several alternative protocols for library creation have been published or posted online. We have attempted to evaluate which procedures are key to successful library preparation for the Illumina Genome Analyzer so that the process can be routinely applied to large numbers of samples. Library preparation involves several steps which begin with DNA fragmentation, creating blunt ends, adding an overhanging 3' A, ligation of appropriate adapters, size selection and purification of ligated molecules, PCR amplification and removal of unincorporated primer. Major impediments to success include the inability to produce molecules of a defined size range, loss of DNA during the multiple purification and handling steps, and quantitation and validation of the libraries prior to sequencing. Modifications that we have evaluated include fragmentation using a Covaris AFA sonicator, alternate sources for enzymes and other reagents, a substitute agarose gel buffer and use of paramagnetic beads for PCR primer removal. We are also evaluating the Illumina multiplexing primers that allow library indexing as well as extended paired-end sequencing to maximize data generated per run. Lastly, we are examining the use of long-range PCR products for targeting genomic regions, esp. those not easily selected with solution or array-based capture technologies.

**Evaluation of performance of gDNA from saliva collected with Oragene®DNA for the purpose of SNP and CNV analysis on the Affymetrix Genome-Wide Human SNP Array 6.0.** *R.M. Iwasiow[1], C. James[1], P. Hu[2], R.F. Wintle[2], S.W. Scherer[2].* 1) DNA Genotek Inc, Ottawa, Canada; 2) The Centre for Applied Genomics, The Hospital for Sick Children, Toronto, Canada.

Genome-wide association studies allow for rapid scanning of markers across entire genomes. The Affymetrix Genome-Wide Human SNP Array 6.0 includes more than 906,000 single nucleotide polymorphisms (SNPs) and more than 946,000 probes for detection of copy number variation (CNV). Such studies deliver most value when samples originate from a well defined population (i.e. Age group, Disease state, Socio-economic status). Often individuals of such groups are dispersed in the general population making sample collection challenging and expensive. OrageneDNA facilitates such collection by providing an alternative to blood collection, eliminating phlebotomy cost and complexity. OrageneDNA is a non-invasive, self-collection device intended for collection of large quantities of high-molecular weight genomic DNA (gDNA) from saliva. DNA is stabilized at room temperature for extended periods enabling sample collection and transport via regular mail and flexibility to process in batches. The current study evaluates the use of gDNA from saliva on the Affymetrix 6.0 Genechip. Saliva from the same four donors was collected using the OrageneDNA kit on three separate days and the gDNA extracted from each of these collections was analyzed. Performance of the gDNA from saliva was assessed by evaluating the SNP and CNV calls from each sample and the reproducibility of the data was determined by comparing the results from three separate collections from the same donor. We report QC call rates > 98% and concordance between samples from the same donor >99.8%. We also used the median of the absolute values of all pairwise difference (MAPD) to evaluate whether the chip/array produce data that is useful for copy number analysis and report MAPD <0.26. Integrated CNV results based on two algorithms (Birdseed, and Partek HMM) identified < 30 CNV per genome. The results indicate that genomic DNA isolated from saliva collected with OrageneDNA can be used as a source in the Affymetrix Genome-Wide Human SNP Array 6.0.

## 2928/F/Poster Board #860

**Successful Transformation of Cryopreserved B Cells by Epstein Barr Virus Ensures Efficient Development of a Renewable Resource for Genotype/Phenotype Studies.** *A. Ansbach[1], K. Reeves[1], K. Gwinn[2], J. Andrews[1], L. Gutmann[3], L. Mamounas[3], R. Zhang[3], C. Beiswanger[1], M. Keller[1], R. Corriveau[1].* 1) NINDS Repository, Coriell Institute for Medical Research, Camden, NJ 08103; 2) Baylor College of Medicine, One Baylor Plaza, Houston, TX 77030; 3) NINDS/NIH, 6001 Executive Boulevard, Bethesda, MD 20892.

Biorepositories that establish lymphoblastoid cell lines (LCL) from whole blood usually do so by infecting freshly prepared mononuclear cells (MNC) with Epstein Barr virus (EBV) to obtain a transformed B cell line. The processing paradigm established in 2002 for the NINDS Repository, which supports discovery of genetic risk factors for complex neurological diseases, was for submitters to send two 8.5 ml ACD tubes of blood per unique individual. Both tubes were used to obtain MNC via density gradient-separation of peripheral blood. Fresh MNC from one tube were immediately transformed with Epstein Barr virus (EBV) to establish an LCL; MNC from the other tube were cryopreserved as a back-up sample. We previously reported that, on average, for samples collected in 8.5 ml ACD tubes with ≥ 4 mls blood volume and in transit ≤ 6 days since venupuncture, the 1st attempt success rate using fresh MNC is 94% (n=8,879). Here we report two new results. First, if the 1st attempt at transformation starting from freshly prepared MNC fails, the success rate for a second attempt using cryopreserved MNC is 75% (n=332). Second, when there is no attempt using fresh MNC, rather, the first attempt to establish an LCL uses cryopreserved MNC, the success rate is 92% (n=1,959), a result that is virtually indistinguishable from the success rate using fresh MNC. This finding has major significance for LCL-based repository science. Establishment of LCLs represent the best available practice for obtaining a renewable resource of biospecimens from a specific individual, yet establishing LCLs from fresh MNC is labor-intensive and time-inflexible. Our results demonstrate that it is not necessary to immediately establish an LCL upon receipt of the peripheral blood sample. Rather, this part of the process can be deferred until after phenotypic and preliminary laboratory data are complete and reviewed for quality control. The NINDS Repository now uses this cost-efficient demand-driven paradigm for sample processing. Two 8.5 ml ACD tubes of blood are received from an individual; one is used for extraction of DNA from blood for distribution via the public web-catalog (http://ccr.coriell.org/NINDS), and the other is used to prepare cryopreserved MNC for demand-driven LCL production.

## 2929/F/Poster Board #861

**Next generation genetic tests: from artisan genetic testing to uniform, streamlined, fully quality-assured and automatic processing of genetic tests using next generation sequencing.** *H. Cuppens[1], T. De Staercke[1], S. Chen[1], L. Vliegen[1], Y. Moreau[2].* 1) Center for Human Genetics, KULeuven, Leuven, Belgium; 2) ESAT, KULeuven, Leuven, Belgium.

Implementation of next generation sequencing in routine genetic testing for monogenetic diseases can be only achieved if robust multiplex amplifications are set up; if samples can be pooled in a cost-effective way; if quality-assurance is guaranteed; and if data can be processed automatically. With respect to pooling, in the established 1-step PCR protocol, primers carry an amplicon specific target region, a tag, and sequencing adapters. For sequencing N amplicons in x individuals, 2N*x primers are needed. We developed a 2-step PCR protocol, the first primers carry amplicon specific sequences and an intermediate adapter which is common in all primers, the second PCR only needs one pair of primers per sample that carry this intermediate adaptor sequence, a sample tag, and the sequencing adaptor. This 2-step protocol only needs 2N+2x primers. Moreover, the second pair of primers are not test-specific and can be used for any gene. For sequencing of a gene of 30 amplicons in 100 individuals, only 260 primers are needed in our 2-step PCR protocol compared to 6000 primers in the 1-step PCR protocol. A quality-assured system and automatic processing was realized by spiking samples with DNA molecules. A DNA library was generated using a 25 nucleotide long random tag, yielding $4^{25}$ different tag molecules. These molecular bar codes can be processed simultaneously with the DNA fragments under investigation. The test will be quality-assured from the moment that the sample is spiked. Spiking is currently performed in the blood sample when it arrives in the lab. The goal will be to collect a blood sample in a tube that already contains the molecular bar code. The only potential error that then still can be made is the moment at which the blood sample is taken. The test will be only valid when the correct sample tag is associated with the molecular bar code at the end of process. Not only can sequencing reveal a mutation, it will also identify the sample carrying the mutation. This allows automatic generation of a report, thereby excluding potential errors compared to reports generated by human intervention when test result and patient information are brought together in a genetic report. In this format, the only difference between different genetic tests will be only the tubes containing the gene-specific amplification primers. For the first time, different genetic tests can now be streamlined in a high-throughput, quality-assured and automated format.

## 2930/F/Poster Board #862

**Genetic Analysis of Single Cells.** *J.-B. Fan[1], C. April[1], H.-I. Chiang[2], H.L. Fung[2], J. Chen[1], B. Klotzle[1], K. Zhang[2].* 1) Department of Applied Genomics, Illumina, Inc, San Diego, CA; 2) Department of Bioengineering, University of California San Diego, La Jolla, CA.

We are developing highly sensitive and quantitative genomic technologies for genetic and expression analysis of single cells or trace amount of DNA/RNA materials, using microarray and next-generation sequencing platforms. We have tested various Multiple Displacement Amplification (MDA)-based protocols under a variety of reaction conditions. With our current protocol and a 300K-SNP chip readout, we were able to obtain 97.2% call rate and 99.98% call accuracy when 750 pg of human genomic DNA was used; we obtained 77% call rate and 97.7% call accuracy with direct cell lysis from 5 cells. To further improve the call rate (for genotyping) and genome coverage (for sequencing) in the single cell amplifications, we added a post-MDA normalization step to our protocol. We are also developing RNA amplification methods for expression profiling of single cells. With our current protocol, we were able to generate reproducible expression profiles ($R^2$ = ~0.85) with 25 cells (250 pg total RNA). In addition, the profiles correlated well with those obtained with standard 100 ng total RNA input ($R^2$ = ~0.78). We are currently using these technologies to study medical specimens such as circulating tumor cells and cancer stem cells. We will report the comparison results of our methods with other commercial kits.

## 2931/F/Poster Board #863

**A novel microfluidic Assay for denaturating high-resolution DNA electrophoresis of MLPA and STR-Typing samples.** *M. Gassmann[1], R. Salowsky[1], J. Coffa[2], K. De Groot[2], M. Aboud[3], B. McCord[3].* 1) Agilent Technologies, Waldbronn, Germany; 2) MRC-Holland, Amsterdam, Netherlands; 3) Florida International University, Department of Chemistry, Miami.

The Agilent 2100 Bioanalyzer instrument platform is designed for performing fast electrophoretic analysis of DNA, RNA, and proteins based on microfluidic chip technology. It is widely used for the analysis of PCR products and restriction digests. However, the resolution of the current DNA assays is not sufficient to separate DNA fragments generated in applications like e.g. short tandem repeat (STR) DNA-typing (microsatellite analysis) and MLPA (Multiplex Ligation-dependent Probe Amplification). As these methods require a very high resolving power in the electrophoresis involving denaturing conditions, usually capillary-based DNA sequencers are used to separate the DNA fragments. However, due to a growing number of new applications, there is a strong demand for an alternative separation platform that is fast, flexible and easy to use. Over the last decade, MLPA and short tandem repeat (STR) DNA-Typing have been established as standard methods in the analysis of genomic DNA. While MLPA is mainly used in the detection of copy number variations causing genetic hereditary diseases, STR-typing is applied in DNA forensics, kinship and population studies. Here we describe a novel assay that is able to perform fast, sensitive, high resolution separation of Cy5-labeled DNA fragments on the Agilent 2100 Bioanalyzer. A new denaturating gel matrix has been developed that enables the separation of single-stranded DNA fragments between 10 and 500 bp with a resolution approaching 2 basepairs. The significantly increased resolution of the new assay permits the Bioanalyzer to successfully separate and analyze MLPA and STR-typing samples.

## 2932/F/Poster Board #864

**Whole genome and transcriptome amplification in large biobanks.** *N. Klopp[1], T. Illig[2], C. Korfharge[3], HE. Wichmann[4].* 1) Klopp N, Institute of Epidemiology, Helmholtz Zentrum München, Neuherberg, Germany; 2) Illig T, Institute of Epidemiology, Helmholtz Zentrum München, Neuherberg, Germany; 3) Korfharge C, QIAGEN GmbH, Hilden, Germany; 4) Wichmann HE, Institute of Epidemiology, Helmholtz Zentrum München, Neuherberg, Germany.

Biobanks are a key resource in unravelling the molecular basis of diseases, identification of new targets for therapy and improvement of attribution in drug discovery and development. The scientific trend in biobanking shows the need for stable techniques for amplification of biomaterials, which can be used for samples stored under very different conditions. The focus of the project is the standardisation and validation of the innovative techniques of whole genome amplification (WGA) and whole transcriptome amplification (WTA) in the context of biobanks. A general standardized protocol for WGA and WTA procedures that use Phi29-DNA-polymerase in biobanking will be developed.The major aims of our project are: 1. To establish standardized WGA protocols for large biobanks 2. To develop standardized WGA tools to recover genomic DNA, which is in plasma or serum samples and from FFPE- tissue or blood spots 3. To optimize the WGA procedure by extensive quality control measures of WGA products 4. To develop and establish WTA of large biobank samples 5. To optimize WTA procedures by extensive quality control of WTA products Furthermore, the concept of the project is to transfer the results of WGA and WTA solution to national and international organisations in the field of biobanking. The development of the proposed, innovative and specialized tools and customized solutions will help to expand and secure biobanks.

## 2933/F/Poster Board #865

**High-density mapping of susceptibility genes to multifactorial diseases using DigiTag2 assay.** *N. Nishida[1], M. Sageshima[1], A. Suyama[2], K. Tokunaga[1].* 1) Dept Human Genet, Univ Tokyo, Tokyo, Japan; 2) Dept Life Sciences, Univ Tokyo, Tokyo, Japan.

DigiTag2 assay performs multiplex SNP typing by encoding all of the SNP genotypes to the well-designed oligonucleotides, named DNA coded numbers (DCNs). The DCNs are assigned to the target SNPs in an unconstrained manner, therefore, the DNA chips prepared to read out the types of DCNs are universally available for any types of SNPs. Moreover, the primers and probes for DigiTag2 assay are designed using fixed designing parameters to carry out SNP typing under the same experimental conditions without any optimization.

DigiTag2 assay is a suitable multiplex SNP typing platform to genotype with a number of samples (adequate genotyping throughput: 192 samples per day) in a 96-plex or a 32-plex form. DigiTag2 assay has other advantages against the conventional platforms in the running cost (for oligonucleotides, reagents, DNA microarrays, etc.), which is estimated to be less than $0.06/genotype, and in the conversion rate (defined by the proportion of successfully genotyped SNPs in the number of SNPs examined), which reaches to 90.72% (929/1,024 SNPs). Moreover, we made a SNP typing using DigiTag2 assay for over 1,000 SNPs with over 26,000 samples in total and revealed that the average call rate are 99.53% in both of 32-plex and 96-plex forms.

The genotyping platform with high conversion rate plays an important role for the replication studies to identify the disease associated genes from candidate loci found in the GWAS (genome-wide association study) stage. The DigiTag2 assay will facilitate a high-density mapping of susceptibility genes to multifactorial diseases in the replication studies.

## 2934/F/Poster Board #866

**A new approach to identify sequence-specific protein-DNA interactions using surface arrays and mass spectrometry.** *M. Olivier, Y. Zhang, S.P. Mirza.* Biotechnology and Bioengineering Center, Med Col Wisconsin, Milwaukee, WI.

A method that can efficiently identify DNA-bound proteins is an indispensable tool for the study of mechanisms involving DNA-protein interactions, such as transcriptional regulation which significantly impacts cellular function. Traditional methods such as electrophoretic mobility shift assay (EMSA) that are usually implemented to test the binding of proteins to short DNA fragments will not help determine the identity of the DNA-bound protein(s). The identity of individual DNA-binding proteins may be confirmed by super shift assays if the protein is known and a quality antibody is available. However, for the vast majority of DNA-bound protein(s), these assays fail to uncover their IDs. Here, we report a novel approach to identify DNA -bound proteins, combining an oligonucleotide surface array and mass spectrometry (MS) for protein identification. We have applied our approach to identify the protein(s) differentially bound to DNA sequences containing single nucleotide polymorphism (SNP) that have been shown to be associated with plasma TG levels in humans. We covalently linked a 5'-amine- modified double-stranded 41-mer oligonucleotide to an aldehyde-terminated self-assembled monolayer on a gold surface. To identify DNA-bound proteins from nuclear extracts, peptides were trypsin digested and analyzed on an ion trap mass spectrometer. A full range MS spectrum was acquired followed by MS/MS of the six most abundant ions from the full MS scan, followed by database searching using the SEQUEST algorithm. The resulting identified proteins were compared between the two allelic forms of the oligonucleotide, and proteins bound only to one oligonucleotide were identified. For SNP rs3734967 of a brain-expressed serontonin receptor, HTR5A, our approach reproducibly (n=3) detected a nuclear protein, Poly(rC)-binding protein 1, bound to the G allele that also demonstrated a differential binding of proteins using EMSA. For SNP rs2721 of a feedback regulator gene for cholesterol synthesis, INSIG1, we identified three major liver nuclear proteins that are differentially bound only to the T allele. Whether or not the SNPs truly modulate the binding to these identified protein candidates awaits further investigation. Nonetheless, our novel surface array-MS approach has been able to identify proteins captured selectively by oligonucleotides in a sequence-specific manner, and could facilitate the high-throughput characterization of protein-DNA interactions.

## 2935/F/Poster Board #867

**Quality Control of Affymetrix Genome Wide Human SNP 6.0 Processing at a High-Throughput Facility.** *J. Romm, B. Marosy, K. Hetrick, B. Craig, M. Zilka, C. Ongaco, S. Pottinger, J. Gearhart, J. Goldstein, D. Leary, M. Barnhart, L. Watkins, E. Pugh, K. Doheny.* Center for Inherited Disease Research, Johns Hopkins University, Baltimore, MD.

The Center for Inherited Disease Research (CIDR), established at Johns Hopkins University in 1996, provides high quality genotyping services and statistical genetics consultation to investigators working to discover genes that contribute to common disease. CIDR has recently begun offering an Affymetrix GenomeWide Human SNP 6.0 genotyping service. We have developed quality control measures and defined workflow to obtain sample QC metrics quickly. We have strict sample acceptance criteria which includes blood or cell line genomic DNA, assaying samples for concentration (>50ng/uL by OD) and for lack of degradation (high molecular weight band >4kb on a 2% agarose gel). CIDR developed a Laboratory Information Management system (LIMs) for tracking workflow and reagent creation and use. There are QC steps in the LIMs that require verification to proceed, and the option to exclude a sample from hybridization to an array. LIMs provides a real-time informatic log of sample ID/array barcode association during manual injection of samples. Before an entire 96 well plate is hybridized, we perform 4 'Test-Hybs' and review gender, barcode and HapMap concordance, Contrast QC (CQC), CIDR QC birdseed call rate and DM QC call rate. In order to quickly generate these statistics, CIDR has developed an AffyCall pipeline which automatically parses and archives output files and updates QC statistics for each sample. To obtain the CIDR QC birdseed call rate, each sample is individually called with a group of 95 standard samples in order to mimic calling data by plate. This allows assessment of each sample independent of the overall batch performance and reduces variables involved in troubleshooting chemistry or sample quality issues. We evaluate the correlation of the STY CQC/NSP CQC at a plate level to confirm that there was no mispooling of a PCR plate before purification. CIDR has defined more stringent internal QC for data that is released to a PI and to public databases than currently recommended by Affymetrix. A releasable sample is one having a DM QC call rate >86%, a CIDR QC birdseed call rate of >98% and a CQC value of >1.0. If a sample does not perform well the first time through the assay, it is repeated once. Our first Affymetrix 6.0 project, a case-control study of T2DM, resulted in a 99.72% blind duplicate reproducibility rate, HapMap concordance of 99.76%, and a total release of 97% of experimental samples. The mean call rate for released samples was 99.6%.

## 2936/F/Poster Board #868

**Maternal Cell Contamination (MCC) Testing on the new 3500 Capillary Electrophoresis System using STR/Microsatellite Markers.** *S.C. Hung[1], C.J. Davidson[1], L. Pique[2], E.S. Nordman[1], B.F. Johnson[1], R.A. Padilla[1], R.N. Fish[1], L.K. Joe[1], S.R. Berosik[1], A. Chhibber[1], J. Lee[1], S.R. Santhanam[1], A.C. Felton[1], A.A. Pradhan[1], I. Schrijver[2].* 1) Life Technologies Corporation, Foster City, CA; 2) Molecular Pathology Laboratory, Stanford University Medical Center, Stanford, CA.

Fetal gDNA samples, isolated from amniotic fluid (AF) or chorionic villus samples (CVS), are commonly used for prenatal genetic testing. AF and CVS samples are extremely valuable samples that are collected via invasive surgical procedures, and as a result could be subject to maternal cell contamination (MCC). Due to the sensitivity of PCR, MCC can potentially contribute a significant source of error in prenatal testing with misinterpretation of a prenatal test thought to be possible at levels of MCC as low as 1-2%. Commercially available forensic human identification kits that employ fluorescent multiplex PCR amplification of polymorphic microsatellite markers are suitable for the MCC detection. To interrogate several informative markers when analyzing samples for MCC, we utilized the AMPFLSTR® Minifiler PCR Amplification Kit, which examines 8 microsatellite loci across four distinct fluorescent dyes. In order to evaluate the new 3500 capillary electrophoresis (CE) instrument, synthetic MCC sensitivity controls (10%, 5%, 2% and 1%) as well AF samples were analyzed. Semi-quantitative calculations of the level of MCC contamination were performed by comparing the peak area of the informative maternal allele to the unique fetal allele; the new CE instrument provided adequate sensitivity for detecting a synthetic MCC control at a level of 2% or greater. Further, we discuss common pitfalls to the analysis of MCC results such as broad peak errors, allelic drop out (ADO), preferential allelic amplification, and the influence of stutter peaks.

## 2937/F/Poster Board #869

**Co-amplification at Lower Denaturation temperature-PCR (COLD-PCR) can be used to increase mutations detection sensitivity of genetic testing.** *A. Milano, A. Goodeve, A. Dalton.* Sheffield Diagnostic Genetic Services (SDGS), Sheffield Children's NHS Foundation Trust, Sheffield, United Kingdom.

Background: One of the main limitations of the most common PCR based techniques used in genetic diagnosis (e.g. Sanger sequencing, Pyrosequencing technology, TaqMan) is the sensitivity of detection for low levels of somatic mutations. However, the identification of these low levels alterations can be critical in several areas of medicine including oncology, virology, microbiology and prenatal diagnosis. Recently, Wang et al (Nature Medicine 2008; 14:579-84) have reported that a major improvement in detection sensitivity can be achieved by the use of "COLD-PCR". This modified PCR is based on the principle of using a sequence specific lower denaturation temperature "Tc" at which only heteroduplexes (of mutant plus wild type alleles) are selectively denatured and amplified.

Methods: We compared our conventional PCR methods with COLD-PCR to determine any improvements in detection sensitivity of the JAK2 p.V617F mutation by TaqMan and KRAS p.G12V mutation by Pyrosequencing analysis. Sensitivity was assessed using serial dilutions of DNA from cell lines homozygous for the above mutations.

Results: COLD-PCR successfully detected mutations in all samples that were positive by conventional PCR, and enhanced the mutant-to-wild-type ratio by an average of 5-fold. This resulted in an increase in sensitivity from 0.5% to 0.1% for TaqMan based analysis of the JAK2 p.V617F and from 5% to 1% for Pyrosequencing analysis of the KRAS p.G12V mutation. All samples were genotyped correctly and no mutations were detected in any of the wild type control samples.

Conclusions: The implementation of COLD-PCR required only minimal optimisation comprising determination of the Tc denaturation temperature; no changes in reagents or instruments were necessary. We can confirm that COLD-PCR is specific and reproducible and that its use results into a significant increase in assay sensitivity, which will have an important impact on clinical decision making.

## 2938/F/Poster Board #870

**High Throughput Targeted Resequencing of Human Genomic Disease Loci using Solution Sequence Capture.** *R. Selzer[1], M. Rodesch[1], H. Halvensleben[1], J. Wendt[1], B. Thomson[1], L. Freeberg[1], G. Weissenberger[2], A. Sabo[2], D. Muzny[2], M. Bainbridge[2], M. D'Ascenzo[1], X. Zhang[1], T. Richmond[1], L. Nazareth[2], D. Burgess[1], T. Albert[1], R. Gibbs[2].* 1) Roche NimbleGen, Inc., Madison, WI; 2) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX.

Oligonucleotide microarrays have been successfully coupled with next generation sequencing platforms for the efficient targeted resequencing of disease candidate loci from ~100Kb up to the entire human consensus coding exome of ~35Mb. These solid phase approaches permit functional genomic elements to be sequenced to high depth, and enable identification of rare variation in human inherited disease, and in cancer. Although the microarray-based methods exhibit superior reproducibility and sequence coverage uniformity compared to solution-based hybridization methods, their utility for studies of very large sample numbers has so far been limited by the lack of automated, high-throughput, processing routines. This has been alleviated to some extent by sample pooling strategies, including the use of sequence tags (MIDs), but there is still a need to be able to process samples more rapidly. We have devised a highly scalable, novel sequence capture method that combines the advantages of solution-based hybridization approaches with the desired functional attributes of microarray-based techniques. Application of this method to analyze a 400Kb contiguous target region on human chr15 resulted in greater than 70% of the subsequent ~600,000 454 GS FLX Titanium sequence reads mapping to the capture target. More than 95% of the target bases were covered, with average and median coverage each greater than 300X, sufficient for the automated calling of rare sequence variants with high confidence. Targets larger than 5Mb have also been successfully captured and targets of 30Mb are theoretically possible. This rapid, scalable and cost-effective method provides an efficient means of characterizing chromosomal regions identified through genome-wide association studies of many individuals, and will facilitate the simultaneous analysis of common and rare sequence variation in inherited diseases.

**Miniaturizing RNAi Assays: Acoustic Droplet Ejection (ADE) Enables Efficient and Reproducible siRNA Library Screens at Low Volumes.** *C. Jarman[1], V. Bruzzel[2], A. Davies[2], S. Pickett[1].* 1) Labcyte Inc., Sunnyvale, CA, USA; 2) Institute of Molecular Medicine, Trinity College, Dublin, Ireland.

The use of RNA interference (RNAi) for loss of function studies has revolutionized our ability to characterize gene function or to identify potential therapeutic targets for drug discovery. To facilitate large-scale, high-throughput functional genomics studies using RNAi, we have investigated the use of acoustic droplet ejection (ADE) technology for siRNA library based screening. As the number of siRNA molecules increase per target, cost is quickly becoming the prohibitive factor in conducting a successful genome-wide screen. Previously we have shown the use of ADE technology (unique tipless and touchless liquid transfer technology) in delivering sub-microliter volumes of siRNA molecules, transfection reagent and various cells to conduct library-based screens in standard 96-, 384- and 1536-well plate formats. Recently we have been investigating the use of ADE (Echo(R) liquid handler, Labcyte Inc.) for reverse transfecting cells on microscope slides in volumes as low as 25 nanoliters. Here, we used ADE to deposit siRNAs in a transfection matrix onto glass slides in an array, overlaid this with a monolayer of adherent cells and incubated the slides to allow reverse transfection. We then assessed for the effects of gene silencing by digital image analysis at a single cell level. Results suggest that ADE technology meets the current demands of siRNA library-based assays to enable high-throughput siRNA screening. In addition, by using ADE in an arraying capacity we have significantly reduced the amount of siRNA needed for each assay. This microarray approach further increases the data acquisition speed whilst reducing the reagent and consumables costs of each experiment.

## 2940/F/Poster Board #872

**Testing SNP Markers for Human Identification Application.** *J. Chen, D. Pinnamaneni, C. Wright.* Dept Biol, Claflin Univ, Orangeburg, SC.29115.

Developing a detection system for degraded DNA samples presents a big challenge for the field of DNA-based human identification. Currently commercial human DNA identification methods are based on the use of short tandem repeat (STR) DNA markers. Applied Biosystems' AmpF/STR Identifier and Promega's PowerPlex 16 systems for human identification generate STR PCR fragments up to 370 base pairs and 470 base pairs respectively. When DNA samples are degraded, however, neither kit is able to generate the PCR products required for the identification. We have investigated the use of single nucleotide polymorphism (SNP) markers for human identification. In the SNP approach much shorter DNA fragment are required, this will allow the system to work on degraded DNA samples. We select SNP markers with allele frequencies ranging from 0.35 to 0.5 among the Asian, African and Caucasian populations and test these markers on DNA samples from these populations. We calculated that fifty SNP markers can provide discrimination power about one in 1000 trillion, so the odds that two individuals will have the same 50 SNP DNA profiles are about one in one thousand trillion (except identical twins). The discrimination power from fifty SNP is much higher than the current commercial products. Another advantage of SNP technology is that the SNP probes can be put on DNA chip or array platform. We have tested ten SNP markers on three DNA panels from Asian, Africa America, and Caucasian. The information will be used for SNP Human Identification technology development.

## 2941/F/Poster Board #873

**Next generation SNP genotyping using the Affymetrix platform.** *M. Shapero, R. Mei, J. Zheng, M. Purdy, L. Wang, D. Giberson, M. Borodkin, J. Burrill, M. Yamamoto, S. Cawley, A. Williams, K. Jones.* Genotyping Research, Affymetrix, Santa Clara, CA.

**Purpose**: DNA microarray technology continues to play an important role in identifying the genetic basis of common and complex human diseases through genome wide association studies (GWAS). As large scale sequencing efforts across multiple populations continue to add to the characterization of both common and rare genetic variation in the form of single nucleotide polymorphisms (SNP) , microarrays are well poised to capitalize on this new information content. To this end, Affymetrix has continued to develop new technological approaches to facilitate large-scale GWAS. Here an overview of our next generation genotyping platform is presented: an integrated, high throughput system that includes a highly automated workflow, a new enzymatic-based assay, and novel SNP content that was derived from a large diversity screen.

**Methods**: DNA target preparation, DNA amplification, and enzymatic fragmentation of post-amplification products are all automated on the Beckman ArrayPlex platform. Hybridization of DNA target occurs on peg arrays contained in either 24-well or 96-well plate configurations, with subsequent interrogation of the polymorphic nucleotide via a ligation reaction that uses two differentially labeled solution probes. Following a stringent wash, array staining occurs in concert with a multi-color, CCD-camera based detection scheme. All steps from array plate hybridization to array plate scanning are fully automated using the Affymetrix GeneTitan System. Lastly, all results are displayed via a comprehensive user-friendly software suite.

**Results**: The current SNP content for this platform is derived from a screen of dbSNP Build 128 across a diverse set of 1300 samples. This ligation-based SNP genotyping platform has been tested using several different kinds of input DNA, ranging from cell-line derived DNA to DNA extracted from human blood and saliva. Assay performance was evaluated using overall call rate, trio concordance, and concordance to independent DNA genotype information (HapMap).

**Conclusion**: The next generation platform for GWAS provides comprehensive and accurate genotyping of hundreds of thousands of SNPs in a single assay and offers a sample throughput coupled with minimal manual intervention consistent with the needs of large scale studies being conducted as part of the search for the underlying genetic basis of complex human disease.

## 2942/F/Poster Board #874

**Specificity of TaqMan® Drug Metabolism Genotyping Assays using DNA sequencing by capillary electrophoresis.** *P. Tsang, B. Ching, J. Au-Young, T. Hartshorne, T. Ceccardi.* Applied Biosystems, Foster City, CA.

Genetic polymorphisms in the cytochrome P450 genes are of pharmacogenetics importance due to the significant roles the P450 enzymes have in drug metabolism. Genotyping using TaqMan Drug Metabolism (DME) Genotyping Assays and DNA sequencing are two common methods used for detecting single nucleotide polymorphisms (SNPs), insertions and deletions (indels), and multi-nucleotide polymorphisms (MNPs) in P450 genes for pharmacogenetics applications. Bioinformatics methods were used to design assays that specifically target the polymorphism of interest. The TaqMan DME assays were tested on a total of 180 Coriell samples from four different populations and the frequency of the alleles and genotypes were compared to reported results in public databases and the literature, when available. However, the specificity of TaqMan DME genotyping assays were not further investigated by other concordant laboratory methods. Of particular interest are the DME genes showing significant homology to other loci in the genome, such as pseudogenes or related gene family members. Our objective was to demonstrate the specificity of a subset of TaqMan DME genotyping assays for polymorphisms in CYP2D6, CYP2C9 and CYP2C19 genes by showing concordance between genotyping results obtained with the TaqMan DME assays and DNA sequencing. PCR primers with M13 tails were designed for 39 selected alleles and were used to amplify genomic DNA samples from Caucasian and African American Coriell cell lines. The predicted size and specificity of each amplicon was corroborated by gel electrophoresis. Amplicons of the predicted sizes were sequenced by capillary electrophoresis and their genotypes were determined by aligning the TaqMan DME assay target sequences with the amplicon sequences. By showing concordance between the genotypes obtained from sequencing and TaqMan DME assays, we were able to confirm that correct genotypes were obtained using TaqMan DME genotyping assays. Therefore, TaqMan DME genotyping assays provide a reliable and fast genotyping method for identifying many P450 genetic variants for pharmacogenetics applications.

## 2943/F/Poster Board #875

**Y-SNPs analysis in Japanese male (Tokushima area).** *Y. Yoshida[1,2], S. Kubo[3], Y. Nakahori[2].* 1) Tokushima Police Headquaters, Tokushima, Japan; 2) Department of Human Genetics, Institute of Healthbiosciences, The Tokushima University Graduate School, Tokushima, Japan; 3) Department of Forensic Medicine, Faculty of Medicine, Fukuoka University, Fukuoka, Japan.

In recent years, many researches to discriminate Japanese people are investigated on the basis of the racial classification using SNP. Similarly, it is effective to detect Y-SNP in order to discriminate a Japanese male. In the Y-SNP classification, it is reported that ration of O, D, and C type occupy most in the Japanese male, and N and P system are minority. In general D type peculiar to Japanese is called “Jomon”, and most famous O type in Japan is called “Yayoi”. Also in our previous study, same three types s observed were high frequency, such as O type: 48.8%, D type: 27.3%, C type: 12.4% in the male of Tokushima prefecture. In our comparative study of 4 areas (Gunma, Fukui, Tokushima, Kagoshima), we experienced that a frequency difference was in these three types on Japan . And we could find the characteristics of each type, especially the C type was guessed moving linearly in the inside of Japan from the Y-STRs data of 9loci. Then, in this research we detected not only the 4 loci of P31 (O2), M122 (O3), M216 (C) and M174 (D) which have been used until previous study, but also the loci of M8 (C1), M217 (C3), P186 (O), M231 (N), and P230 (P). The detection method was improved so that regional difference could be examined in detail. We analyze quickly and simply by the Cycleave PCR method (Takara) using real-time PCR equipment. Since this method using a chimera probe has high sensitivity, prepared primer and the probe so that only mutant type could be detected, and detected 2 loci by PCR at once . The result was divided into each type of O, D, C, and N by 1st PCR, and further, the type of C and O were able to be separated into C1 / C3 and O2 / O3 by 2nd PCR. Moreover, the sample which has not been detected to the 1st PCR detected P type by P230. We introduce our examined method and its data about the male of Tokushima area in Japan. Reference: Yoshida Y. et al. Leg Med, 10 243-252 (2008).

## 2944/F/Poster Board #876

**Evolution, expansion and genomic impact of the human retrotransposon SVA.** *D.C. Hancks, A.D. Ewing, J.E. Chen, H.H. Kazazian, Jr.* Genetics, University of Pennsylvania, 515 Clinical Research Building, 415 Curie Blvd, Philadelphia, PA. 19104.

Although most human retrotransposons are inactive; both inactive and active retrotransposons drive genome evolution and may influence transcription through various mechanisms. In humans, three retrotransposon families are still active, but one of these, SVA, remains mysterious. Here we report the identification of a new subfamily of SVA, which apparently formed after an alternative splicing event, where the first exon of the Mast2 gene spliced into an intronic SVA and subsequently retrotransposed. After molecular and computational experiments, we found a number of functional splice acceptor sites within many different transcribed SVAs across the human and chimpanzee genome along with additional examples of splicing followed by retrotransposition in other primates. Likewise, using a mini-gene splicing construct containing an SVA in cell culture, we are able to observe splicing, along with exonization events that shift the reading frame introducing premature termination codons (PTC). Moreover, these results imply that an SVA residing within an intron in the same orientation as the gene may alter normal gene transcription either by gene-trapping or by introducing PTCs through exonization, thereby affecting genome evolution.

**Rapid scale up of a whole genome genotyping platform while implementing a modified management strategy.** *A. Crenshaw, M. Parkin, W. Brodeur, T. Minnetyan, J. Carey, G. Grant, D. Gage, W. Winckler, S. Gabriel.* Gen Analysis Platform, Broad Inst/MIT & Harvard, Cambridge, MA.

The Broad Institute Genetic Analysis Platform was tasked with a rapid scale up of one of its whole genome platforms, which included QC and QA steps taken to ensure quality throughout the process. This was done in real time to accommodate a ~48,000 sample project as well as other projects being planned. This was made possible with the addition of minimal capital equipment and informatics support. In analyzing the process we were able to identify pinch points in the process so that we could increase efficiency and quality without too much upfront costs. We will discuss methods used to ensure high data quality by requiring implementing stringent QA and QC procedures to monitor sample quality, sample identity, and processing controls. We will also discuss the informatics support that is wrapped around this process to enable monitoring of a high throughput environment in easily digestible formats to identify and resolve any issues that might arise in a timely manner. These processes and monitoring have allowed us to produce data in a robust and scalable fashion in a short period of time.

## 2946/F/Poster Board #878

**Non ionizing radiation may induce genomic imbalances in cultured human tissues after being submitted to a cell-phone radiation environment above international exposure limits.** *J.K. Heinrich[1], C.L Campanhol[1], R.M. Rodrigues-Peres[1], W.R. Heinrich[2], A.M. Almeida[2].* 1) CAISM - Women’s Hospital - State University of Campinas - UNICAMP , Campinas, SP, Campinas, Brazil; 2) CPqD Foundation , Campinas, SP, Brazil.

Radiation may cause several cell injuries and genetic alterations such as chromosomal rearrangements, aneuploidy, micronuclei frequency increase, microsatellite instability, mutations, gene amplification, gene transcription changes which culminates in cell transformation and death in the first and following generations of cells after the first insult. The objectives of this study were to access genotoxic and clastogenic effects of non-ionizing radiation, the same kind of radiation employed in cell-phone devices. Conventional karyotyping, micronuclei frequency and gene copy number status of the genes TP53, ERBB-2 and C-MYC through FISH analysis and genome-wide studies through mCGH were applied to 24 blood samples and skin tissue from healthy donors with normal genomic profiles. Cells were submitted to a non-ionizing radiation experimental source during different periods of time. The radiation system was specially designed for the experiment with strict conditions, controls and calibration. The power values were calculated to allow SAR values (specific absorption rates) of 0,8 W/kg, 2W/kg (international limit for public exposure), 5W/kg and 10W/kg with AMPS, CDMA and GSM modulation. Control samples and sham-exposed controls were also analyzed. Chromosomal abnormalities and micronuclei frequency showed to be dose-dependant with higher frequencies for the highest SAR levels after 5W/kg. We failed to observe imbalances for the TP53 gene although a slight number of aneuploid cells were found. Hybridization controls indicated that those copy changes were specific related to radiation. Interclass coefficients and correlation analysis were perfomed. As a correlation between the exposure of non-ionizing radiation and genomic imbalances was observed above international exposure limits, our findings should help for the future proposals of new public policies regarding exposure limits and international guidelines as the number of cell phone users has duplicated in the last years. SUPPORT: FUNTTEL/Brazil.

## 2947/F/Poster Board #879

**Genomic technologies in the analysis of historical relics: identification of remains of Nicholas II Royal family and their servants.** *E.I. Rogaev[1,2,3], A.P. Grigorenko[1,2,3], Y.K. Moliaka[2,3], G. Faskhutdinova[2], E.L.W. Kittler[4], I.Y. Morozova[1,2].* 1) Department of Genomics and Laboratory of Evolutionary Genomics, Vavilov Institute of General Genetics, Russian Academy of Science, Gubkina Street, 3, Moscow, 119991, Russian Federation; 2) Brudnick Neuropsychiatric Research Institute, University of Massachusetts Medical School, 303 Belmont Street, Worcester, MA 01604; 3) Research Center of Mental Health, Russian Academy of Medical Science, Zagorodnoe Shosse 2/2, Moscow, 113152, Russia; 4) University of Massachusetts Medical School, CFAR, Worcester, MA, USA.

We have performed the genomic analysis of historical specimens from two graves found in 1993 and 2007 presumably belonging to Nicholas II royal family members and their attendants who were murdered during the Russian Civil War in 1918. We successfully reconstructed the sequences from complete mitochondrial (mt) genome and determined Y-chromosome and autosomal chromosome profiles for the old skeleton specimens. We extended our analysis of the Royal family to testing of skeleton remains presumably belonging to their three servants and a court physician. As the reference samples the specimens from the distant relatives of the servants were tested along with the living descendants of the European Royal families. In addition, ~117 year old blood traces of Nicholas II from museum historic relic were examined. We developed multiplex PCR assays and high-throughput sequencing technologies for analysis of highly degraded nuclear and mitochondrial DNA from badly damaged old biological specimens. To predict the historical and population origin of the remains the SNPs haplotypes were determined for the Y-chromosome and mt genomes. In addition to individual STR and SNP profiles the genotype-phenotype correlations (hair and eye color) were made by direct re-sequencing of ultra-short amplicons generated for some nuclear genes. The results of our study demonstrated that comprehensive genomic analysis can provide a very accurate and efficient individual and kinship identification for very old historical relics and severely damaged forensic specimens. Our data provide evidence without reasonable doubt that the remains of Royal Family attendants and all members of Romanov family (father, mother and five children), including Anastasia and Alexei, have been identified.

## 2948/F/Poster Board #880

**The detailed genomic and epigenetic characterization of human 15q11-13 in an autism endophenotype family.** *S.G. Gregory[1], A.J. Towers[1], L.L. Sullivan[2], H.A. Cope[1], M.L. Cuccaro[3], M.A. Pericak-Vance[3], B.A. Sullivan[2], G.R. DeLong[4].* 1) Dept Med, Duke Ctr Human Gen, Durham, NC; 2) Department of Molecular Genetics and the Institute for Genome Sciences & Policy, Durham, NC; 3) Miami Institute for Human Genomics, University of Miami, Miami, FL; 4) Department of Medicine, DUMC, Durham, NC.

Classic autism (AutD) comprises a spectrum of behavioral and cognitive disturbances of childhood development. The core AutD phenotype includes deficits in social interaction, impaired language development and patterns of repetitive behaviors and/or restricted interests. Estimates of population prevalence range between 1/300 to 1/150, with a male to female ratio of 4:1. The disorder has been shown to be highly heritable with the relative risk for siblings being 50-100 times that of the general population. Despite the considerable efforts of previous genetic studies only a small percentage of AutD cases (<10%) have been ascribed to single gene disorders. Although this likely reflects the underlying genetic heterogeneity of the disorder, investigators are rethinking the model of inheritance associated with autism to include epigenetic mechanisms, including genomic imprinting and epimutations. We have adopted a highly innovative, multi-faceted approach to profile the genomic and epigenetic signatures of a multi-generational, co-morbid family that has a clinical history of autism, albinism, splinter skills and bipolar disorder. A number of previous genetic studies have linked 15q11-13 with autism however, additional studies have singularly established a link between genes within 15q11-13 to bipolar disorder, via the GABA(A) receptor cluster, oculocutaneous albinism, via OCA2, and special memory abilities or splinter skills to the region. We have used state of the art high-resolution Nimblegen oligo tilepath microarrays to carry out copy number, ChIP-chip and DNA methylation analysis of DNA from peripheral blood from our co-morbid autism family. Additionally, we have correlated epigenetic profiles with gene expression using Illumina's genome-wide expression arrays. Here we report these analyses and the DNA methylation and histone modification (H3K4me2/H3K4me3/H3K9me2/H3K9me3) profiles within proximal 15q of 12 members from the co-morbid autism family.

## 2949/F/Poster Board #881

**Global analysis of chromatin marks in human pancreatic islets provides insights to type 2 diabetes susceptibility loci.** *D.S. Pearson[1], M.L. Stitzel[1], P. Chines[1], M.R. Erdos[1], L. Song[2], T. Furey[2], G.E. Crawford[2], F.S. Collins[1].* 1) Genome Technology Branch, NHGRI, Bethesda, MD; 2) Institute for Genome Sciences & Policy, Duke University, Durham, NC.

Genome-wide association studies have so far identified 18 variants associated with type 2 diabetes (T2D). Two thirds of these variants are associated with impaired insulin secretion or processing, and the vast majority reside in non-coding portions of the genome. These data suggest that altered regulatory function in the pancreatic islet may play an important role in T2D pathophysiology, but the regulatory landscape of the human islet epigenome is largely unknown. Recent chromatin studies in cell lines and other tissues suggest that regulatory elements are found in open chromatin regions and are enriched for certain histone H3 modifications. To characterize the islet epigenome and identify important regulatory elements that may be disrupted in T2D, we characterized the genome-wide distribution of a host of histone H3 lysine methylation marks (monomethylation of lysine 4, dimethylation of lysines 9 and 79, and trimethylation of lysines 4, 27, and 36) and regions bound by p300, CHD7, and CTCF using chromatin immunoprecipitation coupled with next generation sequencing (ChIP-Seq). Regions of open chromatin were defined using genome-wide DNase hypersensitivity mapping. These approaches were highly successful in identifying known promoters and enhancer elements in human islets. Extending these analyses to 18 regions of T2D association, our data suggest the existence of approximately 80 putative regulatory elements. For several of these, a SNP associated with increased T2D risk is located within or near the newly identified regulatory element. Currently, we are evaluating the function of wildtype and variant versions of a subset of these elements using dual-luciferase assays that assess enhancer, enhancer blocker, and silencer activity. Characterizing the entire repertoire of human islet regulatory elements will enhance our understanding of gene regulation in the human islet and should provide critical insight into the molecular mechanisms involved in diabetes susceptibility.

## 2950/F/Poster Board #882

**Feasibility for Detecting Epigenetic Abnormalities in Autism Brain.** *R. Person, S. Kim, X. Zhang, Y.H. Jiang, R. Chen, Y. Li, W. Li, A. Beaudet.* Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX.

There is increasing evidence that de novo and recent mutations at any one of many heterogeneous loci cause a substantial fraction of autism. These findings are entirely consistent with the high heritability of autism, as evidenced by the high concordance between monozygotic (MZ) twins. Yet, the etiology of autism remains unknown for a large fraction of individuals, particularly for nondysmorphic, higher functioning males. Epigenetics refers to regulation of gene expression without change in the underlying DNA sequence. Important, analyzable components of epigenetic expression include expression of mRNA and miRNA, DNA methylation, and histone modifications. Epigenetics plays at least some role in the etiology of autism as evidenced by the fact that usually maternal but not paternal interstitial duplications of chromosome 15q11-q13 cause autism. Epigenetic abnormalities could be more widely important in the etiology of autism, and could contribute to the heritability seen in MZ twins if epimutations arose prior to MZ twinning. As a proof of principle, we wished to demonstrate the feasibility of using existing methods to detect the known epigenetic aberrations within 15q11-q13, responsible for Prader-Willi syndrome (PWS) and Angelman syndrome (AS) syndromes. To investigate DNA methylation, MBD2 and MBD1 proteins were used to enrich methylated and unmethylated CpG rich DNA respectively. Histone modifications were examined using native chromatin immunoprecipitation (N-ChIP), followed by analysis either using Agilent microarrays or massively parallel Solexa DNA sequencing. Finally, the expression of 723 human and 76 human viral miRNAs were examined using the Agilent human miRNA (V2) microarray system. Using MBDs to examine the status of DNA methylation, we confirmed the ability to detect the known abnormalities in PWS and AS brain. Using NChIP to detect histone H3 lysine 4 trimethylation, a marker of active transcription, we confirmed its presence exclusively on the paternal SNRPN allele - present in AS but not PWS individuals. Finally, we found a significant upregulation of three miRNAs in 6 of 20 autism and in 0 of 20 control cerebellum samples. Thus, we have demonstrated the ability to use these methodologies to detect known epigenetic abnormalities in PWS and AS brain and the feasibility of detecting changes in autism brain if they occur. Additionally, we've shown a significant elevation of three miRNAs in a subset of autism cerebellum samples.

## 2951/F/Poster Board #883

**Genome-wide comparison of high resolution maps of nucleosome organization from purified human cells uncovers substantial complexity in the chromatin landscape.** *A. Valouev[1], S. Johnson[3], C. Smith[2], S. Boyd[2], A. Fire[1], A. Sidow[1].* 1) Department of Pathology, Stanford University, Stanford, CA; 2) Department of Genetics, Stanford University, Stanford, CA; 3) Department of Microbiology & Molecular Biology, Brigham Young University.

Chromatin organization of a cell is defined by complex interactions of nucleosomes packaging the DNA, transcription factors binding to their response elements and chromatin remodeling complexes changing the chromatin landscape according to the needs of the cell. What forces affect positioning of nucleosomes and to which degree this positioning is reproducible across different tissues is currently an actively debated topic in the chromatin field. While significant positioning and phasing of nucleosomes has been observed in synchronized yeast cells (Lee et al 2007, Segal et al 2006), seemingly very little positioning is present in samples from multi-stage whole worm pellets (Valouev et al 2008) suggesting that although positioned nucleosomes can be ubiquitous, they are also extremely cell-type specific ruling out the possibility of a universal DNA code dictating genome-wide organization of nucleosomes. To further investigate the extent of this phenomenon and precisely identify forces involved in chromatin organization, we have generated almost 2 billion SOLiD sequencing reads to produce high-resolution maps of nucleosome positioning within three human cell types purified from the blood of a single individual (granulocytes, CD4 and CD8 T-lymphocytes). Additionally, to specifically address the DNA sequence contribution to the positioning of nucleosomes, we also generated a high-resolution positioning map for the nucleosomes reconstituted in-vitro on human DNA. For dissecting functional effects on nucleosome positioning, we have generated ChIP-Seq data to precisely map behavior of several DNA binding proteins within these blood cells. Our data reveals a complex organization of chromatin and confirms that positioned nucleosomes are common within tissues, but their positions may differ significantly across different tissue types. Our in vitro reconstitution data suggests that although many nucleosomes can be positioned by the sequence, stereotypic positioning of many nucleosomes in vivo is not encoded by the sequence, but can be explained by other forces affecting chromatin in vivo, such as binding of transcription factors.

## 2952/F/Poster Board #884

**Investigating the Pathogenesis and Therapy of Friedreich Ataxia Using Mouse Model Cell Lines.** *C. Sandi, R. Mouro Pinto, V. Ezzatizadeh, S. Al-Mahdawi, M. A Pook.* CCCB/BICGP, Division of Biosciences, School of Health Sciences and Social Care, Brunel University, Uxbridge, Middlesex, UB8 3PH United Kingdom.

Friedreich ataxia (FRDA, OMIM 229300) is an autosomal recessive trinucleotide repeat disease caused by expanded GAA repeats in the first intron of the FXN gene. Normal individuals have 5 to 30 GAA repeat sequences, whereas affected individuals have 70 to 1600 repeats. The effect of the GAA expansion mutation is to reduce the expression of frataxin, a mitochondrial protein. The exact mechanism by which the GAA repeat expansion leads to decreased frataxin expression is unknown and also the function of frataxin is still partly controversial but it is believed to be involved in iron-sulphur cluster biosynthesis (ISCs). Frataxin insufficiency leads to oxidative stress, mitochondrial dysfunction and reduced activities of several enzymes involved in iron-sulfur cluster synthesis. Bisulfite sequence analysis of the FXN flanking GAA regions reveals a shift in the FRDA DNA methylation profile, with upstream CpG sites becoming consistently hypermethylated and downstream CpG sites becoming consistently hypomethylated. It has also been suggested that GAA repeats may produce a heterochromatin-mediated gene silencing effect. There is no effective therapy for FRDA. In order to gain further understanding of FRDA pathogenesis, the physiological function of frataxin and to develop an effective system for testing potential therapies, mouse models of FRDA are considered essential. We have recently generated a GAA repeat expansion mutation-based FRDA mouse model that exhibits GAA repeat instability, epigenetic changes and progressive mild pathology representative of FRDA. We now describe the establishment of neural stem cells (neurospheres) and fibroblasts from this FRDA mouse model. The neurospheres show reduced levels of FXN expression and the fibroblasts show significantly more sensitivity to hydrogen peroxide-induced oxidative stress than control cells. We further show how these cultured cells are now being used to investigate epigenetic-based drug therapies for FRDA. In particular, we demonstrate increased FXN expression by the use of DNA hypo/demethylating agents and histone deacetylase inhibitors (HDACi) for the development of novel therapies for FRDA.

## 2953/F/Poster Board #885

**Epigenetic Profiling in healthy Aging and Exceptional Longevity.** *G. Atzmon[1,2], A. Bergman[3], T. Budagov[1], R. Thompson[1], N. Barzilai[1,2], J.M. Greally[1,2].* 1) Dept Med, AECOM, Bronx, NY; 2) Dept Genetic, AECOM, Bronx, NY; 3) Dept Systems & Computational Biology, AECOM, Bronx, NY.

Epigenetic alterations may play a role in extension of lifespan and incidence of age-related degenerative diseases. We systematically assess the contribution of epigenetic changes, and in particular DNA methylation status to the aging process and phenotype. We have piloted for the first time Epigenome Wide Association Study (EGWAS) in 15 Ashkenazi subjects (8 centenarians, and 7 young unrelated controls), analyzing more than 1.3 million features across the human genome utilizing the genome-wide cytosine methylation assay-HELP and Nimblegen array. In the young unrelated controls 79% of loci fail to cut by the methylation-sensitive restriction enzyme HpaII (indicating hypermethylation) vs. 87% in centenarian. These initial results support the hypothesis that subjects with exceptional longevity may exhibit different levels of DNA methylation than controls that change globally with age. Three percent of the total epigenetic loci exhibit two (or greater) fold changes between the groups, of which 5% of loci showed a complete transition (from hyper to hypo-methylation or vice versa). The majority of loci with two fold or greater changes in methylation status, showed increasing methylation with age. These preliminary results indicate for the first time that although most of the methylation loci may not change significantly, some changes can be seen with respect to age. The role of epigenetics in human aging and life span has not yet been elucidated. Here we bring together a novel technology and a unique genetically homogenous population (Ashkenazim) between ages 60-110 years. We are therefore ideally poised to investigate the role of epigenetic changes in life span. Our exiting preliminary results demonstrate the power and advantage of utilizing whole genome epigenetic association study in aging and longevity.

## 2954/F/Poster Board #886

**Comprehensive DNA methylation analysis in neuronal and non-neuronal cells.** *K. Iwamoto[1], M. Bundo[1], J. Ueda[1], Y. Nakano[1], M. Oldham[2], W. Ukai[3], E. Hashimoto[3], T. Saito[3], D. Geschwind[2], T. Kato[1].* 1) RIKEN Brain Science Institute, Wako, Japan; 2) University of California Los Angeles, CA, USA; 3) Sapporo Medical University, Sapporo, Japan.

DNA methylation in the brain cells likely reflects their developmental history, neuronal activity, and environmental exposures, and is associated with behavior. Despite the previous efforts of DNA methylation profiling in the human brain, little is known about epigenetic differences between neurons and non-neurons. However, such knowledge is critical to a more complete understanding of the role of the genome in brain functions. We performed comprehensive DNA methylation analysis in neuronal and non-neuronal nuclei obtained from the human prefrontal cortex by cell sorter based method. The analytical methods we used included global methylation assay by pyrosequencing reaction, site-specific methylation quantification using Illumina beads technology, and Affymetrix promoter tiling array analysis. We found that while non-neuronal nuclei showed similar DNA methylation pattern to bulk cortex, neuronal nuclei manifested qualitatively and quantitatively distinctive DNA methylation patterns. Through the tiling array data analysis, we also found that genes related to neuronal activity were methylated in non-neuronal nuclei, while genes expressed in astrocytes were methylated in neuronal nuclei. Such DNA methylation differences may contribute to the phenotypic differences between neurons and non-neurons.

## 2955/F/Poster Board #887

**Design Principles for Methylation Sensitive High Resolution Melt Assay and Successful Direct Sequencing.** *A. Tobler, M. O'Donoghue, N. Koch.* Applied Biosystems - part of Life Technologies, Foster City, CA.

DNA methylation plays a critical role in the regulation of gene expression in development, differentiation, and disease. While methylation of promoters correlates with suppression of gene expression, global hypomethylation of genomic DNA has been observed in tumor cells. Most of the techniques available to study DNA methylation do not offer enough sensitivity to confidently detect methylated DNA levels less than 10%. Methylation Sensitive High Resolution Melting (MS-HRM) is an effective technique to screen samples for estimated DNA methylation levels. MS-HRM amplicons can further be sequenced to determine the exact methylation pattern. Awareness of some basic factors that influence detection sensitivity will improve the chance of a successful MS-HRM assay. In this report, MS-HRM assay design principles are discussed and the methylation of the MTA1 promoter is examined. Sensitivity to detect samples with as low as 0.1% methylation is demonstrated with primers containing methylation sites. We further present sequencing data of DAPK1 amplicons that were directly sequenced after MS-HRM analysis. These results demonstrate the sensitivity and suitability of the Applied Biosystems MS-HRM Workflow to screen samples for differences in methylation levels, and the option to directly sequence MS-HRM amplicons.

## 2956/F/Poster Board #888

**Genomic Methylation Variation Correlated with Metabolic Syndrome-Related Phenotypes.** *M.A. Carless, T.D. Dyer, D.L. Rainwater, A.G. Comuzzie, M.C. Mahaney, J. Blangero.* Department of Genetics, Southwest Foundation for Biomedical Research, San Antonio, TX.

Metabolic syndrome is a complex disorder that is reaching pandemic proportions worldwide and is a strong predictor of diabetes and cardiovascular disease. Few studies have assessed involvement of genomic methylation in metabolic syndrome and very little is currently known about the importance of epigenetic variation in disease risk. In this study, we quantified relative methylation in 190 individuals of Mexican American descent, within the San Antonio Family Heart Study, at 1,505 gene-centric CpG sites using an Illumina GoldenGate assay to identify epigenetic correlates with metabolic syndrome-related phenotypes. Variance component analysis using SOLAR revealed that approximately 25% of the relative methylation of CpG sites were significantly heritable. The median heritability was 0.11 and although this is lower than that observed for mRNA (0.32) or miRNA (0.43) expression in the same population, it strongly suggests that methylation is mediated by genetic factors in addition to environmental factors. After removing X-linked sites, we showed significant sex effects upon methylation in 19% of sites with most showing a substantial increase in methylation in females. Linear models (allowing for non-independence amongst family members) were used to identify a number of consistent correlations across multiple dimensions of the metabolic syndrome for a number of CpG sites in highly relevant genes. For example, CpG methylation within *POMC* was found to be correlated with fasting (p=0.031) and 2 hour (p=0.020) insulin, high density lipoprotein cholesterol (HDL-C; p=0.002) and triglycerides (p=0.009). Deficiencies in *POMC* are strongly correlated with obesity and it is possible that methylation reflects another mechanism by which decreased expression influences body weight. Importantly, methylation within *POMC* was also associated with metabolic syndrome (p=0.011), classified as a dichotomous trait. Methylation of CpG sites in other candidate genes such as *RYK*, *RUNX1T1* and *TGFBR3* were also correlated with a number of metabolic syndrome phenotypes including fasting and 2 hour glucose, fasting and 2 hour insulin, body mass index, waist circumference, HDL-C, triglycerides and metabolic syndrome. Of interest is the fact that methylation at each of these sites was associated with a more detrimental profile of phenotypes. We are currently sequencing CpG islands within several genes to further investigate the effect of methylation on metabolic syndrome in a larger cohort.

**Methylation profile of placentas with confined mosaicism for trisomy 16.** *D. Diego-Alvarez[1,2], R. Yuen[1,2], M.S. Penaherrera[1,2], W.P. Robinson[1,2].* 1) Department of Medical Genetics, University of British Columbia, Vancouver, BC., Canada; 2) Child and Family Research Institute, Vancouver, BC, Canada.

Trisomy 16 is estimated to occur in 1% of clinically recognized pregnancies. When confined to the placenta (CPM16), it can contribute to fetal malformations and placental insufficiency. Because of the central role that the placenta has in fetal and maternal physiology, it is presumed that variation in placental gene expression patterns might be linked to important abnormalities in maternal or fetal health. However, the genetic and cellular processes altered in both fetus and placenta in the presence of a trisomy remain poorly understood. We propose the hypothesis that epigenetic differences between trisomic and diploid cells such as DNA methylation can be used to assess the effects of trisomy on tissue-specific genome-wide gene regulation. These differences may be used to identify groups of genes altered in specific trisomies and thus the basic processes affected. To assess differences in methylation profiles in placental samples, the Illumina GoldenGate Methylation Cancer Panel I, which evaluates 1505 CpG sites (807 genes, many of which are important in placental development), was used as a first approach. Samples consisted of trophoblast from 6 CPM16 and 4 euploid placentas, all obtained after delivery. An additional 5 euploid samples from the second trimester of gestation were used for further comparison of the effect of gestational age. Differentially methylated genes were identified using Significance Analysis of Microarrays based on a False Discovery Rate of <10% and an absolute difference of >20%. Analysis of the CPM16 samples and both groups of controls revealed 45 differentially methylated CpG sites from 39 genes, none of them locating to chromosome 16. This suggests that a trans-acting effect on genome methylation may occur in the presence of the trisomy. Furthermore, a greater number of CpG sites (149) appeared differentially methylated in a comparison of second trimester of gestation and term controls, most likely reflecting the difference in cell composition of trophoblast at different times of gestation. The most significant and biologically meaningful candidate genes are being followed up with pyrosequencing using larger samples.

## 2958/F/Poster Board #890

**Effect of X-chromosome inactivation in an autosome: Implication for clinical features in an unbalanced translocation t(X;15) case.** *S. Sakazume[1], R. Sohma[1], N. Harada[2], K. Endo[4], H. Ohashi[3], T. Nagai[1], T. Kubota[4].* 1) Pediatrics, Dokkyo univ, Koshigaya, Saitama, Japan; 2) Kyusyu MNedical science, Nagasaki, Japan; 3) Saitama Children's Medical Center, Saitama, Japan; 4) Epigenetic Medicine, Univ. Yamanashi, Yamanashi, Japan.

(Introduction) X-chromosome inactivation (XCI) is an intrinsic mechanism in females, which compensate genome unbalance between females and males. In an X-autosome translocation case, when XCI extends to the translocated autosome and inactivates genes, this could lead abnormal phenotype. (Clinical features) We report here 5-year-old boy with 46,XY,t(X;15)(p21.2;q11.2). He had similar features to Prader-Willi syndrome patients with 15q deletions, such as hypotonia, hypo-gonadism, and hypo-pigmentation, but he had different appearances in the face and fingers and had severer developmental delay. (Results) FISH demonstrated XIST gene in the translocated X chromosome, and BrdU incorporated-replication study demonstrated that proximal 15q region is late replicated. Bisulfite sequencing and RT-PCR assays showed that OCA2 gene at 15q13 was half-methylated and down-regulated, whereas UBR at 15q15.2 and TRIP15 at 15q21.1 was not either methylated and down-reglulated. Methylation-specific PCR assays revealed that one of two SNRPN alleles at 15q11.2 was methylated, and that the X-translocated chromosome 15 was maternally inherited. (Conclusion and Implication) All these results suggest that functional border of XCI lies between 15q13 and 15q15.2, and that aberrant methylation and suppression of OCA2 leads to the hypo-pigmentation in skin and hairs. Further studies using genome microarray will reveal XCI border at the molecular level and may reveal sequence-based structure of the border.

## 2959/F/Poster Board #891

**Epigenetic associations with triglyceride response to a high-fat meal: A Pilot Study of The Genetics of Lipid Lowering Drugs and Diet Network (GOLDN) Study.** *M.K. Wojczynski[1], D.M. Absher[2], H.K. Tiwari[1], E.K. Kabagambe[1], D.K. Arnett[1].* 1) University of Alabama at Birmingham, Birmingham, AL 35294, USA; 2) HudsonAlpha Institute for Biotechnology, Huntsville, AL 35806, USA.

Postprandial lipemia (PPL) is a physiological response occurring 2-12 hours after consuming a meal. PPL is implicated as a cause of atherogenesis as an elevated or elongated response precipitates increased production of atherogenic cholesterol enriched remnant lipoprotein particles, formation of small, dense LDL particles, reduction in HDL, and upregulation of thrombotic factors. PPL exhibits a large between person variance suggesting an interaction between dietary and genetic factors regulating PPL. Additionally, diet is known to modify an individuals' epigenetic profile. Similar to the more traditional genotype-environment interactions, epigenetic mechanisms may interact with environmental factors to influence phenotypes. We hypothesize that epigenetic modification, specifically DNA methylation, mediates the influence of dietary fat on gene expression and modulates PPL. We selected three-generational families displaying large average triglyceride area under the curve (TG AUC) values during PPL and the largest corresponding within family standard deviation from the GOLDN study (n=23 individuals). Participants ingested a standardized high-fat meal containing 83% fat and 700 calories/$m^2$. We measured PPL using blood drawn from participants to obtain lipid profiles before eating the meal and at 3.5 and 6 hours after ingestion. We processed stored DNA on the Illumina Methylation27 arrays to examine 20,692 CpGs in ~14,000 genes. We calculated the methylation proportion for each CpG probe per individual to distinguish methylation states from the CpG probe raw signal intensity. We analyzed the methylation proportions using a hierarchical clustering algorithm and identified CpGs near genes that had statistically significant methylation proportions associated with TG AUC values after correction for age and familial effect by modeling the kinship matrix in a mixed model. Based on the pedigrees, the observed methylation patterns are suggestive of maternal transmission. Fourty-eight CpGs demonstrated p-values<$10^{-3}$, and many have biologic plausibility as contributors to lipid metabolism and metabolic syndrome. Notable associated genes were SORBS1, INS, PTPN9, PLA2R1, CHST8, and GMDS as these are involved in carbohydrate metabolism, inflammation, and HDL catabolism. We conclude that specific methylation patterns may play a role in the regulation of PPL in response to a high-fat meal.

## 2960/F/Poster Board #892

**Extensive Parent-Of-Origin Genetic Effects on Fetal Growth.** *R. Adkins[1], J. Krushkal[2], G. Somes[2], J. Fain[3], J. Morrison[4], C. Klauser[4], E. Magann[5].* 1) Le Bonheur Child Med Ctr, Univ Tennessee-Hlth Sci Ctr, Memphis, TN; 2) Department of Preventive Medicine, Univ. TN Health Science Center, Memphis, TN; 3) Department of Molecular Sciences, Univ. TN Health Science Center, Memphis, TN; 4) Department of Obstetrics and Gynecology, Univ. MS Medical Center, Jackson, MS; 5) Department of Obstetrics and Gynecology, Naval Medical Center, Portsmouth, VA.

Epigenetic effects have recently been recognized as playing a very significant role in several normal and pathological phenotypes. Imprinting, the silencing of either the paternally or maternally inherited allele, is one of the most pervasive and consistent epigenetic mechanisms across species and individuals. The majority of imprinted loci are involved in fetal growth regulation, and several defects in the epigenetic regulation of these genes are associated with extremes of fetal growth. We surveyed patterns of SNP variation in imprinted loci in a cohort of African-American mother-newborn pairs selected using stringent inclusion/exclusion criteria intended to enrich for the genetic component of fetal growth regulation. All association analyses were adjusted for admixture using a suite of ancestry informative SNP markers. By comparing maternal and fetal genotypes, we could unambiguously infer the parental origin of associated alleles in the majority of newborns. We found significant parent-of-origin effects in the insulin, H19 and GNAS genes that were completely consistent with their known patterns of imprinting.

## 2961/F/Poster Board #893

**Whole Genome DNA Methylation Profiling of Major Depression.** *F. Haghighi[1], A. O'Donnell[3], Y. Xin[1], B. Chanrion[4], Q. Yuan[2], Z. Zhou[2], P. Graham[1], V. Arango[1], A. Dwork[1], D. Goldman[2], J. J Mann[1], T. Bestor[3].* 1) Dept Psychiatry, Columbia Univ, New York, NY; 2) Laboratory of Neurogenetics, NIAAA, NIH, Bethesda, MD; 3) Department of Genetics and Development, Columbia University, New York, NY; 4) Columbia Genome Center, Columbia Univ, New York, NY.

Epigenetics may play a role in the etiology of neuropsychiatric disorders, possibly through abnormal genomic DNA and histone methylation patterns that regulate genes involved in brain development or physiology. The aim of the present study is to explore the epigenetic profile of major depressive disorder (MDD). In order to better understand both the wild type genomic DNA methylation patterns and aberrant methylation events that occur in disease states, we have developed a cost-effective, unbiased, whole-genome methylation profiling technique that can assay the methylation state of more than 80% of the CpG sites in the human genome. Using our methodology, which couples advances in next generation sequencing with enzymatic fractionation of DNA by methylation state, we are mapping the methylation at high coverage of 4 controls and 4 MDD cases. We also mapped the histone methylation, H3K4me3 patterns in these same samples using ChIP-seq. We focused on the prefrontal cortex (PFC) due to converging evidence from neuroimaging and functional studies implicating this region in MDD. In the first genome-wide DNA and histone methylation profiling study of major depression, we identified aberrant methylation at several genes including those related to serotonergic and cholinergic pathways, neurotransmitter release, receptor functioning, and synaptogenesis. Subsequent to validation of these differentially methylated regions on the Sequenom platform, we are expanding our analysis of these regions to a large sample of PFC tissue from 60 controls and MDD cases with comprehensive clinical and toxicological profiles. These DNA methylation abnormalities may have clinical utility as biomarkers, and evaluation of the frequency of these alterations may help identify etiologic factors involved in MDD.

## 2962/F/Poster Board #894

**Molecular Testing for Beckwith-Wiedemann and Russell-Silver Syndrome: Growth Disorders at the Opposite Ends of Phenotypic Spectrum.** *B. Coffee, B. Billotte, M. Lee, S. Dharamrup, M. Tayeh.* Emory Genetics Laboratory, Department of Human Genetics, Emory University, Atlanta, GA.

Beckwith-Wiedemann Syndrome (BWS) is characterized by macrosomia, macroglossia, growth asymmetry, omphalacele and tumor predisposition. Conversely, Russell-Sliver Syndrome (RSS) is characterized by growth retardation (both prenatal and postnatal), dysmorphic facial features and growth asymmetry. BWS and RSS represent opposite ends of the phenotypic spectrum. Both disorders are caused by defects in imprinted gene expression at 11p15.5 due to alterations in DNA methylation at Lit1 and H19. In addition, approximately 10% of RSS is caused by maternal uniparental disomy of chromosome 7 (matUPD7). We have developed two novel assays to detect and measure DNA methylation at these imprinted loci. For Lit1 and H19 methylation analyses, we use Taqman methylation sensitive PCR to quantify DNA methylation. For matUPD7 analysis, we use conventional methylation sensitive PCR targeting two different differentially methylated regions (DMRs) in the PEG1/MEST and GRB10 genes. Unlike traditional testing for uniparental disomy, parental samples are not required for methylation analysis making testing available to individuals when one or both parents are not available. Combined, we have tested approximately 1000 individuals for BWS and RSS. We will present our overall experience in testing for these disorders and several interesting cases that include maternally inherited duplications, variation of methylation within an individual and discordance of methylation among twins.

## 2963/F/Poster Board #895

**Genome wide methylation analysis in Beckwith Wiedemann syndrome reveals CpG methylation alterations at several imprinted loci.** *S. Choufani[1], K. Millar[2], JC. Ferreira[1,3], P. Lapunzina[4], C. Shuman[1,2], R. Weksberg[1,2,3].* 1) Dept Genetics & Genomic Biol, Hosp Sick Children, Toronto, ON, Canada; 2) Div Clinical & Metabolic Genetics, Hosp Sick Children, Toronto, ON, Canada; 3) Ins Medical Sciences, Univ Toronto, Toronto, On, Canada; 4) Ins Genetica Medica Y Molecular, Hosp Universitario La PAz, Univ Autonoma de Madrid, Spain.

Beckwith Wiedemann syndrome (BWS) is an overgrowth syndrome that is in most cases associated with epigenetic and genetic alterations of chromosome 11p15. The most common epimutation is a loss of methylation at the imprinting control center 2 (IC2) present in 50% of BWS cases. A subset of BWS cases with loss of methylation (LOM) at IC2 were described to have loss of maternal methylation at other differentially methylated regions (DMRs) such as PLAGL1 on chromosome 6 and GNAS on chromosome 20. However, the status of many imprinted DMRs remains unknown. We hypothesize that LOM at IC2 in BWS patients could be associated with one or more epigenetic aberrations at imprinted DMRs that have not yet been investigated. Therefore, we undertook a genome-wide approach to analyze DNA methylation in BWS patients with LOM at IC2. We used bisulfite modified genomic DNA from 20 BWS patients and 20 controls and hybridized it to the Illumina methylation 27 array. This array covers ~27,600 CpG sites (promoter of ~14000 genes). Comparison of whole genome CpG methylation patterns between BWS patients and controls revealed a similar bimodal distribution of CpG methylation in the 2 groups. Methylation analysis of the CpG sites according to their genomic location within or outside CpG islands and across the different autosomes also showed a parallel distribution between BWS and controls. We then performed a detailed analysis of all CpG sites that overlap known imprinted DMRs. We identified a subset of BWS patients demonstrating CpG methylation alterations at several imprinted loci including PLAGL1 and GNAS. Using a targeted pyrosequencing assays, we found the frequency of PLAGL1 and GNAS epimutations in a larger cohort (n=70) of BWS (with IC2 LOM) to be 31 and 13% respectively. Interestingly, the analysis of imprinted loci identified 2 cases with pUPDs not involving chromosome 11p15. One case was confirmed by microsatellite markers to have pUPD20. Our approach provides the most comprehensive analysis to date for characterizing genome wide deregulation of imprinted loci in BWS. Furthermore, we report here the first case of pUPD20 for the entire chromosome. Further analysis is needed to understand how the interaction among the different imprinted genes can impact the clinical manifestations of human disorders caused by imprinted gene deregulation.

## 2964/F/Poster Board #896

**High reslolution microarray analysis of DNA methylation.** *A. Wong[1], R. Straussman[2], Z. Yakhini[1], I. Steinfeld[1], A. Ashutosh[1], H. Cedar[2], D. Roberts[1].* 1) Agilent Technologies, Inc. Santa Clara, CA; 2) Dept. of Cellular Biochemistry and Human Genetics, Hebrew University, Jerusalem, Israel.

CpG islands are stretches of high GC content DNA containing multiple CpG dinucleotides. When CpG dinucleotides within these islands are methylated, especially in promoter regions, expression of the corresponding downstream genes is most often repressed. Aberrant CpG island methylation is implicated in genetic diseases and especially cancer. We have developed a microarray based solution for determination of methylated and unmethylated CpG islands in the human genome. This microarray contains ~244,000 oligo probes tiling the 21 megabases of ~25,000 unique CpG islands, with an average spacing between probes of ~100 base pairs. We also tile ~5000 additional regions outside of canonical CpG islands. Methylated DNA is immunoprecipitated (mDIP), fluorescently labeled, and competitively hybridized to the array against differentially labeled pre-immunoprecipitated DNA. We have developed a methylation calling algorithm to accurately determine methylated and unmethylated regions. We describe the application of this method and algorithm in a normal adult liver DNA model system. We demonstrate the ability of the assay to discriminate between regions confirmed to be methylated or unmethylated by bisulfite sequencing. We then apply the whole-genome assay to multiple tissues, including colon and colon carcinoma tissue DNA. We describe differential methylation between these tissues and between normal and cancer tissues.

## 2965/F/Poster Board #897

**MeDIP-chip detection and quantitative DNA methylation analysis of differentially methylated regions in imprinted loci.** *K. Nakabayashi[1], W. Yoshida[1], K. Yamazawa[2], M. Kusumi[1], T. Ogata[2], K. Hata[1].* 1) Dept. of Maternal-Fetal Biol; 2) Dept. of End. & Metab., National Research Institute for Child Health and Development, Tokyo, Japan.

Genomic imprinting, an epigenetic phenomenon whereby genes are differentially expressed according to their parental origin, is known to be crucial for placental development and fetal growth in mammals. Most imprinted loci contain a differentially methylated region (DMR) harboring allelic DNA methylation inherited from the male or the female gamete (germline DMR). Mutations/epimutations affecting DMRs cause rare imprinting disorders such as Silver-Russell and Beckwith-Wiedemann syndromes. Whether imprinted genes also play critical roles in the more common abnormal pregnancy cases such as preeclampsia and intrauterine growth restriction (IUGR) is an important question yet to be fully evaluated. With the aim of addressing this question, we established quantitative COBRA (Combined Bisulfite Restriction Analysis) assay conditions for 30 DMRs from 22 loci that include the majority of known human imprinted DMRs. We first measured DNA methylation levels at these DMRs in twelve blood samples from healthy individuals and twelve placental tissues from normal pregnancies to assess the extent of tissue specificity and individual varieties of methylation levels. Using this dataset as a reference, we are currently screening for epimutations at DMRs of the cord blood and placenta samples derived from 50 IUGR cases. Dnmt3L, a Dnmt3 methyltransferase family member lacking a functional methyltransferase domain, is shown to be a key regulator of maternal imprint establishment. Mouse embryos produced from Dnmt3L$^{-/-}$ females arrest in development by embryonic day 10.5, and completely lack maternal methylation at germline DMRs. As an approach to identify novel maternal DMRs, we obtained DNA methylation profiles for 16,000 CpG islands of these mutant and wild-type embryos (day 9.5) using the methylated-DNA immunoprecipitation (MeDIP) technique followed by array hybridization. Comparison of the mutant/wild-type profiles allowed us to detect decreased levels of methylation at 16 known DMRs as well as 36 novel candidates. Bisulfite sequencing analyses for the top five candidates have revealed that at least three of them are maternally methylated DMRs. The human orthologous regions are being characterized to determine if the regions are differentially methylated. Our COBRA assay system for DMRs is applicable to screen for epimutations in other conditions such as imprinting disorders and infertility, and will become more comprehensive by integrating newly identified DMRs.

## 2966/F/Poster Board #898

**Genome-wide DNA methylation patterns associate with genetic and gene-expression variation.** *J.T. Bell, A. Pai, J.B. Veyrieras, Y. Gilad, J.K. Pritchard.* Department of Human Genetics, University of Chicago, Chicago, IL.

DNA methylation is a critical regulator of transcription that affects phenotypic variation and disease. However, associations between methylation and gene-expression have not been well characterized on the genome scale, and the extent of genetic regulation of DNA methylation itself remains unclear. To this end, we interrogated genome-wide DNA methylation in lymphoblastoid cell lines from 58 Yoruba HapMap individuals, by assaying the methylation status of 27,211 CpG sites near the transcriptional start sites (TSS) of 12,823 Ensembl genes across the genome using the Illumina HumanMethylation27 BeadChip assay. First, we compared variation in DNA methylation and gene-expression using previously published gene-expression data in these samples (Stranger et al. 2007 Science). We observed a strong negative correlation between methylation and gene-expression across 9,500 genes (mean r = -0.4). Further analyses estimated the effect of location of the CpG-sites within CpG islands, within sequence motifs, and relative to the TSS, on the association between methylation and gene-expression. Second, we assessed the evidence that genetic variation contributes to DNA methylation variation. We performed genome-wide association analyses with the methylation data as phenotypes and 2.6M autosomal SNP genotypes from the HapMap consortium with the aim of identifying and characterizing methylation-associated QTLs (metQTLs). Significant associations for cis metQTLs were identified for SNPs within 500kb of approximately 70 genes at a false discovery rate of 1%. We are currently extending these analyses by comparing metQTLs to previously identified eQTLs, and revisiting eQTL results by considering both DNA methylation and gene-expression data in the analyses. These findings help elucidate the functional relationship between DNA methylation and gene-expression and provide a first detailed insight into the genetic control of DNA methylation.

## 2967/F/Poster Board #899

**Epigenetic changes characterized by DNA methylation profiling are associated with risk and phenotypic variation in multiple sclerosis.** *F.B.S. Briggs[1], S. May[1], J.R. Oksenberg[2], A. Bernstein[3], C. Schaefer[3], L.F. Barcellos[1,3].* 1) Division of Epidemiology, School of Public Health, University of California, Berkeley; Berkeley, CA; 2) Department of Neurology, University of California, San Francisco; San Francisco, CA; 3) Division of Research, Kaiser Permanente; Oakland, CA.

Multiple Sclerosis (MS) is a clinically heterogeneous autoimmune disease (AD) of the central nervous system characterized by incomplete concordance in monozygotic twins and greater female preponderance. Both genetic and environmental factors are known to be involved in the pathogenesis of MS. A role for epigenetic mechanisms has also been strongly implicated in autoimmunity. These mechanisms include DNA methylation, which occurs on CpG sequences in DNA and is involved in regulating many cellular processes including gene expression and genomic stability. Maintaining DNA methylation homeostasis is critical for the development and function of immune cells. Aberrant DNA methylation has been associated with several autoimmune diseases, including rheumatoid arthritis, scleroderma, psoriasis and systemic lupus erythematosus. Given the dynamic and heritable nature of the epigenome, epigenetic changes provide a mechanism by which environmental effects can have long-term effects on gene expression and disease manifestation. We performed a large and comprehensive epigenetic investigation in MS cases and controls (total N~200 individuals). Both site specific methylation profiles and global methylation measures in DNA samples derived from peripheral blood mononuclear cells were characterized. DNA methylation patterns were investigated using two approaches: 1) a total of 1,505 CpG loci from 807 (mostly immune related) genes were studied in 146 MS female cases (20 PPMS, 126 RRMS) and 40 healthy controls; 15 MS cases had mild disease (EDSS<2), 15 had severe disease (EDSS>8), and a total of 30 also had comorbid ADs), and 2) 27,578 CpG loci across the genome were investigated in 13 MS cases (4 PPMS females, 5 RRMS females, 4 RRMS males). The LTA locus on 6p21.33 was significantly more methylated (p=4 x 10-4) in RRMS cases compared to healthy controls. TJP2 on 9q21.11 was significantly more methylated (p=7 x 10-5) in PPMS cases compared to controls, while LYN on 8q12.1 was less methylated (p=6 x 10-4). In a case-only analysis of females with either RRMS or PPMS, PPMS cases were significantly less methylated at the EDNRB locus on 13q22.3 (p=1.3 x 10-6) and EGFL4 on 19q13.2 (p=4.2 x 10-5) and more methylated at CLN5 on 13q22.3 (p=1.9 x 10-4). These results demonstrate a prominent role for epigenetic mechanisms in the complex etiology of MS, and highlight the need to incorporate the evaluation of genetic, environmental and epigenetic factors in future studies of MS.

## 2968/F/Poster Board #900

**Testing Candidate Proteins for their role in DNA demethylation.** *A. Burant, A. Beaudet.* Molecular and Human Genetics, Baylor College Med, Houston, TX.

DNA methylation is a major regulator of gene expression and plays a role in many processes including differentiation, X inactivation, and imprinting. Aberrant methylation during these processes can lead to many diseases including cancer, imprinting disorders such as Prader-Willi and Angelman syndrome, and autism spectrum disorders such as Rett and Fragile X syndromes. Much is known about how DNA becomes methylated, however very little is known about the mechanism and proteins involved in DNA demethylation. Three hypotheses have been proposed for the mechanism of demethylation: removal of the methyl group, removal of the methyl-cytotsine, followed by base excision repair (BER), or removal of the methyl-cytosine along with neighboring nucleotides, followed by nucleotide excision repair (NER). In previous studies, three proteins have been identified as potential demethylases, Thymine DNA Glycosylase (TDG), Growth Arrest and DNA Damage inducible (Gadd45A), and Methyl-binding domain 4 (MBD4). TDG and MBD4 are members of the BER pathway and may work with Activation Induced Cytidine Deaminase (AID) to perform demethylation. Gadd45a has been shown to function along with Xeroderma Pigmentosa G (XPG), a member of the NER pathway. To determine the role of these proteins in demethylation, we expressed the various candidate proteins along with an in-vitro methylated promoter driving luciferase in HEK293 cells. Using the SV-40 promoter as well as the pluripotency Oct-4 promoter, MBD4, Gadd45a and XPG were able to increase the expression of luciferase indicating a possible demethylating role for these proteins. Similar studies are also underway with ES cells containing the endogenous, imprinted SNRPN promoter driving GFP. We have also performed studies on mice knockouts of the demethylase candidate proteins by staining one cell stage embryos with methyl-C antibodies to determine if the genome wide wave of demethylation still occurs in these knockout mice. Thus far, we have found that AID and Gadd45a knockout mice have normal demethylation indicating these proteins are not required for demethylation. A TDG conditional knockout is currently being constructed for these studies using recombineering. We hope that these studies will lead to a better understanding of DNA demethylation.

## 2969/F/Poster Board #901

**Genome-wide analysis reveals overrepresentation of intragenic CpG islands in developmental genes.** *Z.X. Chen[1], X. Wu[2], A.D. Riggs[1].* 1) Department of Cancer Biology, Beckman Research Institute of the City Hope, Duarte, CA 91010; 2) Department of Molecular Medicine, Beckman Research Institute of the City Hope, Duarte, CA 91010.

In mammalian genomes, CpG dinucleotides are globally depleted with the exception of regions called CpG islands (CGIs), which show a relatively high frequency of CpG sites. CGIs located in promoter regions are well studied and known to be important for regulating transcription. In particular, methylation of promoter CGIs has been shown to play critical roles in fundamental physiological processes such as X-chromosome inactivation and genomic imprinting, as well as in silencing tumor suppressor genes during carcinogenesis. In addition to those associated with promoters, many CGIs located in intragenic and intergenic regions have been identified, but so far little is known about their biological roles. In this study, we analyzed all mouse RefSeq genes containing intragenic CGIs to explore the functional significance of the presence of CGIs in gene bodies. We found that intragenic CGIs are overrepresented in genes carrying H3K4me3/H3K27me3 bivalent marks at their promoters in mouse embryonic stem cells. This suggests a possible link between intragenic CGIs and developmental genes, which have been reported to be associated with bivalent promoters in embryonic stem cells. Consistent with this, gene ontology analysis of genes with intragenic CGIs revealed a significant enrichment for genes involved in developmental processes, such as ectoderm development, embryogenesis, and neurogenesis. Together, our results suggest that intragenic CGIs may play a role in the complex regulation of developmental genes.

**Maternal DNA Hypomethylation as a Risk Factor for Congenital Heart Defects.** *S. Chowdhury, M.A. Cleves, S.L. MacLeod, C.A. Hobbs.* Department of Pediatrics, University of Arkansas for Medical Sciences; Arkansas Children's Hospital Research Institute, Little Rock, AR.

**Background:** Congenital heart defects (CHDs) are the most prevalent and serious of recognized birth defects. Multiple factors including genetic susceptibilities, epigenetic mechanisms, and environmental influences are thought to contribute to the development of non-syndromic CHDs. Folic acid deficiency is a risk factor for various birth defects and is associated with increased homocysteine levels. Elevated maternal homocysteine increases the likelihood of having a CHD-affected pregnancy, and is implicated in aberrant DNA methylation patterns. Fluctuations in three additional biomarkers in the homocysteine pathway are also associated with an increased risk of CHDs and altered DNA methylation patterns. These data lead to the hypothesis that maternal DNA hypomethylation contributes to the development of CHDs. We assessed maternal DNA global methylation in 40 women who had CHD-affected pregnancies and 40 women with unaffected pregnancies to test our hypothesis. **Methods:** The proposed study builds on the National Birth Defects Research and Prevention Study (NBDPS), an ongoing multi-site population based case-control study. Blood was collected from Arkansas NBDPS participants who delivered a singleton live birth with a non-syndromic CHD and women who had a live birth without a major defect. Our initial sample population was selected by creating a vector utilizing data from four biomarkers in the homocysteine pathway. Using these data, participants were organized into extreme metabolic phenotype groups and their DNA methylation was assessed. Utilizing methylation of the LINE-1 repetitive element, a Methylight technique was developed to assess global DNA methylation in a total of 80 mothers. The Methylight technique, in conjunction with bisulfite conversion of DNA, allows rapid analysis of methylated and unmethylated alleles. The Mann-Whitney U test was used to compare percent methylation by case and control status. **Results:** Significant DNA hypomethylation was found in case mothers when compared to controls (means 78.9% vs. 86.9% respectively; $p<0.007$). **Conclusions:** Our findings indicate maternal global DNA hypomethylation is associated with an increased risk of CHDs. Aberrations in maternal DNA methylation converge with previous evidence that indicate folate-dependent genetic and metabolic susceptibilities increase the risk of CHDs. A larger sample size to verify associations and multi-factorial analysis are warranted based on our preliminary evidence.

**Loss of paternal methylation affecting the MEG3 locus located on chromosome 14q32.2 imprinted region in a girl with maternal upd-like phenotype.** *B. DEMEER[1], G. MORIN[1], R. GOURON[2], L. RAZAFIMANANTSOA[3], S. KANAFANI[4], J. ANDRIEUX[5], H. COPIN[4], L. CUISSET[6], M. MATHIEU[1].* 1) Dept Gen, Univ Hosp, Amiens, France; 2) Department of Orthopaedics, University Hospital, Amiens, France; 3) Pediatric Department, Beauvais, France; 4) Department of Cytogenetics, University Hospital, Amiens, France; 5) Department of Molecular Genetics, University Hospital, Lille, France; 6) Department of Molecular Genetics, Cochin-Saint Vincent de Paul Hospital, Paris, France.

We report the case of a 8-year old girl seen in the orthopaedic department for scoliosis. She is the third child of non consanguinous healthy parents. She was born after an uneventful pregnancy (BW : 2.330kg, BH : 47.5cm, BHC : 32 cm, Apgar score 10,10). Neonatal feeding difficulties and moderate axial hypotonia were noted. Motor milestones and speech were delayed. From the age of 2 years, she began to put on weight and developed obesity. At 8 years 2/12, parameters are 38.4kg (+4SD), 136.5cm (+2.2SD), BMI 20.6; Tanner stages : S1A1P2. She presents a 40° dorsal scoliosis, rather short hands and feet, no dysmorphic facial features and no mental retardation. Cerebral MRI was normal. Karyotype is 46, XX, ish15q11-13(SNRPNx2), and Array-CGH did not detect any microdeletion or microduplication. As maternal uniparental disomy for chromosome 14 (maternal UPD 14) was suspected, microsatellite studies and methylation analysis of Maternally Expressed Gene 3 (MEG3) located in the 14q32.2 region were performed. Maternal UPD 14 was excluded by showing biparental inheritance of microsatellite markers. Methylation of the MEG3 locus showed loss of paternal methylation with normal profil methylation of both parents. Yet very few patients with exclusively maternal methylation profil of the MEG3 locus have been described, but notably clinical features seemed to be grossly similar in epimutation patients and maternal UPD 14 patients.

**DNA methylation variation at CpG islands in children with autism spectrum disorders.** *D. Grafodatskaya[1], C. Marshall[2], A. Lionel[2], W. Roberts[3], S.W. Scherer[2], R. Weksberg[1].* 1) Genetics and Genome Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) The Centre for Applied Genomics,The Hospital for Sick Children, Toronto, Ontario, Canada; 3) Autism Research Unit, The Hospital for Sick Children, Toronto, Ontario, Canada.

Although epigenetic factors have been postulated to play a role in the etiology of autism spectrum disorders (ASD), no specific epigenetic determinants have yet been identified. We compared genome-wide DNA methylation in the white blood cells (WBC) of 5 ASD patients to 7 healthy controls. Methylated DNA was immunoprecipitated and hybridized to Agilent CpG island arrays that contain 97% of USCS genome browser annotated CpG islands. To identify DNA methylation differences, a sample from one control was selected as a reference and a methylation profile for each sample was compared to this reference using Partek Genomic Suite. A fold change in methylation was calculated for each probe and the Hidden Markov Model (HMM) was applied to find genomic regions with methylation variation in consecutive probes. Three sets of HMM parameters were applied, including fold changes in methylation and number of affected consecutive probes: 20-fold in 2 probes, 8-fold in 3 probes and 6-fold in 5 probes. There were no significant differences observed in the number of hypo and hypermethylated regions detected by the 3 sets of parameters between control and ASD samples, indicating that there is no genome-wide loss or gain of DNA methylation at CpG islands in WBCs of ASD patients. Further, we filtered out the genomic regions detected in at least one control sample. ASD-specific methylation variation included: loss of methylation at LHX6 and DUSP22 and gain of methylation in MARCKS, ZNF713 and the 2q12.2 intergenic region. LHX6, DUSP22 and MARCKS are involved in neural pathways, suggesting that these genes are good candidates for further validation. Methylation variation was then compared to copy number variation data for each ASD patient. The gain of methylation in the promoter of ZNF713 was detected in 2 ASD sibs. Both of them had a 6.7 kb deletion inherited from the father that was located ~800 kb downstream of ZNF713. Using bisulphite pyrosequencing, we confirmed ~30% methylation in the ASD patients and their father, hemizygous for the deletion, and ~0% methylation in the mother who did not carry the deletion. We also observed ~0% methylation in this region for 9 unrelated controls. That is, deletions in this genomic region can be associated with DNA methylation changes several 100 kb away. Such epigenetic changes associated with genomic alterations have been previously shown to be important factors in human diseases involving imprinting and trinucleotide repeats.

**Comparison of DNA Methylation Patterns in Three Types of Mouse Tissue.** *B.F. Johnson[1], C.J. Davidson[1], M. Kondo[2], L.K. Joe[1], S.R. Berosik[1], A. Chhibber[1], R.N. Fish[1], S.C. Hung[1], J. Lee[1], R.A. Padilla[1], D. Rodriguez[1], A.A. Pradhan[1], A.C. Felton[1].* 1) Life Technologies, Foster City, CA; 2) Applied Biosystems-Japan, Tokyo, JP.

Enzymatic methylation of the cytosine (C) residues at CpG motifs in genomic DNA (gDNA) has been shown to suppress gene expression and play a role in pathology. New technologies like microarrays and next generation sequencing allow identification of methylation patterns on a genome-wide scale but capillary electrophoresis analysis is ultimately used for detailed information about each CpG site in an amplicon and remains the gold standard in validating DNA methylation results. In this study a specific gene region from three mouse tissues was bisulfite treated and cloned into pGEM-T vector, amplified and sequenced with BigDye® Terminator Cycle Sequencing v3.1 chemistry, and analyzed by capillary electrophoresis. The level of methylation in two possible epigenetic sites of high CpG content of a target gene in mouse epithelial cells from the cornea and conjunctiva was determined and compared to methylation levels in mouse epidermis tissue. A number of factors affect the reliability of methylation patterns revealed by sequencing. In addition to purity of the gDNA and enzymatic bias during PCR, failure to complete bisulfite conversion will yield inaccurate methylation values. The extent of cytosine conversion by bisulfite is affected by the presence of protein associated with gDNA, the denaturation state of the target DNA and well as the quantity of DNA in the conversion reaction. In this study a fragment analysis protocol is described that corroborates the extent of conversion for improved reliability in interpreting methylation profiles. This assay can be used either to verify the conditions used for performing bisulfite conversion or be used to evaluate the ratio of methylated to unmethylated DNA in experimental procedures.

## 2974/F/Poster Board #906

**Genome-Wide Screen of Promoter Methylation Identifies Novel Markers in Melanoma.** *Y. Koga[1,2], M. Pelizzola[3], E. Cheng[4], M. Krauthammer[5], AM. Molinaro[3], K. Miyazaki[2], R. Halaban[4], S. Weissman[1].* 1) Dept Genetics, Yale Med Sch, New Haven, CT; 2) Dept Surgery, Saga Med Sch, Saga, Saga, Japan; 3) Dept Epidemiology and Public Health, Yale Med Sch, New Haven, CT; 4) Dept Dermatology, Yale Med Sch, New Haven, CT; 5) Dept Pathology, Yale Med Sch, New Haven, CT.

DNA methylation is an important component of epigenetic modifications that influences the transcriptional machinery and aberrant in many human diseases. In this study we present the first genome-wide integrative analysis of promoter methylation and gene expression for the identification of methylation markers in melanoma. Genome-wide promoter methylation and gene expression of ten early-passage human melanoma cell strains were compared to newborn and adult melanocytes. We used linear mixed effect models (LME) in combination with a series of filters based on the localization of promoter methylation relative to the transcription start site, overall promoter CpG content, and differential gene expression to discover DNA methylation markers. This approach identified 76 markers, of which 68 were hyper- and 8 hypo-methylated (LME $P < 0.05$). Promoter methylation and differential gene expression of five markers (COL1A2, NPM2, HSPB6, DDIT4L, MT1G) were validated by sequencing of bisulfite modified DNA and real-time reverse transcriptase PCR, respectively. Importantly, the incidence of promoter methylation of the validated markers increased moderately in early- and significantly in advanced-stage melanomas, employing early-passage cell strains and snap frozen tissues ($n = 18$ and $n = 24$, respectively) compared to normal melanocytes and nevi ($n = 11$ and $n = 9$, respectively). Our approach allows robust identification of methylation markers that can be applied to other studies involving genome-wide promoter methylation. In conclusion, this study represents the first unbiased systematic effort to determine methylation markers in melanoma, and revealed several novel genes regulated by promoter methylation that were not described in cancer cells before.

## 2975/F/Poster Board #907

**Epigenomic analysis of discordant monozygotic twins in autism.** *C. Ladd-Acosta[1,2], D. Fradin[1,3], D. Arking[4], K. Cheslack-Postava[3], A. Chakravarti[2,4], D. Fallin[3], W. Kaufmann[5,6], A. Feinberg[1,2].* 1) Center for Epigenetics, Institute for Basic Biomedical Sciences, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Department of Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 3) Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 4) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 5) Department of Psychiatry and Behavioral Sciences, Johns Hopkins University School of Medicine, Baltimore, MD; 6) Kennedy Krieger Institute, Baltimore, MD.

Idiopathic autism is a common neurodevelopmental disorder defined by three key features: impairment in reciprocal social interaction and communication as well as a markedly restricted repertoire of activity and interests. Although the molecular basis of autism is elusive, epigenetic aberrations play a central role in several related disorders, namely, Angelman, Fragile X, and Rett syndromes, in which affected individuals share or present clinical attributes of idiopathic autism. One approach to identify epigenetic alterations in autism is to examine DNA methylation (DNAm) in monozygotic twins discordant for the autism phenotype. Discordant monozygotic twins provide a valuable model for studying epigenetic changes because these individuals have the same DNA sequence; thus discordance must be related to changes other than the DNA sequence itself. We used Comprehensive High-throughput Arrays for Relative Methylation (CHARM) to examine DNA methylation (DNAm) across the genome in lymphoblast cells from nine monozygotic twin pairs, four female and five male, discordant for strict autism. Using CHARM, we identified several genomic regions with a gain or loss of DNAm in the individuals with strict autism compared to their twin counterparts with milder autistic features. Examination of three differentially methylated regions (DMRs) using bisulfite pyrosequencing, an independent, highly quantitative approach that measures DNAm at single nucleotide resolution, confirmed the CHARM results both in magnitude and direction. Preliminary analysis also suggests some overlap between parent-of-origin specific SNP data and some DMRs identified by CHARM. This approach provides a pathway to understanding a possible role of epigenetics in the pathogenesis of autism.

**Comprehensive genetic analysis of Silver-Russell syndrome by methylation-sensitive high resolution melting(MS-HRM) and whole genome strategy.** *SY. Lin[1,2], SP. Lin[3], M. Gorre[4], J. Kim[4], YN. Su[1,2].* 1) National Taiwan University Hospital, Taipei, Taiwan; 2) Graduate Institute of Clinical Medicine, College of Medicine, National Taiwan University, Taipei, Taiwan; 3) Mackay Memorial Hospital, Taipei, Taiwan; 4) CMDX, Irvine, USA.

Background: Silver-Russell syndrome(SRS) is a clinically and genetically heterogenous congenital disorder characterized by severe growth restriction. Hypomethylation of H19 DMR and maternal UPD7 only account for 30 to 75 percent patients. Material and method: We investigated the methylation pattern at H19 DMR by methylation-specific multiplex PCR, MS-MLPA and MS-HRM in 50 patients with SRS and 5 with SRS-like syndrome. We also studied the methylation status in the GRB10 gene, MEST gene, IGFBP1 gene and IGFBP3 gene by MS-HRM. BAC array CGH was applied to identify microdeletion. Results: Nine patients with SRS had hypomethylation at H19 DMR. One patient with SRS-like syndrome had hypermethylated GRB10 gene, MEST gene, IGFBP1 gene and IGFBP3 gene by MS-HRM, which indicated maternal UPD7. The BAC array CGH identified one patient with a 2.6-Mb deletion on chromosome 7p15.3 and a 4.4-Mb deletion on chromosome 15q26.2qter, which were confirmed by multiplex PCR. Discussion: The overall mutation detection rate was 22 percent by MS-HRM and BAC array-CGH. Although epimutation may be the major cause of SRS and can be identified well by MS-HRM, whole genome array-CGH may also provide information in the etiology of SRS.

**Direct Methylation Detection From Cancer Cells, Blood and Tissues: High Speed Conversion Followed By High-Resolution Melting, Methylation Specific PCR and Sequencing.** *C. Liu, S. Dong, N. Chen, J. Wang, A. Tobler, V. Boyd, J. Stevens.* MBS R & D, Applied Biosystems, Foster City, CA.

Aberrant DNA methylation patterns are one of the hallmarks of cancer. DNA methylation changes are detectable not only in tumors, but also in blood, as tumor-derived DNA is released into the bloodstream due to tumor necrosis and apoptosis. DNA methylation patterns are lost when amplifying in a PCR, thus the treatment of DNA with bisulfite, which converts C to U but leaves 5-methyl-C unchanged, forms the basis of many analytical techniques for DNA methylation analysis. The conventional bisulfite conversion usually starts from genomic DNA with longer incubation time which can be time consuming and labor intensive. Therefore, a faster and more stream-lined protocol is desirable. We describe a procedure for the direct bisulfite conversion from cancer cell lines within 2 hours. Direct bisulfite conversion from blood was evaluated along with FFPE samples. Succesful use of FFPE samples opens up large collections of clinical tissue banks, providing more and more value to the studies of epigenomics. All currently available methods require deparaffinization of the specimen prior to DNA extraction. The procedure described is capable of direct bisulfite conversion from the unprocessed FFPE sample, and complete conversion is achieved within 2 hours. Following bisulfite conversion, several methods have been used to measure the level of DNA methylation, including methylation-specific polymerase chain reaction (MSP), methylation sensitive high-resolution melting (MS-HRM), sensitive melting analysis after real time methylation specific PCR (SMART-MSP) as well as sequencing analysis. In cancer research, especially for the early diagnosis, tumor-derived material is hard to detect because of the presence of material from normal cells, and thus highly sensitive methods are needed. The protocol described demonstrates a detection sensitivity of at least 1% or lower methylated template with MS-HRM and 0.1% methylated template with SMART-MSP. The procedure described overcomes many of the common challenges of methylation detection after bisulfite conversion. Very low sample input down to 50pg genomic DNA or 5 cells for each conversion reaction can be used to achieve a 100% conversion rate, avoiding the false-positives inherent to incomplete conversions. In addition, this method allows for single molecule PCR which could greatly facilitate single cell epigenetic studies as well as clinical diagnosis with FFPE, blood cards and tissue LCM samples.

## 2978/F/Poster Board #910

**Studying the extent and function of epigenetic variation in twins.** *R. Lyle[1], G. Gilfillan[1], K. Gervin[1], H.E. Akselsen[1], M. Hammerø[1], R. Moe[1], H. Gjessing[2], J. Harris[2], D.E. Undlien[1,3].* 1) Department of Medical Genetics, Oslo University Hospital Ullevål, Oslo, Norway; 2) Division of Epidemiology, Norwegian Institute of Public Health, Oslo, Norway; 3) Institute of Medical Genetics, Faculty Division Ullevål University Hospital, University of Oslo, Oslo, Norway.

The phenotypic differences between individuals are an outcome of genetic and epigenetic variation. Whereas variation at the sequence level (SNPs and CNVs) has been studied extensively, much is still unknown regarding the extent and function of epigenetic variation. Disturbance in DNA methylation leading to aberrant gene expression has been shown to be involved in many diseases, and variation in DNA methylation may contribute to the risk of common disease. The aim of this study is to explore variation and patterns of epigenetic variation using twins. Since each cell type has its own epigenome, we have isolated different lymphocyte subpopulations (CD19+, CD8+, CD4+ and CD4+CD25+) from more than 300 twin pairs. The results presented here are from CD4+ cells. We have used both region-specific and genome-wide analyses. First, we studied DNA methylation in the classical human major histocompatibility complex (MHC). The MHC is a gene dense and highly polymorphic region on human chromosome 6p21.3, containing genes with a broad range of functions within the innate and adaptive immune systems. We performed extensive bisulphite sequencing of 1670 individual CpG sites distributed in 176 regions in the classical human Major Histocompatibility Complex (MHC) in 49 monozygotic (MZ) and 40 dizygotic (DZ) healthy Norwegian twin pairs. Regions of interest include CpG islands, the 5'end of genes and non-coding conserved regions. We observed significant variation in DNA methylation both between and within regions. Interestingly, the heritability of this variation is low, ~6% for individual CpGs and ~11% for amplicons, suggesting DNA methylation variation is not under strong genetic control. By measuring gene expression levels in 42 genes in the MHC, the influence of DNA methylation variation on gene expression variation can be seen. Second, we developed methods to perform genome-wide bisulphite sequencing using the Illumina platform. In parallel, covalent histone modifications were examined by chromatin immuno-precipitation (ChIP). Modifications associated with both transcriptionally active chromatin (H3K4me1 and H3K4me3) and those associated with repressive heterochromatin (H3K9me3 and H3K27me3) were examined. Immunoprecipitated DNA was quantified by high throughput sequencing (ChIP-seq). Data collected so far document the variation seen between three normal MZ twins pairs, the link between histone modifications and DNA methylation on a global scale.

## 2979/F/Poster Board #911

**DHPLC screening strategy identifies novel apoptotic gene targets of aberrant promoter hypermethylation in prostate cancer.** *T.M. Murphy, A.S. Perry, C. Lane, L. O'Connor, M. Lawler.* Prostate cancer research group, Institute of Molecular Medicine, Dublin , Leinster, Ireland.

Introduction: Aberrant DNA methylation has been implicated as a key survival mechanism in cancer, whereby promoter hypermethylation silences genes essential for many processes including apoptosis. To date, only limited data exists on the methylation status of apopotic genes in prostate cancer. The aim of this study was to profile methylation of apoptotic-related genes in prostate cancer using a Denaturing High Performance Liquid Chromatography (DHPLC) platform. Methods: A bioinformatics approach was first applied to generate a list of apoptotic genes, which were identified as possible targets of methylation in prostate cancer. PCR assays were designed to amplify whole CpG islands in the gene promoters. Genes were screened for CpG methylation in a panel of prostate cancer cell lines (LNCaP, DU145, PC-3, 22RV1, RC58) and normal prostate cell lines (RWPE1 and PWR1E) using an automated (DHPLC) instrument. Methylation levels were quantified using real time quantitative methylation specific PCR (QMSP). Quantitative real time PCR was performed in our panel of prostate cancer cell lines and PC3 cells treated with a methylation inhibitor (5aza2'deoxycytidine). Results: Our DHPLC methylation screen identified seven targets of CpG promoter methylation, three of which are novel targets of methylation in prostate cancer (BIK, BNIP3 and CFLIP), while our methylation findings for TMS1, DCR1, DCR2 and CDKN2A are consistent with previous methylation studies in prostate cancer. In order to assess the methylation status of individual CG sites QMSP assays were designed to encompass CG sites in the 5'UTR and/or transcriptional elements identified by our promoter CpG island characterisation. Our gene expression analysis for BIK, TMS1, CDKN2A and DCR1/2 shows a significant decrease in gene expression in PC3 cells compared to normal RWPE1. These findings are consistent with our methylation results, showing strong methylation of these genes in PC3 cells. Furthermore, treatment of PC3 cells with a methylation inhibitor causes a moderate to strong increase in expression in each of these genes. Conclusion: Methylation levels are currently being quantified using QMSP in a prostate cancer biorepostitory, representing prostate cancer, normal adjacent prostate and benign prostatic hyperplasia. Determining the methylation profile of a fundamental cellular process such as apoptosis could yield a biomarker signature for early disease and disease progression in prostate cancer.

## 2980/F/Poster Board #912

**Identification of Differential Methylation in Normal and Cancer Cells.**
*D. Murray[1], K. Lo[1], A.L. Iniguez[1], C. Kashuk[1], H. Holster[1], H. Rosenbaum[1], A. Sharp[2], R. Brazas[1], T. Takova[1], T. Richmond[1], J. Jeddeloh[1], R. Selzer[1].* 1) Roche Nimblegen, Madison, WI; 2) Department of Genetic Medicine and Development, University of Geneva, Switzerland.

Epigenetic mechanisms, such as DNA methylation and histone modification, play critical roles in the development of normal cellular differentiation, as well as many human diseases including cancer, pediatric syndromes and genetics disorders. Understanding the role epigenetics plays in cellular differentiation and the development of disease will ultimately lead to the development of diagnostics and hopefully preventative and therapeutic options. Recent advances in high density oligo microarray platforms affords the opportunity to examine epigenetic events using methyl-DNA immunoprecipitation followed by microarray (MeDIP-chip) assays at unprecedented scale and resolution. This study was undertaken to measure the sensitivity and reproducibility with which DNA methylation can be detected with MeDIP-chip on samples that demonstrate differential methylation in imprinted regions of the genome and between normal and cancer cells. Each genomic DNA sample was fragmented and immunoprecipitated using an antibody against 5-methyl-cytosine. IP sample and input genomic DNA were labeled with Cy5 and Cy3, respectively, and hybridized to the array, which contains probes tiled across all annotated CpG islands, gene promoters, and miRNA promoters. Data demonstrate that (1) methylated DNA fragments with as few as two methyl groups can be detected and with high reproducibility (R= 0.94) using the reported methods, (2) the positive, negative and non-CG control regions on the array correlate with expected methylation status making them a useful indicator for assessing MeDIP-chip performance, and (3) differential regions of imprinting are sensitively and accurately identifiable between normal male, normal female, and cancer cells.

## 2981/F/Poster Board #913

**The relationship of DNA methylation with age, gender and genotype in twins and healthy controls.**
*R.A. Ophoff[1,2], D.J. Weisenberger[3], E.M. Derks[4], E. Strengman[2], E. Janson[2], I.E. Sommer[4], R.S. Kahn[4], M.P.M. Boks[4].* 1) Neuropsychiatric Inst, Gonda, Univ California Los Angeles, Los Angeles, CA; 2) Department of Medical Genetics, University Medical Center Utrecht, Utrecht, The Netherlands; 3) USC Epigenome Center and USC/ Norris Comprehensive Cancer Center Keck School of Medicine, University of Southern California, Los Angeles, CA, USA; 4) Rudolf Magnus Institute of Neuroscience, Department of Psychiatry, University Medical Center Utrecht, Utrecht, The Netherlands.

Cytosine-5 methylation within CpG dinucleotides is a potentially important mechanism of epigenetic influence on human traits and disease. In addition to influences of age and gender, genetic control of DNA methylation levels has recently been described. We used whole blood genomic DNA in a twin set (23 MZ twins and 23 DZ twins, N=92) as well as healthy controls (N= 96) to investigate heritability and relationship with age and gender of selected DNA methylation profiles using readily commercially available GoldenGate bead array technology. Despite the inability to detect meaningful methylation differences in the majority of CpG loci due to tissue type and locus selection issues, we found replicable significant associations of DNA methylation with age and gender. We identified associations of genetically heritable single nucleotide polymorphisms with large differences in DNA methylation levels near the polymorphism (cis effects) as well as associations with much smaller differences in DNA methylation levels elsewhere in the human genome (trans effects). Our results demonstrate the feasibility of array-based approaches in studies of DNA methylation and highlight the vast differences between individual loci. The identification of CpG loci of which DNA methylation levels are under genetic control or are related to age or gender will facilitate further studies into the role of DNA methylation and disease.

## 2982/F/Poster Board #914

**DNA methylation and the evolution of gene regulation in primates.**
*A.A. Pai, J.T. Bell, J.K. Pritchard, Y. Gilad.* Department of Human Genetics, University of Chicago, Chicago, IL.

Heritable DNA methylation is an important epigenetic mechanism, which affects the regulation of gene expression. Specifically, we know that many spatial and temporal gene expression patterns are the result of regulation through DNA methylation. However, while methylation patterns have been described in many contexts within species (for example, across different human tissues), the extent to which these signatures are conserved across primates has not been well characterized. To this end, we assayed genome-wide DNA methylation patterns in liver, heart, and kidney samples from multiple humans and chimpanzees, and combined these data with previously collected gene expression data from the same individual tissue samples. Using the multi-species gene expression and methylation data, we were able to study the evolution of gene regulation in the context of conservation or changes in DNA methylation patterns across species. Specifically, we confirmed that hyper-methylation is correlated with decreased expression levels across tissues and species, and identified individual genes whose regulation across tissues and species can be explained, at least in part, by specific methylation patterns.

## 2983/F/Poster Board #915

**MAOA Promoter Methylation Is Associated with Nicotine Dependence in DNA Prepared from Lymphoblasts and from Whole Blood.**
*R. Philibert[1], S.R.H. Beach[2], T. Gunter[3], G. Brody[4], A. Madan[5].* 1) Dept Psychiatry, Univ Iowa, Iowa City, IA; 2) Institute for Behavioral Research, University of Georgia, Athens, GA; 3) Department of Neurology and Psychiatry, St. Louis University, St. Louis, MO; 4) Center for Family Studies, University of Georgia, Athens, Ga; 5) Neuroscience Institute, Swedish Hospital, Seattle, WA.

Introduction: Nicotine Dependence (ND) results from a dynamic, chronologically dependent, interplay of genetic and environmental, and gene-environment interactions. To date, a handful of small effect sequence variants have been isolated, but the majority of the biological factors, both genetic and epigenetic, that initiate, promote and maintain ND are still undefined. In previously published work using DNA and clinical material from 192 subjects from Iowa Adoption Studies (IAS), we demonstrated that methylation of the two MAOA promoter associated CpG islands was associated with lifetime history of ND and with MAOA genotype. This is of particular interest because the maintenance of ND is thought to be mediated through dopaminergic mechanisms, MAOA is the key enzyme in the catabolism of dopamine, and some agents used to treat ND target MAOA. Objective and Methods: To extend to confirm these prior findings, we re-examined these relationships at MAOA using DNA and clinical material from another 289 subjects using the same methodologies. Results: First, we demonstrate that the methylation signature at the MAOA promoter associated CpG islands is dependent on current smoking status and MAOA genotype. Second, we conduct factor analyses to demonstrate that there appears to be three distinct regions of this CpG enriched region that may function in different ways for males and females. Third, we directly compare methylation signatures in DNA whole blood and from lymphoblasts and provide suggestive evidence favoring the use of lymphoblasts. Conclusion: We conclude that smoking decreases methylation at the MAOA promoter associated CpG islands with the exact extent being dependent on the region being examined, MAOA genotype, smoking history and gender.

**A human genome-wide study of aging-associated DNA methylation dynamics.** *V.K. Rakyan[1], S. Maslau[2], T. Andrew[3], M. Falchi[4], T.A. Down[2], T.D. Spector[3].* 1) Queen Mary University of London, London, United Kingdom; 2) The Gurdon Institute, University of Cambridge, Cambridge, UK; 3) King's College London St. Thomas' Hospital, Twin Research and Genetic Epidemiology Department, London, UK; 4) Genomic Medicine, Imperial College London, London, United Kingdom.

Aging is a complex multidimensional process associated with biological, psychological, and social changes. In biological terms, aging can be defined as cellular senescence, which results in a diminished ability to respond to stress, increased homeostatic imbalance and risk of disease, and eventually death. Research in a variety of organisms has revealed that many factors impact on the aging process at the molecular level. These include telomere shortening, accumulation of genetic mutations, oxidative stress, and molecular pathways altered by quantitative and qualitative changes in nutrition. More recently, evidence has emerged to suggest that stochastic, or possibly even genetically programmed, events that alter transcriptional and epigenetic programs are involved in the aging process in a variety of organisms including humans. Epigenetic modifications, such as DNA methylation and post-translational modifications of histone proteins, are indispensable for many aspects of genome function including gene expression. The perturbation of epigenetic and transcriptional landscapes during aging could potentially have major implications for cellular function. We have performed a genome-wide study of DNA methylation dynamics during human aging. Methylated DNA Immunoprecipitation (MeDIP) was combined with custom microarrays (MeDIP-chip) to generate high-resolution DNA methylation profiles of >40,000 regulatory features (nearly all known CpG islands and promoters, along with other known elements such as enhancers and CTCF binding sites) in whole blood from 22 monozygotic (MZ) twin pairs spanning a >50 year age range. An important feature of this project was that two time-points (10 years apart) were analyzed for each monozygotic twin pair, allowing elucidation of age-related DNA methylation dynamics both cross-sectionally in unrelated individuals, and longitudinally in the same individual. Key findings include: (i) a genetic influence on age-related DNA methylation dynamics; (ii) identification of the regulatory elements in the human genome that are most susceptible to age-related DNA methylation changes in whole-blood; (iii) identification of the key molecular pathways that display perturbed DNA methylation profiles. Overall, our study represents the first truly genome-wide study of aging-related epigenetic changes in mammals and provides novel insights into the molecular events that underlie the aging process.

## 2985/F/Poster Board #917

**Identification of tissue-specific methylation signatures in the 2nd trimester fetus and placenta.** *W. Robinson, L. Avila, M. Peñaherrera, R. Yuen, D. Diego-Alvarez, D.E. McFadden, M. Kobor.* Dept Med Gen, Univ British Columbia, Vancouver, BC, Canada.

While it is well established that there are tissue-specific methylation patterns, the exact nature and extent of these is not well-known. To investigate this, the Illumina GoldenGate Methylation Cancer Panel I (1,505 CpG loci from 807 genes) was used to interrogate DNA extracted from 2nd trimester fetal tissues (kidney, brain, lung, muscle, skin) and placenta (trophoblast and mesenchyme) samples from 6 chromosomally normal and 8 trisomic pregnancies. Hierarchechal clustering showed that the DNA methylation profile of placental trophoblast was distinct from all other tissues (average r=0.72). Placental mesenchyme clustered more closely with fetal tissues (r=0.87) than placental trophoblast, consistent with its developmental origin from the epiblast. The distribution of DNA methylation values was similar amongst all placental and fetal tissues, with the majority of CpG-island associated CpGs (N=1044) being hypomethylated (<10% methylation) and most non-island associated CpGs (N=461) highly methylated (>75%). However, using Significance Analysis of Microarrays (SAM) with a False Discovery Rate (FDR) of <1% and an absolute difference of >20%, numerous sites were identified as differentially hypomethylated (N=101) or hypermethylated (N=165) in trophoblast as compared to mesenchyme, supporting a role for DNA methylation in gene regulation in the placenta. A number of tumor suppressor genes were specifically hypermethylated in trophoblast, consistent with its invasive properties. Similarly, 429 of 1454 autosomal CpGs showed significant tissue specific differences in methylation by ANOVA (P<0.05) when considering brain, kidney, skin, lung and muscle only. From among these candidates, we were able to identify a subset of "signature CpGs" for which the methylation status is predictive of tissue type. Identification of normal tissue specific patterns of methylation can thus provide useful tools for identification of the tissue-source of biological specimens of unknown origin, as well as providing a framework to understand normal and abnormal development.

## 2986/F/Poster Board #918

**DNA methylation for subtype classification and prediction of treatment outcome in childhood acute lymphoblastic leukemia.** *A-C. Syvänen[1], L. Milani[1], A. Lundmark[1], J. Nordlund[1], A. Kiialainen[1], M. Gustafsson[1,2], G. Lönnerholm[3], Nordic Society of Pediatric Hematology and Oncology.* 1) Dept of Medical sciences, Uppsala University, Uppsala, Sweden; 2) Linneaus Centre for Bioinformatics, Uppsala University, Uppsala, Sweden; 3) Dept of Children's and Women's Health, Uppsala University, Uppsala, Sweden.

Cells from patients with acute lymphoblastic leukemia (ALL) are characterized by complex genomic rearrangements, but the specific genes and molecular mechanisms that cause ALL and affect clinical outcome remain to be elucidated. We have previously used allele-specific gene expression measured by quantitative genotyping of single nucleotide polymorphisms in 8000 genes as a guide for identifying genes with cis-acting regulatory elements in primary ALL cells (Milani et al. 2009 Genome Res.19:1). Based on this analysis we selected 381 genes with putatively strong cis-acting regulatory factors for DNA methylation analysis. We genotyped 1320 CpG sites in the regulatory regions of these genes in bisulphite-treated DNA samples from 400 bone marrow or peripheral blood samples from children with ALL. We found that CpG sites located outside "CpG islands" had higher methylation levels and larger variability in CpG site methylation than CpG sites within "CpG islands". Binary-split hierarchical clustering of 300 CpG sites with the largest inter-individual variation in their methylation levels stratified the patients with high hyperdiploidy (HeH) and t(12;21) ALL into two subgroups with different probability of disease-free survival. The two HeH groups also differed in their *in vitro* sensitivity to doxorubicin and vincristine. Using supervised learning we constructed multivariate classifiers in an external cross-validation procedure. We identified nine genes that consistently contributed to accurate discrimination between T-ALL and BCP ALL, and a corresponding set of 44 genes for discrimination between the main subtypes of BCP ALL. By Kaplan-Meijer analysis of patients grouped according to methylation levels of individual CpG sites, we identified 28 genes that appeared to predict relapse of leukemia. We conclude that DNA methylation analysis should be further explored as a method to improve stratification of ALL patients for different treatment protocols.

## 2987/F/Poster Board #919

**Global DNA methylation in polycystic ovary syndrome.** *N. Xu[1], R. Azziz[2], M.O. Goodarzi[1,2,3].* 1) Div Endocrinology, Cedars Sinai Medical Center, Los Angeles, CA; 2) Department of Obstetrics and Gynecology, Center for Androgen Related Disorders, Cedars-Sinai Medical Center, Los Angeles, California,; 3) Medical Genetics Institute, Cedars-Sinai Medical Center, Los Angeles, California.

Polycystic ovary syndrome (PCOS) is one of the most common endocrine disorders, occurring in about 7% of reproductive age women. Although its genetic basis has been established, causative genes for PCOS remain elusive. Prenatally androgenized animal models suggest intrauterine androgen exposure during development may predispose individuals to PCOS. This phenomenon has been formulated as the fetal origins hypothesis of PCOS. However, the underlying mechanism is unknown. Environmental factors during development may lead to permanent changes via epigenetic modification. DNA methylation is an important mechanism of epigenetics, which plays a role in cancer, aging and complex chronic diseases. In the present study, we began to determine the role of epigenetics in the development of PCOS. DNA was extracted from peripheral leukocytes of 20 PCOS patients and 20 age- and BMI-matched control women. The total amount of methylated DNA was measured through an ELISA-like reaction. A dilution series of a 100% methylated control reagent was included in each experiment to generate a standard curve, which was used to calculate absolute global methylation percentage. The global methylation percentage for each subject was obtained by taking an average of triplicate results, and then compared between women with PCOS and controls. A ratio representing the global methylation alteration of each PCOS subject compared to an age- and BMI- matched control was examined for each PCOS subject as well. The median (interquartile range) global methylation percentages were 5.70% (2.40%) for PCOS women and 5.75% (2.75%) for controls. We found no significant difference in the global methylation percentage in PCOS patients compared to matched controls (Mann-Whitney U test: P=0.79; non-parametric one-sample sign test for Log[ratio]: P= 0.82). However, it was observed that five out of 20 PCOS samples (25%) had normal ratios (defined as a ratio 0.8-1.2), and 15 PCOS samples (75%) had abnormal ratios, including 9 (45%) with hypermethylation (ratio >1.2) and 6 (30%) with hypomethylation (ratio <0.8). In conclusion, the global methylation percentage in peripheral leukocyte DNA is not significantly altered in PCOS women compared to matched controls. Our study represents an initial step focusing on DNA methylation in PCOS, which deserves further effort to elucidate the epigenetic process in tissues more relevant to PCOS (e.g. ovary, adrenal, adipose) and/or specific target genes or regions.

## 2988/F/Poster Board #920

**Identification of epipolymorphisms in the human placenta.** *R. Yuen[1], M. Peñaherrera[1], P. von Dadelszen[2], L. Lefebvre[1], M. Kobor[1], W. Robinson[1].* 1) Department of Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 2) Department of Obstetrics and Gynaecology, University of British Columbia, Vancouver, BC, Canada.

Genomic sequence polymorphisms, such as single nucleotide polymorphisms (SNPs) and copy number variants (CNVs), have been widely investigated in a whole genome fashion. However, little is known of genome-wide epigenetic variation among individuals. To identify genes with a high degree of interindividual DNA methylation variation in the human placenta, we surveyed the human genome using the Illumina GoldenGate Methylation Cancer panel targeting 1505 CpG sites of 807 genes in 62 placental samples. Several placenta-related genes were identified to have a polymorphic bimodal distribution of DNA methylation variation at their promoter region which was confirmed by bisulfite pyrosequencing. The methylation polymorphism at the promoter of these genes is concordant with mRNA allelic expression, suggesting it can be a cis-acting factor affecting gene expression. Its placenta specificity and absence in mouse implies a biological significance to the phenotypic diversity of human placenta. Similar to the epimutation of MLH1 and MSH2 found in cancer patients, epipolymorphism identified here can also silence the genes that are crucial for placental development in an allele-specific manner. Thus further investigation of epipolymorphism in human tissues should improve our understanding of interindividual phenotypic variability and complex disease susceptibility.

## 2989/F/Poster Board #921

**Hypermethylation of *OPRM1* in DNAs Extracted from Peripheral Blood of Alcoholics.** *H. Zhang[1,2], A.I. Herman[1,2], H.R. Kranzler[3], R.F. Anton[4], A.A. Simen[1], J. Gelernter[1,2].* 1) Psychiatry Dept, Yale University School of Medicine, New Haven, CT; 2) VA Connecticut Healthcare System / 116A2, West Haven, CT; 3) Psychiatry Dept, University of Connecticut School of Medicine, Farmington, CT; 4) Psychiatry and Behavioral Sciences Dept, Medical University of South Carolina, Charleston, SC.

The $\mu$-opioid receptor (MOR) mediates the rewarding effect of opioids, non-opioid drugs and alcohol. A recent study demonstrated an increased DNA methylation level in the MOR gene (*OPRM1*) in a sample of former heroin addicts. Based on this finding, we hypothesized that hypermethylation of *OPRM1* also occurred in subjects with alcohol dependence (AD). We examined the methylation status of 16 CpG sites in the potential regulatory region (93 bp upstream and 84 bp downstream of the translation start site) of *OPRM1* in 190 European Americans (EAs) with AD and 133 EA healthy controls. Direct sequencing of bisulfite-treated DNA (extracted from peripheral blood) indicated that the overall methylation level of the 16 CpG sites was elevated in AD cases (7.8%) compared with controls (5.0%) ($\chi^2$=14.36, df=1, $P$=0.0002). Individual CpG site analyses showed that three CpG sites (at -80, -25 and -18) had significantly increased methylation levels in AD cases (11.6%, 15.3% and 8.4%, respectively) compared to controls (3.0%, 7.5% and 2.3%, respectively) (-80CpG: $\chi^2$=7.77, df=1, $P$=0.0005; -25CpG: $\chi^2$=4.42, df=1, $P$=0.032, and -18CpG: $\chi^2$=5.37, df=1, $^P$=0.032). Controlling for sex and age using backward logistic regression analysis, two CpG sites showed significantly elevated methylation in AD cases (-80CpG: $\beta$=1.41, $P$=0.013, odds ratio=4.08; -18CpG: $\beta$=1.40, $P$=0.042, odds ratio=4.06). The findings from this research indicate that *OPRM1* methylation is associated with AD in EAs. Functional studies are needed to clarify whether CpG hypermethylation in the *OPRM1* regulatory region alters *OPRM1* expression levels.

## 2990/F/Poster Board #922

**CpG methylation proximal to the CTG/CAG tract of the DM1 locus in patients and transgenic mice.** *C.E. Pearson[1,2], M. Nakamori[3], D. Chitayat[1,2,4,5], G. Gourdon[6], C.A. Thornton[3], A. López Castel[1].* 1) Genetics and Genome Biology, Hospital for Sick Children, Toronto, ON, Canada; 2) Department of Molecular Genetics, University of Toronto, Toronto, ON, Canada; 3) Department of Neurology, University of Rochester School of Medicine and Dentistry, Rochester, NY, USA; 4) Deparment of Obstetrics and Gynecology, Mount Sinai Hospital, Toronto, Canada; 5) Department of Pediatrics, Hospital for Sick Children, Toronto, Canada; 6) Inserm U871, Hopital Necker-Enfants Malades, Paris, France.

Myotonic dystrophy type 1 (DM1), as well as other trinucleotide repeat diseases, are often characterized by complex patterns of inherited and tissue-specific instability and pathogenesis. Disease progresses as the patient ages and is coincident with increasing instability. Repeat-expansion associated epigenetic effects have been recently described at the DMPK locus, although a link to tissue-specificity had not been assessed. We established a highly detailed DNA methylation profile of the DM1 locus in several human (fetuses and adult autopsies) and transgenic DM1 mouse tissues that included tissues from the central nervous system, different muscles and various organs. Our analysis included the CTCF binding sites upstream and downstream of the DM1 CTG tract, as the methylation-sensitive binding of this insulator protein has been demonstrated to affect chromatin packaging, transcriptional regulation of the DMPK locus, and possibly CTG instability. We studied the effects of CTG repeat size, tissue source and age of patient/mouse upon methylation pattern. CpG methylation profiles showed a strong link between appearance of this DNA modification and long expanded alleles, but evident only upstream (5') from the CTG repeat including that methyl-sensitive CTCF binding site. This enrichment of methylation was evident only in patient or mouse tissues with a CTG expansion, and appeared to be specific for the expanded allele. Tissue-specific differences in methylation and CTG instability were evident, with some tissues consistently showing either high levels or low levels of methylation. In addition, age-dependant changes in methylation levels were apparent with a decrease in degree with age. Our data offer novel insights into the dynamics and regulation of the DM1 disease locus at the epigenetic level.

## 2991/F/Poster Board #923

**Maternal, but not paternal, interstitial duplications of chromosome 15q11.2-q13 are associated with ASD in 7 individuals.** *L. Reiter[1,2], J. Cleary[3], V. Brewer[2], J.T. Jabbour[4], N.C. Schanen[5], N. Urraca[1].* 1) Dept Neurology, Univ Tennessee HSC, Memphis, TN; 2) Dept Pediatrics, Univ Tennessee HSC, Memphis, TN; 3) Dept Audiology Speech Lang Path, University of Memphis, Memphis, TN; 4) Memphis Neurology, Memphis, TN; 5) Dept Biological Sciences, University of Delaware, Newark, DE.

It has been estimated that ~3-5% of all autism cases may be the result of duplications of the 15q11-q13 region. Unfortunately, genotype-phenotype correlations have not consistently demonstrated that these duplications are the sole cause of autism spectrum disorder (ASD) in these cases. Maternally transmitted 15q duplications consistently show autistic features with variable degrees of developmental delay. Only a few cases of paternally transmitted 15q duplication have been reported and are associated with speech delay and behavior problems, but not autism. The aims of the present study were to perform an in depth phenotype analysis of individuals with interstitial 15q duplications and determine if maternal duplication is required for the diagnosis of ASD. We used neuropsychological, language and ASD diagnostic tools for phenotypic analysis in patients recruited through the IDEAS parent support group (www.idic15.org). In addition we performed High Resolution Melting analysis (HRM) of the maternally methylated SNRPN locus to determine the parent of origin of the duplications. Eight pediatric subjects with interstitial duplication 15q have participated in the study. Seven patients scored as ASD upon ADOS/ADI-R analysis and one scored "no ASD" on both tests. In the neuropsychological evaluations 3/8 patients had a low average IQ score, 2/8 were borderline and the others had mental retardation, although the patients were noted to have a higher verbal IQ than performance, they had a low-moderate adaptive functioning score on the Vineland II evaluation. All patients performed below age corrected average for receptive vocabulary (Peabody Picture vocabulary test). HRM analysis was done in 7 patients: 6/7 had a maternal duplication and 1/7 had a paternal duplication. The sizes of the duplications ranged from 5Mb to 12.77Mb and included typical BP1-BP3, BP2-BP3 and duplications including the BP1-BP3 region plus additional regions upstream or downstream. The size of the duplication involved does not appear to correlate with the severity of the phenotype or the ASD diagnosis. In conclusion: in our study only maternally derived interstitial duplications result in ASD, not paternal duplications. It should be noted that several of our patients were adopted so parental DNA was unavailable for genotype analysis. HRM analysis for maternal specific methylation patterns at the SNRPN locus allowed us to determine the parental origin of the duplication in all samples.

**Allelic mRNA expression imbalance in inflammasome related genes.**
*A.A. Awomoyi[1], A. Papp[2], G. Smith[2], W. Sadee[2], M. Wewers[1].* 1) Internal Medicine, Ohio State University, Columbus, OH; 2) Department of Pharmacology, Ohio State University, Columbus, OH.

Multiprotein complexes, termed inflammasomes, are assembled in a stimulus dependent manner for the activation of caspase-1 and ultimate release of the endogenous pyrogen, interleukin-1β (IL-1β) and the interferon inducing factor, IL-18. Because IL-1β and IL-18 are central to the innate host response, dysregulated inflammasome functioning is associated with numerous diseases and disorders including auto inflammatory diseases, autoimmunity, and leukemias. Therefore, naturally occurring genetic variations within any of the components of the inflammasome have the potential to modulate the activation and assemblage of this complex. One important variation that, to our knowledge, has not yet been systematically investigated in the context of inflammasome function is the possibility that regulatory polymorphisms in specific inflammasome genes may result in altered mRNA expression, which is detectable as an allelic mRNA expression imbalance in subjects heterozygous for a marker SNP in the transcribed exonic region of the genes. These so called, “cis acting regulatory polymorphisms” are thought to account for a main portion of genetic variability in humans. To search for these cis acting polymorphisms, we have selected 6 genes of particular importance to inflammasome function: NLRP1, NLRP3, PYCARD, MEFV, CASP1 and CASP12. We have used the public data bases to identify TagSNPs in exonic regions that have high frequency of heterozygosity within these 6 inflammasome genes. We will use a single base extension technique (SNaPshot, Applied Biosystems) to measure allele mRNA expression ratios in primary human blood monocytes and MCSF derived macrophages from heterozygous individuals, in comparison to the corresponding genomic allele ratios measured in the same subjects. A relative deficit in one allele compared to the alternate allele suggests a cis acting regulatory element within the gene locus of interest. Using this approach we show that specific inflammasome genes will be regulated at least in part by cis acting genetic elements. We show differential expression of similar genotypes. Heterozygotes exhibit monoallelic expression of inflammasome gene maybe due to DNA methylation. For those monoalleleic expressions that are not found to be due to DNA methylation, extracellular stimulus (LPS)is able to restore the heterozygous state. This finding has profound implications for interpretations of genetic linkage, association studies and pharmacogenetics.

## 2993/F/Poster Board #925

**MicroRNAs involved in BMP2 mediated osteoblast differentiation.**
*Y. Bae[1], D. Baldridge[1], B. Dawson[1], T. Bertin[1], B. Lee[1, 2].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Howard Hughes Medical Institute, Houston, TX.

Osteoblast differentiation requires tight regulation of program of gene activation and suppression in response to physiological ques. Bone morphogenic proteins (BMPs) are potent morphogens that activate transcriptional programs of mesenchymal stem cells to commit into specific lineage. BMP2 can activate osteoblastogenesis via activating Runx2 and Osterix, which are osteoblast specific transcription factors. MicroRNAs (miRNAs) have emerged as key negative regulators of various biological and pathological processes, including developmental timing, organogenesis, apoptosis, cell proliferation, and differentiation and in the control of tumorigenesis. How BMP2 mediated osteogenesis is regulated by miRNAs remains unknown. In this study, to identify miRNAs related to the osteoblast differentiation, Exiqon miRNA array was performed using total RNA from 72 hours of BMP2-treated and vehicle treated C2C12 premyoblast mesenchymal cells. Two biological replicates were included for each BMP2 treated and control group. In response to BMP2, Runx2 and Osterix mRNA were induced along with other osteoblast markers indicating the osteoblast lineage was committed by BMP2 treatment. The result showed that the total number of 34 miRNAs were more than 2 fold differentially expressed between control and BMP2 treated groups. Among BMP2 mediated up-regulated miRNAs, miR-140 was enriched which has identified as cartilage specific miRNA previously. Fourteen miRNAs were down-regulated in response to BMP2, among these, myogenic miRNA including miR-206, miR-1, miR-133b and miR-133a were all significantly down-regulated. Our study suggest that BMP2 can promote osteogenic lineage commitment by tightly regulating miRNAs by both suppressing alternative lineages and relieving the repression of the targets of miRNAs specific to bone differentiation. However, the analysis of putative targets of miRNAs relevant to osteoblast lineage is still under investigation to understand the function of miRNA during bone development.

## 2994/F/Poster Board #926

**Role of microRNAs in the Regulation of Telomerase (hTERT) in Ovarian Cancer.**
*B. Herbert, M. Fox, S. Skillman.* Dept Med and Molec Gen, Indiana Univ Sch Medicine, Indianapolis, IN.

A hallmark of cancer is its limitless proliferative potential which is governed in part by elevated levels of human telomerase (hTERT) or telomerase activity. Most normal cells do not have sufficient expression of active telomerase and are mortal, while an estimated 90% of cancer cells express active telomerase. Therefore, the understanding of how telomerase can be regulated in normal cells, and how this regulation can be lost during cancer progression, has led to the search for suppressors of telomerase. MicroRNAs (miRNA or miR) are evolutionarily conserved, small, non-coding, single-stranded, ~19-23 nucleotide RNA molecules that are estimated to negatively regulate protein encoding genes. Recent evidence has shown that alteration of microRNA levels can lead to cellular transformation and cancer development. We aimed to test the hypothesis that microRNAs play a role in telomerase regulation in normal cells and that hTERT microRNA expression is lost during cancer progression leading to active telomerase and sustained growth. Based on *in silico* analyses, microRNAs were predicted to target different regions of the hTERT mRNA, suggesting that telomerase expression in normal cells may be regulated in part by microRNA-mediated repression of hTERT mRNA translation and ultimately protein expression. By using commercial microRNA isolation and detection protocols, we demonstrated a correlation of the predicted hTERT microRNAs with the levels of telomerase in normal and cancerous (of different stages and recurrence) ovarian cells. We identified nine candidate microRNAs that may play a role in telomerase regulation. Next, we observed that precursor microRNAs to these candidate microRNAs reduced telomerase activity in ovarian cancer cells and their cell growth. Telomerase inhibition by microRNA can thus lead to new nonviral gene therapy as well as an understanding of how cancer progresses (from normal, early, then to late stage).

## 2995/F/Poster Board #927

**Systematic gene regulation pathway involving functional small RNAs during neuronal differentiation of mouse embryonic carcinoma cell.**
*H. Hohjoh, A. Eda, Y. Tamura, M. Yoshida.* NCNP, Natl Inst Neuroscience, Tokyo, Japan.

MicroRNAs (miRNAs) are small noncoding RNA, with a length of 19- to 23-nucleotide, which are processed from longer transcripts by digestion with a microprocessor complex in the nucleus and Dicer in the cytoplasm. Matured miRNAs are incorporated into the RNA-induced silencing complex (RISC) and function as mediators in gene silencing; and the gene silencing involving miRNAs appears to play an important role in regulation of gene expression in development, differentiation and proliferation. In this study, we examined a gene regulation system during neuronal differentiation of mouse P19 embryonic carcinoma cells and described a systematic gene regulation pathway involving miRNAs. In the pathway, the upstream Lin-28 gene is suppressed and let-7 is upregulated after induction of the differentiation, thereby triggering suppression of the downstream High Mobility Group A2 (Hmga2) gene expression via activation of gene silencing mediated by the let-7 miRNAs. Our data further suggest that miR-9, as well as miR-125b, participate in the reduction of the Lin-28 gene expression, and that the pathway for the gene regulation is already constructed in undifferentiated P19 cells. Taken together, such a systematic pathway for gene regulation likely contributes to a rapid and programmed change in gene expression under cell differentiation.

**A Highly Effective and Long-lasting Inhibition of miRNAs with PNA-based antisense oligonucleotides.** *S. Oh, Y. Ju, H. Park.* Panagene, Daejeon, Korea.

MicroRNAs (miRNA) are non-coding RNAs, of approximately 22 nucleotides in length. They play a role in the regulation of such major processes as cellular development, differentiation and apoptosis. The inhibition of miRNA using antisense oligonucleotide (ASO) is a unique and effective technique for characterizing miRNA function and subsequent therapeutic targeting of miRNA. Recently, advances in ASO chemistry are increasingly being utilized to increases nuclease-resistance, target affinity and specificity. PNAs are artificial oligonucleotides constructed on a peptide-like backbone. PNAs have a stronger affinity and greater specificity than DNA or RNA and are resistant to nuclease, which is essential characteristic for a miRNA ASO that will be exposed to abundant serum and cellular nucleases. We evaluated the effect of a PNA-based ASO on anti-miRNA activity. In this experiment, PNAs were conjugated with CPPs at N-terminal for increasing cell penetration. We studied cell penetration of CPP-conjugated PNAs by confocal microscopy. Among the tested 10 types of CPPs, Tat-modified peptide-conjugated PNAs have most effective function for cell penetration. We confirmed that PNA-based ASOs are more effective ASOs than LNA-modified DNA and 2'-O-Methyl-oligonucleotide. Microarray and real time PCR analysis confirmed that the level of miRNA expression was decreased by PNA-based ASO in dose-dependent manner. These miRNA inhibition effects by PNA-based ASO were sustained for 15 days after transfection. We found that inhibition activity of PNA-based ASO can be lasted after 20 week storage at room temperature. PNA-based ASOs showed lower cytotoxicity than other nucleic acid-based miRNA ASOs. Especially, we tested PNA-based ASOs for over 100 miRNAs and found that all of the PNA-based ASO could act as powerful miRNA ASOs. These results demonstrated that PNA-based ASO was demonstrated to be a more effective inhibitor of miRNA than other miRNA ASOs.

## 2997/F/Poster Board #929

**Transcription Control and Myogenesis: Mapping Genome-Wide Changes In DNaseI-Hypersensitive Sites in Chromatin.** *M. Ehrlich[1], K. Tsumagari[1], L. Song[2], T.S. Fuery[2], D. London[2], A.P. Boyle[2], G.E. Crawford[2].* 1) Hayward Genetics Program, SL31, Tulane Med. Sch., New Orleans, LA; 2) Inst. for Genome Sciences & Policy, Duke Univ., Durham, NC.

Induction of the formation of multinucleated myotubes from cultured human myoblasts is one of the best *in vitro* models for human cell differentiation. Nonetheless, high-resolution genome-wide studies of human myoblast epigenetics have been lacking. We have begun mapping DNaseI-hypersensitive sites (DH sites) throughout the genomes of human myoblast cell strains before, during, or after differentiation to myotubes. The analysis used next-generation DNA sequencing (DNase-seq). DH sites represent nucleosome-free regions that are usually associated with transcription control elements actively engaged in or poised for transcription. Our comparison of myoblasts and myotubes to other cell types indicated the expected muscle lineage-specificity for many DH sites in or near muscle-related genes. Some DH sites that were located 5' to a myogenesis-associated gene, inside it, or downstream increased in signal intensity in myotubes *vs.* myoblasts. Such genes included *MB* and *DES*, which encode myoglobin and desmin. Their increase in DH character is consistent with increased production of the gene product during differentiation of myoblasts to myotubes. Other genes had decreases in intensity of DH sites in myotubes *vs.* myoblasts. For example, *SMARCD3* had muscle lineage-specific DH sites near the 3' end that might indicate the presence of an enhancer. They were much reduced in myotubes relative to myoblasts. As a subunit of a chromatin remodeling protein, SMARCD3 was reported to be critically involved in positively regulating the onset of zebrafish myogenesis; therefore, downregulation of SMARCD3 production might be necessary once myogenesis is underway. Not only can DNase-seq reveal new transcription control elements associated with differentiation, but also it can point to unanticipated associations of genes with myogenesis. For example, *PLEKHA7*, a provisional gene that encodes a protein with actin cytoskeleton-like structure, had a greatly reduced DH site at its 5' end in myotubes compared with myoblasts, suggesting that the dramatic changes in cellular morphology during myotube formation require a decrease in PLEKHA7 production. We have demonstrated that DNase-seq is a powerful tool for analysis of myoblast differentiation and therefore should also be very valuable for elucidating gene dysfunction in muscular dystrophies. (Supported by NIH Grants NS048859 and HG003169, the FSH Global Research Foundation, and the National Human Genome Research Institute).

## 2998/F/Poster Board #930

**Widespread reprogramming of human DNA replication across cell lineages.** *R. Hansen.* Med/Div Med Gen, Univ Washington, Seattle, WA.

Faithful transmission of the genetic material to daughter cells involves a characteristic temporal order of DNA replication, which may play a significant role in the inheritance of epigenetic states. We developed a high-resolution; genome-scale approach to map newly replicated DNA using next-generation sequencing and applied it to study regional variation in human DNA replication time in multiple human cell types and embryonic stem cells. We find that different cell types exhibit characteristic replication signatures that comprise both regional variations in replication time during S-phase and also distinct patterns of replication fork movement. We observed striking plasticity in regional DNA replication patterns between cell types covering nearly 50% of the genome. Additionally, we identified hundreds of autosomal regions with marked biphasic replication timing, including some known imprinted regions as well as many previously uncharacterized domains. High-resolution genome-wide profiling of chromatin accessibility revealed that DNA replication stereotypically initiates in accessible chromatin domains comprising clustered DNaseI hypersensitive sites. The data collectively provide an unprecedented view of chromosomal replication patterns and a unique genome-wide picture of the epigenetic compartmentalization of the human genome.

## 2999/F/Poster Board #931

**Risk of tuberculosis (TB) among close contacts to TB patients: the role of Interleukin- 12 receptor, $\beta$1 gene polymorphisms and environmental factors.** *C. Luo[1], M. Reichler[1], B. Chen[1], E. Sigman[1], F. Maruri[2], T. Sterling[3].* 1) Division of TB Elimination, CDC, Atlanta, GA; 2) Tennessee Dept of Health, Nashville, TN; 3) Vanderbilt University, Nashville, TN.

**Background**: Single nucleotide polymorphisms (SNP) in the Interleukin-12 $\beta$1 receptor gene (IL12RB1) have been implicated in susceptibility to TB, but reports have been inconsistent and associated with low attributable risk.

**Methods**: We enrolled U.S.-born contacts with latent TB infection or active TB disease with >180 hours of exposure to smear + TB patients at 9 sites. Blood was collected and genotyped for IL12RB1 gene SNPs G378R and M365T and epidemiologic data collected by contact interview. Pair-wise analysis was conducted using $\chi^2$ tests with homozygous wild genotype as the referent group. This analysis is limited to contacts of non-Black race/ethnicity (White, Hispanic, American Indian, and Asian).

**Results**: Among 132 contacts, 7 had active TB and 125 had a positive tuberculin skin test (TST+). Compared with TST+ contacts, those with active TB were more likely to have the homozygous mutant genotype for IL12RB1 G378R (OR=3.78, P=.12) but the difference did not reach statistical significance. The association between mutant genotype for the G378R gene SNP and TB was increased for contacts that smoked (SM), used alcohol (ALC), and used street drugs (ST). (OR=7.33, P=.10 among SM; OR=12.00, P=.05 among ALC; and OR=11.00, P=.08 among ST). TST+ contacts and contacts with active TB were equally likely to have the homozygous mutant genotype for IL12RB1 M365T (OR=1.34, P=.79).

**Conclusions**: In this U.S. population, there was a trend towards a greater risk for active TB among contacts having a homozygous mutant genotype for IL12RB1 G378R, with stronger associations observed for contacts with SM, ALC, or ST. These findings suggest that the risk of active TB after exposure may be modulated by both genes and environmental factors such as SM, ALC, and ST.

## 3000/F/Poster Board #932

**Derivation of live Angelman syndrome neurons from induced pluripotent stem (iPS) cells.** *S.J. Chamberlain[1,3], F. Lemtiri-Chlieh[2], E.S. Levine[2], D. Rosenblatt[4], M. Lalande[1,3].* 1) Department of Genetics and Developmental Biology, University of Connecticut, Farmington, CT; 2) Department of Neuroscience, University of Connecticut, Farmington, CT; 3) Stem Cell Institute, University of Connecticut, Farmington, CT; 4) Department of Human Genetics, McGill University, Montreal, Quebec, Canada.

The recent discovery of reprogramming human somatic cells into induced pluripotent stem cells (iPS) offers an innovative approach to the study of human genetic disorders. Like human embryonic stem cells, iPS cells self-renew indefinitely and have unlimited developmental potential. The creation of patient-specific iPS cells holds great promise for understanding genetic disease mechanisms and for *in vitro* testing of potential therapies.

We have generated an *in vitro* model of Angelman syndrome (AS) using iPS technology. AS is a neurogenetic disorder characterized by severe mental retardation, lack of speech, seizures and ataxia. About 70% of all AS cases result from deletion of chromosome 15q11-13, a region that is subject to genomic imprinting. The gene encoding the E3 ubiquitin ligase, *UBE3A*, maps to 15q11-q13, displays maternal allele-specific expression, and is inactivated by mutation in some AS cases. How the loss of UBE3A function leads to AS has not been completely elucidated. Moreover, the timing and tissue-specificity of *UBE3A* imprinting during human neuronal development has not previously been studied due to the lack of a suitable model system.

iPS cell lines have been created from AS deletion and normal fibroblasts. The iPS cell lines express NANOG and OCT4, two markers that characterize the undifferentiated stem cell state. The iPS cell lines can be differentiated into mature neurons, using a technique that mimics neural development in the embryo. During this process of *in vitro* neurogenesis, there is upregulation of PAX6, a marker of neuronal precursors, at early stages, followed by expression of MAP2 and TUJ1 in neurons. A marked decrease in *UBE3A* mRNA is observed in neurons derived from AS iPS cells, indicating that silencing of the paternal *UBE3A* allele occurs in our in vitro model of AS. These AS neurons have also been subjected to single-cell recordings to measure action potentials (APs)and spontaneous synaptic activity. Some cells with mature APs showed robust spontaneous excitatory post-synaptic potentials (ePSPs), while some did not, suggesting a developmental delay of excitatory neuronal circuits, consistent with recent findings in the mouse model of AS. Our human *in vitro* model of AS may prove invaluable for examining the developmental timing and regulation of *UBE3A* imprinting and for characterizing the functional abnormalities of human AS neurons.

**Chromatin Structure and Regulatory Elements of the Imprinted Mouse *Snrpn* Locus: Evidence the Prader-Willi Syndrome Imprinting Center Consists of Multiple Functional Components.** *S. Rodriguez-Jato[1], J. Khadake[1], K.A. Johnstone[2], J.L. Resnick[2,3], T.P. Yang[1,3].* 1) Dept Biochemistry & Molecular Biology, Univ. Florida, Gainesville, FL; 2) Dept Molecular Genetics and Microbiology, Univ. Florida, Gainesville, FL; 3) Center for Epigenetics, Univ. Florida, Gainesville, FL.

Genes in the imprinted Angelman/Prader-Willi syndrome (AS/PWS) domain are controlled by a bipartite imprinting center (IC) associated with the *SNRPN* gene. The human PWS-IC, which spans 4.3 kb and includes the *SNRPN* 5' flanking region and 1st intron, acts to establish and maintain the paternal epigenotype within the domain, whereas the ~0.8 kb human AS-IC is located ~35 kb upstream of the PWS-IC and establishes the maternal epigenotype. The syntenic region of mouse chromosome 7 contains the same genes organized in the same order and exhibiting the same pattern of genomic imprinting. The mouse PWS-IC is defined by a 35 kb deletion of the *Snrpn* locus spanning the 5' flanking region and 1st intron that when paternally-inherited disrupts the paternal epigenotype across the AS/PWS domain and yields offspring with features of PWS. We now have identified 5 DNase I hypersensitive (DH) sites in primary mouse brain cells that are all located within the 35 kb PWS-IC/Snrpn deletion and are specific to the paternal chromosome. We hypothesize that these 5 DH sites comprise functional components of the murine PWS-IC. Similar analysis of the PWS-IC in mouse spleen cells, which express the paternal genes in the domain at very low levels, yielded no DH sites in this region, suggesting these DH sites may play a role in tissue-specific activation of paternal genes. The location of these hypersensitive sites in brain cells relative to previous targeted ES cell deletions of the murine PWS-IC also may explain the varying effects of these deletions on imprinting and suggests that the PWS-IC contains functionally redundant components. To identify regulatory factors within these DH sites that may mediate PWS-IC function, in vivo footprinting and/or chromatin immunoprecipitation assays were performed on primary mouse brain cells. Binding of both nuclear respiratory factor-1 (NRF-1) and YY1 was detected within multiple hypersensitive sites specifically on the paternal chromosome. Both NRF-1 and YY1 were previously identified to bind within the human PWS-IC region on the paternal chromosome. Binding of nuclear respiratory factors and YY1 have also been detected in the promoter region of the paternal allele of other imprinted genes (*Mkrn3*, *Ndn*) within the AS/PWS domain. Thus, these transcription factors may play a role in PWS-IC function and in the coordinate regulation of gene expression and imprinting across the AS/PWS domain on the paternal chromosome.

## 3002/F/Poster Board #934

**Regulation of the Imprinted Mouse Mkrn3 Locus.** *J.X. Shan[1], A.D. Heggestad[1], S. Rodriguez-Jato[1], C. Mione-Kiefer[1], K.A. Johnstone[2], J. Dostie[5], J. Dekker[5], J.L. Resnick[2,3], T.P. Yang[1,3,4].* 1) Department of Biochemistry and Molecular Biology, University of Florida College of Medicine, Gainesville, FL 32610; 2) Department of Molecular Genetics and Microbiology, University of Florida College of Medicine, Gainesville, FL 32610; 3) Center for Epigenetics, University of Florida College of Medicine, Gainesville, FL 32610; 4) Division of Pediatric Genetics, University of Florida College of Medicine, Gainesville, FL 32610; 5) Program in Gene Function and Expression, Department of Biochemistry and Molecular Pharmacology, University of Massachusetts Medical School, Worcester, MA, 01605.

The Angelman/Prader-Willi syndrome (AS/PWS) domain contains at least 8 imprinted genes governed by an imprinting center (IC) that regulates imprinting across the domain. The PWS-IC is required to establish and maintain the paternal epigenotype and is postulated to act as a positive regulator of genes expressed specifically from the paternally-inherited chromosome, whereas the AS-IC establishes the maternal epigenotype and is postulated to function as a negative regulator of the PWS-IC. Genes in the syntenic region of mouse chromosome 7 are organized and imprinted similarly to the human domain. The Mkrn3 gene is located within the AS/PWS domain, expressed only from the paternal chromosome, and located ~2.4 Mb upstream of the murine PWS-IC. The mechanism by which imprinting and transcription of genes within the domain, such as Mkrn3, is regulated by the IC is not well-understood. Analysis of long-rang interactions between Mkrn3 and the murine PWS-IC by chromosome conformation capture (3C) demonstrates a close physical association specifically on the paternally-inherited chromosome. This is consistent with a mechanism of PWS-IC function in which the PWS-IC locates itself in close proximity to its target genes via long-range loop formation to activate transcription of these genes on the paternal chromosome. To identify potential regulatory factors that may mediate PWS-IC function and long-range interactions, we mapped DNase I hypersensitive (DH) sites in both the murine PWS-IC and the Mkrn3 locus and performed in vivo footprinting and/or chromatin immunoprecipitation (ChIP) analyses of these DH sites. Previous analysis of DH sites in the human and mouse PWS-IC detected binding of nuclear respiratory factor-1 (NRF-1) and YY1 specifically on the paternal chromosome. Analysis of the differentially methylated DH site in the Mkrn3 promoter detected binding of nuclear respiratory factor-2 (NRF-2), YY1, Sp1, and STAT1 exclusively on the paternal allele. ChIP analysis of the promoter region of the imprinted mouse Necdin locus, located adjacent to Mkrn3 and expressed only from the paternal chromosome, also detected binding of YY1 and NRF-1 to the paternal allele. Based on these results, we hypothesize that the PWS-IC functions as an active chromatin hub that facilitates localization of its target genes on the paternal chromosome to a transcription factory enriched in nuclear respiratory factors and YY1.

## 3003/F/Poster Board #935

**Epigenetically Altered Wound Healing in Keloid Fibroblasts.** *S.B. Russell, S.R. Opalenik, L.B. Nanney, A.H. Broquist, L. Raju, S.M. Williams.* Vanderbilt University School of Medicine, Nashville, TN.

Keloids are benign fibrotic tumors of the dermis that form during a prolonged wound healing process in genetically susceptible individuals. The predisposition to form keloids is found predominantly in people of African and Asian descent. The key alteration(s) responsible for the pathological process has not been identified and there is no satisfactory treatment for this disorder. We have reported phenotypic differences in growth and matrix synthesis between fibroblasts cultured from normal scars and keloid lesions, including glucocorticoid resistance of keloid fibroblasts to downregulation of collagen, elastin and CTGF gene expression. Gene profiling studies revealed altered regulation of multiple genes in several signaling pathways associated with fibrosis, including IGF/IGFBP and Wnt. As previously observed for the pattern of glucocorticoid resistance we now find that the differential expression of fibrosis-associated genes, including decreased expression of Wnt inhibitors SFRP1 and SFRP2 and overexpression of IGFBP5, is seen only in fibroblasts cultured from the keloid nodule; fibroblasts from perilesional and normal dermis of keloids behave like fibroblasts from normal skin and scar. In agreement with these in vitro findings, immunohistochemical examination of lesional and perilesional sites of keloid relative to normal scar tissue reveals differential expression of SFRP1, SFRP2 and IGFBP5 only in lesional sites. In addition, the pattern of differential gene expression in keloid cells is maintained throughout their in vitro lifetime. Preliminary studies using Chip-chip analysis and inhibitors of DNA methylation and histone deacetylation support a differential pattern of DNA methylation and histone acetylation in keloid relative to normal fibroblasts. These findings support the hypothesis that abnormal regulation of growth and matrix synthesis in keloid fibroblasts is due to an epigenetically altered wound healing program. Characterization of this program may give clues to the mechanism(s) that initiates the pathological process. Epigenetically altered wound healing in keloids suggests therapeutic strategies to treat or prevent keloids and possibly other fibrotic disorders, including asthma, hypertension, nephrosclerosis, sarcoidosis, scleroderma, and uterine fibroma, that disproportionately affect individuals of African ancestry. Supported by NIH grants F33AR052241, R03AR048938, P50DE10595, P30AR041943 and UL1RR024975.

## 3004/F/Poster Board #936

**Epigenetic silencing in Friedreich ataxia is associated with depletion of CTCF (CCCTC-binding factor) and antisense transcription at the *FXN* locus.** *S.I. Bidichandani, Y.K. Chutake, I. De Biase.* Dept of Biochemistry and Molecular Biology, University of Oklahoma Health Sciences Center, Oklahoma City, OK.

Friedreich ataxia (FRDA) patients are homozygous for an expanded GAA triplet-repeat sequence in intron 1 of the *FXN* gene. The expanded GAA triplet-repeat results in severe deficiency of *FXN* gene transcription, which is reversed via administration of histone deacetylase inhibitors indicating that the transcriptional silencing is due to an epigenetic abnormality. We found a severe depletion of the chromatin insulator protein CTCF (CCCTC-binding factor) in the 5'UTR of the *FXN* gene in FRDA, and coincident heterochromatin formation via enrichment of H3K9me3 and recruitment of heterochromatin protein 1. We identified FAST-1 (Frataxin Antisense Transcript - 1), a novel antisense transcript that overlaps the CTCF binding site in the 5'UTR, which was expressed at higher levels in FRDA. The reciprocal relationship of deficient *FXN* transcript and higher levels of FAST-1 seen in FRDA was reproduced in normal cells via knockdown of CTCF. CTCF depletion therefore constitutes an epigenetic switch that results in increased antisense transcription, heterochromatin formation and transcriptional deficiency in FRDA. These findings provide a mechanistic basis for the transcriptional silencing of the *FXN* gene in FRDA, and broaden our understanding of disease pathogenesis in triplet-repeat diseases.

## 3005/F/Poster Board #937

**Deciphering the early stages of human X-chromosome inactivation.** *J. Minks, J.C. Chow, N.P. Thorogood, S.E.L. Baldry, C.J. Brown.* Medical Genetics, University of British Columbia, Vancouver, British Columbia, Canada.

X inactivation in female mammals is achieved by epigenetic silencing of one of the two X's to ensure equal dosage of X-linked genes in both sexes. This silencing, driven by the non-coding XIST/Xist RNA, occurs early in development and has been most extensively studied in mouse. To learn more about human X inactivation, our lab has developed a HT1080 male fibrosarcoma cell line harboring an *XIST* cDNA transgene which, when induced with doxycycline, rapidly silences an *EGFP* reporter.

**Chromatin changes in XIST-induced silencing:** Chromatin immunoprecipitation-qPCR shows that ~2/3 of H3K9ac is lost after 90 days of XIST expression; however this deacetylation does not occur within the first 5 days when *EGFP* becomes ~90% silenced. Moreover histone deacetylase inhibitors do not prevent the XIST induced silencing, suggesting that deacetylation is a consequence rather than cause of silencing in our system. Thus we propose that XIST accomplishes *EGFP* silencing either by recruiting other repressive chromatin remodeling complexes or by a more direct inhibition of transcription.

**Defining the minimal functional XIST:** Using RT-qPCR, we have found that *XIST* transcription does not vary substantially among female somatic cells and, although alternatively spliced, most XIST transcripts extend to the end of the 19 kb transcript. The level of expression induced from the transgene is equivalent to normal female *XIST* expression and we have assessed the ability of XIST deletion constructs to localize and silence the reporter. Truncation of multiple *XIST* regions has limited impact on the localization of the XIST RNA and *EGFP* silencing. However deleting the 5' repeat A sequence abolishes the capacity of XIST to silence, although we have shown that the RNA is still retained in the nucleus. Intriguingly, we have also observed *EGFP* silencing in the absence of a localized XIST signal when the 5' repeat A is repositioned to the very 3' end of XIST.

We thus hypothesize that the XIST-induced silencing of the proximally located *EGFP* reporter is achieved by the repeat A region and may be independent of chromatin changes, suggesting that XIST is involved in multiple pathways driving X-chromosome inactivation. Further analysis of XIST fragments in the well-defined transgenic system will provide insights into the mechanisms of XIST action. *The work is supported by CIHR-13690, IWRH and UGF.*.

## 3006/F/Poster Board #938

**Combinatorial Use of Gene Therapy and Nitric Oxide Donors to Rescue a Mouse Model of Argininosuccinic Aciduria.** *O.A. Shchelochkov[1], A. Erez[1], N. Brunetti-Pierri[1], S.C.S. Nagamani[1], Y. Chen[1], D. Palmer[1], N.S. Bryan[2], B. Lee[1, 3].* 1) Molecular & Human Genetics, Baylor Col Medicine, Houston, TX, USA; 2) Brown Foundation Institute of Molecular Medicine, UT Health Science Center at Houston, TX, USA; 3) Howard Hughes Medical Institute.

Argininosuccinic aciduria (ASA) is characterized by elevated plasma argininosuccinic acid and depletion of plasma arginine. Despite the diligent control of hyperammonemia with a low-protein diet and arginine supplementation, many patients still develop mental retardation and hepatic dysfunction. It has been suggested that decreased intracellular arginine, the substrate for nitric oxide (NO), results in NO dysregulation and could be in part responsible for these findings. In order to dissect out the NO contribution to ASA, we conducted experiments on human $Asl^{-/-}$ fibroblasts, performed in vivo stable isotope studies in ASA patients, and pursued NO rescue experiments in a novel hypomorphic ASA mouse model. In vitro studies using $Asl^{-/-}$ fibroblasts and in vivo stable isotope infusion showed that normalization of plasma arginine in ASA patients did not result in increased NO production. In contrast, classic citrullinemia patients were able to use arginine for NO generation emphasizing the importance of ASL in NO synthesis. The utility of restoring NO biology was supported by improved survival and optimized NO production in ASA mice treated with arginine and sodium nitrite (an NO donor). To assess the utility of liver transplantation in the treatment of ASA, we conducted a liver-targeted *Asl* gene transfer in hypomorphic ASA mice. Such animals were predicted to recapitulate physiological consequences of liver transplantation after treatment with a helper-dependent adenoviral vector carrying mouse *Asl* under control of a liver-specific promoter. ASA mice were supplemented with low-dose arginine, sodium benzoate, and sodium nitrite from birth until 4 weeks of life, when they were randomized to receive either the *Asl* vector (n=6) or saline (n=7). Mice treated with the *Asl* vector showed dramatic improvement in their physical growth, had a statistically significant weight difference already 10 days after injection (p = 0.001) and 100% survival at age 165 days. In contrast, ASA mice, which received saline only, expired by age 103 days. Plasma amino acids from ASA mice treated with *Asl* vector showed a normalization of ASA, citrulline, glutamine compared to the wild type. In summary, we demonstrate that NO dysregulation is one of the possible mechanisms contributing to ASA phenotype. The restoration of normal ASA and NO biology by combining NO donors and *Asl* gene transfer offers a new approach to the treatment of this disorder.

## 3007/F/Poster Board #939

**Identification of proteins interacting with the OCTN2 transporter responsible for primary carnitine deficiency.** *O. Ardon[1], N. Longo[1,2].* 1) ARUP Inst Clin Exp Path, ARUP Laboratories, Salt Lake City, UT; 2) Med Genet/Pediatrics and Pathology, Univ Utah.

Carnitine is essential for the transfer of long chain fatty acids into the mitochondrial matrix for subsequent beta oxidation. Defects in the OCTN2 carnitine transporter cause primary carnitine deficiency (OMIM 212140) resulting in increased loss of carnitine in the urine, low plasma carnitine levels and decreased uptake of carnitine in tissues. Patients can present with hypoketotic hypoglycemia, hepatic encephalopathy and/or cardiomyopathy. Primary carnitine deficiency is autosomal recessive with an overall population frequency of 1:40,000. The diagnosis is confirmed by finding markedly reduced carnitine transport in fibroblasts of affected patients. DNA studies shave identified heterogeneous mutations in the *SLC22A5* gene encoding the OCTN2 carnitine transporter in patients with carnitine deficiency, although there is no definite genotype/phenotype correlation. In a few patients, no abnormalities in this gene have been found, despite the lack of carnitine transport in fibroblasts. We have hypothesized that these patients could have a defect in proteins that interact and regulate the activity of the OCTN2 carnitine transporter. Co-immunoprecipitation was used to identify OCTN2 interacting proteins from HEK293 cell lysates. Mass spectrometry analysis identified several candidate proteins that co-immunopreciptated with the OCTN2 carnitine transporter. Some of the proteins identified with this technology were adaptor proteins, linking the cytoskeletal system to membrane proteins. Several of these proteins contain PDZ domains and others were cytoskeletal proteins. These include actin crosslinking and molecular scaffold proteins (spectrin, PDZK1, Shrm), structural proteins (nonmuscle myosins), and proteins associated with intracellular trafficking. The potential interaction of some of these proteins with OCTN2 was confirmed by additional specific co-immunoprecipitation and immunofluorescence co-localization. Additional studies are aimed to confirm an effect of these proteins on the transport activity of the OCTN2 transporter. This study shows that OCTN2 interacts with the cytoskeleton trough specific adaptor proteins and may lead to the identification of new gene(s) responsible for primary carnitine deficiency.

## 3008/F/Poster Board #940

**Characterization of Gaucher Disease Bone Marrow Mesenchymal Stromal Cells Reveals an Altered Inflammatory Secretome.** *P.M. Campeau[1, 2], M. Rafei[2], M.-N. Boivin[2], Y. Sun[3], G.A. Grabowski[3], J. Galipeau[2, 4].* 1) Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) The Montreal Center for Experimental Therapeutics in Cancer, Lady Davis Institute for Medical Research, Montreal, QC, Canada; 3) Division of Human Genetics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 4) Division of Hematology/Oncology, Jewish General Hospital, McGill University, Montreal, QC, Canada.

Gaucher disease causes pathological skeletal changes which are not fully explained. Considering the important role of mesenchymal stromal cells (MSCs) in bone structural development and maintenance, we analyzed the cellular biochemistry of MSCs from an adult patient with Gaucher disease type 1 (N370S/L444P mutations). Gaucher MSCs possessed a low glucocerebrosidase activity and consequently had a 3-fold increase in cellular glucosylceramide. Gaucher MSCs have a typical MSC marker phenotype, normal osteocytic and adipocytic differentiation, growth, exogenous lactosylceramide trafficking, cholesterol content, lysosomal morphology and total lysosomal content, and a marked increase in COX-2, prostaglandin E2, IL-8 and CCL2 production when compared to normal controls. Transcriptome analysis on normal MSCs and cells treated with the glucocerebrosidase inhibitor conduritol B epoxide revealed an upregulation of an array of inflammatory mediators, including *CCL2*, and other differentially regulated pathways. These cells also demonstrated a decrease in sphingosine-1-phosphate. In conclusion, Gaucher disease MSCs display an altered secretome which could contribute to skeletal disease and immune disease manifestations in a manner distinct and additive to Gaucher macrophages themselves.

## 3009/F/Poster Board #941

**Oxidized Cholesterol: Therapeutic and Diagnostic Biomarkers for Niemann-Pick Disease, type C.** *D.S. Ory[1], V. Molugu[1], M.H. Lanier[1], D.E. Scherrer[1], S.J. Langmade[1], N.M. Yanjanin[2], J.E. Schaffer[1], F.D. Porter[2].* 1) Department of Medicine, Washington University, St. Louis, MO; 2) PDGEN, NICHD, NIH, DHHS Bethesda, MD.

Niemann-Pick disease, type C (NPC) is an autosomal recessive disorder that results in progressive neurodegeneration due to the intracellular accumulation of cholesterol and other lipids. The lack of well defined outcome measures has prevented the testing of potential therapeutic interventions. In addition, although therapeutic interventions are likely to be of greater benefit prior to the development of significant neurological impairment, diagnostic delay is on the order of five years. This diagnostic delay underscores the critical need for a blood-based screening/diagnostic test. At the cellular level, mutations in NPC1 gene profoundly affect the intracellular trafficking of cholesterol and, as a consequence, lead to multiple sterol homeostatic defects. Evidence is emerging that the sequestration of unesterified cholesterol in endolysosomes is accompanied by cellular oxidative stress. NPC1-deficient cells exhibit elevated reactive oxygen species (ROS) and harbor signs of chronic oxidative damage. Cellular levels of cholesterol oxidation products (i.e. oxysterols), which are produced non-enzymatically through interaction of cholesterol with ROS, are markedly elevated in NPC1-deficient cells. We show that this finding is recapitulated in the mouse model of NPC1 disease, in which there are similar elevations of these oxysterols both in tissues and in plasma, and the level of plasma oxysterols associated with disease progression. To study whether plasma oxysterol levels are associated with human NPC disease, we measured by mass spectrometry a panel of oxysterols in plasma samples from 25 NPC subjects (1-51 yrs; mean age 11.3 yrs), 25 age-matched controls and 17 obligate heterozygotes. We identified several oxysterol species, which were strikingly elevated in NPC subjects but not in the heterozygotes or the matched controls. To evaluate the specificity of the elevated plasma oxysterols for NPC disease, we measured circulating oxysterol levels in several other lysosomal storage diseases, including those with known CNS involvement, and found that the oxysterol profile was able to differentiate NPC subjects from subjects with other lysosomal storage diseases. Taken together, these findings suggest that plasma oxysterols may serve as novel diagnostic test for NPC, have the potential to be used in a newborn screen, and may have utility as an outcome measure for therapeutic trials.

### 3010/F/Poster Board #942

**The association of primary iron overload, chronic liver diseases and common mutations in HFE gene (C282Y & H63D) in India.** *P.M. Tamhankar[1], D. Tewari[1], R. Sharma[1], G. Chaudhari[2], S. Agarwal[1].* 1) Medical Genetics, Sanjay Gandhi Postgraduate Institute of Med Sci, Lucknow, Uttar Pradesh, India; 2) Gastroenterology, Sanjay Gandhi Postgraduate Institute of Med Sci, Lucknow, Uttar Pradesh, India.

Background and Aim: Present research indicates conflicting data on the association of Histone family E gene (HFE) mutations responsible for hereditary hemochromatosis (primary iron overload (PIL)) and PIL in chronic liver diseases. We aimed to find out the association of the common HFE mutations (viz., C282Y & H63D) with primary iron overload in chronic liver disease (CLD) patients in India. Materials and Methods: Polymerase chain reaction-restriction fragment length polymorphism method was used for screening C282Y and H63D mutation in a total of 496 various CLDs (Hepatitis B virus associated (HBV) cirrhosis = 74, Hepatitis C virus associated cirrhosis (HCV) = 50, alcoholic cirrhosis with hepatitis = 38, alcoholic cirrhosis without hepatitis = 92 & cryptogenic cirrhosis = 242) and 502 randomly selected healthy controls. A transferrin saturation of >45% or serum ferritin of >1000 ng/mL with normal total exogenous iron intake (sum of dietary, supplementary and transfused blood iron) was suggestive of PIL. Liver biopsy was performed for confirmation of parenchymal iron overload by haematoxylin and eosin stain and Perls Prussian blue stain. Results: Out of 496 patients with cirrhosis, 13 (2.6%) were found to have PIL. Among these thirteen patients, 9 (69.2%) had cryptogenic cirrhosis, 2 (15.3%) had alcoholic cirrhosis without hepatitis, 1 (7.6%) had HBV-cirrhosis and 1 had alcoholic cirrhosis with hepatitis. However, only two (15.3%) of the 13 patients (1 with cryptogenic cirrhosis and other with HBV cirrhosis) were found positive for H63D heterozygous mutation. All the subjects of the present study were found to be C282Y wild type, except single compound heterozygote (C282Y/H63D) who however did not have PIL. The overall frequency of H63D allele in patients and controls was not significantly different (5.95 and 4.58 respectively, p = 0.22). A highly significant H63D allele frequency (p value<0.005) was observed in two patients subgroups i.e. HBV cirrhosis (10.82) and alcoholic hepatitis with cirrhosis (11.84) but there was no associated iron overload. Conclusion: Primary iron overload is not a significant problem in Indian patients with chronic liver disease. The allele C282Y is rare in India. Primary iron overload in chronic liver disease patients in India is not associated with the common HFE gene mutations.

### 3011/F/Poster Board #943

**SUCLG1 mutations: 3 new patients expanding the phenotypic spectrum of this rare cause of mild methylmalonic aciduria.** *A.S Lebre[1], C. Haudry[1], V. Serre[1], M. Barth[2], N. Boddaert[1], J.B. Arnoux[1], M. Rio[1], D. Rabier[1], A. Vassault[1], V. Cormier-Daire[1], A. Munnich[1], P. de Lonlay[1], A. Rötig[1], J.P. Bonnefont[1], V. Valayannopoulos[1].* 1) Université Paris Descartes, Hôpital Necker-Enfants Malades et Inserm U781 et U797, Départements de Génétique, de Radiologie pédiatrique, des Maladies du développement et de Biochimie B, Paris F-75015 France; 2) Université d'Angers, Hôpital d'Angers et Inserm U694, Département de Génétique, Angers F-49000 France.

Background: Deficiencies in two subunits of the succinate-Coenzyme A synthetase (SUCL) have been involved in patients with encephalomyopathy and mild methylmalonic aciduria (MMA). SUCL is the enzyme complex that catalyzes the conversion of succinyl-CoA to succinate in the Krebs cycle. The patients reported so far with SUCLG1 mutations displayed a very severe antenatal phenotype with early mortality within a few days of life. The phenotypes of patients with SUCLA2 mutations were milder with hypotonia, muscle weakness, a Leigh-like disorder with hearing impairment and dystonia, and they had a life span of up to 21 years. Results: We describe the clinical, radiologic, biochemical and genetic features of 3 SUCLG1 patients from European families presenting with early onset encephalopathy, hypotonia, muscle atrophy and dystonia. Recurrent attacks of lactic acidosis, epilepsy or liver impairment were not constant. One patient was deceased at age 12 months while the other 2 patients are alive at age 5 and 10 years. The constant diagnostic hallmarks were mild MMA and characteristic brain MRI findings with basal ganglia lesions. High propionylcarnitine (C3) and methylmalonyl carnitine (C4-DC) in urine were observed when searched. All three patients presented with combined respiratory chain deficiencies in muscle but mtDNA depletion was not constant (25% to 128%). Conclusion: This report enlarges the phenotypic spectrum of SUCLG1 mutations and confirms that mild MMA and brain MRI lesions are the hallmarks of the disease. Moreover, our findings may suggest alternative physiopathological mechanisms than mtDNA depletion to explain the combined respiratory chain deficiency observed in SUCLG1 patients.

### 3012/F/Poster Board #944

**Impaired cellular $Ca^{2+}$ homeostasis and endoplasmic reticulum (ER) stress in Smith-Lemli-Opitz Syndrome (SLOS).** *J.-B. Roullet[1], G. Ren[2], L. Merkens[1], R. Steiner[1], T. Tulenko[2].* 1) Pediatrics, Oregon Hlth & Sci Univ, Portland, OR; 2) Surgery, Thomas Jefferson Univ., Philadelphia, PA.

Smith Lemli Opitz (SLOS) is an autosomal recessive multiple malformation/mental retardation syndrome caused by deficiency in 7-dehydrocholesterol reductase (DHCR7), the last enzyme in cholesterol synthesis. The pathophysiology of SLOS is incompletely understood and there is no proven treatment. In SLOS, cholesterol is reduced while 7DHC accumulates. Since sterols are key structural components of cell membranes, we postulate that altered membrane properties play a role in the pathogenesis of SLOS. Earlier studies by our group demonstrated increased plasma-membrane dependent $Ca^{2+}$ permeability and fluidity in SLOS skin fibroblasts as well as impaired caveolae-mediated signaling (Tulenko, 2006). We now have preliminary data showing that intracellular membranes may be affected as well. In a first series of experiments, we determined intracellular $Ca^{2+}$ concentration in SLOS and control skin fibroblasts, using fura-2. Basal free cytosolic $Ca^{2+}$ concentration was reduced (~30%) and the response to thapsigargin, an inhibitor of endoplasmic reticulum (ER)-bound $Ca^{2+}$ pump (SERCA) was completely abolished in SLOS cells suggesting impaired ER-membrane dependent signaling and depleted ER $Ca^{2+}$ stores in SLOS. Cell proteins are transported to the ER for folding, where, if folding is not fully realized, activation of the unfolded protein response (UPR or "ER stress response") occurs. If the UPR is sustained, apoptosis is triggered. Since 7DHC accumulates in SLOS cell membranes, UPR may be activated in SLOS cells and result in further cell alterations. Supporting this idea, we now demonstrate UPR activation in SLOS fibroblasts as reflected in the increase (~4 fold) in BiP (GRP78), the signature protein marking UPR activation. Significant ($p<0.05$) UPR activation is also demonstrated in rat brain-derived astrocytes incubated with 7DHC and AY9944, a selective inhibitor of DHCR7, and in human neuroblastoma cells (BE-2 cells) incubated with oxidized sterols generated by UV exposure of the cells in the presence of 7DHC. Lastly, we demonstrate that tauroursodeoxycholic acid, a bile acid and small molecule chaperone, inhibits the increase in BiP observed in SLOS fibroblasts. These studies point to a significant impairment of ER-mediated signaling in SLOS and suggest new molecular targets for restoring compromised cell function and perhaps for treating patients with SLOS.

**Peripheral immune status in patients with Juvenile Neuronal Ceroid Lipofuscinosis.** *M. Velinov, N. Dolzhanskaya.* Dept Human Genetics, Institute for Basic Research in Dev. Disabilities, Staten Island, NY.

Juvenile Neuronal Ceroid Lipofuscinosis (JNCL) is the most prevalent type of Batten disease. Evidence of immune dysregulation was previously shown in mouse model and JNCL patients. We studied total gene expression in peripheral native mononuclear cells in three JNCL patients and two controls. Three immunity-associated genes shown in the table below were found to be most significantly down-regulated in affected individuals:

| Gene symbol | affected/non-affected mRNA signal ratio | Gene description summary |
|---|---|---|
| CXCL12 | 1: 5.35 | chemokine ligand 12 |
| HLA-DQA1 | 1: 25.77 | MHC-class II gene |
| HLA-DQA2 | 1: 4.7 | MHC-class II gene |

Additional 12 genes: LILRA3, HLA-DOB, IGHD, SERPINB4, CCL7, CD244, CNR2, CCL19, FCGR2B, CCL2, LILRB1 and CMKLR1 were significantly down-regulated and 8 genes: PXDN, MICA, IL1R2, OSM, CXCL1, CCR2, CNR2, HLA-DQB1, were significantly up-regulated in JNCL. Down regulation of MHC class II gene expression was previously shown to be associated with repeat exposure to bacterial endotoxin in cases of burns and septic shock. Such down regulation may be associated with abnormal antigen presentation, immune suppression and autoimmunity. It may be speculated that chronic exposure to toxic storage metabolite(s) in JNCL leads to immune dysfunction by similar mechanisms, as in cases of repeat endotoxin exposure. CXCL12 (chemokine stromal cell-derived factor 1 (SDF-1) participates in B-lymphocyte proliferation, migration and differentiation, and possibly in immune surveillance. Our data supports the presence of immune abnormalities that may play an important role in the JNCL pathogenesis.

**Metformin sensitizes insulin signaling through AMP-mediated PTEN down regulation in adipocyte cells.** *S. Lee, J. Lee, J. Kim, J. Jung, S. Park, H. Kim.* KOREA University, Seoul, Korea.

PTEN acts as a tumor suppressor gene through the action of its phosphatase protein product. This phosphatase is involved in the various cellular events, such as cell cycle, proliferation, dividing, and migration. Until now, however, the role of PTEN in insulin-related signaling is still unclear. To gain insights into the role of PTEN in insulin-mediated signaling, we investigated the effect of metformin, a well known insulin signal sensitizer, on PTEN expression. In results, we found that metformin suppresses PTEN expression in adipocyte 3T3L1 cells. Metformin also stimulates JNK and its downstream molecule c-Jun, a direct substrate of JNK. Phosphorylation of both JNK and c-Jun was not observed in the presence of Compound C, a specific AMPK inhibitor, suggesting the involvement of AMPK in metformin-induced JNK signaling. Moreover, chemical inhibition of JNK blocked metformin-induced PTEN suppression. Knock-down of AMPK blocked metformin-induced PTEN suppression. JNK phosphorylation was also impaired in the AMPK knock-down cells. In conclusion, our results suggest that metformin may have insulin signal sensitizing effect through PTEN suppression via AMPK-mediated JNKdependent pathway.

## 3015/F/Poster Board #947

**Metformin modulates GLUT4 translocation through AMPK-AS160-Rab4-PKC ζ pathways in both skeletal muscle and adipocyte cells.** *J. Lee, S. Lee, J. Jung, J. Kim, S. Park, H. Kim.* Korea univesity college of medicine, seoul, Korea.

Metformin is one of the major components of oral anti-diabetic drug. In the diabetes, GLUT4 trafficking to the plasma membrane is key cellular event for regulating glucose homeostasis. Till now, however, the mechanism of GLUT4 trafficking is not completely understood. To understand the signal transduction mechanism of GLUT4 trafficking, we examined the effect of metformin, a current drug for diabetes on Rab4, a vesicle related protein GTPase. In results, we found that metformin induces mRNA and protein expression of Rab4 with reverse transcriptase-polymerase chain reaction (RT-PCR) and western immune-blotting, in both skeletal muscle C2C12 cells and adipocyte 3T3L1 cells, respectively. Metformin stimulates AMP-activated protein kinase (AMPK) activity and also triggers GLUT4 translocation from cytosol to the plasma membrane. In addition, metformin increases the phosphorylation of AS160 Rab GTPase-activating protein, a direct substrate of Akt, and PKC zeta. Knock-down of Rab4 blocked the metformin-induced AS160 and PKC zeta phosphorylation. Moreover, GLUT4 translocation due to metformin treatment was disappeared in Rab4 knock-down cells. Furthermore, GLUT4 translocation was impaired in the AMPK knock-down cells, suggesting the involvement of AMPK in metformin-induced GLUT4 vesicle trafficking. In summary, our results demonstrates that metformin modulates GLUT4 translocation in skeletal muscle and adipocyte cells via AMPK-Rab4-AS160-PKC zeta pathway and provide novel role of AMPK as a key regulator of GLUT4 trafficking.

## 3016/F/Poster Board #948

**Heterodimerization of the Sialidase NEU1 with the Chaperone PPCA Prevents its Premature Oligomerization.** *E. Bonten[1], Y. Campos[1], V. Zaitsev[2], A. Nourse[1], B. Waddell[1], G. Taylor[2], A. d'Azzo[1].* 1) Dept of Genetics and the Hartwell Center for Bioinformatics and Biotechnology , St Jude Children's Research Hospital, Memphis, TN, USA; 2) Centre for Biomolecular Sciences, University of St Andrews, St Andrews, Scotland.

Lysosomal neuraminidase 1 (NEU1) initiates the intralysosomal hydrolysis of sialo-oligosaccharides, and -glycoproteins by removing terminal sialic acid residues. NEU1 forms a high molecular weight complex with β-galactosidase (β-gal) and protective protein/cathepsin A (PPCA). By virtue of its association with PPCA, which acts as a molecular chaperone, NEU1 is transported to the lysosome, catalytically activated and stabilized. Deficiency of NEU1 is associated with 2 neurodegenerative diseases of glycoprotein metabolism: sialidosis, caused by structural lesions in the lysosomal NEU1 locus, and galactosialidosis (GS), a combined deficiency of NEU1 and β-gal, due to a primary defect of PPCA. Patients with sialidosis and those with GS share clinical and biochemical features, and are classified according to the age of onset and severity of the symptoms. The understanding of the interaction between NEU1 and PPCA, and the determinants that control their association, will provide important insights into their regulation and function, both in physiologic and pathologic conditions. We have analyzed the biochemical, analytical and hydrodynamic properties of PPCA, selected PPCA mutants, NEU1, and a complex of the 2 proteins. We measured by surface plasmon resonance the binding between NEU1 and PPCA, or with a series of synthetic overlapping 15-mer peptides spanning the entire PPCA or NEU1 sequence, and identified key binding sites on both proteins. We found that one of these sites on NEU1 is needed for its binding to PPCA but also to other NEU1 molecules, albeit with lower affinity. Therefore, NEU1 tends to self-assemble into chain-like oligomers in absence of PPCA. Using analytical ultracentrifugation we demonstrated that self-association of NEU1 could be reversed by addition of PPCA, which resulted in the disassembly of NEU1-oligomers and the formation of a new PPCA-NEU1 heterodimeric complex with different hydrodynamic properties compared to PPCA and NEU1 homodimers. The identification of binding sites on both proteins has allowed us to generate alternative structural models of the NEU1 oligomer and the PPCA-NEU1 heterodimeric complex. We propose a novel mechanism of interaction between NEU1 and its accessory protein PPCA, which may provide a rationale for the secondary deficiency of NEU1 in galactosialidosis. (Supported in part by NIH grants GM60905 and DK52025, the Assisi Foundation of Memphis, and the American Lebanese Syrian Associated Charities (ALSAC)).

## 3017/F/Poster Board #949

**Delineating the spatio-temporal nature of neurochemical and pathological change in the MPS IIIA mouse brain.** *K.M. Hemsley, H. Beard, S. Hassiotis, A.L. Luck, J.J. Hopwood.* Lysosomal Diseases Research Un, SA Pathology (WCH Campus), North Adelaide, South Australia, Australia.

Mucopolysaccharidosis type IIIA (MPS IIIA) is a neurodegenerative lysosomal storage disorder resulting from a lack of the lysosomal enzyme sulphamidase (SGSH). Heparan sulphate [HS]-derived oligosaccharides accumulate intracellularly and subsequent to this primary insult, a cascade of neuropathological changes occurs, including sequestration of GM2 and GM3 gangliosides and cholesterol and neuroinflammation and neurodegeneration. The spatio-temporal nature of these changes within discrete brain regions, how they impact upon the function of neuronal circuits, ultimately leading to appearance of clinical symptoms has yet to be elucidated. We have begun to examine the time-course of neuropathological changes in the MPS IIIA mouse brain. The mouse is a good model of a human disease, with biochemical, pathological and clinical deficits analogous to the human condition. In tests applied so far, clinical changes are apparent from 12 weeks of age. In the present study, we have undertaken quantitative immunohistochemical analyses on brain tissue from mice in the pre-symptomatic, symptomatic and advanced disease stages (4 to 21 weeks of age). We examined the lysosomal integral membrane protein-II (LIMP-II), a marker of microgliosis (isolectin B4) and astrogliosis (glial fibrillary acidic protein; GFAP). The spatio-temporal pattern of accumulation of GM3 and cholesterol is being assessed. From our data thus far, it is apparent that one of the earliest pathological changes is microglial activation. Mice aged four weeks exhibited widespread, statistically significant increases in LIMP-II and large numbers of activated microglia in all brain areas assessed. The number of activated microglia was not different in 4 week-old and advanced disease mice. Astrocytosis was apparent in some but not all brain regions at 4 weeks of age, but progressed as mice aged. These data (and those from our published studies in symptomatic mice) enable us to devise a hypothesised schema outlining the cascade of neurochemical and neuropathological changes occurring within the MPS IIIA mouse brain during disease development. In order to devise and effectively target therapies for this untreatable condition, it is vital that we elucidate the cascade of neuropathological change that occurs within the brain. Understanding these processes will also lead to the development of biomarkers of disease and disease amelioration.

### 3018/F/Poster Board #950

**Correlation between thrombospondin-1, vascular endothelial growth factor, and adiponectin in kidney of mouse model of fabry disease, a sphingolipidosis.** *M.H. Lee, E.N. Choi, J.-O. Choi, J.-W. Park, H.-Y. Park, S.-C. Jung.* Depart of Biochemistry, School of Medicine, Ewha Wonans University, Seoul, Korea.

Fabry disease is a lysosomal storage disease caused by a deficiency of α-galactosidase A, which results in abnormality of glycosphingolipid metabolism and accumulation of globotriaosylceramide (Gb3). As correlations between the level of Gb3 and clinical manifestations of Fabry disease have not been developed, we investigated altered gene expression. Hepatic and renal gene expression of male α-galactosidase A-deficient mice (Fabry mice) was compared with that of wild type mice. Microarray analysis was performed using samples taken before and after intravenous infusion of α-galactosidase A. The identified genes were validated using quantitative real-time PCR and Western blot assay. Expression of hepatic Saa1 (Serum Amyloid A1), S100a8 (S100 Calcium-binding protein A8), S100a9 (S100 Calcium-binding protein A9) and Lcn2 (Lipocalin 2) and renal Npy (Neuropeptide Y), Tsp2 (Thrombospondin 2) and Tsp4 (Thrombospondin 4) was significantly upregulated in Fabry mice compared with wild type mice and was normalized by enzyme replacement therapy. Upregulation of Saa1, S100a8, S100a9 and Lcn2 may modulate inflammation and Lcn2, Npy and Tsp may be associated with vascular and renal involvement in Fabry disease. The expression of Tsp-1 protein and adiponectin was increased in the kidney of the Fabry mice, but VEGF expression is decreased. Therefore their expression might play a role in the kidney dysfunction, especially in mouse model of fabry disease. This study was supported by a research grant of the Life Insurance Philanthropy Foundation. Keywords: Fabry disease, Gene expression, Tsp-1, VEGF.

**Mice doubly-deficient in lysosomal hexosaminidase A and neuraminidase 4 show epileptic crises accompanied by rapid loss of cortical and hippocampal neurons.** *A. Pshezhetsky[1,5], V. Seyrantepe[1], A. Caqueret[1], J. Michaud[1], L. Carmant[2], T. Levade[3], R. Gravel[4], C. Morales[5].* 1) Dep. of Medical Genetics, CHU Ste-Justine, University of Montreal , Montreal, Quebec, Canada; 2) Dep. of Neurology, CHU Ste-Justine, University of Montreal, Montreal, Quebec, Canada; 3) INSERM U858, Laboratoire de Biochimie “Maladies Metaboliques”, CHU Toulouse, France; 4) Dep. of Biochemistry & Molecular Biology, University of Calgary, Calgary, Alberta, Canada; 5) Dep. of Anatomy and Cell Biology, Faculty of Medicine, McGill University, Montreal, Quebec, Canada.

Tay-Sachs disease is a severe lysosomal disorder caused by mutations in the *HEXA* gene coding for the α-subunit of lysosomal β-hexosaminidase A, which converts $G_{M2}$ to $G_{M3}$ ganglioside. HexA-/- mice, depleted of β-hexosaminidase A, remain asymptomatic to at least 1 year of age, owing to the ability of these mice to catabolize stored $G_{M2}$ ganglioside via a lysosomal sialidase into glycolipid $G_{A2}$. $G_{A2}$ is further processed by β-hexosaminidase B, to yield lactosyl-ceramide, thereby completely bypassing the β-hexosaminidase A defect. This bypass is not effective in humans, with the outcome that infantile Tay-Sachs disease is fatal in the first years of life. Our data provide an explanation for the difference in Tay-Sachs disease severity in humans and mice and suggest a novel therapeutic approach for this disease. Previously we have identified a novel lysosomal sialidase/neuraminidase 4 (Neu4) abundantly expressed in brain neurons and showed that Neu4 is a functional component of the ganglioside metabolizing system (Seyrantepe et al., Hum. Mol. Genet. 2008). Now we demonstrate that mice with targeted disruption of both Neu4 and HexA genes show seizures characterized by myoclonic jerks which correlate with polyspike discharges on electroencephalograms originating from the cortical electrodes. Siblings with a single HexA or Neu4 deficiency do not show any of the above symptoms. Microscopic and electromicroscopic examination of brain tissues show that double-knockout, but not single knockout mice have multiple degenerating neurons in the hippocampus and cortex. They also show multiple layers of cortical and hippocampal neurons accumulating $G_{M2}$-ganglioside. Altogether our data suggest that Neu4 plays a role of a modifier gene in the mouse model of Tay-Sachs disease, effectively “treating” the disease through the metabolic bypass.

### 3020/F/Poster Board #952

**Self-complementary Adeno-associated virus mediated delivery of Pro-opiomelanocortin to the ventral tegmental area ameliorates dietary obesity in rats.** *L.M. Andino, M. Judge, Y. Zhang, A. Shapiro, N. Tumer, P.J. Scarpace.* Pharmacology and Therapeutics, University of Florida, Gainesville, FL.

The activation of Pro-opiomelanocortin (POMC) neurons in different regions of the brain, including the arcuate nucleus of the hypothalamus (Arc) and the nucleus of the solitary tract have been demonstrated to curtail feeding. The region believed to be most responsive to POMC activation is considered to be the Arc. Because we were able to identify corresponding POMC melanocortin 4 receptors in brain punches of the ventral tegmental area (VTA) of rats, we hypothesized that this region of the brain would be responsive to POMC activation. Here we compare the effects of delivery of an Adeno-associated viral (AAV) construct encoding POMC to the Arc and the VTA. Our experimental design consisted of three groups of four month old F344×Brown Norway rats. The animals were all high fat fed for 14 days after which unilateral stereotaxic injections were performed with coordinates targeting either the VTA or the Arc. Self-complementary AAV (scAAV) constructs expressing either green fluorescent protein (GFP) or the POMC gene were administered. The control group received scAAV expressing GFP either in the Arc or the VTA and the experimental groups received scAAV expressing POMC into the VTA or the Arc. Food intake and body weight were measured over the course of 10 weeks. About four weeks post injection, the groups receiving POMC into the VTA and Arc were beginning to display a change in body weight that was significantly different from the control treated group. Interestingly, the group injected into the Arc was transiently significantly different for about 3 weeks time after which their delta body weight was comparable to control treated animals. At ten weeks post-injection, the GFP injected control group had gained over 78 grams, the group injected into the Arc had gained greater than 60 grams while the VTA injected group had only gained 40 grams ($p<0.005$). Additionally, caloric intake was unaltered amongst the 3 groups, suggestive of increased energy expenditure. Consistent with this was a significant increase in oxygen consumption with the VTA treated group consuming 25% more oxygen than controls ($p<0.0001$). Our results are the first to show direct activation of POMC neurons in the VTA via expression of a POMC vector. In addition, it appears that activation of POMC neurons in the VTA are more effective at curtailing high fat feeding than those in the Arc although, the Arc is the putative primary site of POMC anorectic function in the brain.

### 3021/F/Poster Board #953

**A systematic cell-based analysis for the patients with cytochrome *c* oxidase deficiency.** *H. Hatakeyama, K. Sawa, Y. Goto.* Mental Retard & Birth Def Res, Natl Inst Neurosci, NCNP, Kodaira, Tokyo, Japan.

Cytochrome *c* oxidase (COX) is a terminal protein in mitochondrial electron transport system with oxidative phosphorylation and is composed of 13 structural COX subunits: The largest 3 are encoded in mitochondrial DNA (mtDNA), and the remaining 10 are encoded in nuclear DNA (nDNA). Recently, some pathogenic mutations have been reported in nDNA-encoded COX assembly factors as well as in genes of mtDNA- and even nDNA-encoded structural COX subunits. However, the relationship between the biochemical abnormality in COX and its contributions to aberrant mitochondrial biogenesis and cellular activity is to be extensively studied because the phenotypic differences in molecular and cellular levels in relation to the clinical symptoms have been barely clarified so far. Here, we introduced a systematic analysis to characterize the phenotypic differences in mitochondrial biogenesis and cellular activity for the patients exhibiting mitochondrial diseases with infantile-onset COX deficiency ($n$=8). The established myoblasts from each patient revealed the decreased activity in COX with different severities confirmed by enzymatic analysis and cytochemical COX staining. Protein analysis obviously indicated the structural abnormality in mature COX only in the 3 patients with enzymatically severe COX deficiency (less than 20% activity of controls; $n$=10). Furthermore, we demonstrated that COX-specific abnormality actually triggers the critical defects in mitochondrial biogenesis; the decreased ATP level, the increased ROS level, and the abnormal membrane potential, all of which may lead to drastically decreased cellular viability, metabolisms, and dynamics. In this case, however, mutation analysis in genes of all mtDNA-encoded COX subunits, entire mitochondrial tRNAs, and typically known nDNA-encoded COX assembly factors showed all negative. Protein analysis for the detection of all 13 structural COX subunits revealed almost normal level. Our results may suggest that there still remain some candidate genetic determinants hidden in other unidentified nDNA-encoded COX-associating factors. In conclusion, our cell-based functional analysis would be advantageous as powerful tools to effectively examine the molecular pathogenesis in COX deficiency. Additionally, our method seems comprehensive and systematic enough to be applicable in functional diagnosis and pathogenic study of various mitochondrial diseases.

### 3022/F/Poster Board #954

**Evaluation of a Unique Metabolomic Signature for Monitoring Therapeutic Efficacy and Disease Progression in Cystinosis.** *F.F. Snyder[1,2], D.S. Sinasac[2], E. Fung[2], K.B. Mantik[2], A. Parenta[2], K.S. Reid[2], D.M. Scheuchner[2], J.P. Midgley[3].* 1) Dept. of Medical Genetics, University of Calgary, Calgary, AB, Canada; 2) Biochemical Genetics Lab, Alberta Children's Hospital, Calgary, AB, Canada; 3) Dept. of Pediatrics, University of Calgary, Calgary, AB, Canada.

Nephrotic cystinosis is an autosomal recessive storage disorder resulting from mutations in the *CTNS* gene (OMIM 606272) encoding cystinosin, the lysosomal membrane transporter responsible for exporting disulfide cystine into the cytoplasm. Here we apply a restricted metabolomic survey of cystinosis patient samples to define a metabolite pattern which may be an informative biomarker in monitoring the efficacy of therapy and/or disease status. Metabolomics utilizes multivariate statistical methodologies to identify patterns of metabolites that can function as unique signatures in differentiating between physiological states. Oral cysteamine is known to be an effective therapy in converting cystine to cysteine and the mixed disulfide cysteine-cysteamine, both of which can exit the cystinotic lysosome and deplete accumulating cystine. Here we describe a unique urine metabolomic cystinosis profile and compare it with the conventional measurement of leukocyte half-cystine content. We serially sampled nine patients with nephrotic cystinosis, ranging from one to 20 years of age, and monitored their leukocyte half-cystine levels (measured by an amino acid analyzer) and their urine organic acids (measured by gas chromatography-mass spectrometry) over a three year period. Score plots derived from a principal component analysis of their urine organic acids showed substantial although incomplete segregation of cystinosis patients from controls. Loading plots did reveal a subset of 6 urine metabolites which contribute to this distinction, with the greatest change being found in pyroglutamic acid (mean value of 2400 mmol/mol creatinine in cystinosis versus <300 in controls; p=<0.05). This suggests that flux through the gamma-glutamyl cycle in cystinosis may be impacted by reduced cytoplasmic cystine and ATP levels; a perspective supported by a report of pyroglutamic aciduria resolving after cysteamine therapy (J. Inher. Metab. Dis. 22; 224, 1999). Finally using individual patient-class membership probability scores to compare the mean leukocyte half-cystine levels with the urine metabolomic signature in order to evaluate its utility as an alternate or supplementary biomarker, only a weak correlation was found (R=0.53). Based on our initial evaluation, our metabolomic signature although unique for cystinosis, requires further refinement to be of utility in evaluating the therapeutic status of cystinosis patients on cysteamine therapy.

### 3023/F/Poster Board #955

**Study on feto-placental outcomes affected by different onset of preeclampsia-like symptoms in wild-type and apoE-/- mouse model.** *Z. Yang, R. Ma, M. Sun.* Dept Ob & Gyn, Peking University Third Hospital, Beijing, China.

Background and aims: This study aimed to explore the effects of onset at multiple gestational stages of preeclampsia-like on feto-placental changes in mouse model. Method: preeclampsia-like model were established in C57 wild-type (WT) and apoE-/- pregnant mice at early, mid and late gestational stages by injecting nitric oxide synthase (NOS) inhibitor L-arginine methyl ester (L-NAME) subcutaneously. Control groups were received normal saline (NS) simultaneously. Groups were subdivided into subgroups at early, mid and late gestational stages in L-NAME and NS groups in both WT and apoE-/- mice respectively. Blood pressure was measured until day 14 and 18 of gestation when the fetuses and placentas were removed under anesthesia. Blood pressure and urine protein were measured for identification of mice model, fetus and placenta histological changes were analyzed and compared among each groups. Data were analyzed statistically. Results: Blood pressure and urine protein in all the L-NAME subgroups in WT and apoE-/- mice were significantly higher than those in all the gestational age matched NS control groups (p<0.05). A lower live fetus rate and fetal weights as well as placental weights, and a higher absorbed fetus rate were found in early L-NAME subgroups in both WT and apoE-/- groups than those in the NS controls at day 14 and day 18 of pregnancy, whereas no significant difference among the late L-NAME subgroups and the NS controls in both WT and apoE-/- mice (p>0.05). The early L-NAME subgroups had lower living fetus rate and fetal and placental weights and higher absorbed fetus rate than those in the mid, late L-NAME subgroups in both WT and apoE-/- mice (p <0.05). Placenta and fetal weights were lower in apoE-/- L-NAME subgroups than in each WT L-NAME control subgroups (p<0.05). Morphological examination of placental showed that varying degrees of fibrinoid necrosis. Villi interstitial edema were found in the early and mid L-NAME groups in both WT and apoE-/- mice, but there were no significant pathological changes found in the placenta in late L-NAME subgroups and NS control subgroups. Conclusions: Preeclampsia-like symptoms occurred on earlier stage in pregnant mice were more likely to have remarkable feto-placental impacts especially in apoE-/- mouse model.

### 3024/F/Poster Board #956

**Tandem mass spectrometry analysis of whole blood glutathione in mitochondrial disorders and organic acidemias.** *G.M. Enns[1], K.R. Atkuri[2], T. Moore[3], L.A. Herzenberg[2], L.A. Herzenberg[2], T.M. Cowan[3].* 1) Dept Ped, Div Med Gen, Stanford Univ, Stanford, CA; 2) Dept Genetics, Stanford Univ, Stanford, CA; 3) Dept Pathology, Stanford Univ, Stanford, CA.

Primary mitochondrial disorders and organic acidemias are associated with respiratory chain dysfunction and resultant impaired redox balance. Intracellular reduced glutathione (iGSH) is the major defense mechanism for combating oxidative damage. Previous studies in our lab using high-dimensional flow cytometry (Hi-D FACS) and biochemical analysis provided evidence for the existence of chronic oxidative stress in patients who have disorders characterized by mitochondrial dysfunction; iGSH levels in T-lymphocyte subsets, monocytes and neutrophils were low and plasma protein carbonyls were elevated. We further analyzed blood samples from patients with primary mitochondrial disorders (n=13) and organic acidemias (n=7) using both Hi-D FACS and a novel tandem mass spectrometry (MS/MS) assay. The MS/MS assay was performed after derivitization of sulfhydryl groups with *N*-ethylmaleimide (NEM) in order to prevent glutathione oxidation and GSH-$^{13}$C -$^{15}$N-NEM was used as an internal standard. Whole blood GSH concentration, as determined by MS/MS, correlated with Hi-D FACS measurement of cellular iGSH levels. Compared to normal controls, whole blood GSH as determined by MS/MS was significantly lower in both mitochondrial disease patients (p<0.0058) and those with organic acidemias (p<0.0001). Although GSH levels were low in mitochondrial disease patients as a whole, a strikingly low level of GSH was detected in one patient who had associated oxoprolinuria. Overall, GSH levels were lower in organic acidemia patients when compared to mitochondrial patients, but this may have been related to poor clinical status (samples were more frequently collected during hospitalization for acute metabolic crisis in the organic acidemia group). Whole blood GSH and iGSH are promising biomarkers for disorders characterized by mitochondrial respiratory chain dysfunction, with potential to make relatively non-invasive monitoring of disease status and response to therapies possible.

### 3025/F/Poster Board #957

**Role of saposin C in CNS impairment and in vivo function of acid β-glucosidase (GCase).** *Y. Sun[1,4], H. Ran[1,4], M. Zamzow[1,4], K. Kitatani[6], M.R. Skelton[2,4], M.T. Williams[2,4], C.V. Vorhees[2,4], D.P. Witte[3,5], Y.A. Hannun[6], Y.H. Xu[1,4], G.A. Grabowski[1,4].* 1) Div Human Gen; 2) Div Neurology; 3) Div Pediatric Path, Cincinnati Children's Hosp Med Center; 4) Dept Pediatric; 5) Dept Pathology, U of Cincinnati, Cincinnati, OH; 6) Dept Biochem and Mol Biology, Medical U of SC, Charleston, SC.

Saposins A, B, C and D are derived from a common precursor, prosaposin (*psap*). Saposin C enhances the activity of the Gaucher enzyme, GCase. Saposin C deficiency leads to a Gaucher-like central nervous system (CNS) disease attributed to diminished glucosylceramide (GC) cleavage activity by GCase. A saposin C deficient mouse was made by knocking-in a Cys-to-Pro in exon 11 on *psap*. C-/- mice were selectively deficient in saposin C, but prosaposin and saposins A, B and D proteins were present at near wild-type levels. By 1 year, C-/- mice had weakness of the hind limbs and progressive ataxia with foamy cells in the dorsal root ganglion, and progressive loss of cerebellar Purkinje cells and atrophy of cerebellar granular cells. EM revealed inclusions in axonal processes in the spinal cord, sciatic nerve and brain. Activated microglial cells and astrocytes were diffusely present in the CNS. No storage cells were in visceral organs. Moderate increases in GC and lactosylceramide and their deacylated analogues were in the CNS. Backcrossing C-/- into V394L or D409H GCase mutant mice produced a nearly pure neuronal (V394L) disease and a visceral (D409H) storage disease. The nature of the storage lipids depended upon the kinetic properties of the mutant enzyme with primarily glucosylsphingosine in the CNS V394L disease and GC in the visceral D409H disease. These results support the concept that saposin C has a prominent role in CNS function and GCase substrate preference, as well as in axonal integrity and as an optimizer/stabilizer of GCase.

## 3026/F/Poster Board #958

**A murine model of mut (0) methylmalonic acidemia (MMA) treated by orthotopic liver transplantation.** *I. Manoli[1], R.J. Chandler[1], P. Zerfas[2], V. Hoffmann[2], C.P. Venditti[1]*. 1) Genetics and Molecular Biology Branch, NHGRI, NIH, Bethesda, MD; 2) Diagnostic and Research Services Branch, Division of Veterinary Resources, NIH, Bethesda, MD.

To study hepatocyte targeted gene expression as a therapy for methylmalonic acidemia (MMA) and create a mouse model of MMA treated by orthotopic liver transplantion, we generated mice that express the methylmalonyl-CoA mutase (*Mut*) gene in a liver specific fashion on the $Mut^{-/-}$ background. A transgene, $Tg^{INS\text{-}Alb\text{-}}$*Mut*, was engineered to express the *Mut* gene from the murine albumin promoter and then insulated with chicken HS4 globin locus barrier elements. $Mut^{-/-}$;$Tg^{INS\text{-}Alb\text{-}}$*Mut* animals were present in expected Mendelian proportions at weaning. Analysis of various tissues from the $Mut^{-/-}$;$Tg^{INS\text{-}Alb\text{-}}$*Mut* animals between 2-7 months of age by qPCR revealed liver restricted *Mut* mRNA expression. To assess the *in vivo* function of the transgene, metabolism of 1-$^{13}$C propionate into $^{13}CO_2$ was measured. The $Mut^{-/-}$;$Tg^{INS\text{-}Alb\text{-}}$*Mut* mice metabolized 54.7±9.2% of administered label in 25 minutes, compared to 76.5±4.5 in the $Mut^{+/-}$ and 10±2 in the $Mut^{-/-}$ mice. Challenge with a high-protein diet resulted in significant weight loss at one and 6 months in the $Mut^{-/-}$;$Tg^{INS\text{-}Alb\text{-}}$*Mut* mice, compared to a large weight gain in control $Mut^{+/-}$ littermates on the same diet. Plasma methylmalonic acid levels (μM) in the $Mut^{-/-}$;$Tg^{INS\text{-}Alb\text{-}}$*Mut* mice were elevated at 500±177 at baseline and substantially increased to 1500±620 after 2 months on the high-protein feeds. After 6 months, $Mut^{-/-}$;$Tg^{INS\text{-}Alb\text{-}}$*Mut* mice developed tubulointerstitial nephritis with microvesicular tubular degeneration, accompanied by increased BUN levels. The proximal tubular epithelial cells were full of megamitochondria, while the liver showed no abnormalities. This mouse model proves that selective hepatic expression of the Mut enzyme by transgenesis in hepatocytes can result in complete rescue from the neonatal lethality of the $Mut^{-/-}$ state. Furthermore, the lack of hepatic pathology in the $Mut^{-/-}$;$Tg^{INS\text{-}Alb\text{-}}$*Mut* mice suggests that cell or mitochondrial autonomous effects are responsible for disease manifestations. As in patients who have received liver transplantation, circulating metabolites remain elevated, despite the presence of a large reservoir of functional hepatic enzyme. A high-protein diet induced metabolic changes and the development of kidney disease very similar to that described in humans with MMA. These animals will be useful to study the renal, pancreatic and CNS pathophysiology of MMA, and test therapies aimed at treating these manifestations.

## 3027/F/Poster Board #959

**Evaluation of nonsense suppressor therapies in cells from patients with peroxisome biogenesis disorders.** *P. Dranchak[1], A. Snowden[2], E. Di Pietro[3], W.Y. Yik[1], N. Braverman[3], S. Steinberg[2], J. Hacia[1]*. 1) Department of Biochemistry and Molecular Biology, University of Southern California, Los Angeles, CA, USA; 2) Peroxisomal Diseases Laboratory, Kennedy Krieger Institute, Baltimore, MD, USA; 3) Department of Human Genetics, McGill University, Montreal, Quebec, CA.

Peroxisomal biogenesis disorders (PBDs) are a group of autosomal recessive neurodegenerative disorders caused by mutations in *PEX* genes. Our goal is to evaluate the efficacy of a set of newly developed drugs capable of selectively promoting the read-through of premature stop codons (nonsense suppressor compounds) in *PEX* genes as therapeutic agents for a subset of individuals with PBDs. One such nonsense suppressor drug, PTC-124 is in clinical trials for the treatment of inherited disorders caused by nonsense mutations. Other drugs, including the aminoglycoside G418, have shown nonsense suppressor activity in cell culture assays. Here, we conducted a series of functional assays on drug-treated cultured skin fibroblasts derived from PBD patients with previously identified nonsense mutations in *PEX* genes (*PEX1* R183X / S1246fs, *PEX2* R119X / R119X and R125X / R125X, *PEX7* L292X / Y40X, *PEX10* E298X / Nt4delG, *PEX12* R180X / Nt887_888delTC, and *PEX26* W99X / W99X). This includes the biochemical, immunolocalization, immunoblot, and reporter gene-based characterization of peroxisome protein function and assembly in treated cells. Although the aminoglycoside G418 shows promising activity in cultured fibroblasts derived from a subset of PBD patients (*PEX2* R119X / R119X and *PEX12* R180X / Nt887_888delTC), PTC-124 treatment has not resulted in appreciable rescue of peroxisome biochemical function or peroxisome assembly. Furthermore, co-treatment of patient fibroblasts with nonsense suppressor drugs and an inhibitor of the nonsense-mediated mRNA decay (NMD) pathway did not lead to measurable improvements in peroxisomal functions. Using a mammalian two-hybrid system, we screened these compounds for their ability to read-through all reported nonsense mutations in *PEX7*. In preliminary experiments, PTC-124 appeared to cause an increase in luciferase activity with wild-type *PEX7* which could reflect the luciferase stabilizing ability of PTC-124. However, after correction, PTC-124 also promoted read-through of some of the nonsense codons. Overall, our studies provide an initial evaluation of the potential efficacy of nonsense mutation suppressor therapies for PBDs. This represents an important step towards our longer-term goal of identifying novel treatments for PBDs.

## 3028/F/Poster Board #960

**Effects of growth differentiation factor 3 signaling on Adiposity.** *J.C. Bournat[1], J.J. Shen[4], L. Huang[1], L. Li[3], C. Jorgez[2], M.M. Matzuk[1], C.W. Brown[1]*. 1) Molecular and Human Genetics, Baylor College Medicine, Houston, TX; 2) Urology, Baylor College Medicine, Houston, TX; 3) Pediatrics, MD Anderson Cancer Center, Houston, TX; 4) Children's Hospital of Center California, Madera, CA.

Growth differentiation factor 3 (GDF3) is a member of the TGF-beta superfamily located on human chromosome 12p13.1, a region genetically linked to obesity and that has positive associations with obesity-related phenotypes, including BMI and fat mass. GDF3 is expressed in white adipose tissues where it is induced by high fat diet (HFD). Body weight and adipose tissue mass normally increase under HFD conditions, and these processes are augmented when GDF3 is overexpressed systemically. In contrast, GDF3 knockout mice under HFD conditions have less adipose tissue mass than wild type mice and exhibit higher basal metabolic rates. These results suggest that GDF3 may act as an adipogenic factor under conditions of caloric excess, and that GDF3 deficiency results in the dysregulation of energy expenditure, creating a relative hypermetabolic state under HFD conditions. However, the signaling pathway(s) that mediate these effects are unknown. Recent reports suggest that GDF3 signaling can occur through the TGF-beta superfamily type I receptor, Alk7, which is located on human chromosome 2q24.1, another locus with linkage to obesity-associated traits. Alk7 is highly expressed in normal human adult adipose tissues, whereas its expression is reduced in obese individuals, and correlates with factors implicated in the metabolic syndrome. Alk7 knockout mice have reduced fat accumulation and resistance to diet-induced obesity. In addition, GDF3 can inhibit bone morphogenetic protein (BMP) signaling. Several BMPs play important roles in adipogenesis, and BMP7 is sufficient to initiate and sustain brown adipose differentiation in vitro and in vivo with consequential effects on energy expenditure. Interestingly, the brown adipose tissue markers, PGC1-alpha, CPT1b and UCP1 are overexpressed selectively in the white adipose tissues of GDF3 knockout mice on HFD, suggesting that GDF3 may modulate the activity of BMP signaling on fate decisions during adipocyte differentiation. We are studying the potential molecular mechanisms underlying the effects of GDF3 on adipogenesis and energy expenditure using pre-adipocyte cell lines. In addition, we are developing transgenic mouse models of GDF3 expression under spatiotemporal control. Ultimately, these in vivo and in vitro models will help us to better understand the roles of TGF-beta superfamily signaling in human obesity and energy expenditure.

## 3029/F/Poster Board #961

**Salivary Methylmalonate and Salivary Microbiome Profiling in Methylmalonic Acidemia.** *C.W. Bassim[1], P.P. Sulima[1], J. Sloan[2], C.P. Venditti[2], T.C. Hart[1]*. 1) NIDCR, NIH, Bethesda, MD; 2) NHGRI, NIH, Bethesda, MD.

**Background:** The methylmalonic acidemias (MMA) are autosomal recessive enzymopathies with massive accumulation of bodily fluid methylmalonate and propionate-derived metabolites. Isolated MMA is caused by mutations in methylmalonylCoA mutase (MUT), a cobalamin-dependent enzyme in the mitochondrial matrix, or by defects that impair cofactor metabolism (*cblA*, *cblB*). MMA is clinically and biochemically heterogeneous but many patients exhibit failure-to-thrive, strokes, kidney disease, and early mortality. Based on our previous studies, we hypothesized that elevated methylmalonate salivary levels may affect oral health. **Objectives:** 1) To analyze salivary and plasma methylmalonate in affecteds and controls. 2) To compare caries index in affecteds and controls. 3) To characterize dental plaque microbial flora in affecteds and controls. **Methods:** Blood and saliva were collected from 14 *mut* and 1 *cblA* MMA patients and from 9 controls. Metabolites were measured using mass spectrometry. Caries index was calculated as decayed/missing/filled teeth (DMFT) from clinical and radiographic analysis of 35 affecteds and 70 controls. Dental plaque samples were collected from 5 *mut* MMA patients. Microbial profiling followed the amplification, cloning and bioinformatic analysis of 16SrDNAs from the dental plaque of 5 mut MMA patients. **Results:** MMA patients had significantly higher salivary methylmalonate levels than controls (geometric mean 4549 ± multiplicative SD 5 vs. 195 ± 2 nmol/l, p<0.0001) that correlated with serum methylmalonate concentration (p=0.0003). MMA patients had nonsignificantly lower DMFT than controls (mean 1.23 ± SD 2.67 vs. 1.81 ± 2.55 teeth, p=0.281). A reduced oral microbiome was seen in the MMA patients, with limited caries-associated oral flora and a complete absence of *Lactobacillus*. **Conclusions:** The novel finding of elevated salivary methylmalonate in MMA patients raises the possibility of the use of saliva as a non-invasive diagnostic medium for metabolic monitoring. Clinically, the MMA patients show limited dental caries. Salivary methylmalonate may alter the oral microflora, possibly impacting oral and gastro-intestinal health. Genomic analysis of the oral microbial flora showed a reduction in bacterial diversity, a trend towards less cariogenic species, and the striking observation of absent cariogenic species such as *Lactobacillus* in the MMA plaque samples. These findings may correlate with clinical severity in MMA in addition to oral health.

**ACYLCARNITINE PROFILING AND FATTY ACID TOXICITY IN FIBROBLASTS FROM PATIENTS WITH FATTY ACID OXIDATION DEFECTS.**
*U.C.N. Erlingsson[1], A. Liu[2], O. Ardon[2], M. Pasquali[2,3], N. Longo[1,2,3].* 1) Medical Genetics/Pediatrics, University of Utah, Salt Lake City, UT; 2) ARUP Institute for Clinical and Experimental Pathology® ARUP Laboratories, Salt Lake City, UT; 3) Department of Pathology, University of Utah, Salt Lake City, UT.

Inherited disorders of the carnitine cycle and mitochondrial beta oxidation can impair the oxidation of fatty acids and result in hypoglycemia, liver failure, cardiomyopathy, cardiac arrest and death. Unfortunately, establishing a diagnosis in affected patients is not always straightforward since biochemical abnormalities might disappear while the patient is well and DNA analysis might not identify all possible mutations/deletions/rearrangements. Functional assays, such as fatty acid fluxes and acylcarnitine profiling can be performed in cells derived from affected patients. Some of these methods, however, cannot distinguish among different fatty acid oxidation defects and some of them cannot differentiate well carriers from affected patients. We have developed a method for the evaluation of fibroblasts from patients with fatty acid oxidation defects. These cells were incubated with a mixture of fatty acids that more closely resembled that of human serum. The acylcarnitines produced by the cells after 3 days were analyzed by tandem mass spectrometry and had a profile very similar to that observed in affected patients while acutely stressed for most fatty acid oxidation defects. Specifically, this method detected increased levels of C14:1 carnitine in cells from patients with Very Long Chain Acyl CoA dehydrogenase deficiency and other characteristic metabolites in long-chain fatty acid oxidation defects. We also noted that, in some glucose-free media, cells from patients with fatty acid oxidation defects were more sensitive than normal cells to high concentrations of fatty acids, while albumin had a protective effect. We are currently testing whether nutritional supplements can protect fibroblasts of patients with fatty acid oxidation defects from fatty acid toxicity. These results indicate that the use of a more physiological mixture of fatty acids allows the *in vitro* differentiation of fatty acid oxidation defects. Free fatty acids seem to have increased toxicity towards cells from patients with fatty acid oxidation defects.

## 3031/F/Poster Board #963

**Early detection of neuropsychological deficits in adult non-compliant patients with PKU.** *M. Bik-Multanowski, J.J. Pietrzyk.* Chair of Pediatrics, Jagiellonian Univ, Krakow, Poland.

Adult patients with phenylketonuria (PKU) demonstrate serious compliance problems often leading to discontinuation of dietary treatment. In some of such patients serious neurological or psychiatric symptoms are reported. Prefrontal cortex-dependent deficits are considered to be early symptoms of brain dysfunction in these patients. However, no standardized tests for reliable, early detection of such deficits are available. The aim of this pilot study was to evaluate usefulness of computerized neuropsychological tests for detection of prefrontal cortex dysfunction in adults with PKU. Methods: Young, early treated adults (treatment for at least the first 12 years of life) with classical PKU and normal mental development were tested by means of computerized CANTABeclipse system (Cambridge Cognition Ltd), which includes normative database for assessment of results of the tests used. Neuropsychological tests assessing prefrontal cortex-dependent functions such as attention, working memory and executive functions were applied. Results: A group of 15 patients (homozygotes or compound heterozygotes for null mutations of the phenylalanine hydroxylase gene: p.R408W and p.P281L) aged 17-24 years participated in the study. At the study time 10 patients were off-diet (mean phenylalanine levels > 1.2 mmol/L) and 5 of them followed dietary recommendations (mean phenylalanine levels < 0.8 mmol/L). Attention deficits were detected in 9 out of 10 non-compliant patients (mean SD of the results: -2.53; Rapid Visual Information Processing Test) accompanied by a tendency to impaired working memory capacity (mean SD: -1.86; Spatial Working Memory Test). Lower speed of choice response (Choice Reaction Time Test) positively correlated with the above findings. On the contrary, the results achieved by all compliant patients were within normal range. Conclusion: CANTABeclipse system allows for reliable detection of neuropsychological deficits in non-compliant adults with PKU. Study was sponsored by government research grants NN402329233 and N40708032/3085.

## 3032/F/Poster Board #964

**A Custom Microarray for Fatty Acid Oxidation Disorders.** *T. Lewis[1], N. Longo[2,3], E. Lyon[2,3].* 1) ARUP Institute for Clinical and Experimental Pathology, Salt Lake City, UT; 2) ARUP Laboratories, Salt Lake City, UT; 3) Department of Pathology, University of Utah Health Sciences Center, Salt Lake City, Utah.

**Introduction:** Deletions and duplications involving DNA regions are known to cause many genetic disorders by leading to under-expression, over-expression, or disruption of the gene. Recently, high-resolution comparative genomic hybridization microarrays have been shown to be a valuable tool for examining genomic regions for deletions and duplications. An advantage of high-resolution CGH microarrays over other methods is ability to interrogate many probes per exon, include intronic regions, and cover a large number of genomic target regions. Here we describe the development, design, and validation of a high-resolution CGH microarray for the detection of both deletions and duplication in thirteen fatty acid genes. **Methods and Results:** A custom microarray was developed to analyze 13 genes involved in fatty acid metabolism. The array was constructed on a NimbleGen 4x72K platform using unique oligomers with an average length of 53 base pairs. Probe coverage extended across all exons and introns of each gene and an additional 5kb both upstream and downstream of each genomic region. The median probe spacing was nine base pairs, providing a resolution of 100 base pairs. Self-self, within run, and between run hybridizations were performed to validate the array design. Two self-self hybridizations were performed to confirm probe validity, estimate a false positive rate, and to verify the parameters used for data analysis. Seven samples were hybridized in duplicate on the same slide to confirm reproducibility of results. Four of the samples were additionally repeated on different arrays to examine between run reproducibility. In total, 6 control samples were examined and 11 clinical samples were analyzed on thirty-two arrays. The clinical samples had established biochemical diagnosis of fatty acid oxidation disorders but gene sequencing had not been able to confirm the presence of two mutations. In two of the clinical samples, deletions of a single exon were detected using the high-resolution fatty acid oxidation CGH array. **Conclusions:** A high-resolution custom microarray for fatty acid oxidation disorders is useful in cases where sequencing does not detect mutational changes. The tightly spaced, tiled probe design of our array allow for detection of deletions as small as 100 base pairs. These findings indicate that high-resolution microarrays provide a highly sensitive approach for the detection of single and multi-exon deletions or duplications.

## 3033/F/Poster Board #965

**A New Tandem Mass Spectrometry (MS/MS) Method For Detecting Pompe Disease In Dried Blood Spots.** *K. Cusmano-Ozog, A. Le, G.M. Enns, T.M. Cowan.* Stanford University, Stanford, CA.

Pompe disease is caused by a deficiency of acid alpha-glucosidase (GAA). Typical findings in the infantile-form include hypotonia, weakness and cardiomyopathy. Treatment with enzyme replacement therapy (ERT) has improved survival. Early diagnosis by expanded newborn screening (NBS) will allow for optimal treatment that may minimize morbidity and mortality in Pompe disease and other lysosomal storage diseases (LSDs). Recently, a laboratory approach was developed for identification of LSDs based on enzymatic assays of dried blood spots (DBS) using synthetic substrates, stable-isotope standards (IS) with detection of products by tandem mass spectrometry (MS/MS). The reaction occurs in a solution of salt and detergent, which must then be removed by a lengthy and complex process of liquid/liquid and solid phase extractions prior to MS/MS analysis. We have developed a novel, simplified method for MS/MS detection of GAA product. In brief, DBS are rehydrated and incubated with GAA substrate and IS (provided by Genzyme through the CDC) in 2% dimethyl sulfoxide. Acarbose is added to inhibit an alpha-glucosidase isomer present in neutrophils. Salting-out assisted liquid/liquid extraction (SALLE) with acetonitrile is used to stop the reaction and prepare the sample for MS/MS analysis. We have been able to evaluate the performance of this new technique in an infant with classic Pompe disease. A four-month-old was evaluated following the death of her monozygotic twin from cardiomyopathy. She appeared critically ill and had respiratory distress, severe hypotonia, weakness, macroglossia and elevated CK level. GAA activity was low using our novel method for blood spot analysis and confirmed by standard blood enzymology. She was started on ERT and has shown dramatic improvement; she now has spontaneous movements against gravity and is weaning off CPAP. This case reinforces the importance of NBS for LSDs. By detecting infants before the onset of symptoms, appropriate therapy can be initiated early, with subsequent decreases in morbidity and mortality. Our novel, straightforward method can detect individuals with Pompe disease and is appropriate for NBS. Ongoing studies include validating this method on a larger number of individuals with Pompe disease and expanding this approach to other LSDs in order to streamline high-throughput analysis.

## 3034/F/Poster Board #966

**Erythropoietic Protoporphyria: Molecular Analysis Reveals Patients with X-Linked Causative Mutations in the Erythroid-Specific 5'-Aminolevulinate Synthase 2 Gene.** *D. Doheny[1], I. Nazarenko[1], M. Balwani[1], L. Liu[2], R.J. Desnick[1].* 1) Dept Gen & Genomic Scienc, Mount Sinai Sch Med, New York, NY; 2) Dept Medicine, Liver Diseases, Mount Sinai Sch Med, New York, NY.

Erythropoietic Protoporphyria (EPP), the most common erythropoietic porphyria, is an inherited disorder characterized by acute photosensitivity and painful cutaneous lesions. Autosomal recessive EPP is biochemically diagnosed by elevated levels of ertythrocyte protoporphyrins (PROTO) with free-PROTO greater than zinc-PROTO. Most cases result from mutations in the ferrochelatase (FECH) gene that cause the markedly deficient activity of ferrochelatase, the last enzyme in the heme biosynthetic pathway. To date, 119 FECH mutations have been described (Human Gene Mutation Database, 2009), as well as the common hypomorphic IVS3-48T>C allele. Recently, an X-linked variant of EPP was described with similar symptoms, elevated erythrocyte PROTO with equal proportions of free-PROTO and Zn-PROTO, and no FECH mutations; however, causative mutations were identified in the C-terminus of the erythroid-specific 5'-aminolevulinate synthase 2 (ALAS2) gene at Xp11.21 (Whatley et al, 2008). We performed FECH mutation analysis on 22 unrelated patients with biochemical and/or clinical evidence suggestive of EPP, identifying FECH mutations in 15 patients. Among these, six had novel mutations, including one deletion (c.1052delA), one insertion (c.215-216insT), two splice-site (c.1077-1G>T, c.314+1T>G), two nonsense (c.832C>T (p.Q278X), c.181C>T (p.Q61X)), Of the seven cases with no detectable FECH mutation, we identified three patients with ALAS2 lesions. Of these, a 19 year old male had photosensitivity since childhood, elevated PROTO with equal proportions of free-PROTO and Zn-PROTO, and a fluorescence peak at 633nm consistent with EPP. The patient's mother reported mild photosensitivity. Molecular studies revealed a novel ALAS2 frame-shift mutation, c.1734delG, in exon 11. The two other patients, a 7 year old male and 3 month old female, had the previously reported ALAS2 c.1706-1709delAGTG mutation. These findings indicate that X-linked EPP is not rare among EPP patients (14% of index cases; 43% of FECH-mutation negative cases) and that ALAS2 mutation analysis should be undertaken in patients with EPP symptoms of acute photosensitivity who have elevated erythrocyte PROTO, high Zn-PROTO, and no detectable FECH lesion.

## 3035/F/Poster Board #967

**Defects of pyruvate metabolisim in cultured lymphoblastoid cells from 70 Japanese patients with Leigh syndrome.** *E. Naito[1,2], T. Hashimoto[1], Y. Kotani[2], S. Kagami[2].* 1) Division of Pediatrics, Japanese Red Cross Tokushima Hinomine Rehabilitat , Komatsushima City, Tokushima, Japan; 2) Department of Pediatrics, Institute of Health Biosciences, The University of Tokushima, Graduate School, Tokushima, Japan.

Leigh syndrome is a neurodegenerative disease caused by defects in mitochondrial energy generation, including pyruvate dehydrogenase complex (PDHC) and components of the respiratory chain. It is characterized by progressive neurological disease with motor and intellectual regression, with onset typically in infancy, and by characteristic lesions of the basal ganglia and brainstem. Elevated lactate levels in both blood and cerebrospinal fluid (CSF) are often present. We investigated defects of pyruvate metabolisim in 70 Japanese patients with Leigh syndrome. Biochemical and molecular defects were studied using cultured lymphoblastoid cells obtained from 41 boys and 29 girls with this clinical diagnosis. All patients had a progressive neurological disease with developmental delay; raised lactate levels in blood and/ or CSF; and the abnormalities in bilateral basal ganglia on computed tomography or magnetic resonance imaging. Defects identified in 35 patients (50 per cent), i.e., PDHC deficiency in 5, NADH-cytochrome c reductase (complex I) deficiency in 4, cytochrome c oxidase (COX) deficiency in 4, and a point mutation of mitochondrial DNA in 22 (A3243G in 1, A8344G in 1, T8993C in 2, T8993G in 16, and G13513A in 2). Five patients with PDHC deficiency had mutations in the X-chromosomal gene encoding the E1$\alpha$ subunit of PDHC. Three patients with COX deficiency had mutations of the SURF-1 gene. Cultured lymphoblastoid cells were useful for elucidating the etiologies of Leigh syndrome. T8993G mutation was the most common cause in Japanese patients with Leigh syndrome. In 4 of 5 patients with PDHC deficiency, PDHC showed reduced affinity for thiamine pyrophosphate. Treatment with high doses of thiamine resulted in decreased lactate and clinical improvement in these four patients, suggesting that some patients with Leigh syndrome may have a thiamine-responsive PDHC deficiency.

## 3036/F/Poster Board #968

**Screening for Fabry disease using dried blood spots on filter paper: an improved alpha-galactosidase A assay.** *E. CAUDRON[1], P. PROGNON[2], F. JABBOUR[3], L. LACASTAIGNERATTE[3], C. BOUCLY[3], D.P. GERMAIN[4].* 1) Groupe de Chimie Analytique, EA 4041, Faculté de Pharmacie Paris XI, Châtenay-Malabry, France; 2) Département de Pharmacie, Hôpital Européen Georges Pompidou, 75015 Paris, France; 3) Laboratoire de Biochimie. Hôpital Raymond Poincaré (AP-HP), Garches, France; 4) Unité de Génétique Médicale et Centre de Référence de la maladie de Fabry. Hôpital Raymond Poincaré (AP-HP), Garches, France. dominique.germain@rpc.aphp.fr.

Background: Fabry disease (FD, OMIM 301500) is an X-linked glycosphingolipid storage disorder caused by the deficiency of the lysosomal enzyme $\alpha$-galactosidase A. A fluorimetric method that uses filter paper cards containing dried blood spots (DBS) instead of peripheral white blood cells pellets as the enzyme source was recently introduced for diagnosis, allowing storage of the samples for up to 6 months due to stability of the enzyme on the filter paper [1]. However, the original DBS fluorimetric reference method is impaired by fluorescence quenching due to hemoglobin interference. In this study, we describe an improved assay based on protein precipitation by zinc sulfate. Methods: A simple and sensitive fluorimetric microassay was designed for an improved determination of $\alpha$-galactosidase A activity on DBS and tested in 60 hemizygotes, 68 heterozygotes, and 81 controls. Fluorogenic 4-methylumbelliferyl-$\alpha$-D-galactose was used as a substrate. The enzymatic reaction was stopped and proteins were precipitated by the addition of 300 $\mu$L of zinc hydroxide suspension (aqueous zinc sulphate heptahydrate (2%, w/v): 0.1 mol.L-1 sodium hydroxide) to eliminate interfering species (hemoglobin). In addition, a comparison with the originally published DBS assay was performed on 33 individuals (8 hemizygotes, 12 heterozygotes and 13 controls). Results : A cut-off level of 2.1 $\mu$mol.h-1.L-1 (control values: 5.6 ±2.0 $\mu$mol.h-1.L-1, mean ± SD) was chosen corresponding to 40% of median control value. For the 60 hemizygotes, all alpha-gal A activities were below 1.1 $\mu$mol.h-1 .L-1 (0.11 ± 0.2 $\mu$mol.h-1 .L-1). For the 68 heterozygotes, $\alpha$-gal A activities ranged from 0 to 7.8 $\mu$mol.h-1 .L-1 (2.2 ± 1.7 $\mu$mol.h-1 .L-1). Two third of the heterozygous females were correctly identified using this assay. Conclusion: This modified alpha-gal A assay on DBS proved sensitive, robust and decreased the frequency of false-positive results when compared to the originally published procedure [1] where hemoglobin was responsible for quenching of fluorescence. The new assay can be applied for the screening of patients undergoing haemodialysis or presenting with left ventricular hypertrophy or cryptogenic stroke who may have unrecognized FD. However, screening studies using enzymatic assays fail to detect 1/3 of heterozygotes due to random X-linked inactivation. Chamoles NA et al Fabry disease: enzymatic diagnosis in dried blood spots on filter paper. Clin Chim Acta 2001;308:195-6.

## 3037/F/Poster Board #969

**Evaluation of mutant $\alpha$-galactosidase A activity - a rapid screening method to determine disease relevant defects.** *J. Lukas[1], U. Goelnitz[2], A. Wree[3], R. Köhling[4], A. Rolfs[1,2].* 1) Albrecht-Kossel-Institute, University of Rostock, Rostock, Mecklenburg-Vorpommern, Germany; 2) Centogene GmbH, Rostock, Germany; 3) Department of Anatomy, University of Rostock, Rostock, Germany; 4) Department of Physiology, University of Rostock, Rostock, Germany.

Fabry disease is a lysosomal storage disorder caused by the deficiency of $\alpha$-galactosidase A (AGLA) activity. So far, about 300 AGLA missense mutations have been described according to the Human Gene Mutation Database (HGMD). However, numerous amino acid exchanges appear to have only mild effects on enzyme activity reduction. Bioinformatic tools cannot reliably predict the effects of these changes and inevitably need to be supported by enzymatic measurements. Therefore, a rapid screening procedure for all AGLA mutations will be invaluable for this purpose. To solve the limitations of all routine methods we developed an in vitro model based on the overexpression of AGLA mutants using a HEK293 cell system. Using fluorescence enzyme activity assays we are able to determine the activity of mutant enzymes. This procedure has shown that the following mutations, which have been found in our screening programs for Fabry have to be interpreted as SNPs and not clinically relevant AGLA mutations: D83N, S102L, S126G, R220Q and R252T. Tools for the systematic in-vitro evaluation of newly detected mutations are also of high value for the evaluation of the consequences of new therapeutic strategies, e.g. using pharmacological chaperones (PCs) such as 1-Deoxygalactonojirimycin (DGJ). Thus, we started a substance screen in order to find mutation-specific PCs performing better on chosen mutations with regard to a higher efficacy, potency and therapeutic index.

**Standard Protocols to Investigate Brain Structure and Function for the Lysosomal Disease Network.** *E. Shapiro[1], I. Nestrasil[2], A. Ahmed[1], K. Bjoraker[1], K. Delaney[1], R. Ziegler[1], L. Charnas[1], C. Whitley[1], Lysosomal Disease Network.* 1) Dept Pediatrics, Univ Minnesota, Minneapolis, MN; 2) Dept Neurology, Univ Minnesota, Minneaoplis, MN.

Background: The Lysosomal Disease Network (NIH 1U54NS065768-01) will use quantitative and qualitative standardized MRI and neuropsychological protocols to longitudinally track brain structure and function in the course of lysosomal disease, seek markers of change, and evaluate treatment response. This multi-center multi-disease endeavor requires repeatable standardized protocol sets that will serve both research and clinical needs including diffusion tensor imaging (DTI) and volumetric analysis. Quantitative methods may yield addition disease-specific localization of pathology, correlated with disease stage and rate. Standard repeatable neuropsychological protocols include tests that are age- specific and measure specific deficits associated with brain regions. Tests of cognitive ability, memory, attention/executive function, sensory and motor function, spatial ability, language, adaptive functions, emotion/behavior, and quality-of-life for each age group have been selected for their sensitivity, specificity, reliability, validity, and repeatability. Methods: Pilot studies are being done on patients with MPS I (n=20), MPS II (n=10), and MPS VI (n=10) using various MRI analysis methods and associations with neuropsychological tests. Pilot studies of the reliability of the volumetric MRI data have been carried out comparing automated (FreeSurfer) and manual programs (Brains2). Results: Measurement of hippocampus and amygdala volumes are not reliable on automated programs but can be reliably measured with manual programs such as Brains2. Other calculations such as white matter and gray matter volumes, ventricular volume, as well as volumes of larger and more discrete structures can be reliably carried out using FreeSurfer. DTI Studio has yielded positive results. Pilot studies indicate strong associations of neuropsychological tests with neuroimaging. Examples: 1) hippocampal size and memory in attenuated forms of MPS I; 2) DTI - fractional anisotropy with attention/reaction time measures in Hurler syndrome treated with HCT. Conclusions: Reliable methods of quantification of brain structure have been developed which can be correlated with functional capacity on neuropsychological tests. These methods identify late treatment effects and quantify disease status for the Lysosomal Disease Network. The next step is validating these measures as markers of change in brain disease both at diagnosis and in the late effects of treatment.

## 3039/F/Poster Board #971

**The spectrum of Lysosomal Storage Disorders (LSDs) in children with neuroregression in India.** *J. Sheth[1], F. Sheth[1], P. Gambhir[2], U. Dave[3], N. Oza[1], M. Mistri[1].* 1) Biochem & Molec Bio, Inst Human Gen, Ahmedabad, India; 2) Birth Right Clinic, Pune, India; 3) Preventine Life Care, Mumbai, India.

Background: Neurodegenerative disorders are commonly observed in pediatric population with multiple frequencies due to different causes. This includes polygenic condition in 50 % and chromosomal abnormality in 30 % of the cases. Other rare causes are injury in developing brain [10%], multiple congenital anomalies (MCA) [4-5%] and endocrine-metabolic disorders in 3-5% of the cases. Nonetheless, neuroregression affecting large number of children are commonly seen with Lysosomal Storage Disorders [LSDs]. However due to its rarity and lack of investigational facility in India, they remain under diagnosed. Phenotypic heterogeneity and central nervous system (CNS) involvement further complicates the diagnosis at an early stage. Therefore present study is aimed to know the spectrum of LSDs associated with neuroregression in Indian children. Objective: To know the prevalence of different LSDs associated with progressive neuroregression. Material and Method: The study consisted of 500 children in the age range of newborn to 12 years referred for various LSDs. Of these, 161children were found to have neuroregression and lysosomal enzyme study from leucocytes, fibroblasts and/or plasma were analyzed for β-Hexosaminidase, β-Galctosidase, Sphingomyelinase, various enzyme for MPS (I to VII), β-Galactocerebrosidase, β-Glucocerebrosidase and Neuraminic acid (Free & Total). Results: Of 161 children having neuroregression or neurodegentration, 119(73.9%) were normal and remaining 42 (26.1%) have shown different types of LSDs associated with neuroregression. This includes, GM2 gangliosidosis in 15 (9.3%), Metachromatic leucodystrophy in 8 (4.96%), GM1 gangliosidosis in 3 (1.86%), Gaucher disease in 3 (1.86%), Sialic acid storage disorder in 3 (1.86%), Morquio-B in 3 (1.86%), Krabbe disease in 2 (1.24%), Morteoux-lamy syndrome (MPSVI) in 2 (1.24%), Sanfilippo disease (MPS III B) in 1 (0.62%), Sly syndrome (MPS VII) in 1 (0.62%) and Niemann-Pick disease A/B in 1 (0.62%) cases. Conclusion: LSDS are highly prevalent in children with neuroregression and common neurology screen for LSDs can help to identify the disease at an early age for better therapeutic or prognostication advise in addition to prenatal diagnosis in the subsequent pregnancy.

## 3040/F/Poster Board #972

**Fabry disease: Identification of large deletions in α-galactosidase gene.** *R. Dobrovolny, I. Nazarenko, D. Doheny, D. Bishop, R. Desnick.* Genetics & Genomic Sciences, Mount Sinai School Medicine, New York, NY.

Fabry disease is an X-linked inborn error of glycosphingolipid metabolism caused by the deficient activity of lysosomal α-galactosidase A (α-Gal A) leading to the progressive accumulation of glycosphingolipids with terminal α-galactosyl residues. In the patients with classical phenotype who have little or no enzymatic activity, the disease presents in the childhood and progresses to renal failure, cardiac involvement, cerebrovascular disease and early demise. Patients with the later-onset phenotype present in adulthood with heart or kidney disease, and are often misdiagnosed. In males with either phenotype, the diagnosis is reliably made by the markedly deficient α-Gal A enzyme activity. In female heterozygotes, accurate diagnosis requires mutation analysis. However, suspect heterozygotes can be missed by the occurrence of deletions that include entire exons, or by mutations that result in PCR failures due to alterations involving the PCR primers. Therefore, we developed a simple semi-quantitative method for PCR detection of gene dosage which can detect the copy number of the amplified α-Gal A genomic regions. Absence of the mutated region was determined by comparison with the signal heights of normal male and female α-Gal A gene sequences. For a deletion, the exact breakpoints can be identified by finer mapping and direct sequencing. To date, this method has been used for deletion screening of 27 unrelated females with decreased α-Gal A activity suggesting heterozygosity for Fabry disease, but no detectable α-Gal A mutation. Two novel deletions were identified in these heterozygotes: c.369+3_c.547+954del4096bp which was low for exons 2-4 by gene dosage and c.194+2051_c.369+787del2623insCG which deleted the entire exon 2. The latter deletion was confirmed by RT-PCR. This method simplifies the detection of α-Gal A deletions and is useful for deletions that cannot be detected by standard sequencing protocols and when RNA sources are not available.

## 3041/F/Poster Board #973

**Creatine Deficiency Syndromes: Clinical experience of a diagnostic laboratory.** *J. Goldstein, S. Young, A. Vaisnins-Carroll, E. Winchester, D. Koeberl, D. Millington.* Biochemical Genetics Laboratory, Dept. of Pediatrics, Duke University Medical Center, Durham, NC.

Creatine deficiency syndromes (CDS) are caused by defects in creatine synthesis and transport. Clinical symptoms include expressive speech and language delay, mental retardation (MR), seizures, autistic features, and movement disorder. The full phenotypic spectrum is unknown but emerging evidence suggests that these disorders vary widely in presentation. Some patients have presented with intractable seizures, while others have presented only with speech delay. From previous published studies, X-linked creatine transporter deficiency is found in about 0.3-3.5% of males with developmental delay/MR. Initial diagnosis of CDS can be made by measuring creatine and guanidinoacetate in urine and plasma. The diagnosis may be confirmed by creatine uptake studies, DNA analysis, and proton magnetic resonance spectroscopy. Prompt diagnosis is important because dietary treatment can ameliorate the symptoms of creatine synthesis disorders. The goal of this study is to describe the experience of our clinical diagnostic laboratory in measuring urine and plasma creatine and guanidinoacetate by stable isotope dilution liquid chromatography electrospray-tandem mass spectrometry (LC-MS/MS). In total, 402 patients were referred for testing urine and 159 for testing in plasma. The majority of patients had two or more of the classical clinical features for this disorder. Two male patients (0.5%), ages 6 and 7 years, had persistent marked elevations of urinary creatine suggestive of X-linked creatine transporter deficiency (mean 3860 mmol/mol creatinine; control range <823). Both patients had features typical of this disorder. Thirty-six patients had marked elevation of creatine in one urine sample and no follow-up sample was received. Ten patients (2.5%) had elevated creatine in an initial urine sample that normalized upon repeat, suggesting that the first result was a false positive, caused by another factor such as diet. Autistic features are a characteristic of CDS. Detailed review of medical records from 49 patients referred for testing revealed 39 with autism spectrum disorder (ASD). All of them had additional clinical features such as developmental delay or seizures. Our results indicate that testing for CDS should be considered for patients with speech delay, developmental delay/MR and seizures. Further studies are required to fully delineate the clinical spectrum, including larger studies to determine the prevalence of CDS in individuals with ASD.

## 3042/F/Poster Board #974

**Spectrum of Mutations Identified in Saudi Arabian Patients with Various Inherited Metabolic Disorders.** 
*F. Imtiaz[1], Z. Al-Hassnan[2], M. Al-Owain[2], M. Al-Hamed[1], B. Al-Mubarak[1], A. Mustafa[1], R. Allam[1], D. Trabzuni[1], M. Rashed[1], H. Khalak[1], B.F. Meyer[1], M. Al-Sayed[2].* 1) Department of Genetics, King Faisal Specialist Hospital & Research Centre, Riyadh, Saudi Arabia; 2) Department of Medical Genetics, KFSH & RC, Riyadh, Saudi Arabia.

The number, complexity and varied clinical presentation of inherited metabolic diseases (IMDs) present a formidable challenge simultaneously for clinicians and for the laboratory in the pursuit of a rapid and precise molecular genetic diagnosis. Single gene defects result in abnormalities in the synthesis of various carbohydrates, proteins or fats. Most IMDs are caused by a defect in an enzyme or a transport protein that results in a block in a metabolic pathway. As a consequence of extensive consanguinity, IMDs are relatively common in Saudi Arabia. In our laboratory we are committed to characterizing the molecular defects underlying a large number of IMDs. Recently, we have characterized a large number of such disorders and have identified between 85-95% of the disease-causing mutations (novel and previously published) that are specifically responsible for the occurrence of Argininosuccinic Lyase Deficiency, HMG-CoA Lyase Deficiency, Medium Chain Acyl-CoA Dehydrogenase Deficiency and Very-Long Chain Acyl-CoA Dehydrogenase Deficiency in the Saudi population. We have also made considerable progress with respect to the molecular detection of pathogenic mutations in Saudi patients with Methylmalonic Aciduria, Propionic Acidemia and Tyrosinemia Type 1. From a diagnostic standpoint, we have also performed and reported mutation analysis on a further 33 metabolic diseases. To date, in total we have identified 127 mutations, 55 of which are novel in 40 different metabolic diseases. As a direct result of this effort, efficient molecular diagnosis of these diseases in Saudi Arabia is now possible and lays the foundation for preventative measures including inductive screening of extended families, counseling, prenatal diagnosis, pre-implantation genetic diagnosis and regional pre-marital screening.

## 3043/F/Poster Board #975

**Random screening for late onset Pompe disease using GAA activity on dried blood spot assays in a Brazilian rehabilitation center (ABBR-RJ/Brazil).** 
*J.C. Llerena[1], C. Pimentel[2], S.M.M.Q. Martins[2], A.C.B. Franzói[2], K.B. Müller[3], V. D'Almeida[3], A.M. Martins[3], D. Horovitz[1], REBREPOM/BRAZIL.* 1) Medical Genetics, IFF/FIOCRUZ, Rio de Janeiro, Rio de Janeiro, Brazil; 2) Associação Brasileira Beneficente de Reabilitação (ABBR) - Rio de Janeiro - Brazil; 3) Centro de Referência em Erros Inatos do Metabolismo-IGEIM/UNIFESP - São Paulo - Brazil.

Late-Onset Pompe Disease (LOPD) is a metabolic neuromuscular disorder caused by deficiency of the lysosomal enzyme, acid alpha-glucosidase (GAA). The disease manifests at various ages and is characterized by muscle weakness and respiratory insufficiency. Respiratory failure causes the major morbidity and mortality of this form of the disease. Diagnosis of LOPD is made through the measurement of GAA enzyme activity in fibroblasts, muscle, peripheral leukocytes, and lately, on dried blood spots (DBS); thus allowing rapid and sensitive analysis. Considering that the clinical spectrum of PD is manifested predominantly in the skeletal muscular system, with muscular weakness and/or respiratory symptoms, the investigation of GAA enzyme activity in patients with no presumptive diagnosis under treatment in a motor rehabilitation and/or respiratory physiotherapy clinic could uncover new undiagnosed cases. We conducted a random search for LOPD in a physiatrist rehabilitation center using DBS GAA activity. Four hundred and thirty seven patients attending different sectors at ABBR (Rio de Janeiro, Brazil) were enrolled in 2008. A cut-off of 87% maltose inhibition was used and a NaG/AaGIA ratio below 40 was considered as an unaffected case. No cases of LOPD were detected, and a 1% (4 patients) false positive rate was found taking into consideration the maltose inhibition fraction only in discordance with NaG/AaGIA ratio. These patients were clinically reevaluated and none had LOPD (one case each of neonatal hypoxia, HTLV-1 positive child, post-surgery for cervical vertebral disc hernia, and arthrosis). Such discrepancy was interpreted as related to the sample conditions once preparing the DBS. Twenty nine cases (6.6%) had a second DBS collected due to technical reasons. Our series showed a median value for maltose inhibition and NaG/AaGIA ratio of 70.72±11.72 (range 8.60-86.76) and 14.20±6.09 (range 5.17-34.47), respectively; compared to our lab series of 18 LOPD cases of 90.56±2.17 (range 88.39-92.73) and 60.04±17.75 (range 44.0-75.79), respectively. Fourteen cases of neuromuscular disorders, 17 of stroke, 25 of flaccid paraplegia, 48 of developmental delay, and 193 cases of cerebral palsy were of interest and remained with no etiological diagnosis. GAA activity screening through DBS proved to be successful in our series; however, technical pitfalls and drawbacks related to the DBS as a screening method should not be underestimated.

## 3044/F/Poster Board #976

**Compound Heterozygosity of the POLG1 Gene Presenting with Liver Failure and Hypotonia.** 
*M.F. Walsh[1,2], T. Wang[1,2], K. Schwartz[2], T. Crawford[2], M. Hirano[3], L. Wong[4], R.D. Cohn[1,2].* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins Hospital, Baltimore, MD; 2) Department of Pediatrics, Johns Hopkins Hospital, Baltimore, MD; 3) Department of Neurology, Columbia University, New York, NY; 4) Department of Molecular and Human Genetics, Baylor Colege of Medicine, Houston, TX.

The association of psychomotor retardation, seizures and hepatic failure was described previously in two non-related teenagers at a British Hospital as Alpers Syndrome. Mitochondrial DNA mutations, specifically in the POLG1 gene have been implicated in Alpers Syndrome. A study of nine infants with Alpers Syndrome revealed different allelic mutations in the POLG1 gene which were associated with multiple deletions, depletion or point mutations of mitochondrial DNA (mtDNA). Here we describe an 8 month-old female who presented with hypoglycemia and liver failure but otherwise normal motor and cognitive development. Over the course of two months she developed significant hypotonia and developed seizures associated with loss of cognitive function. Laboratory investigations demonstrated elevated transaminases, elevated alpha fetal protein, decreased cholesterol and hypoglycemia. A brain MRI bared no structural abnormalities. A gastric emptying study was positive for delayed motility and an EEG was positive for diffuse electrical disturbance. A liver biopsy was performed and electron microscopy revealed abnormal architecture and depletion of the mitochondria. A biopsy of intestinal cells did not manifest the same findings. Interestingly, a muscle biopsy was completed and initial structural evaluation did not expose any abnormalities. However, analysis of the mitochondrial DNA content as well as respiratory chain function of the muscle exhibited significant abnormalities of mitochondrial DNA content, respiratory chain function and abnormalities of mitochondrial metabolism, thus supporting the diagnosis of a systemic mitochondrial DNA depletion syndrome. Genetic analysis of various genes associated with mitochondrial DNA depletion syndromes unveiled an abnormality in the POLG1 gene. Our patient is heterozygous for a known G737R mutation previously associated with Alpers syndrome and an unclassified variant of V855L. The V855L mutation has previously not been described, however, this is a highly conserved residue that is invariant from yeast to man. Moreover it is in the thumb domain of the polymerase active site and biochemical studies of this areas show decreased POLG enzyme activity. We believe that it is highly likely that the compound heterozygous state of the patient is indeed disease causing and therefore represents a novel mutation in a patient with an unusual clinical presentation of Alpers syndrome.

## 3045/F/Poster Board #977

**A Novel LCR- and *Alu*- Mediated Rearrangement of the Iduronate-2-Sulfatase (*IDS*) Gene in a Patient with Mucopolysaccharidosis Type II.** 
*D. del Gaudio[1], J. Oshima[1], A.M. Breman[1], P.H. Fernandes[1], D. Babovic-Vuksanovic[2], P.A. Ward[1], C.M. Eng[1].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, Texas 77030; 2) Department of Medical Genetics, Mayo Clinic, Rochester, Minnesota 55905.

Mucopolysaccharidosis type II (MPSII; Hunter syndrome) is a rare X-linked recessive inborn error of metabolism caused by mutations in the iduronate-2-sulfatase (*IDS*) gene that spans approximately 24 kb on Xq28.2. The deficiency of iduronate-2-sulfatase leads to accumulation of heparan sulfate and dermatan sulfate within the lysosomes ultimately leading to the development of Hunter syndrome that occurs in both severe and mild forms. While the majority of *IDS* mutations are missense, nonsense, splicing and small deletions, in about 20% of MPSII patients the disorder is caused by gross *IDS* structural rearrangements. In some cases, highly homologous sequences promote nonallelic recombination events between the *IDS* gene and its nearby pseudogene (*IDSP1*) that has been annotated as a low copy repeat (LCR). Here we report the identification of a novel complex rearrangement involving *IDS* and the *IDSP1* pseudogene in a 3 years old male with MPS II. Standard *IDS* mutation analysis failed to amplify exon 8 suggesting the presence of a hemizygous deletion spanning exon 8. This finding was confirmed by MLPA analysis. Sequence analysis of the breakpoints, facilitated by oligonucleotide array-CGH testing, revealed that the mutant allele consisted of a 6 kb deletion spanning IDS exon 8 and a ~50 kb insertion in the deleted region. The 50 kb insert was derived through an inverted duplication of a telomeric region of *IDS* and it was flanked by the *IDSP1* (i.e. LCR) on one side and a combination of repetitive elements, L1-*Alu*-L1, on the other side. This duplicated fragment was inserted between the highly homologous LCR in *IDS* intron 7 and the L1-*Alu*-L1 elements in *IDS* intron 8 most likely through a nonallelic recombination mechanism. RT-PCR analysis confirmed the presence of aberrant mRNA transcripts. This rearrangement was detected in this patient's mother, indicating that the mutation is not a de novo event. There has been series of reports describing rearrangements involving *IDS* and *IDSP1*, suggesting that these events may not be infrequent. However, detailed analyses of these rearrangements have often been difficult because the extent of the recombination events could not be easily estimated. Given the involvement of LCRs and repetitive elements, this particular complex rearrangement may represent one of the common aberrations involving *IDS*.

## 3046/F/Poster Board #978

**ETFDH gene mutations in Italian patients presenting Multiple Acyl-CoA Dehydrogenase Deficiency.** *C. Gellera[1], B. Castellotti[1], V. Pensato[1], C. Antozzi[2], B. Garavaglia[1], G. Uziel[3], M. Rimoldi[1], F. Taroni[1].* 1) Genetics of Neurodegeneration, IRCCS - Neurologico C. Besta, Milano, Italy; 2) Department of Neurology, IRCCS - Neurologico C. Besta, Milano, Italy; 3) Department of Child Neurology, IRCCS - Neurologico C Besta, Milano, Italy.

Mutations in genes encoding for Electron Transfer Flavoprotein (ETF) and Electron Transfer Flavoprotein Dehydrogenase (ETFDH) are the pathogenic cause of Multiple Acyl-CoA Dehydrogenation Deficiency (MADD), a metabolic disorder of fatty acid catabolism also known as glutaric aciduria type II (GAII). ETF is a mitochondrial-matrix heterodimer protein composed by a 30kD alpha subunit (ETFA) and a 28kD beta subunit (ETFB) and contains one FAD and one AMP per heterodimer. ETFDH is a 64kD monomer integrated in the inner mitochondrial membrane and contains one FAD and an iron-sulfur cluster. Both enzymes are required for electron transfer from at least 9 mitochondrial flavin-containing dehydrogenases to the main respiratory chain. The clinical phenotypes of GAII and MADD can have variable presentation ranging from a severe encephalopathy of childhood (more frequently associated with ETFA or ETFB mutations) to the mild myopathic form of adults, (more frequently associated with ETFDH mutations). We have studied 22 index cases, in which the biochemical spectrum and the clinical presentation were compatible with the diagnosis of MADD. Six patients had a positive familial history for the presence of an affected sibling, the onset was variable from childhood to adult age. AcylCoA-dehydrogenase activities of short, medium and long chain fatty acids were marked reduced in the analyzed cases (10/22) showing a residual activity of less than 10% in two cases, and about 50% in the remaining 8 patients. Analysis of Acyl-Carnitines showed a pathological increase of medium and long chain esterified carnitines in plasma along with a pathological pattern of urinary organic acids. Molecular analysis of ETFDH was performed in all index cases. We have identified 13 different missense mutations either in homozygous or in compound heterozygous form in 14/22 patients, thus confirming in these cases the clinical diagnosis. Eleven mutations were newly described. In three patients we identified mutations on one allele only. This latter result needs to improve molecular analysis by RT-PCR in order to search for the possible presence of intra-genic deletions. The remaining 8 patients resulted negative for mutations in ETFA and ETFB genes. Our study indicates that mutations in ETFDH gene are the major cause of MADD and support the hypothesis that other genes can be implicated in the pathological mechanism of this rare metabolic disease.

## 3047/F/Poster Board #979

**Mutation screening of the PAH gene causing phenylalanine hydroxylase deficiency in Greek patients with phenylketonuria and hyperphenylalaninemia.** *M. Grigoriadou[1], H. Kokotas[1], K.H. Schulpis[2], A. Skarpalezou[2], E.D. Papakonstantinou[2], M. Kalogerakou[2], A. Giannoulia-Karantana[3], M.B. Petersen[1].* 1) Department of Genetics, Institute of Child Health, 'Aghia Sophia' Children's Hospital, Athens, Greece; 2) Department of Inborn Errors of Metabolism, Institute of Child Health, 'Aghia Sophia' Children's Hospital, Athens, Greece; 3) Department of Pediatrics, Athens University Medical School, 'Aghia Sophia' Children's Hospital, Athens, Greece.

Phenylketonuria (PKU) is an autosomal recessive inborn error of metabolism resulting from a deficiency of phenylalanine hydroxylase, an enzyme that catalyzes the hydroxylation of phenylalanine to tyrosine, the rate-limiting step in phenylalanine catabolism. If undiagnosed and untreated, phenylketonuria can result in impaired postnatal cognitive development resulting from a neurotoxic effect of hyperphenylalaninemia. Early diagnosis of phenylketonuria, a cause of mental retardation, is important because it is treatable by dietary means. Features other than mental retardation in untreated patients include a 'mousy' odor, light pigmentation, peculiarities of gait, stance, and sitting posture, eczema and epilepsy. To investigate the spectrum of mutations of the PAH gene in Greek patients, we tested 100 patients by Denaturing Gradient Gel Electrophoresis (DGGE) and confirmed the findings by direct sequencing. From our cohort, 56 were referred for PKU of mild to severe degree, 36 had hyperphenylalaninemia (12 were off diet), and one patient had tetrahydrobiopterin (BH4) deficiency leading to hyperphenylalaninemia. Clinical uncertainty characterized seven patients, and therefore no clinical data were provided. Five pairs of siblings were present in our cohort. Two mutations, previously described, were detected in 82 cases, one known mutation and no other finding was present in 4 cases, whilst one known mutation and one other finding of unknown significance were present in 6 cases. One case presented with one finding of unknown significance and no other known finding, while no pathogenic finding was present in four of our cases. Testing was not performed in three of the cases due to unsuccessful PCR amplification. A total of 203 known polymorphisms were found. Our ongoing study will determine the spectrum of the PAH gene mutations in the Greek population and will contribute to the understanding of the clinical manifestations worldwide.

## 3048/F/Poster Board #980

**Knock-down of insulin gene using Adeno-associated virus vector.** *S.H. Pedersen, K. Brusgaard, N. Michelsen.* Biochem., Pharma. and Genetics, Odense University Hospital, Odense, Odense C, Denmark.

Congenital hyperinsulinism (CHI) is a relatively rare disease in western populations with incidences of 1:40.000 newborn/year whereas areas with high consanguinity have shown incidences of 1:2.500-3.000 newborn/year (Ashkenazi-Jews and areas in Saudi-Arabia and Finland). The disease is characterized by hyperinsulinemic hypoglycemia irrespective of blood glucose levels and is associated with a high risk of developing neurological handicaps. Most cases appear neonatal, but appearances in the late infancy and adulthood are seen. It is a heterogeneous disease with respect to phenotype and genetics. Depending on the underlying genetic cause and the severity of the disease, treatment includes conservative and medical management, and alternatively pancreasresection (resection of 60-95% of the organ). Mutations in 7 genes are so far known to be responsible for the development of CHI accounting for approximately 50% of the incidences: the genes 1) ABCC8 and 2) KCNJ11 (encoding the two subunits of the ATP-dependent potassium channel, the sulfonylurea receptor (SUR1) and the potassium inwardly-rectifier channel subunit (Kir6.2)), and the genes encoding the enzymes 3) glucokinase (GCK), 4) glutamate dehydrogenase (GLUD1) and 5) short-chain L-3-hydroxyacyl-CoA dehydrogenase (SCHAD). SUR1, Kir6.2 and GCK have shown to be involved in developing neonatal diabetes. Also, mutations in the HNF4a gene result in hyperinsulinisme lasting for a short or longer period of time - even years. Eventually, these patients will develop maturity onset diabetes of the young (MODY). The latest finding was mutations in the monocarboxylase transporter that is normally only expressed in liver tissue under anaerob conditions during physical exercise. The channel transports pyruvate into the cells. The disease-causing mutations result in expression of the transporter in the membrane of beta cells resulting in active uptake of pyruvate. So, the main problem to solve is hyperinsulinaemic hypoglycaemia. We are going to use silencing RNAs (siRNAs) to knock-down insulin secretion. Synthesis of a siRNA that specifically targets the insulin gene is the aim of this project. We are going to insert the siRNA in to an Adeno-associated virus vector system in order to get a stable and constantly expressed siRNA in Ins-1e cells. The overall purpose is to make a system where insulin synthesis is constantly downregulated post-transcriptionally.

## 3049/F/Poster Board #981

**CYP27B1 and PDCD1 polymorphisms in Polish patients with type 1 diabetes and Addison's disease.** *D. Januszkiewicz[1,3], M. Fichna[1,2], M. Zurawek[1], M. Gryczynska[2], P. Fichna[4], J. Sowinski[2], J. Nowak[1].* 1) Molecular Pathology, Institute of Human Genetics Polish Academy of Scie, Poznan, Poznan, Poland; 2) Department of Endocrinology and Metabolism, Poznan University of Medical Sciences, Poznan, Poland; 3) Department of Paediatric Oncology, Haematology and Transplantology, Poznan University of Medical Sciences, Poznan, Poland; 4) Department of Paediatric Endocrinology and Diabetes, Poznan University of Medical Sciences, Poznan, Poland.

CYP27B1 gene (chr.12q13.1-q13.3) encodes 1alpha-hydroxylase, responsible for conversion of the vitamin D3 precursor into its most active metabolite, involved in the immune function. Its promoter C(-1260)A polymorphism (rs10877012) might affect 1alpha-hydroxylase expression and therefore contribute to autoimmunity. PDCD1 gene (chr.2q37.3) encodes an inhibitory cell-surface receptor, expressed on activated lymphocytes, which plays a role in maintaining immune tolerance. PDCD1 G7146A variant (rs11568821) with putative regulatory function, has previously been associated with various autoimmune disorders. Autoimmune destruction of glandular cells is the main reason of type 1 diabetes (T1D) and Addison's disease (AAD). Both endocrine diseases present complex genetic background with several susceptibility loci. The aim of this study was to investigate the associations of the CYP27B1 C(-1260)A and PDCD1 G7146A polymorphisms with T1D and AAD in the Polish population. The study comprised 215 T1D patients and 101 AAD subjects compared to 251 healthy controls. Mean age of disease onset was 8.3 (±4.3) years for T1D and 35.8 (±12.6) years for AAD. Genotyping was performed by PCR-RFLP method, using TfiI and PstI restriction enzymes, respectively. The CYP27B1 C(-1260) allele appeared significantly more frequent in AAD patients compared to the control group (p=0.020), yielding an OR of 1.53 (95%CI 1.07-2.19). The distribution of C(-1260)A genotypes in AAD vs. control groups also demonstrated statistical significance (p=0.011) with a considerable increase in wild-type homozygotes observed among patients (57.4% vs. 40.2% in healthy individuals). In contrast, no association with CYP27B1 polymorphism was found for T1D (p=0.594 and p=0.989 for alleles and genotypes, respectively). The frequencies of alleles and genotypes at the PDCD1 G7146A polymorphism did not present significant differences between affected subjects and controls (p>0.05). In conclusion, this study confirms the association of the CYP27B1 C(-1260)A polymorphism with AAD in Polish patients, whereas its contribution to T1D risk seems less likely. PDCD1 G7146A does not appear associated with endocrine autoimmunity in Polish subjects. Supported by Ministry of Science Grant N402162533.

## 3050/F/Poster Board #982

**Corrections in Fabry mice by recombinant adeno-associated virus 2/8-mediated gene therapy.** *U.Y Yu, J.O Choi, S.C Jung.* Department of Biochemistry , School of Medicine. Ewha Womans University, Seoul , Korea.

In fabry disease, genetic deficiency of lysosomal enzyme αα-galactosidase A results in abnormal Gb3 (glycosphingolipids) accumulation in endothelial cells that leads to renal failure, cardiac and cerebrovascular disease. In this study, we generated a pseudotyped rAAV 2/8-hAGA vector and injected it into 15-week-old male fabry mice through tail vein. We characterized the efficacy of the gene therapy at 6, 12 and 24 weeks after treatment. Tissues of liver, spleen, kidney, heart, and brain were examined for Gb3 levels and αα-gal A enzyme activity were analyzed. Treatment of fabry mice with rAAV 2/8-hAGA resulted in the clearance of accumulated Gb3 in tissues such as liver, spleen, kidney, heart, and brain with concomitant elevation ofαα-gal A enzyme activity.αα-gal A enzyme activities (means ± SD) in liver, spleen, kidney, heart and brain from fabry mice of 6 weeks after treatment were 2137.53 ± 80.92, 6413.80 ± 336.88, 4614.68 ± 179.75, 1267.59 ± 30.77 and 310.26 ± 7.48 nmol/h/mg. Enzyme activity was elevated for more than 24 weeks. In addition, fabry mice at 6, 12 and 24 weeks after treatment decreased Gb3 level compared with wild-type mice. Western analyses, expression of the GLA protein identified in the presence of rAAV 2/8-hAGA at 6, 12 and 24 weeks after treatment.. Liver toxicity by rAAV 2/8-mediated gene therapy was not observed. In this study, we have demonstrated the safety and improved efficacy of rAAV 2/8-hAGA mediated gene therapy in fabry mouse model.

## 3051/F/Poster Board #983

**Rhizomelic Chrondrodysplasia Punctata Type 2 Resulting From Paternal Uniparental Disomy of Chromosome 1.** *G.A.M. Nimmo[1], S. Monsonego[1], S. Steinberg[2], N.E. Braverman[1,3].* 1) Montreal Children's Hospital Research Institute, McGill University, Montreal, Quebec, Canada; 2) Kennedy Krieger Institute and Department of Neurology, Johns Hopkins University, Baltimore, Maryland, USA; 3) Departmant of Human Genetics and Pediatrics, McGill University, Quebec, Canada.

Rhizomelic Chondrodysplasia Punctata (RCDP) is a rare autosomal recessive disorder resulting from mutations on one of three genes essential for ether lipid biosynthesis. Affected patients have characteristic features including shortening of the proximal long bones, stippling of the epiphyses, bilateral cataracts, facial dysmorphism, and severe delays in mental development. Here we describe a patient in a nonconsanguineous family with the characteristic clinical features of RCDP. Differential biochemical analysis determined the deficiency is in the peroxisome localized enzyme glyceronephosphate O-acyltransferase (GNPAT), classifying the disease as RCDP type 2. All exons of the *GNPAT* gene, containing 16 exons and spanning 40.2 kb genomic DNA, were amplified using primers in the flanking intronic regions. The PCR fragments were directly sequenced in both directions. We found an apparent homozygous single nucleotide mutation [c.1428delC] causing a premature stop codon. The patient's karytoype was normal: 46, XY. The father was determined to be a heterozygous carrier of this mutation, while direct sequencing of the maternal *GNPAT* genes revealed only wild type sequence. Southern analyses, performed on gDNA from both parents using the full *GNPAT* cDNA sequence as a probe, did not show any evidence for a gene deletion in the mother. A single informative SNP in the 5'UTR of *GNPAT* suggested that no maternal alleles were inherited. Amplification and length analysis of 5 (to date) dinucleotide repeat markers spanning chromosome 1 in the patient and both parents revealed paternal uniparental inheritance. The absence of non-RCDP syndromic clinical features in this patient supports the hypothesis, proposed in other reports of uniparental disomy (UPD), that there are no imprinted genes on chromosome 1. We will discuss the possible mechanisms for the occurrence of the UPD in this patient, as well as an approach for genetic counseling. This is the first description of RCDP resulting from UPD.

## 3052/F/Poster Board #984

**Non-Hematopoietic-Derived TNFα is a Key Modulator of Neurodegeneration in a Mouse Model of Sandhoff Disease.** *H. Abou-Ouf[1], A. Hooper[1], A. Lessan[1], B. Trigatti[3], S.A. Igdoura[1,2].* 1) Department of Biology, McMaster University, Hamilton, ON, Canada; 2) Department of Pathology and Molecular Medicine, McMaster University, Hamilton, ON, Canada; 3) Department of Biochemistry and Biomedical Sciences, McMaster University, Hamilton, ON, Canada.

Inflammation cascades appear often to lead the pathogenic process of several neurodegenerative diseases. Tumor necrosis factor-α (TNFα) has been demonstrated as a key modulator of the immune response in the CNS. A variable net effect of TNFα on the pathogenic process has been attributed to the differential profile of microglial distribution and their inflammatory mediators and as such the overall impact of TNFα has been difficult to determine. Sandhoff disease is a lysosomal storage disorder caused by deficiency in hexosaminidase B (hexb). We have previously generated a double knockout of Tnfα and hexb in which we demonstrated that deficiency of TNFα attenuates the neuropathological deficit in Sandhoff disease. In our studies, the involvement of hematopoietic-derived TNFα in the neurodegenerative process was evaluated using bone marrow transplantation (BMT) in a mouse model of Sandhoff disease. Double knockout mice were transplanted with bone marrow from either hexb-/-tnfα+/+ or hexb-/-tnfα-/- mice. We also, transplanted hexb-/-tnf+/+ mice with bone marrow from either hexb-/-tnfα+/+ or hexb-/-tnfα-/- mice. Survival curves and body weights revealed that the double knockout recipients outperformed the hexb-/- recipients regardless of the genotype of the donor. Furthermore, deficiency of non-hematopoietic-derived TNFα in hexb-/- resulted in improved performance in several neurological tests such as wire hang, rotorod and righting response tests when compared to hexb-/- mice receiving single or double knockout BMT. We propose that neurological improvement was achieved through reduced levels of glia/neuronal-derived TNFα rather than reduced levels of blood-derived TNFα. In conclusion, TNFα is an important factor during the progression of neurodegeneration and as a result a potential therapeutic target. However, therapeutics involving TNFα inhibition will require crossing the blood-brain barrier in order to attenuate neuropathogenesis.

## 3053/F/Poster Board #985

**Construction and characterization of new mouse models for Types A & B Niemann-Pick disease.** *X. He, I. Jones, C. Huang, E. Schuchman.* Genetics and Genomic Sciences, Mount Sinai Sch Medicine, New York, NY.

The currently available mouse model of acid sphingomyelinase (ASM) deficiency (ASMKO) is a complete knockout of the ASM gene (SMPD1). While these animals have been extremely useful for the preclinical assessment of treatment for Types A & B Niemann-Pick disease (NPD), they do not express any residual protein and therefore cannot be used to evaluate enzyme enhancement (e.g., "chaperone") approaches. In addition, they develop a rapidly progressive neurological disease, making them a more appropriate model for Type A than Type B NPD. Since all ASM-deficient NPD patients contain point mutations in the SMPD1 gene and express some residual enzymatic activity, we undertook the development of mutation-specific mouse models for this disorder. Two mutations were chosen for these experiments: R496L, a common Type A NPD mutation found in ~40% of Ashkenazi Jewish patients, and ΔR608, a common Type B NPD mutation found in ~20% of patients from North American and Western Europe. Constructs were generated in which the mutations were introduced into the full-length human SMPD1 cDNA, and expression was driven by a fragment derived from the mouse SMPD1 promoter. These constructs were introduced into ASMKO blastocysts, and breeding colonies were generated that express the transgenes on the complete ASMKO background. One founder line for the R496L mutation and three for the ΔR608 mutation have been established. RNA expression analysis in the brains and livers of these animals revealed that the R496L line and two of the three ΔR608 lines had normal levels of SMPD1 RNA expression. As expected, the R496L line had no detectable residual ASM activity, while expression was detected in the ΔR608 lines. Importantly, and in agreement with the ASM activity and patient findings, ΔR608 mice also had markedly improved performance on an accelerating rotorod apparatus as compared to the R496L mice. Studies are currently underway to further characterize the clinical and pathological findings of these animals, and in the future they will be used to evaluate new approaches to enhance residual ASM activity. Funding by NIH grant R01 HD28607 & The National Niemann-Pick Disease Foundation (NNPDF).

## 3054/F/Poster Board #986

**Mutations of the GLA gene in Korean patients with Fabry disease and frequency of the E66Q allele in Korean newborns.** *S. Heo[1], G. Kim[1,2], J. Park[1], J. Lee[2], B. Lee[1,2], H. Yoo[1,2,3].* 1) Genome Res Ctr/Asan Inst, Asan Medical Ctr, Seoul, Korea; 2) Medical Genetics Clinic and Laboratory, Asan Medical Center, Seoul, Korea; 3) Department of Pediatrics University of Ulsan College of Medicine, Asan Medical Center, Seoul, Korea.

Fabry disease is an X-linked recessive lysosomal storage disorder caused by alpha-galactosidase A (GLA) deficiency. To date, more than 400 disease-causing mutations have been identified in GLA gene located on Xq22. We have previously identified 23 distinct mutations (L21F, M42V, H46R, E66Q, I91T, R112C, F113L, C142W, D231G, D266N, S297F, R301Q, T349R, T47X, C90X, Y86X, R220X, R227X, R342X, Q98fsX23, L268delfsX1, I359MfsX32 and T412SfsX37) in GLA in 25 unrelated Korean patients In this report, we observed that E66Q, previously-known as a controversial variant in Fabry disease, shows 40% of wild-type enzyme activity in COS-7 cells by in vitro transient expression assay, indicating that E66Q might be a mild mutation or a functional single nucleotide polymorphism (SNP). In order to investigate the allele frequency of E66Q in Korean newborns, genotype analysis was done using dried blood spots from 803 (459 males, 344 females) newborns by the allele specific TaqMan probe SNP assay. Out of 1,147 alleles tested, 12 alleles (2 male hemizygotes & 10 female heterozygotes) harbor the E66Q variant, subsequently confirmed by sequencing analysis. Therefore, the allele frequency of E66Q turned out to be as frequent as 1.05%.. In summary, the E66Q is highly prevalent in Korean population as well as only identified variant in some Korean Fabry patients. Further study is needed to address the clinical significance of the E66Q variant in the development or modification of Fabry disease phenotype.

## 3055/F/Poster Board #987

**Mutation analysis and genome-wide gene expression profiling on patients with primary lactic acidosis.** *M. Al-Owain[1], D. Colak[1], A. AlBakheet[1], B. AlYounes[1], A. Al-Aqeel[1], F. AlFadhli[1], A. Al-Hashem[1], A. Al-Odaib[1], M. Faiyaz-Ul-Haque[1], Z. Al-Hassnan[1], H. AL-Zeydan[1], Z. Al-Rahbeeni[1], M. Al-Sayed[1], S. AL-Alaiyan[1], K. Abu-Amero[1], P. Ozand[2], N. Kaya[1].* 1) Dept Med Gen, MBC 75, King Faisal Specialist Hosp, Riyadh, Saudi Arabia; 2) Duzen Laboratories, Istanbul, Turkey.

A significant pathology in the newborn period is infants who develop lactic acidosis within few days after birth, and expire within months. The neonatologist remains helpless since no information for its pathogenesis exists precluding a rationalistic therapy or preimplantation or prenatal diagnosis. This study reports findings from clinical, biochemical, molecular genetics and genomics studies performed on a selected cases having developed severe lactic acidosis during their early infancy. Our mtDNA screening indicated that one of the patients has a novel transversion causing conversion of Thr to Pro in ATPase6 gene. Global gene expression profiling experiments, functional pathway analysis, and gene annotation analysis were performed on the whole blood of selected patients and their age and sex matching controls. Significant PANTHER molecular function terms indicated enrichment of genes related to protein folding, nuclear transport, intracellular protein traffic, nitrogen utilization, oxidative phosphorylation, electron transport, coenzyme metabolism, protein complex assembly, mitochondrial transport in the differentially expressed gene clusters. We also investigated biological pathways significantly represented among the differentially expressed genes. The most significantly overrepresented pathways included the ubiquitin proteasome pathway, parkinson disease pathway, cell cycle, TCA cycle, cytoskeletal regulation by Rho GTPase, heme biosynthesis, huntington disease pathway. Based on the gene expression studies, mutation screening of nuclear genes such as MRPS16 were also performed and these screening studies did not gave positive results. Our results will help better understanding of the pathology of this complex disease.

## 3056/F/Poster Board #988

**Identification and characterization of a novel homozygous deletion in the alpha-N-acetylglucosaminidase gene in a patient with Sanfilippo type B syndrome (mucopolysaccharidosis III B).** *K. Champion[1], I. Maystadt[2], A. Destrée[2], P. Vannuffel[2], T. Wood[1], M. Basehore[1].* 1) Molecular Diagnostic Lab, Greenwood Gen Ctr, Greenwood, SC; 2) Centre de Genetique Humaine, Institut de Pathologie et de Genetique, Gosselies, BELGIUM.

Sanfilippo syndrome type B (mucopolysaccharidosis IIIB) is an autosomal recessive disease that is caused by a deficiency of the lysosomal enzyme $\alpha$-N-acetylglucosaminidase (NAGLU). Over 100 different mutations in the *NAGLU* gene have been identified in Sanfilippo syndrome type B patients; however, no large deletions have been reported. Here we present the first case of a large homozygous intragenic *NAGLU* gene deletion identified in an affected child of consanguineous parents. Long range and multiplex PCR methods were used to characterize this deletion which encompasses exons 3 and 4 and is 1,146 base pairs long. We propose that *Alu* element-mediated unequal homologous recombination between an *Alu-Y* in intron 2 and an *Alu-Sx* in intron 4 is the likely mechanism for this deletion, thereby contributing further insight into the molecular etiology of this disorder and providing additional evidence of its genetic heterogeneity.

## 3057/F/Poster Board #989

**Identification of Novel Mutations in Key Regulatory Regions of the Aldolase B Gene that cause Hereditary Fructose Intolerance.** *E.M. Coffee, D.R. Tolan.* Biology, Boston University, Boston, MA.

Hereditary fructose intolerance (HFI) is a potentially fatal inherited metabolic disease. It is caused by a deficiency of aldolase B enzyme activity in the liver and kidney, tissues where fructose metabolism occurs. To date, 43 mutations known to cause the disease have been identified in the protein coding region of aldoB. Here we report the first identification of mutations upstream of the coding portion of aldoB. The promoter, the 5'-untranslated first exon, and the intronic enhancer of several HFI patients revealed single base mutations in each of these key regulatory regions. Two mutations (g.-132G>A, g.-129T>A) are located in the promoter at the consensus C/EBP binding site, one mutation (IVS1+1G>C) is at the exon-1 donor splice site, and four mutations (IVS1+214A>G, IVS1+1873T>A, IVS1+1887G>A, IVS1+2379T>C) are located in the first intron in or near the known transcriptional enhancer. For the promoter mutations, in vivo studies using luciferase reporters suggest that the mutations in the promoter cause a decrease in aldoB expression. In vitro gel-shift assays are described that should confirm a decrease in C/EBP binding at these mutant sites. For the splicing mutation, cDNA synthesized from cells transfected with the exon-1 donor splice site mutant results in aberrant splicing of the transcript. In addition, reporter assays are described that should show cells are unable to synthesize any functional protein when the luciferase is inserted in frame. These data indicate the mutations in the promoter and exon-1 splice junction lead to HFI. Mutations identified in the intronic enhancer region seem likely to be single nucleotide polymorphisms common to HFI patients. The consequences of these single nucleotide changes in the regulatory regions of aldoB are discussed in the context of genotype/phenotype relationships.

## 3058/F/Poster Board #990

**Restoration of biological function of cystathionine beta-synthase mutants by chemical chaperones.** *J. Kopecká, J. Krijt, V. Koich.* Institute of Inherited Metabolic Disorders, First Faculty of Medicine, Charles University, Prague, Czech Republic.

Misfolding and aggregation of mutant enzymes have been proposed to play a role in pathogenesis of homocystinuria due to cystathionine $\beta$-synthase (CBS) deficiency. Chemical chaperones that can stabilize mutants and prevent aggregation have been recently explored as mediators of proper folding of several CBS mutants (Singh, et al., 2007). Our study was aimed at determining the effect of a different set of chaperones on quaternary structure and activity of a large panel of 27 pathogenic mutations representing two thirds of all known patient-derived alleles. Chemical chaperones were used in an E. coli expression system and their effect on folding and catalytic activity of mutants was examined by native western blotting and radiometric and LC-MS/MS assay. Two thirds of mutants was responsive to the presence of either 0.5 mM delta-aminolevulinic acid, 100 mM betaine and/or 750 mM glycerol during expression; these chaperones increased formation of correctly assembled tetramers which was in most cases accompanied by an increase in catalytic activity. Nine mutants (R266K, P49L, C165Y, R125Q, K102N, R369C, V180A, P78R, S466L) were rescuable by all of these three substances and they are potential candidates for chaperone therapy. This study has brought some new aspects of mechanism of CBS folding and suggests that new modality of treatment may become useful for subset of homocystinuria patients. Work was supported by a grant from Grant Agency of Charles University No. 84507 and by Research Project of Charles University No. MSM20620806.

## 3059/F/Poster Board #991

**Functional complementation in yeast allows molecular characterization of missense argininosuccinate lyase mutations.** *E. Trevisson[1], A.B. Burlina[2], M. Doimo[1], L. Cesaro[3], G. Sartori[3], L. Salviati[1].* 1) Pediatrics Dept - Genetics Unit, University of Padova, Italy; 2) Pediatrics Dept- Metabolic Disorders Unit, University of Padova, Italy; 3) Biochemistry Dept, University of Padova, Italy.

Argininosuccinic aciduria (ASAuria) is an autosomal recessive urea cycle defect due to mutations in the ASL gene, which encodes argininosuccinate lyase. This disorder may present with a severe neonatal onset form, or with a late onset phenotype. To date phenotype-genotype correlations are still not clear because biochemical assays of ASL activity correlate poorly with clinical severity in patients. Moreover, patients are often compound heterozygotes for different mutations, and direct measurements cannot discriminate the role of individual alleles. We employed a yeast-based functional complementation assay to assess the pathogenicity of 12 missense ASL mutations, to establish genotype-phenotype correlations, and to screen for intragenic complementation. The S.cerevisiae ARG4null strain harbours a deletion of ARG4, the yeast homologue of the human ASL gene, and is auxotrophic for arginine. Rather than determining ASL enzyme activity directly, we measured the growth rate in arginine-free medium of the yeast ARG4null strain transformed with individual mutant ASL alleles. Individual haploid strains were also mated to obtain diploid, "compound heterozygous" yeast. We show that the late onset phenotypes arise in patients who harbour either individual alleles retaining high residual enzymatic activity, or because of intragenic complementation among different mutated alleles. In these cases complementation occurs because in the hybrid tetrameric enzyme, at least one active site without mutations can be formed, or because the differently mutated alleles can stabilize each other, resulting in partial recovery of enzymatic activity. Patients with the severe phenotype can harbour mutations of any class; on the other hand, none of the patients with the mild phenotype had two mutations that completely abolish enzymatic activity, indicating that residual ASL activity is necessary, but not sufficient, to ensure a milder phenotype in the patients. Functional complementation in yeast is simple, sensitive, reproducible, and allows the analysis of large numbers of mutant alleles. Moreover, it overcomes the problems inherent to classical biochemical assays, it is not affected by the genetic background of the patient and can be easily adapted for the analysis of mutations in other genes involved in metabolic disorders.

## 3060/F/Poster Board #992

**A new case of ALG8 deficiency (CDG-Ih) with neurological impairment.** *K. Vesela[1], T. Honzik[1], H. Hansikova[1], M.A. Haeuplte[2], J. Semberova[3], Z. Stranak[3], T. Hennet[2], J. Zeman[1].* 1) Department of Pediatrics, First Faculty of Medicine, Charles University, Prague, Czech Republic; 2) Institute of Physiology, University of Zürich, Zürich, Switzerland; 3) Institute for the Care of Mother and Child, Prague, Czech Republic.

Congenital disorders of glycosylation (CDG) represent an expanding group of inherited diseases. One of them, ALG8 deficiency (CDG-Ih), leads to protein N-glycosylation defects caused by malfunction of glucosyltransferase 2 (Dol-P-Glc:Glc1-$Man_9$-$GlcNAc_2$-P-P-Dol glucosyltransferase) resulting in inefficient addition of the second glucose residue onto lipid-linked oligosaccharides. So far, only five patients have been described with ALG8 deficiency. We present a new patient with neonatal onset. The girl was born at $29^{th}$ week of gestation complicated by oligohydramnion. Although the early postnatal adaptation was uneventful (APGAR score 8 and 9 at the $5^{th}$ and $10^{th}$ minutes), generalized oedema, multifocal myoclonic seizures, and bleeding due to combined coagulopathy were present since the first day. Diarrhea progressing to the protein-losing enteropathy with ascites and pericardial effusion developed in the $3^{rd}$ week of life. Pharmacoresistant seizures and cortical, cerebellar and optic nerves atrophy indicated neurological involvement. No symptoms of liver disease except coagulopathy were observed, however steatofibrosis with cholestasis was found at autopsy. The girl died at the age of 2 months due to the progressive general oedema, bleeding and cardio-respiratory insufficiency. Isoelectric focusing of serum transferrin revealed a glycosylation pattern typical for CDG type I. The lipid-linked oligosacharide profile was directing to an ALG8 deficiency (CDG-Ih). Molecular analysis of the *ALG8* gene showed two heterozygous mutations: c.139A>C (p.T47P) and a novel mutation c.1090C>T (p.R364X). The new mutation was found in heterozygous form in the mother, but it was not present on any allele of 150 healthy controls.

*Conclusion:* The prognosis of patients with ALG8 deficiency is unfavorable. Majority of affected children have early onset of the disease with heterogeneous symptoms including multi-organ dysfunction, coagulopathy and protein losing enteropathy. Neurological impairment is not a general clinical symptom, but it has to be taken into consideration when thinking about ALG8 deficiency.

*Supported by:* LSHM-CT-2005-512131-EUROGLYCANET and IGA-MZ NR9410-3.

## 3061/F/Poster Board #993

**Medium-chain acyl-CoA dehydrogenase deficiency - the molecular aspect.** *B.Z. Yang, N.Z. McNeill, J.H. Ding.* Inst Metabolic Disease, Baylor Res Inst, Dallas, TX.

Medium-chain acyl-CoA dehydrogenase (MCAD, E.C. 1.3.99.3) is responsible for the first step in mitochondrial β-oxidation of fatty acids, a process which provides energy, especially during fasting conditions. MCAD deficiency is the most common inherited defect of fatty acid oxidation, characterized by episodes of illness in early childhood. The disorder may present after fasting with symptoms resembling Reye Syndrome, coma, hypoglycemia, hyperammonemia, fatty liver, and sudden death. To investigate the molecular aspect, forty-three unrelated patients with MCAD deficiency were studied recently. The common mutation 985A>G had been tested, which presented only in 57% of all defective alleles in our group. To screen for other mutations within the MCAD gene, all 12 exons and their flanking intronic sequences were amplified. The PCR products were purified and sequenced. A total of 27 different rarer mutations, including eight novel variants, have been detected. Among them, eight mutations have been identified in a few unrelated patients, while the remaining nineteen have each been found in only a single pedigree. The novel mutations, including G275X and R349X were also verified by a PCR/restriction test, but were not detected in the normal control subjects. Our data and others indicated significant phenotypic heterogeneity of MCAD deficiency, even with the same genotype. The low percentage of the common mutation in our group has also been discussed.

## 3062/F/Poster Board #994

**Homozygosity mapping reveals new genes and gene defects in consanguineous families with OXPHOS disease.** *M. Gerards[1,2], B. van den Bosch[1,2], W. Sluiter[3], E. de Wit[3], K. Schoonderwoerd[4], A. van der Kooi[5], I. de Coo[6], H. Smeets[1,2].* 1) Dept Clinic Genet, Maastricht UMC, Maastricht, Limburg, Netherlands; 2) Research School GROW, Univ Maastricht, Maastricht, The Netherlands; 3) Dept Biochem, Mitochondrial Research Unit, Erasmus MC, Rotterdam, The Netherlands; 4) Dept Clin Genet, Erasmus MC, Rotterdam, The Netherlands; 5) Dept Neurol, Academic Medical Center, Amsterdam, The Netherlands; 6) Dept Neurol, Erasmus MC, Rotterdam, The Netherlands.

Mitochondrial or OXPHOS disorders are clinically and genetically highly heterogeneous, making the identification of the underlying gene defect a major challenge. Classification based on clinical or biochemical criteria or gene expression profiling remains difficult and only applicable to small subgroups of patients. Therefore, the most successful approach for finding the genetic defect still remains SNP-based homozygosity mapping and candidate gene analysis, as illustrated for 2 consanguineous families with OXPHOS disease. In the first family with 3 children affected with Leigh syndrome, a homozygous region of 11.5Mb on chromosome 20 was identified containing 8 mitochondrial genes. Patients were homozygous for an amino acid substitution (p.L159F) in C20orf7, an new assembly factor of OXPHOS Complex I. Blue native gel electrophoresis showed in blood a decrease to 30% of mature Complex I in patients compared to controls indicating the pathogenic mechanism of this mutation. A homozygous region on chromosome 1 containing 4 mitochondrial genes was detected in the second family with 3 children with progressive cerebellar ataxia. Mutation screening of CABC1 (the chaperone, ABC1 activity of bc1 complex homologue gene) revealed a homozygous nonsense mutation (c.1042C>T, p.R348X). CABC1 is the homologue of the yeast COQ8 gene, which is involved in the ubiquinone biosynthesis pathway. An additional 4 patients with cerebellar ataxia were screened for mutations in the CABC1 gene. One patient was compound heterozygous for the same c.1042C>T mutation and had an additional nonsense mutation (c.1136T>A, p.L379X). The pathogenic role for both CABC1 mutations is evident as they either lead to a truncated protein missing important protein kinase motifs required for ATP binding or to nonsense mediated mRNA decay. We conclude that homozygosity mapping is the preferred method to identify pathogenic mutations in consanguineous families and maybe also in idividual patients.

## 3063/F/Poster Board #995

**Characterization of *Caenorhabditis elegans* gene *C17G1.7* - an ortholog of human cystathionine β-synthase.** *R. Vozdek[1], A. Hnizda[1], J. Krijt[1], M. Kostrouchova[1], M. Kodicek[2], V. Kozich[1].* 1) Institute of Inherited Metabolic Disorders, First Faculty of Medicine, Charles University in Prague and General University Hospital in Prague; 2) Department of Biochemistry and Microbiology, Faculty of Food and Biochemical Technology, Institute of Chemical Technology, Prague.

Nematode *Caenorhabditis elegans* could be a suitable model to study metabolic and cellular consequences of homocystinuria due to cystathionine β-synthase (CBS) deficiency. However, metabolism of sulfur amino acids in *C. elegans* is as yet unknown, namely the steps in cysteine biosynthetic pathways. Cysteine can be synthesized either via the transsulfuration pathway which utilizes homocysteine by CBS or via the assimilation pathway which uses sulfide by cysteine synthase (CS).

*In silico* analysis of *C. elegans* database WormBase identified five orthologs of human CBS, namely *F54A3.4*, *ZC373.1*, *C17G1.7*, *K10H10.2* and *R08E5.2*. The aim of this study was to characterize the gene *C17G1.7*. Although this gene is expressed at high level (according to WormBase), our data show that *C. elegans* mutant strain carrying deletion of *C17G1.7* has normal morphology, behaviour, lifespan and egg-laying compared to wild type nematodes. Unaffected phenotype of deletion mutant was also observed at the metabolite level; concentration of aminothiols in crude extracts was undistinguishable from wild type strain. Subsequently, gene *C17G1.7* was expressed in prokaryotic system and purified to homogenity. We determined that purified enzyme has specific enzymic activity for CS reaction; other possible activities were not detected. Recombinant C17G1.7 exhibited $K_M$ values for *O*-acetyl-serine and sulfide of 5.54 and 4.23 mM, respectively, and a turnover number of 139 and 134 $s^{-1}$, respectively.

Our enzymological data suggests that *C17G1.7* gene could play an important role in cysteine metabolism, however, deletion mutant does not lead to an abnormal clinical and biochemical phenotype. This fact supports an assumption that the insufficient activity of one enzyme could be compensated by another paralogs.

**Identification of a novel mutation of SLC6A19 gene in a Korean patient with Hartnup disorder.** *C. Chong Kun[1], Y. Han Wook[2].* 1) Pusan National University Children Hospital, Geungsang Nam Do , Korea C.K. Cheon; 2) Department of Pediatrics, Asan Medical Center, Children and Adolescent Hospital, University of Ulsan College of Medicine, H. W. Yoo.

Backgound: Hartnup disorder is an inborn error of renal and gastrointestinal neutral amino acid transport with reported clinical association with pellagra-like rash, ataxia and psychotic behavior. Diagnostically,elevated urinary neutral amino acids are the first indication of the disord er. Mutations in SLC6A19, encoding the amino-acid transporter B0AT1, mediating neutral amino acid transport from the luminal compartment into the cells are causative for autosomal-recessive Hartnup disorder. Objective: To report on an 8 year, 5 month old Korean boy with Hartnup disorder who was confirmed by SLC6A19 gene analysis. Results: To confirm the diagnosis of Hartnup disorder, direct sequencing analysis of 12 coding exons and the exon-intron boundaries of SLC6A19 gene wa s performed. The result of sequence analysis sho wed that he was a compound heterozygote possessing two mutations.908C>T (Ser303Leu) and 1787_1788 insG (Thr596fsX73). The former was a novel mutation and also, the latter is a novel frameshift mutation with known 336 polymorphism after stop codon. Conclusion: We experienced one case of Hartnup disorder with a novel mutation of SLC6A19 gene. Although Hartnup disorder is a rare disease in Korea,it should be considered in the differential diagnosis of any infant or child presenting with neutral amin noaciduria and seizure, especially in patients with past history of pella gra-like rash.

## 3065/F/Poster Board #997

**Molecular analysis of two enzymes, HPRT and PRPP synthetase, causing X-linked inborn errors of purine metabolism.** *Y. Yamada, K. Yamada, A. Yamano, N. Nomura, N. Wakamatsu.* Dept Gen, Inst Dev Res, Aichi Human Service Ctr, Kasugai Aichi, Japan.

Deficiency in the activity of a purine salvage enzyme, hypoxanthine guanine phosphoribosyltransferase (HPRT, EC 2.4.2.8; MIM308000), associated with Lesch-Nyhan syndrome (MIM300322) and HPRT-related gout (MIM300323). On the other hand, PRPP synthetase superactivity (MIM300661) is an X-linked inborn error of metabolism in which increased enzyme activity is associated with hyperuricemia and gout, sometimes including neurodevelopmental abnormalities. Human PRPP synthetase (PRPS; EC 2.7.6.1) exists as heterogeneous aggregates composed of two catalytic subunits (PRSI and PRSII) and two associated proteins. Mutations of *PRPS1* (PRSI subunit gene; MIM311850) were found in patients with PRPS superactivity. Recently, in affected males with X-linked recessive Charcot-Marie-Tooth disease-5 (CMTX5; MIM311070), the *PRPS1* mutations responsible for decreased enzyme activity were identified. Furthermore, the mutations resulting in a loss of PRPS activity with hypouricemia were also identified in the patients of Arts syndrome (MIM301835). We have identified a number of HPRT mutations in Asian patients manifesting different clinical phenotypes, by analyzing all nine exons of the HPRT gene (*HPRT1*) from genomic DNA and reverse transcribed mRNA using the PCR technique coupled with direct sequencing. Two mutations were detected in two Lesch-Nyhan families after the last our report (Yamada et al., Nucleosides Nucleotides Nucleic Acids 27: 570-574). One of them, a new single nucleotide substitution (130G>T) resulting in a missense mutation D44Y was detected in the exon 2 of *HPRT1*. The RT-PCR amplification showed not only a cDNA fragment with normal size, but also a small amount of shorter fragment skipping exons 2 and 3. The other missense mutation F74L (222C>A) was detected firstly in a Japanese patient, whereas reported previously in Europe. In four hyperuricemia patients with mild neurological abnormality, no mutations responsible for partial HPRT deficiency were identified on *HPRT1*. In those four patients, we also performed molecular analysis of *PRPS1*, using the PCR and direct sequencing of genomic DNA and mRNA, but any abnormalities as generating PRPS superactivity have not been found.

## 3066/F/Poster Board #998

**Genotype and phenotype of Japanese patients with X-linked adrenoleukodystrophy.** *N. Shimozawa[1], A. Arai[1], N. Kajiwara[1], S. Kozawa[1], T. Nagase[1], Y. Takemoto[1], Y. Suzuki[2].* 1) Life Sci Res Ctr, Gifu Univ, Gifu, Japan; 2) Medical Educat Develop Ctr, Gifu Univ Sch of Med, Gifu, Japan.

X-linked adrenoleukodystrophy (ALD) is a severe neurodegenerative disease associated with accumulation of very-long chain saturated fatty acids (VLCFA) in tissues and body fluids. Patients manifest various neurological disturbances, including intellectual, psychological, visual, hearing, gait, swallowing, autonomic, and sensory disturbances. We have been studying peroxisomal diseases for more than 20 years, and doing biochemical and molecular diagnosis on Japanese patients with peroxisomal diseases. In this study, we document genotype and phenotype of Japanese patients with ALD. We have been identified 46 kinds of ABCD1 (the ALD gene) mutations in 49 Japanese ALD families, including 41 patients with the childhood and adolescent cerebral form, 7 with adrenomyeloneulopathy (AMN), 1 with Addison only, 14 with pre-symptomatic and 40 females with ALD carriers. Most kindreds have a unique mutation, including 31 kinds of missense mutations, 3 of nonsense mutations, 2 of in frame amino acid deletions, 6 of frame shift mutations, 2 of exon deletions and 2 of large deletions. There is no genotype-phenotype correlation and the prognosis of the affected patients can not be predicted, therefore further approaches using these resources are needed to find out another factor that determined the clinical outcome of the ALD patients.

## 3067/F/Poster Board #999

**Effect of Vitamin D Receptor (VDR) genotypes on risk for osteoporosis in patients with non-neuronopathic Gaucher disease.** *A. Greenwood[1], G. Altarescu[2], A. Zimran[1], D. Elstein[1].* 1) Gaucher Clinic, Shaare Zedek Medical Center, Jerusalem, Israel; 2) Genetics Unit, Shaare Zedek Medical Center, Jerusalem, Israel.

The almost universal finding of osteopenia in Gaucher disease and the unpredictable advent of avascular necrosis and/or pathological fractures are clinically relevant issues that are not necessarily reversed by specific enzyme replacement therapy (ERT). However, genetic/epigenetic factors may explain as much as 70% of the variance for bone mineral density (BMD) in the normal population. Quantitative trait loci for BMD have been identified by genome screening and linkage approaches; among the candidate gene polymorphisms, those of the Vitamin D Receptor (VDR) have been correlated with BMD and/or fracture risk in various populations. The purpose of this study is to assess VDR polymorphisms on BMD at the lumbar spine (LS) and femoral neck (FN) in patients with Gaucher disease regardless of ERT use. Helsinki Committee approval was received for this study. DNA was derived from blood samples taken from 74 patients with non-neuronopathic Gaucher disease for whom there was recent BMD data at LS and FN and from 15 healthy individuals. Four VDR polymorphisms (FokI, ApaI, TaqI, and BsmI) were tested. Clinical and demographic data were taken from files. Associations between PAR1 and categorical variables were analyzed by chi-square and Fisher's exact tests; assessment of associations with quantitative variables used ANOVA and Scheffe post-hoc for multiple pairwise comparisons. Non-parametric Kruskal-Wallis ANOVA was used when one category was small. All tests were 2-tailed; p values less than 0.05 was considered statistically significant. FokI was not correlated with any variables tested. ApaI was significantly correlated with Gaucher genotype (N370S/N370S vs others) (p=0.029) but not with the presence of bone disease, need for splenectomy, need for ERT, or BMD. TaqI was significantly correlated with BMD at FN (p=0.03) but with no other variables. There were trends to significance for correlation of BsmI genotype with Gaucher genotype (p= 0.061) and with LS Z-scores (p=0.084), and a significant correlation with the presence of overt bone disease (p=0.018). We conclude that as in other populations, VDR polymorphic genotype, in particular BsmI, may be an independently-sorting modifier in the prediction of bone disease in Gaucher disease. This may have management ramifications.

## 3068/F/Poster Board #1000

**The phenylalanine hydroxylase c.30C>G (p.G10G) synonymous variation is a pathological mutation that functions by creating a common exon splicing silencer motif.** *B.S. Andresen[1], T. Miller[2], S.F. Dobrowolski[3].* 1) Dept Biochem & Molec Biol, Univ Southern Denmark, Odense M, Denmark; 2) Idaho Technology, Salt Lake City, Utah, USA; 3) Department of Pathology, University of Utah, Salt Lake City, Utah, USA.

Correct splicing of exons is determined by a finely balanced interplay between cis-acting regulatory sequences like exonic splicing enhancers (ESE) and exonic splicing silencers (ESS). Mutations that create or disrupt ESS/ESEs may disturb this balance and cause missplicing and disease, irrespective of the perceived consequence dictated by the genetic code. Deleterious mutations in the phenylalanine hydroxylase (PAH) gene may cause Phenylketonuria. In three siblings previously reported to have different clinical phenotypes, but a common PAH genotype defined by RFLP analysis we identified compound heterozygosity for a deleterious c.284-86delTCA variation and a c.30C>G variation. The c.30C>G variant is ostensibly the synonymous variant p.G10G, and would therefore not be expected to be deleterious, and it is cataloged in the Phenylalanine Locus Knowledgebase as a neutral variation, but was not present in 400 control chromosomes. The c.30C>G variation creates a CAGGGT motif within exon 1. We have previously shown that this motif functions as an ESS in other genes and because the 5' splice site of PAH exon 1 is intrinsically weak, we speculated if the c.30C>G variation could cause missplicing and thus be deleterious. The ESS created by the c.30C>G variant was characterized in a splicing reporter minigene, and shown to cause exclusion of an alternatively spliced exon. Moreover, a hybrid minigene harboring the relevant part of exon 1 and part of intron 1 was used to demonstrate that the c.30C>G variation causes aberrant splicing also in its native context. Using nuclear extracts and RNA affinity purification with different wild type and c.30C>G mutant RNA oligonucleotides we demonstrated that c.30C>G creates a binding motif for the splicing inhibitory protein hnRNPH, which can bind to splicing silencers with GGG triplets. The present study provides a new example on how synonymous substitutions can be deleterious by disrupting the finely tuned balance between splicing regulatory elements in constitutive exons. The PAH genotype is valuable diagnostically, to predict disease severity, and to predict efficacy of 6R-tetrahydrobiopterin therapy. Given the critical nature of the PAH genotype, understanding the molecular pathology of variants has significance to patient care. Potential effects on mRNA splicing should therefore always be considered when the consequences of identified sequence variations are evaluated.

## 3069/F/Poster Board #1001

**Early liver transplantation in urea cycle defects: a developmental outcome study.** *P. Pivalizza[1], P.M. Campeau[2], A.A. Tran[2], K.L. McBride[3], G. Miller[4], S. Carter[2], S. Karpen[5], J.A. Goss[6], B.H. Lee[2,7].* 1) Center for Develop. Pediatrics, Baylor College of Medicine, Houston; 2) Human and Molecular Genetics, Baylor College of Medicine, Houston, TX; 3) Center for Molecular and Human Genetics, The Research Institute at Nationwide Children's Hospital, Columbus, OH; 4) Department of Pediatrics, Yale School of Medicine, New Haven, CT; 5) Pediatrics-Gastroenterology, Baylor College of Medicine, Houston, TX; 6) Liver Center, Baylor College of Medicine, Houston, TX; 7) Howard Hughes Medical Institute, Houston, TX.

Patients with urea cycle defects (UCDs) typically have a poor prognosis in terms of survival and neurological outcome when the presentation is in the neonatal period, despite aggressive pharmacological and dietary therapy. Liver transplantation can prevent subsequent metabolic decompensations, but the preexisting neurological status, dependent on the severity of hyperammonemic episodes, is a major factor in the final outcome. Previous studies indicate that most of the children who receive transplants remain significantly neurologically impaired. We performed a prospective developmental outcome study to determine whether aggressive metabolic management of ammonia levels after early referral/transfer to a metabolism center and early liver transplantation would result in better neurologic outcomes. We report on 5 children with UCDs transplanted between 2000-2003; 2 male patients with X-linked ornithine transcarbamylase deficiency and 2 male patients with carbamoyl phosphate synthase deficiency, all of whom had neonatal presentations and underwent liver transplantation before 1 year of age, and 1 female patient with partial X-linked ornithine transcarbamylase deficiency that was intractable to medical therapy, who underwent transplantation at 35 months of age. All children had metabolic cures. There was 1 death 40 months after liver transplantation caused by hepatic artery thrombosis in the immediate post-transplantation period leading to biliary strictures which caused end-stage liver disease. The 6-year survival rate is thus 80%. Developmental testing with the Griffiths scale was performed on average on 5 occasions, 12 months apart, up to 7 years after transplantation. Full-scale indices for the 4 children who underwent early transplantation (now averaging 9 years of age) showed average developmental quotients of 69 (range 51-86), whereas the average developmental quotient for the female who underwent transplantation at 35 months was 80. We conclude that early liver transplantation and aggressive metabolic management improve early neurologic outcomes for children with UCDs.

## 3070/F/Poster Board #1002

**Optic Neuropathy in a Maple Syrup Urine Disease Patient with Poor Dietary Control.** *M. Wick, D. Babovic-Vuksanovik.* Medical Genetics, Mayo Clinic & Foundation, Rochester, MN.

Maple syrup urine disease (MSUD) is an inborn error of metabolism caused by a defect of the branched chain oxoacid dehydrogenase multi-enzyme complex. The defect results in accumulation of the branched chain amino acids (BCAA) leucine, isoleucine and valine. Neurologic toxicity including cerebral edema, cerebrovascular compromise and brain stem herniation is due to leucine and 2-isocaproic acid accumulation. Early disease manifestations include vomiting/feeding difficulties, lethargy and hypertonicity. Untreated, symptoms rapidly progress to seizures, coma and death. Untreated patients who survive are neurologically devastated with severe retardation. Patients treated from the newborn period with dietary restriction of BCAA have normal development and intellectual outcome. However, these patients are at risk for acute decompensation characterized by apathy, choreoathetosis, ataxia, stupor, convulsions and coma. Here we describe a 26 year old patient who presented with optic neuropathy approximately twelve months after self-discontinuation of the MSUD diet. Leucine, isoleucine and valine levels were elevated at 2,165mmol/L, 425mmol/L and 825mmol/L respectively. He was restarted on the protein restricted diet with MSUD Complex supplementation. This resulted in normalization of valine and isoleucine within 2 weeks, while leucine levels remained mildly elevated at 425mmol/L. The patient reported resolution of spells and sense of well being within two weeks. Opthalmologic examination 6 months after re-initiation of diet revealed some improvement in vision. Optic neuropathy is a previously unrecognized finding in MSUD. In our patient it was likely a consequence of his poor metabolic control and his case emphasizes the importance of continuous dietary treatment. Adults with this condition need to remain on BCAA restricted diet to prevent complications, including neurologic, ophthalmologic and other manifestations.

### 3071/F/Poster Board #1003

**Cervical Cord Compression in Mucopolysaccharidosis Diseases.** *B.M. Diethelm-Okita, C.B. Whitley.* Lysosomal Disease Network, University of Minnesota, Minneapolis, MN.

Background: Cervical cord compression is an important, but probably under appreciated problem in mucopolysaccharidosis (MPS) conditions. The mechanism in most cases is pachymeningitis cervicalis. The standard treatment to date has been decompressive laminectomy, which has uncertain outcomes, the success of which may be syndrome dependant. Many of the published case studies that measure laminectomy outcomes for MPS were completed decades ago, before the advent of current therapies. Hematopoietic stem cell transplantation (HSCT) reduces the GAG level in the CNS, but enzyme replacement therapy (ERT) does not. We sought to assess the outcomes associated with surgical de-compression laminectomy for a cohort of patients with MPS seen at the University of Minnesota, and from the literature. Materials & Methods: We reviewed our records for cases of MPS patients who had undergone surgical laminectomy. Concomitant therapies are also noted. We created a ratings scale from 0 to 4 with 0 being equal to death, 1 equal to a significant loss of function (paresis or hemiparesis), 2 equal to minor loss of function, 3 equal to no change in condition, and 4 to improvement over pre-operative condition. Scores were assigned by physician assessment. Results: Nine subjects were identified in our records: MPS IS, II (2 subjects each), and VI (3 subjects) are presented with outcomes ranging from no complication (rating score =3) to death. Of the 8 patients assessed none had post-surgical improvement, 2 had no complications but no improvement, 1 had minor loss of function, 2 had a significant loss of function, and 2 patients died. Overall, 63% of subjects had less than favorable. Conclusions: Decompressive laminoplasty is a dangerous procedure; especially for those with advanced MPS IS, II or VI disease. Underlying MPS disease predisposes the patient to severe respiratory distress and cardiac morbidity and mortality. Speculation: New approaches to treatment would be important for the quality of life of affected individuals.

### 3072/F/Poster Board #1004

**A case of maculopathy associated with homocystinuria secondary to presumed methylene tetrahydrofolate reductase (MTHFR) deficiency.** *A. Atherton, U. Garg, S. Olitsky, M. Stass-Isern, L. Smith.* The Children's Mercy Hospitals and Clinics, Kansas City, MO.

Homocystinuria, a rare inborn error of metabolism, results from defects in homocyst(e)ine remethylation or transsulferation. The disorders associated with homocystinuria include cystathionine beta synthase deficiency, methylene tetrahydrofolate reductase, folate deficiency and disorders of intracellular cobalamin metabolism. Differentiation of these disorders can be inferred by differing patterns of biochemical markers. We present an unusual case of a 20 month old male child who at birth had a normal expanded newborn screen. At 6 weeks of age, he was admitted to the hospital for feeding difficulties, failure to thrive and loss of developmental milestones. He was noted to be microcephalic and found to have hepatomegaly. Initial work up revealed elevations of plasma and urine homocyst(e)ine with normal to low levels of plasma methionine. There were no elevations of urine methylmalonic acid. Megaloblastic anemia has not been identified. At 2 months of age, he was noted to have horizontal nystagmus. Exotropia was identified at 10 months. Ophthalmologic evaluation at 10 months of age was remarkable for bilateral large atrophic maculopathy. Although complete DNA sequencing of the MTHFR gene failed to identify any mutations, biochemical and laboratory studies are most consistent with a diagnosis of homocystinuria/hyperhomocysteinemia due to MTHFR deficiency. MTHFR enzymatic analysis is currently pending. Nystagmus has been previously described in this disorder as well as central retinal dysfunction and retinal vein occlusion. Salt and pepper maculopathy has been described in CblC deficiency but not in MTFHR deficiency. To our knowledge, this is the first report of large atrophic maculopathy/salt and pepper retinopathy associated with MTHFR deficiency.

### 3073/F/Poster Board #1005

**Growth velocity in patients with Hunter syndrome treated with idursulfase: results from the Hunter Outcome Survey (HOS).** *C. Tifft[1], M. Beck[2], J. Muenzer[3], G. Schulze Frenking[2].* 1) Div Gen & Metabolism, Children's Hosp Natl Med Ctr, Washington, DC; 2) Children's Hospital, University of Mainz, Mainz, Germany; 3) Department of Pediatrics, University of North Carolina, Chapel Hill, NC.

Introduction: The Hunter Outcome Survey (HOS) is a global outcomes database for gathering long-term data on the natural history of Hunter syndrome (MPS II) and the safety and effectiveness of enzyme replacement therapy (ERT) with idursulfase (Elaprase$^{TM}$; Shire HGT, Inc., Cambridge, MA, US). Untreated patients with MPS II have markedly reduced growth velocity after 8 years of age. Methods: As of April 16, 2009, 367 patients were reported as treated with idursulfase in HOS. This analysis provides data on patients who started therapy between 8 and 12 yrs of age (when growth restriction develops and while the patients are generally pre-pubertal) with available height and weight data at start of ERT (baseline) and 1 yr after start of ERT. Results: The eligible population for height and weight were 30 and 36 patients, respectively. At baseline, the mean height for patients was 122.8 cm with a mean Z-score of -2.5 (SD: 10.5 and 1.6, respectively). After one year of ERT, the mean height was 127.7 with a mean Z-score of -2.4 (SD: 12.8, 1.8). For weight, the mean baseline was 30.4 kg with a mean Z-score of -0.6 (SD: 5.4, 1.2). After one year of ERT, the mean weight was 32.6 kg with a mean Z-score of -0.8 (SD: 6.8, 1.3). The mean growth velocity was 4.9 cm/yr and patients seem to be following their own trajectory. Conclusions: We have observed an improvement in the growth of Hunter syndrome patients (8 to 12 years of age) one year after starting ERT based on historical data. Given that typically patients with Hunter syndrome have plateaued their growth by this age, the apparent normal growth is best explained by either a direct effect of ERT on cartilage or by a more general effect of ERT on health and well-being. Ongoing collection of data in HOS, including analysis of the effects of ERT in relation to pubertal development status (Tanner stage), is needed to further elucidate the effect of idursulfase on growth.

### 3074/F/Poster Board #1006

**MPV17-Associated Hepatocerebral Mitochondrial DNA Depletion Syndrome: New Patients and Novel Mutations.** *F. Li, A. El-Hattab, E. Schmit, S. Zhang, W. Craigen, LJ. Wong.* Molec & Human Gen, Balor College Med, Houston, TX.

Mitochondrial DNA depletion syndromes are autosomal recessive diseases characterized by a severe decrease in mitochondrial DNA content leading to organ failure. They are phenotypically heterogeneous, with myopathic, encephalomyopathic and hepatocerebral forms. The later has been associated with mutations in PEO1, POLG1, DGUOK genes and recently with mutations in MPV17 gene which encodes an inner mitochondrial membrane protein where it plays an as yet poorly understood role in mitochondrial DNA maintenance. Mutations in MPV17 gene have been reported in patients with a hepatocerebral mitochondrial DNA depletion syndrome who came to medical attention early in life with liver failure, hypoglycemia, failure to thrive and neurological symptoms. The homozygous p.R50Q mutation was identified in patients with infantile onset Navajo neurohepatopathy. To date 11 different mutations in 19 patients with MPV17-associaated hepatocerebral mitochondrial DNA depletion syndrome have been reported. We report eight new patients and identified seven novel mutations; four missense mutations (p.K88E, p.G94R, p.P98L, and p.A162D), one in-frame deletion (c.271_273 del3), one invariant splice site substitution (c.186+2T>C), and an insertion (c.22_23insC). The p.R50Q mutation, which occurs in CpG sequence, is the most common mutation. Clinically, patients with homozygous p.R50Q and compound heterozygous of p.G94R and p.P98L mutations have a better prognosis, with all the other mutations are associated with early death if not treated by liver transplantation. Localizing the mutations to the predicted MPV17 protein structure showed clustering of mutations in the region of the putative protein kinase C phosphorylation site.

### 3075/F/Poster Board #1007

**Unusual symptoms in a 14-year-old girl with Wilson disease.** *J. Lin[1,2,3].* 1) Pediatric department, Chang Gung Children's Hospital; 2) Chang Gung Memorial Hospital; 3) College of Medicine, Chang Gung University, Taoyuan, Taiwan.

The 14-year-old girl suffered from headache, dizziness, high blood pressure, arthralgia at bilateral wrists, elbows and knees. Blurred vision was complained later on and optic neuritis was diagnosed. Autoimmune disease was suspected first. Series of test was arranged and turned out to be negative. Kayser-Fleischer ring was accidentally found by slit lamp later. Wilson disease was diagnosed by lower serum copper, ceruloplasmin, and excess copper amount of 24 hours urine. Mutations on ATP7B gene exon 8 (PR778L) and exon 13 (P992L) were detected respectively. She developed acute pancreatitis after trientine and zinc acetate were prescribed. Further phenotype and genotype relationship will be discussed and paper reviewed.

### 3076/F/Poster Board #1008

**20-Year Follow-up of Bone Marrow Transplantation In A Mucopolysaccharidosis VI Patient with Substantial Residual Pathology.** *H.C. Andersson.* Hayward Gen Ctr, Tulane Univ Med Ctr, New Orleans, LA.

Mucopolysaccharidosis type VI (Maroteaux-Lamy Syndrome) is characterized by lysosomal storage causing visceromegaly, corneal clouding, and bone dysplasia (dysostosis multiplex). This rare mucopolysaccharidosis has been treated with bone marrow transplantation (BMT) and, more recently, enzyme replacement therapy (ERT) with galsulfase has become available. Few reports have described the long-term outcome of BMT in MPS VI; such results are critical to determine whether BMT, ERT or a combination is the most appropriate therapy. A 22-year old woman who underwent BMT at age 2y for arylsulfatase B (ASA-B) deficiency (1.60 nM/mg/hr, nl 148-280, leukocyte) is described. The patient presented at age 2 years with facial coarsening, umbilical hernia, splenomegaly, and dysostosis multiplex (broad ribs, platyspondyly). She was transplanted with a male noncarrier allogeneic marrow and had no episodes of rejection. She received bilateral corneal transplantation at age 13years, underwent back surgery for spinal stenosis at 17 yrs and has had 6 sets of PE tubes for recurrent otitis media. At age 22y, her BMT shows 100 percent engraftment, leukocyte ASA-B is normal and urine MPS spot test is negative. Adult height is much less than 5 percentile (50th percentile for 8y6mo female), head circumference is 75 percentile. Spine radiographs demonstrate platyspondyly and the patient has chronic back and neck pain. Echocardiography demonstrates mitral valve prolapse and cardiopulmonary stress test revealed moderate to severe aerobic impairment. Otolaryngologic evaluation for hoarse voice demonstrated incomplete adduction of the vocal cords secondary to thickening of the cords. This patient offers the longest outcome of BMT in a MPS VI and documents the continued disease progression in patients with full engraftment. A comparison trial of ERT vs BMT is necessary to identify the most appropriate therapy in MPS VI patients.

### 3077/F/Poster Board #1009

**Quantificaiton of GM2 and GM3 storage in the brains of Mucopolysaccharidosis I and IIIB canines.** *A.D. Dierenfeld[1], J. Jens[1], E.M. Snella[1], P.I. Dickson[2], N.M. Ellinwood[1].* 1) Animal Sci, Iowa State Univ, Ames, IA; 2) Division of Medical Genetics Los Angeles Biomedical Institute at Harbor-UCLA Medical Center, Torrance, CA.

The Mucopolysaccharidoses (MPSs) are lysosomal storage diseases. Lack of a specific lysosomal enzyme results in accumulation of glycosaminoglycans (GAGs). In addition to GAG storage, neuropathic MPSs also show secondary CNS storage of GM2 and GM3 gangliosides. Our study quantified the amount of GM2 and GM3 storage in MPS I and MPS IIIB canine brains. Gangliosides from dissected cerebral gray matter were extracted and quantified by lipid extraction, fractionation, HPTLC, and scanning densitometry. Bands were calculated as mole %. Comparisons used ANOVA, and Tukey and non-parametric Wilcoxon rank sum post hoc tests. Samples included adult MPS IIIB (n=20), MPS I (n=4), and normal dogs (n=6). MPS IIIB levels were: GM2 3.09±0.23; GM3 8.08±0.55. Levels were statistically ($p<0.0001$) higher than normals: GM2 0.90±0.24, GM3 3.53±0.77. Similarly, MPS I dogs (n=4) had statistical ($p\leq0.0028$) elevations: GM2 3.10±0.43; GM3 11.8±4.59. Normal and affected brains were also evaluated for levels during development, at 1 and 3 weeks, and 2 and 3 months of age. Full analysis of these samples is pending. We also evaluated MPS I dogs receiving weekly intravenous (IV) enzyme replacement therapy from birth for 56-81 weeks with recombinant human iduronidase (rhIDU) at the conventional dosage (0.58 mg/kg, n=4), at a higher dosage (1.57 mg/kg, n=3), and at conventional dosage plus quarterly 0.058 mg/kg intrathecal (IT) injections (n=4). Results. Conventional IV ganglioside levels: GM2 1.95±1.24; GM3 8.95±1.53. High IV therapy levels: GM2 1.41±0.62; GM3 6.84±2.32. Conventional IV/IT levels: GM2 1.93±0.88; GM3 6.78±0.22. No statistical normalization was seen. However for GM3 IT vs. low dose saw improved response in IT dogs that approached significance (p=0.0709). Additionally, GM2 high dose vs. untreated saw a response in high dose that approached significance (p=0.0571). Low experimental numbers and high variability appear to be limitations in using these methods.

Secondary GM2 and GM3 CNS storage in MPS I and IIIB patients is also seen in the canine patients. Treatment of MPS I animals from birth with rhIDU may decrease the secondary storage burden. In this study, conventional dosage does not lead to statistical reduction in ganglioside storage, but IT and high dose treatments may be potential treatments for the CNS components of these disorders, based on the response to therapy of these secondary accumulations. Funded by NIH NS054242 (PID).

### 3078/F/Poster Board #1010

**Evolution and Utility of a Rare Genetic Disease Registry: The Gaucher Disease Registry.** *C. Fairley, G. Frohlich, M. Fitzpatrick.* Genzyme Corporation, Cambridge, MA.

The International Collaborative Gaucher Group (ICGG) Gaucher Registry is an ongoing observational program established in 1991. The goal of the Gaucher Registry is to significantly contribute to the medical understanding of Gaucher disease natural history and treatment outcomes, and to improve the quality of care for Gaucher patients worldwide through active publication of Registry findings and disease management approaches. This goal is achieved via the contribution of longitudinal data from 700+ physicians from 61 different countries. Participating physicians submit data to a centralized, confidential database that is reviewed by an International Board of Advisors consisting of leading medical practitioners for Gaucher disease. Since its inception over 15 years ago, the Gaucher Registry has enrolled over 5000 patients with Gaucher disease. This Registry program is sponsored by the Genzyme Corporation; the inclusion criteria is a confirmed diagnosis of Gaucher disease and there are no exclusion criteria. More than 15 peer review articles have been published from the data collected, and tools for managing patient care have been developed by the Gaucher Registry. One such tool that was developed and subsequently modified is the Recommended Schedule of Assessments for disease management by healthcare providers. These recommendations reflect medical practice patterns and have evolved as the understanding of the disease and treatment outcomes has increased. Examples of changes in recommendations are the addition of echocardiograms, DEXAs, and serum immunoelectrophoresis with the understanding of an increased incidence in Gaucher disease patients of pulmonary hypertension, low bone density, and multiple myeloma respectively. The Gaucher Registry also aims to address unanswered questions about Gaucher disease with the development of the Neurologic outcomes subregistry and the pregnancy subregistry. Finally, the Gaucher Registry provides a forum for data review and disease management discussions for participating medical practitioners through annual meetings in the US, the EU, and Latin America.

### 3079/F/Poster Board #1011

**Neonatal manifestations of Mucolipidosis type II: Longitudinal review of skeletal findings and generalized melanocytosis.** *A.M. Hata[1], C.E. Getman[2], R.A. Kahle[2], R.S. Lackman[3], S.A. Boyadjiev[1].* 1) Genetics, UC Davis, Sacramento, CA; 2) Mercy San Juan Medical Center, Sacramento, CA; 3) Cedars-Sinai Medical Center, David Geffen School of Medicine at UCLA, Los Angeles, CA.

Mucolipidosis type II (I-cell disease) is a rare progressive lysosomal storage disease with a poor prognosis resulting in chronic morbidity and mortality in the first decade of life. Mucolipidosis type II (MLII) is often not diagnosed until 6 to 12 months of age and the clinical manifestations in the early neonatal period have not been well defined. We report a Hispanic male who presented at birth with respiratory distress syndrome due to meconium aspiration. An x-ray revealed skeletal changes of the upper extremities and chest and a genetic consult was requested. An underlying lysosomal storage disease was suspected and testing revealed abnormal excretion of oligosaccharides in the patient's urine. A further assay of lysosomal enzymes showed significant elevation of all lysosomal enzymes, consistent with mucolipidosis type II. Genetic testing revealed a c.25C>T(pQ9X) nonsense mutation and a c.616_619delACAG deletion, both of which have not previously been reported in individuals with MLII but are expected to be disease causing. The patient's family history was non-contributory. Because a diagnosis was obtained in the first two weeks of life, we are able to describe features of disease progression in the early neonatal period, including progression of hepatosplenomegaly, skeletal changes, and overall disease advancement. We observed the natural progression of skeletal changes at ages one week, 3 months, and 9 months that has not been previously described. Vacuolated lymphocytes were observed on peripheral blood smear providing a diagnostic clue for a storage disorder. At six months of age, the patient presented with hyperpigmented lesions on the flank raising suspicion of child abuse. Clinical evaluation and skin biopsy documented melanocytosis, a feature not previously reported with MLII. This case provides an opportunity for longitudinal study to observe the progression of skeletal changes in MLII that have not been previously described.

## 3080/F/Poster Board #1012

**Novel Endocrine Findings in Two Siblings with Morquio Syndrome Type B.** *L.E. Polgreen[1], M.K. Hordinsky[1], G.E. Hoganson[2], C.B. Whitley[1].* 1) Pediatrics, University of Minnesota, Minneapolis, MN; 2) Pediatrics, University of Illnois at Chicago, Chicago, IL.

Background: Morquio syndrome type B (MPS IVB) is a rare, autosomal recessive, lysosomal storage disease resulting from deficiency of β-galactosidase. It is characterized by severe short stature and dysostosis multiplex. Neither delayed puberty nor the impact of estrogen replacement therapy has yet been reported in MPS IVB. Results: We report two female siblings, ages 14.3 and 18 years, with MPS IVB who developed severe pubertal delay and have atypical skin findings. The diagnosis of MPS IVB was made based on urine keratan sulfate. The children also had diagnostic levels of leukocyte β-galactosidase: 2.8 and 3.6 nmoles/hour/mg protein respectively (normal 66.9-116.3; deficient 0-9.16). Pubertal delay was diagnosed at age 13.8 years in patient 1 and 17.2 years in patient 2. Both of the girls were treated with oral conjugated estrogens at a dose of 0.3 mg daily. Estrogen replacement therapy resulted in the initiation of puberty based on Tanner stage examination within the first 3 months of treatment. Concomitant with this initiation of puberty was an unusually rapid advancement of the bone age, indicating an increased tempo of growth plate closure. Patient one had a bone age advancement of 2 years over 7 calendar months, and patient two had a bone age advancement of 8 years 3 months over 10 calendar months on estrogen replacement therapy. Interestingly, both patients have severe, progressive, biopsy confirmed angiokeratomas on their feet, hands, knees and elbows, which has not been reported in patients with MPS IVB. Conclusions: This is the first case report of severe delayed puberty in MPS IVB. The unexpected rapid closing of the growth plates that occurred following initiation of estrogen replacement therapy suggests an increased sensitivity to estrogen in the growth plates. This rapid closure of the growth plates results in a significant decrease in ultimate adult height. This is particularly important in MPS IVB because of the already extreme short stature that is characteristic in these patients. This sensitivity to estrogen could influence the treatment of delayed puberty as well as growth promoting therapies in children with MPS IVB.

## 3081/F/Poster Board #1013

**Oropharyngeal dysphagia in young infants with Pompe disease.** *Y. Chien[1], S. Peng[2], N. Lee[1], W. Hwu[1].* 1) Departments of Medical Genetics , National Taiwan University Hospital , Taipei, Taiwan; 2) Departments of Radiology, National Taiwan University Hospital , Taipei, Taiwan.

Background: Dysphagia is common in infants with Pompe disease, and most cases finally require gavage feeding. This study investigated the time of onset of dysphagia and its response to treatments in cases diagnosed at very young ages by newborn screening. Material and Methods: From December 2002 to December 2008, 13 infants (5 detected by newborn screening and 8 detected after clinical presentation) with infantile-onset Pompe disease underwent swallowing videofluoroscopic study (VFSS) every three months. All patients received alglucosidase alpha infusion 20 mg/kg every other week. Results: VFSS from the 5 screened cases performed at an age as early as 0.4 month (median 0.8 month, range 0.4-1.1 months) already showed delayed swallow trigger and pharyngeal residues. VFSS from the 8 clinical cases, however, showed severe abnormalities including laryngeal penetration and aspiration. Follow-up studies in the screened cases revealed stabilization of the VFSS scores and all cases remained orally fed, while dysphagia got worse in all but one clinical case. Conclusion: Dysphagia may develop at the first month in infants with Pompe disease. Early enzyme replacement and careful management could stabilize their swallowing.

## 3082/F/Poster Board #1014

**Atypical presentation of Lysinuric Protein Intolerance in an African-American Infant.** *I.A. Larson[1], U. Garg[2], D. Scott[2], A. Atherton[1], L.D. Smith[1].* 1) Metabolic Genetics, The Children's Mercy Hospital, Kansas City, MO; 2) Biochemical Genetics Lab, The Children's Mercy Hospital, Kansas City, MO.

Lysinuric Protein Intolerance (LPI) an autosomal recessive disorder due to defects in SLC7A7, a dibasic cationic amino acid transporter protein. This results in decreased intestinal absorption and decreased renal reabsorption of cationic dibasic amino acids and is most common in the Finnish population. Case Report: We describe a patient of African American descent with no history of Finnish ancestry, who presented at 3 weeks of age with respiratory distress and impending respiratory failure, metabolic acidosis, hyperammonemia and anemia. The patient was previously identified as having alpha thalassemia trait. The baby was asymptomatic while breastfeeding and a transporter defect was suspected after introduction of formula-based feedings led to acute decompensation. Initial biochemical studies were suggestive of LPI, but did not confirm the diagnosis because there was a lack of orotic aciduria and only mild elevations of urine dibasic cationic amino acids. The diagnosis was confirmed by protein challenge. The case was complicated by renal tubular dysfunction although alveolar proteinosis was not present. Anemia responded to iron therapy suggesting that bone marrow involvement was minimal at the time of diagnosis. Since diagnosis and initiation of diet and citrulline management the patient clinically has done well, has had no progression in symptoms and has had excellent catch-up growth. Conclusion: LPI should be part of a differential diagnosis in any patient with hyperammonemia, metabolic acidosis and anemia and that protein challenges can be extremely helpful as a diagnostic tool.

## 3083/F/Poster Board #1015

**Clinical and metabolic characterization of ten individuals with methylmalonic acidemia following solid organ transplantation.** *J.L. Sloan, I. Manoli, C.P. Venditti.* Genetics and Molecular Biology Branch, National Human Genome Research Institute, Bethesda, MD.

Methylmalonic acidemia (MMA) is caused by deficiency of the methylmalonyl CoA mutase apoenzyme or its cofactor cobalamin and is a devastating disorder, recalcitrant to medical management in many cases. Organ transplantation for MMA was first reported in the 1990s and since then several patients have received kidney (KT), liver (LT) and combined liver-kidney transplants (LKT). There is little information on the outcome and metabolic parameters of these patients and there are currently no guidelines regarding indications for transplant in MMA. We describe the medical history and clinical phenotype, obtained by inpatient evaluation, of 10 individuals with MMA that underwent various transplant procedures. Results: Mutation analysis and/or cellular biochemical studies were performed in all participants. Among the individuals with *mut⁰* MMA, there were: 2 KT, 2 LT, and 5 LKT; 1 combined transplant patient received an auxiliary liver graft. One patient with *cblA* deficiency received a KT and her metabolic parameters significantly improved after reinitiating B12 therapy. All 7 patients with *mut⁰* MMA s/p LKT or LT remained metabolically stable since transplantation (40 years combined follow-up). One *mut⁰* patient with KT and poor metabolic control reported repeat hospitalizations with metabolic acidosis. Another *mut⁰* patient who underwent a staged procedure developed renal failure requiring dialysis 1-year post-LT and a worsening movement disorder after liberalizing her diet. All had massively elevated methylmalonic acid in plasma (19-1047 μM, nl <0.4), urine (20-2276 mmol/mol cr, nl<3) and total whole body MMA output (0.32-51.2 mg/kg/day). Studies in this patient group, the largest assembled to date, afford the following conclusions: 1. LT and LKT, but not isolated KT, completely prevent ketoacidotic crises. 2. After LT, patients can develop renal failure and therefore require careful monitoring. There is a theoretical risk of KT and LKT patients developing renal insufficiency. 3. Although solid organ transplantation improves metabolic parameters, nutritional control and cofactor therapy, in B12 responsive patients, are required for optimal management following the procedure due to persistent metabolite elevations and the risk for late complications of the disease. Further studies on the post-transplant state are needed, particularly the examination of genotype and metabolic correlations between the patients pre- and post-procedure and the outcomes achieved.

### 3084/F/Poster Board #1016

**MAROTEAUX-LAMY SYNDROME OUTCOME IN A SEVERE FORM ASSOCIATED WITH CONGENITAL CARDIOPATHY IN A 3 YEARS OLD PATIENT.** *D. Giovannetti[1], M.A. Acosta[2], M.L. Solano[3].* 1) BioMarin Brasil Farmaceutica, Sao Paulo, Brazil; 2) Human Population Genetics, Titular Profesor in the Medicine Scholl from Universidad del Cauca, Colombia; 3) Hospital and Foundation Cardio-Infantil Bogotá_Colombia.

Mucopolysaccharidosis type VI or Maroteaux-Lamy syndrome is a lysosomal storage disease secondary to the partial to complete deficiency of arylsulfatase B. The patient usually presents coarse facial features, corneal clouding, organomegaly, joint stiffness and multiple dysostosis. Objective: This presentation aimed to report a case of a three years-old patient with MPS VI and a congenital cardiopathy Material and Methods: The patient was born in a small endogamic Indian community named Guambia, in the Department of Cauca - Colombia and have MPS VI symptoms first noted at 6 months old (organomegalia, hearing impairment and umbilical hernia) and a congenital cardiopathy. When she was 10 months old, the cardiac disease decompensate in a congestive cardiac failure due to arteriosus duct patency with great hemodynamic repercussion, severe mitral insufficiency, tricuspid insufficiency and biventricular dysfunction. She underwent a mitral valve replacement with an aortic prosthesis (mitral valve replacement with a biological valve) and a surgical closure of the duct arteriosus, being administered digoxin and antihypertensives in the postoperative period. With 2 years old, she had the MPS VI diagnosis confirmed through enzyme assay: arylsulfatase B activity 2.9 umol/H (reference value: >5.0) Her physical evaluation included coarse facial features, corneal clouding, enlarged tongue, shortened neck, umbilical hernia, hepatomegaly 4 cm. Tomography of cranium with 1 year and 10 months showed a mild ventricular dilatation. Radiographic evaluations dorso-lumbar kyphosis, moderate deformity of lumbar vertebrae caused by anterior wall tapering, bilateral coxa valga and talus varus, metatarsal and metacarpal shortening. Enzyme replacement therapy was started with Galsulfase 1 mg/kilogram/week with 2 years and 11 months and is been delivered weekly without adverse event. An improvement in the respiratory pattern is already noted. Discussion and Conclusions: The congenital cardiopathy's etiology remains uncertain but considering the highly consanguinity rate in the patieny's community, it can be explained by a autossomic recessive inheritance or a multifactorial pattern, and once we don't have any similar case in reported in the literature it's not likely to be related with the MPS VI severity. The ERT associated with early multidisciplinary intervention is safe and have the potential of decrease complications and delay the disease's evolution.

### 3085/F/Poster Board #1017

**Endocrine dysfunction in the mucopolysaccharidoses: a need for further investigation.** *K. Kim[1,2], B. Burton[1,2].* 1) Division of Genetics, Children's Memorial Hospital, Chicago, IL; 2) Department of Pediatrics, Northwestern University, Feinberg School of Medicine, Chicago, IL.

The mucopolysaccharidoses are a group of lysosomal storage disorders with a combined estimated prevalence of 1/22,500. Although highly variable, the disorders in this group are characterized by coarse facial features, skeletal anomalies, short stature, central nervous system abnormalities, cardiovascular disease, and hepatosplenomegaly, due to the progressive accumulation of glycosaminoglycans in various tissues. Little is reported in the literature regarding the endocrine function of MPS patients. Growth hormone deficiency and short stature is a known complication of stem cell/ bone marrow transplantation and has been observed in MPS I patients post-transplantation. Pathology studies post-mortem note accumulation of GAGs in the pituitary gland of MPS patients. One young boy with MPS VI was previously reported in the literature to have significant short stature compared to his affected brother and was found to have growth hormone deficiency. Given that little is known regarding the pituitary function of MPS patients, we examined nine patients with MPS I, II and VI for endocrine disorders and obtained screening labs, including T4, TSH, IGF1, IGFBP3, FSH, LH and fasting AM cortisol. Four patients had no significant findings on exam and normal lab results. Five patients were observed to have one or more of the following: low IGF1, low IGFBP3, premature adenarche, and hypogonadotropic hypogonadism. Given the clinical and laboratory observations in our patient population, we raise the possibility of underlying pituitary dysfunction in some MPS patients and advocate for further study in this area.

### 3086/F/Poster Board #1018

**Vitamin D deficiency and Fabry disease.** *D.P. GERMAIN[1, 2], K. BENISTAN[1], T.C. TRAN[1, 2].* 1) Medical Genetics Unit and Excellence Center for Fabry Disease, Hopital Raymond Poincare, Garches, 92380, France; 2) LGBC, UMR 8159, University of Versailles Saint Quentin en Yvelines, 78035 Versailles, France.

Background: Fabry disease (FD) is an X-linked inborn error of metabolism due to the deficient activity of alpha-galactosidase A, a lysosomal enzyme. FD is a systemic disease characterized by progressive renal insufficiency and added morbidity from cardio-and cerebro-vascular involvement. Vitamin D deficiency is a highly prevalent condition, present in 30% to 50% of the general population [1]. Traditionally, vitamin D has been associated primarily with bone health. However, a growing body of data suggests that low 25-hydroxy-vitamin D [25-OH D] levels may adversely affect cardiovascular (CV) health [1, 2]. Vitamin D deficiency activates the renin-angiotensin-aldosterone system and can predispose to left ventricular hypertrophy (LVH). No data is available regarding vitamin D deficiency in FD but, interestingly, osteopenia has recently been reported in FD [3] a condition in which LVH is highly prevalent. Patients & Methods: Serum 25-OH D levels were investigated in 28 consecutive patients affected with FD (15 M, 13 F) with estimated GFR >60 mL/min/1.73m². Vitamin D insufficiency was defined as 25-OH D serum level <30 ng/mL and vitamin D deficiency as 25-OH D serum level <20 ng/mL. Results: In the study population, the prevalence of vitamin D insufficiency was 82 (n=23) and the prevalence of vitamin D deficiency was 46% (n=13). Seven patients (25%) had serum 25-OH D levels <15 ng/mL while 3 patients (11%) had levels <10 ng/mL (severe deficiency). Normal 25-OH D levels were found in all patients living in the South of France while levels <10 ng/mL were found in all 3 patients with stroke. Discussion: The prevalence of vitamin D insufficiency and deficiency were 82% and 46%, respectively in patients affected with FD. Although FD patients may produce less vitamin D cutaneously because of efforts to minimize sun exposure and of decreased quality of life with indoor lifestyle, our results are comparable with figures found in the general population. Interestingly, very low 25-OH D levels were all associated with cerebrovascular accidents. Vitamin D supplementation is simple, safe, and inexpensive. Larger randomized controlled trials are needed to establish the role of vitamin D status to CV complications in FD but, meanwhile, monitoring serum 25-OH D levels and correction of vitamin D deficiency may prove interesting. 1. Lee JH et al. JACC.2008;52:1949-1956 2. Wang TJ et al. Circulation.2009;117:503-511 3. Germain DP et al. Clin Genet.2005;68:93-95.

### 3087/F/Poster Board #1019

**Surgical intervention in patients with Hunter syndrome: data from HOS - the Hunter Outcome Survey.** *N. Mendelsohn[1], B.K. Burton[2,3], K. Aleck[4] on behalf of the HOS Investigators.* 1) Dept Med Gen, Childrens Hosps Minnesota, Minneapolis, MN; 2) Children's Memorial Hospital, Chicago, IL; 3) Northwestern University Feinberg School of Medicine, Chicago, IL; 4) Saint Joseph's Hospital, Phoenix, AZ.

Hunter syndrome (mucopolysaccharidosis type II) is a lysosomal storage disease characterized by deficiency of the enzyme iduronate-2-sulfatase. Patients with this disorder can present with various signs and symptoms, including dysmorphic facial features and skeletal abnormalities, hepatomegaly and splenomegaly, respiratory problems, progressive hearing loss and cognitive impairment. Some disease manifestations may necessitate surgery. The present analysis was conducted to investigate the surgical interventions typically carried out in patients registered in HOS - the Hunter Outcome Survey - and the age at which these procedures were performed. As of April 2009,, HOS contained data on 681 patients with Hunter syndrome. This study focuses on the 541 HOS patients who were alive at HOS entry. Median age at diagnosis was 3.5 years (1.2-7.1, 10-90th percentile) and median age at last visit was 10.3 (3.7-23.4). In 487 prospective patients for whom surgery data were available, a total of 2067 surgical interventions were reported, with 85% of patients undergoing surgery at least once from birth to last visit in HOS. The most common surgeries were insertion of ear tubes (52%), hernia repair (50%), adenoidectomy (50%), tonsillectomy (35%) and carpal tunnel release (18%). 100 patients (21%) had recurrent hernia repair and 25 patients (5%) had surgery for carpal tunnel syndrome performed more than once. The early surgeries, performed at a median age of <5 years, were hernia (median age: 3.0 years, 0.2-11.5 years), ear tubes insertion (3.2, 1.3-7.5), adenoidectomy (3.5, 1.6-7.4) and tonsillectomy (4.3, 2.0-8.1). Carpal tunnel release was performed at a median age of 8.6 (4.5-19.3). The median times between diagnosis and first surgery were -0.3 (-5.3-7.8), 0.2 (-3.0-3.5), 0.3 (-2.1-3.5), 0.8 (-1.4-4.1) and 4.3 (0.6-11.2) years for hernia repair, ear tubes, adenoidectomy, tonsillectomy, and carpal tunnel release, respectively. These data highlight the early onset of disease manifestations in patients with Hunter syndrome. The frequency and age of which specific interventions were carried out is in line with the natural history of the disorder, with changes to the ears, nose, throat and airway occurring earlier and more frequently than skeletal abnormalities. Whether enzyme replacement therapy can prevent or reverse these manifestations is currently unknown and warrants further investigation.

## 3088/F/Poster Board #1020

**Abnormal Newborn Screening for Glutaric Acidemia Type I Associated with Infantile Renal Failure.** *G. Arnold.* Div Pediatric Gen, Univ Rochester Sch Med, Rochester, NY.

Purpose: Glutaric Acidemia Type I (GAI) is an inborn error of lysine, hydoxylysine and tryptophan metabolism resulting in profound sensitivity of the basal ganglia to permanent neurological damage from metabolic stress. We report three infants with renal failure who presented with false positive abnormal newborn screening (NBS) for GAI.

Case Reports: Case one was noted to be affected with Eagle-Barrett (Prune Belly) Syndrome and renal failure at birth. Initial and follow-up C5-DC levels are noted in the Table. The infant underwent successful renal transplantation. Case two was also noted to be affected with Eagle-Barrett Syndrome at birth. The infant died of sepsis following renal transplantation. Case 3 was noted to have enlarged cystic kidneys at birth. Newborn screen at 48 hours was normal, but repeat screen was abnormal one week later. Follow-up noted normal glutaric acid levels in blood and urine, normal 3-OH glutarate in urine, but minimal elevation of 3-OH glutarate in blood. Renal failure is slowly progressing. Over all cases, there appeared to be a positive correlation between creatinine and degree of elevation of C5-DC (r=0.68).

**Initial and Follow-up C5-DC in Infants with Renal Failure and Abnormal NBS**

| Patient | Creatinine (mg/dl) | NBS C5-DC (uM) | Ratio C5-DC/C3 | Follow-up C5-DC |
|---|---|---|---|---|
| 1 | 2.7-3.9 | 0.19 (nl <0.15) | 0.1 (nl <0.1) | 0.45-0.68 |
| 2 | 2.4-3.2 | 0.18 | 0.27 | 0.35-0.37 |
| 3 | 1.3-2.2 | 0.18 | 0.25 | 0.18 |

Discussion: Infantile renal failure appears to be associated with false positive newborn screening for glutaric adidemia type I. The mechanism might possibly be associated with poor renal filtration of this metabolite.

## 3089/F/Poster Board #1021

**Long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD) deficiency in Poland - population study.** *D. Piekutowska-Abramczuk[1], J. Wierzba[2], R.K.J. Olsen[3], E. Popowska[1], D. Jurkiewicz[1], M. Borucka-Mankiewicz[1], E. Ciara[1], P. Kowalski[1], A. Tańska[1], W. Gradowska[4], M. Oltarzewski[5], J. Sykut-Cegielska[6], M. Krajewska-Walasek[1], N. Gregersen[3], E. Pronicka[6].* 1) Medical Genetics, Children's Memorial Health Institute, Warsaw, Poland; 2) Pediatrics, Hematology, Oncology and Endocrinology, Medical Academy, Gdansk, Poland; 3) Research Unit for Molecular Medicine, University Hospital, Aarhus, Denmark; 4) Biochemistry, Children's Memorial Health Institute, Warsaw, Poland; 5) Screening Test, Institute of Mother and Child; 6) Metabolic Diseases, Endocrinology and Diabetology, Children's Memorial Health Institute, Warsaw, Poland.

Long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD) deficiency, an autosomal recessive disorder, is the most common defect of the mitochondrial fatty acids β-oxidation pathway in Poland. LCHAD activity is encoded by *HADHA* gene located on chromosome 2p23. 60-86% of reported patients with isolated LCHAD deficiency have a prevalent c.1528G>C substitution in exon 15 of the *HADHA* gene. Majority of them originate from the Baltic populations. Based on the urinary GC-MS organic acid profile, MS-MS blood acylcarnitines profile, and molecular studies 43 Polish patients (40 families) with LCHAD deficiency were identified. Using PCR-SSCP analysis, the common c.1528G>C substitution was revealed on 91% of mutated alleles. A tendency for clustering LCHAD deficient patients in northern part of Poland, especially in Pomeranian voivodeship, was found. The aim of our study was to determine the carrier frequency of the common mutation in various districts of Poland, and to verify the probable correlation between high number of Pomeranian patients and expected high frequency of the c.1528G>C carriers in this region. Up to now, 6015 blood samples collected on anonymous Guthrie cards, have been screened. Fifty six heterozygotes for c.1528G>C substitution (including 41 carriers from the Pomeranian region) were detected. No samples homozygous for the c.1528C allele were identified. These preliminary study confirmed the higher frequency of LCHAD deficiency carriers in northern part of Poland than in other parts of the country (1:73 versus 1:203) and the world. The possibility exist, that the common *HADHA* mutation could originate from this region of Poland. The study was partly supported by the Polish Ministry of Science Project 0678/B/P01/2007/33(N407 0678 33).

## 3090/F/Poster Board #1022

**Newborn screening for Fabry disease by measuring GLA activity using tandem mass spectrometry.** *O. Bodamer[1], A. Dajnoki[2], G. Fekete[2], J. Keutzer[3], J. Orsini[4], V. De Jesus[5], N. Chien[6], P. Hwu[6], Z. Lukacs[7], K. Zhang[3], A. Muhl[8].* 1) University Children's Hospital Salzburg, Austria; 2) 2. University Children's Hospital Budapest, Hungary; 3) Genzyme Inc, Boston, MA, USA; 4) Wadsworth Center, NYS State Department of Health, Albany, NY, USA; 5) Center for Disease Control, Atlanta, GE, USA; 6) National Children's Hospital Taipeh, Taiwan; 7) University Children's Hospital Hamburg, Germany; 8) Centogene Inc, Vienna, Austria.

Background: Fabry disease (FD) is an X-linked inherited lysosomal storage disorder caused by the deficiency of α-galactosidase A (GLA) that leads to progressive storage of neutral glycosphingolipids in vascular endothelium, podocytes and other tissues. The clinical phenotype in both affected females and males may include renal insufficiency, cerebro-vascular insults, cardiomyopathy and other symptoms. Enzyme replacement therapy is available and prompt initiation may improve morbidity and mortality. In order to facilitate high throughput screening we evaluated a tandem mass spectrometry method to measure GLA activity in newborn infants as well as adults. Methods: 3.2 mm punches from dried blood spots (DBS) were incubated with substrate (6-benzoylamino-hexyl)-{2-[4-(3,4,5-trihydroxy-6-hydroxymethyl-tetrahydro-pyran-2-yloxy)-phenylcarbamoyl]-ethyl}-carbamic acid *tert*-butyl ester) and internal standard (6-d5-benzoylamino-hexyl)-[2-(4-hydroxy-phenylcarbamoyl)-ethyl]-carbamic acid *tert*-butyl ester for 22 h. The resulting product and internal standard were quantified using MS/MS. The assay was validated and FD gender specific cut-off values were generated using routine newborn screening and adult samples. Results: GLA activity in DBS from 9 known juvenile and adult males with FD was 0.67+0.38 μmol/h/l.; in 32 female juvenile adult females with FD GLA activity was 1.83+1.14 μmol/h/l, while GLA activity in 6 (19%) females was well above the diagnostic cutoff of 2.6 μmol/h/l. GLA activity in 6 Taiwanese newborn infants with FD identified through newborn screening was 0.88+0.38. In addition, GLA activity levels were measured in routine newborn screening samples: male newborns: n = 5,051, median 9.8 μmol/h/l; mean + SD: 11.2 + 6.4 μmol/h/l, CI 95% 9.67-10.02 μmol/h/l; female newborns n= 4,707, median 10.2 μmol/h/l; mean + SD: 11.7 + 6.3 μmol/h/l, CI 95% 10.02-10.38 μmol/h/l) and normal adult samples. GLA activity was stable for 28 days between 37°C and -80°C. MS/MS carry over was negligible, while intra-run and inter-run variability were less than 10%. Conclusion: The MS/MS method for Fabry disease newborn screening is robust and can be readily multiplexed with other lysosomal disorders such as Pompe, Gaucher, Niemann-Pick, and Krabbe diseases.

## 3091/F/Poster Board #1023

**Diagnosis and prognosis: a model of cooperation in newborn screening for lysosomal storage disorders.** *M. Fuller, J. Tucker, D. Lang, M. Snel, J. Hopwood.* LDRU, SA Pathology at Women's and Children's Hospital, Adelaide, South Australia, Australia.

Lysosomal storage disorders comprise a group of about 50 complex, relatively uncommon inborn errors of metabolism resulting in significant mortality and morbidity. Newborn screening provides an opportunity for pre-symptomatic identification and early intervention to prevent or at least mitigate the pathology associated with these disorders. However, the wide phenotypic variability associated with lysosomal storage disorders poses a major caveat for the implementation of a newborn screening program; how will individuals who remain asymptomatic for subsequent years be managed? We are developing a multiplexed immune-quantification assay that is currently able to measure 14 different lysosomal proteins. Dried blood spots from 102 patients representing ten different lysosomal storage disorders along with 1471 controls were assayed to demonstrate the feasibility of this approach for newborn screening. Of the 102 patients included in the study 93 were positively identified by reduced lysosomal protein levels compared to controls, with 2% false positives observed. To address the need for prognostic information for lysosomal storage disorder patients identified at birth, we are developing a "metabolomics" approach. As lysosomal storage disorders are characterized by the accumulation of incompletely degraded material in lysosomes, this material can easily be measured by mass spectrometry. The primary storage material is usually the substrate for the deficient enzyme in each lysosomal storage disorder, and may consist of glycosphingolipids such as glucosylceramide or trihexosylceramide in Gaucher and Fabry diseases respectively; sphingomyelin in Niemann-Pick A/B; glycosaminoglycans in mucopolysaccharidoses; or glycogen in Pompe disease. For many lysosomal storage disorders, the primary storage has been shown to result in impaired lysosomal function leading to the accumulation of secondary metabolites that are not substrates for the deficient enzyme. We have used mass spectrometry to identify and quantify primary substrates as well as secondary altered metabolites in urine, blood and skin fibroblasts in a variety of lysosomal storage disorder patients. The data generated highlights the opportunity for these metabolites to be used in a predictive manner to determine the course the disease will take.

## 3092/F/Poster Board #1024

**Screening for Fabry Disease in Japan.** *K. Nakamura, K. Hattori, S. Matsumoto, H. Mitsubuchi, F. Endo.* Dept Pediatrics, Kumamoto Univ Sch Medicine, Kumamoto, Japan.

Fabry disease is an X-linked disorder of alpha-galactocidase A which causes the accumulation of glycolipids in lysosomes. The incidence of the classical type of the disease is approximately 1 in 40,000 males. Recent studies have revealed the late-onset type of the disease to have a higher frequency than previously known. To determine the disease incidence in Japan, we screened newborns to measure alpha-galactosidase A activity in dried blood spots from Japanese neonates. Enzyme-deficient infants were retested, and infants who were double-screening positive were diagnostically confirmed by enzymatic activity and mutation analyses. Ten neonates had a deficiency in alpha-galactosidase A activities and specific mutations, including two neonates with novel missense mutations, and eight neonates with known missense mutations identified previously in late-onset patients. Based on our newborn screening in Japan, the incidence of alpha-galactosidase A deficiency was 1 in 5,600 (1 in 5,600 male). Based on enzymatic activities, the incidence was 1 in 4,000 (1 in 3,100 male). These results suggest that the late-onset phenotype of Fabry disease is underdiagnosed among both males and females in Japan. The recognition of the existence of these patients suggests the need for both early diagnosis and therapeutic intervention. However, ethical issues need to be taken into consideration in terms of when and whom the screening should be performed.

## 3093/F/Poster Board #1025

**Newborn screening for lysosomal storage diseases by MS/MS: Fabry disease.** *C.R. Scott[1], G. Bellamy[2], J. Daiker[2], S. Shaunak[2], R. Jack[3], A.C. Fox[1], F. Turecek[4], M. Gelb[4].* 1) Dept Pediatrics, Univ Washington Sch Med, Seattle, WA; 2) Washington State Newborn Screening Lab, Shoreline, WA; 3) Seattle Children's Hospital, Seattle, WA; 4) Dept Chemistry, Univ Washington, Seattle, WA.

With the advent of enzyme replacement therapy (ERT) for selected lysosomal storage diseases (LSDs), the issue of newborn screening for these disorders has been proposed. We have synthesized novel substrates and internal standards that can be used for the MS/MS assay of enzymes responsible for Gaucher, Fabry, Pompe, Niemann-Pick A/B, Krabbe, MPS-1, MPS-II, and MPS-VI.

To validate the technology for the MS/MS detection of the LDS's, we have initiated a field trial within the Washington State Newborn Screening laboratory for the newborn detection of Fabry disease. After several thousand assays performed on newborn blood spots, the following outcomes are apparent:

--A single 3-mm blood spot can be used for one or more enzyme assays

--The population distribution of enzyme activity for $\alpha$-galactosidase is "log-normal"

--The median activity for $\alpha$-galactosidase from the 3-mm blood spot is 10$\mu$mol/L/hr

--The enzyme activity from the 3-mm blood spot as determined by MS/MS correlates well with our enzyme activity using a fluorometric substrate ($r^2$=0.93)

--The coefficient of variation (CV) is 0.16, 0.22, and 0.10 for low, medium, and high standards supplied by the CDC

--Affected male patients have activity values $<2\mu$mol/L/hr

The limiting factor in adapting the technology to a newborn screening laboratory is the number of pipetting steps as compared to procedures proceeding MS/MS analysis of amino acids or acylcarnitines that are currently being analyzed. Commercial robotic pipettors will be necessary for successful implementation of MS/MS detection of LSD's by enzymatic quantitation.

Sponsored by NICHD HHSN267200603429 and Genzyme Corporation.

## 3094/F/Poster Board #1026

**The CPT1 p.P479L Allele in Northern Canadian Populations: Does it Confer Risk for Infant Mortality?** *S.A. Collins[1], G. Sinclair[2], H.D. Vallance[2], C.R. Greenberg[3], I. Sobol[4], A. Corriveau[5], B. Hanley[6], G. Osbourne[4], T.K. Young[7], L. Arbour[1].* 1) Dept of Medical Genetics, University of British Columbia, Vancouver, BC; 2) Dept of Pathology and Laboratory Medicine, University of British Columbia, Vancouver, BC; 3) Dept of Pediatrics and Child Health, University of Manitoba, Winnipeg, MB; 4) Health and Social Services, Nunavut; 5) Health and Social Services, North West Territories; 6) Health and Social Services, Yukon; 7) Division of Epidemiology, Dalla Lana School of Public Health, University of Toronto, Toronto, ON.

Introduction: Canada's three Northern territories are home to about 100,000 people, of which nearly 50% are of Aboriginal ancestry. Infant mortality rates increase from west to east, with Nunavut having the highest at 15/1000 live births. Hepatic carnitine palmitoyl-transferase I (CPTI, encoded by *CPT1a*) imports long-chain fatty acids into mitochondria for use in fatty acid oxidation. CPTI deficiency in its severe form may present in infancy with hypoketotic hypoglycemia, seizures, hepatoencephalopathy and sudden death, if not treated. A *CPT1a* variant, p.P479L (c.1436 C>T), is present in British Columbia (BC) First Nations, Canadian and Greenland Inuit and Alaska Natives. Although the association of the variant with infant mortality has not yet been established, a number of homozygous BC First Nations and Inuit children have presented symptomatically. Interestingly, allele frequencies in the Kivalliq region of Nunavut Canada and Greenland Inuit populations are high (0.81 and 0.73 respectively; Greenberg et al. 2009, Rajakumar et al. 2009), but the frequency has not been established in other Canadian Northern populations. Objective: To provide background data of p.P479L allele frequencies in Canada's North and to ultimately determine if the presence of the allele contributes to the excess of infant mortality. Methods: Ethics approval was obtained from university REBs, local research institutes and with consultation with territorial Aboriginal groups. *CPT1a* p.P479L prevalence was determined by genotyping newborn blood spots of infants born in 2006 in Yukon, Northwest (NWT) and Nunavut Territories (n=1584) using the Taqman allelic discrimination RT-PCR assay. p.P479L allele frequencies in the three territories were 0.02, 0.08 and 0.77 in Yukon (n= 325), NWT (n=564) and Nunavut (n=695), respectively. Homozygosity rates were 0%, 3% and 64%. Aboriginal status was available for NWT, with allele frequencies of 0.04, 0.44, 0.00 and 0.01 for First Nations, Inuvialuit/Inuit, Métis and non-aboriginal populations. Conclusion: Although the allele is present in all three territories, the rates of homozygosity are high only in the Inuit populations, suggesting a possible advantage to individuals historically living in the North. Further study is underway to determine if p.P479L variant is associated with infant mortality will provide background information to determine if newborn screening or other preventative health measures are warranted.

## 3095/F/Poster Board #1027

**Newborn screening and early biochemical follow-up in combined methylmalonic aciduria and homocystinuria, cblC type, and utility of methionine as secondary screening analyte.** *J.D. Weisfeld-Adams[1], M.A. Morrissey[2], B. Kirmse[1], B.R. Salveson[1], M.P. Wasserstein[1], P.J. McGuire[1], C. Yu[1], M. Caggana[2], G.A. Diaz[1].* 1) Department of Genetics & Genomic Sciences, Mount Sinai School of Medicine, New York, NY; 2) 2New York State Newborn Screening Laboratory, Wadsworth Laboratory, Empire State Plaza, Albany, NY.

**Introduction**: Combined methylmalonic aciduria and homocystinuria, cobalamin C (cblC) type, is an inherited disorder of vitamin B12 metabolism caused by mutations in MMACHC. CblC typically presents in the neonatal period with neurological deterioration, failure to thrive, cytopenias, and multisystem pathology including renal and hepatic dysfunction. Rarely, affected individuals present in adulthood with gait ataxia and cognitive decline. Treatment with hydroxycobalamin may ameliorate the clinical features of early-onset disease and prevent clinical late-onset disease. Propionic acidemia (PA), methylmalonic acidemia (MMA), and cblC, cblD and cblF diseases are characterized by elevated propionylcarnitine (C3) on Newborn Screening (NBS). Distinctions can made between these disorders with secondary analyte testing. Elevated methionine is already routinely used as a NBS marker for cystathionine $\beta$-synthase deficiency. Low methionine may be useful as a secondary analyte for specific detection of cbl disorders among a larger pool of infants with elevated C3 on NBS. **Methods**: Retrospective analysis of dried blood spot (DBS) data in patients with molecularly confirmed cblC disease. **Results**: 9 out of 10 patients with confirmed cblC born in New York between 2005 and 2008 had methionine below 0.2 mg/dL on NBS. We incorporated elevated C3, elevated C3:C2 ratio, and low methionine into a simple screening algorithm, providing a specific and novel method of distinguishing cblC from other disorders of propionate metabolism prior to recall for confirmatory testing. **Conclusions:** We anticipate that this algorithm will aid in specific and early detection of cblC, cblD, and cblF, with little additional expense to NBS laboratories screening for organic acidemias and classical homocystinuria.

## 3096/F/Poster Board #1028

**Amino acids and acylcarnitines concentration in blood spots from low birth weight infants.** *M. Pasquali[1,3], C. Haslip[3], N. Longo[1,2,3], F. Keune[4], H. Randall[4].* 1) Pathology, Univ Utah, Salt Lake City, UT; 2) Pediatrics, Univ Utah, Salt Lake City, UT; 3) ARUP Laboratories, Salt Lake City, UT; 4) Utah Department of Health, Salt Lake City, UT.

Tandem mass spectrometry (MS/MS) is routinely used for the screening of newborns for inherited metabolic disorders. Amino acids and acylcarnitines are extracted from the blood spots and quantified to allow the identification of amino acidopathies, organic acidemias, and disorders of fatty acid oxidation. As in any screening methods, false positive results can occur. The group of infants with the highest rate of false positive results is represented by infants in neonatal intensive care units, many of whom have low birth weight. These infants often require immediate intervention that may affect the values of the amino acids and acylcarnitines measured by MS/MS. We have analyzed the values obtained in three years of screening by MS/MS in Utah according to birth weight (BW). We arbitrarily chose 4 BW groups: < 1000 g, 1000-2000g, 2000-2500g, and > 2500 g and compared the percentile values for all analytes in all groups both in the first screen (collected at < 6 days of age) and in the second screen (7-28 days of age). Our results show that the median values for most analytes, amino acids or acylcarnitines, do not vary significantly among the BW groups. The biggest differences are observed in the highest percentiles (99th and above) of the amino acids. The two lowest BW groups have the highest values for all amino acids. This most likely reflects intravenous hyperalimentation. Interestingly, the long chain acylcarnitines (C16, C18) show the lowest percentile values in the lowest BW groups. This is likely explained by the fact that this group of infants has the highest rate of transfusion, resulting in a pattern of long chain acylcarnitines resembling the "adult" pattern, with lower concentrations of long-chain acylcarnitines. Among the acylcarnitines, C5-carnitine has the highest values in the lowest BW groups. C5-carnitine is elevated in metabolic disorders and during therapy with ampicillin, an antibiotic frequently used in infants admitted to neonatal intensive care units for possible sepsis. Our study shows that the median concentration of amino acids and acylcarnitines does not change significantly with birth weight. However, the distribution of values around the median is affected by medical treatment (intravenous hyperalimentation, transfusions, antibiotic therapy) frequently given to low birth weight infants. Consideration of these artifacts can reduce the frequency of false positive results in low birth weight infants.

## 3097/F/Poster Board #1029

**Positive Newborn Screening for Carnitine Transporter Deficiency: A Marker for Maternal Genetic/Metabolic Diseases?** *C. Prasad[1], J. DiRaimo[1], P. Chakraborty[2], S. Goobie[1], C.A. Rupar[3].* 1) Department of Pedatrics (Genetics), London Health Sciences Centre, London, ON, Canada; 2) Ontario Newborn Screening Program, Children's Hospital of Eastern Ontario, University of Ottawa; 3) Departments of Pediatrics, Biochemistry, and the Children's Health Research Institute, University of Western Ontario, London, Ontario, Canada.

Background: Primary carnitine deficiency is caused by mutations in the carnitine transporter *OCTN2* gene. Primary carnitine deficiency, 3-methylcrotonyl CoA carboxylase deficiency, and glutaric aciduria type 1 are some of the maternal disorders that have been detected secondary to a positive newborn screen for carnitine transporter deficiency. Methods: Ontario Newborn Screening Program referred 120 newborn screen positive infants to the London Health Sciences centre over last 3 years. Out of these 28 were initially positive for carnitine transporter defect (free carnitine level <10uM). None of them were true positives. We present two cases where the mothers had alternative diagnoses to account for their low carnitine levels. Results and Summary: In the first case, a male infant tested positive for carnitine uptake defect with free carnitine level of 7.4uM. Confirmatory testing was normal.The mother's investigations revealed free carnitine level at 0 umol/L (10-30 umol/L). Her urine organic acids showed suberic acid, phenylpropionyglycine, and suberylglycine and increased levels of C6, C8, C10:1 and C10:2. Molecular investigations showed homozygosity for the A985G mutation in the MCAD gene, confirming diagnosis of MCADD. The mother was 26 years of age, asymptomatic and has had two uneventful pregnancies. The second infant (female) tested positive for carnitine uptake defect with an initial free carnitine level of 7.9uM. Confirmatory testing revealed normal results. The maternal history confirmed diagnosis of cystic fibrosis. She is heterozygous for Delta F508 mutation in exon 10, and a rare R347-->P :G1172-->C mutation in exon 7. The mother's free carnitine and total carnitines were borderline low at 13 umol/L (20-53 umol/L) and 22 umol/L (25-73 umol/L) respectively. Conclusions:The pathogenesis in above scenarios is likely due to poor carnitine stores in the mothers leading to a false positive result for carnitine uptake deficiency in the newborns. These cases illustrate the importance of a detailed maternal history and confirmatory screening by acylcarnitine profile, urine organic acids, and carnitine levels in mothers of newborns with positive carnitine transporter deficiency screening results. The detection of asymptomatic MCADD and other maternal genetic metabolic disorders will provide proper management, family screening, and prevention of complications as sudden deterioration can occur with these disorders at any age.

## 3098/F/Poster Board #1030

**G6PD and CAH in Alexandria, Egypt: A high frequency justifying the need for a community- based newborn screening program.** *S. Tayel[1,2], H. Ismail[2,3], H. Kandil[4], I. Marzouk[5], A. Abd Rabou[2], H. Sallam[2,6].* 1) Anatomy Dept, Genetics Unit, Alexandria Faculty of Medicine, Alex., Egypt; 2) Suzanne Mubarak Regional Centre for Women's Health & Development, Alex., Egypt; 3) High Institute of Public Health, Alex., Egypt; 4) Consultant Pediatrician, Ministry of Health, Alex., Egypt; 5) Pediatrics Department, Faculty of Medicine, Alex., Egypt; 6) Obstetrics & Gynaecology Department, Faculty of Medicine, Alex., Egypt.

INTRODUCTION: Neonatal screening program for congenital hypothyroidism has been established at the national level in Egypt in 2000. Glucose-6-phosphate dehydrogenase (G6PD) deficiency is the most frequent enzyme deficiency. It is a sex-linked genetic disease concerning mostly African, Mediterranean and far-eastern populations. The main clinical expression is a hemolytic anemia which can be acute or chronic. During the neonatal period the disease may manifest as neonatal jaundice. Congenital adrenal hyperplasia (CAH) is increasingly being included in newborn screening programs. The main benefits of screening are avoidance of serious salt loss crises and early proper gender assignment in virilized girls. OBJECTIVES: To determine the prevalence of G6PD deficiency and CAH in Alexandria, Egypt. METHODS: From June, 2008 to May, 2009, a total of 13,000 samples from newborns at 3-7 days of age were screened by the time resolved fluoroimmunoassay method (DELFIA; PerkinElmer) for the quantitative measurement of G6PD activity (6000 samples from male newborns) and for 17-hydroxyprogesterone determination (7000 male and female samples). Any neonate with a value < 2.6 U/gHb and > 30 nmol/l was considered positive for G6PD deficiency and CAH respectively. RESULTS: Of the 6000 male newborns screened, 149 (2.12%) were found to have G6PD deficiency. Of the 7000 male and female newborn screened, 11 (0.16% or 1.6/1000) were affected by the CAH. The mean enzyme activity in G6PD deficient patients was 1.27 +/- 0.4 U/gHb. CONCLUSION: The relatively high prevalence of G6PD deficiency and CAH in Alexandria, Egypt justifies the recommendation to include these two diseases in the national hypothyroidism screening program in Egypt. Efforts are now being undertaken to ensure their nationwide implementation in the newborn screening program.

## 3099/F/Poster Board #1031

**Neuropsychological function in individuals with phenylketonuria treated with Kuvan.** *D.K. Grange[1], S.E. Christ[2], D.A. White[3].* 1) Dept of Pediatrics, Div of Genetics and Genomic Medicine, Washington University, St Louis, MO; 2) Dept of Psychological Sciences, University of Missouri, Columbia, MO; 3) Dept of Psychology, Washington University, St. Louis, MO.

Phenylketonuria (PKU) is a hereditary disorder resulting in disrupted metabolism of phenylalanine (Phe). The profound effects of elevated Phe once associated with PKU, such as mental retardation and seizures, have largely been eliminated through dietary restriction of Phe. However, Phe often remains elevated even in patients considered to be well treated by diet alone. As a result, although more subtle than in the past, PKU patients continue to exhibit neurologic abnormalities and impaired cognition. Kuvan (sapropterin dihydrochloride/BH4) is a pharmaceutical treatment that lowers Phe in BH4 responders and holds promise for improving brain function and cognition. In our study, brain and cognition are examined in PKU patients immediately before beginning treatment with Kuvan (20 mg/kg/day) using MRI and neuropsychological tests of intelligence (IQ), executive abilities, and reaction time (RT). For patients who respond to Kuvan with a reduction of ≥20% in Phe within 4 weeks of beginning treatment, brain and cognition are again examined after 6 months of Kuvan treatment. We hypothesize that improvements in brain and cognition will occur with Kuvan treatment. Here we report results from the baseline neuropsychological evaluation of the first 7 PKU patients enrolled. Patients are from 9 to 20 years of age (M=14, SD=4), with Phe ≥360μmol/L. Patients' neuropsychological performance is compared with that of 10 normal controls from 8 to 22 years of age (M=15, SD=5). Our findings indicate that PKU patients have significantly poorer IQ and executive abilities than controls. The IQ of PKU patients ranged from 75 to 109 (M=92, SD=12), whereas the IQ of controls ranged from 89 to 117 (M=107, SD=9), t(15)=2.7, p<.05. Regarding executive abilities, PKU patients performed more poorly than controls on tests of inhibitory control, working memory, and strategic processing, t(15)≥3.0, p<.01 in all instances. The PKU and control groups, however, were not significantly different on measures of simple RT (p>.05). These results reflect specific impairments in intelligence and executive abilities in PKU patients treated with diet alone prior to treatment with Kuvan. Data collection is ongoing. At the conference, baseline findings from newly enrolled patients will be presented. In addition, findings from 6 month evaluations of BH4 responsive patients will be presented to evaluate whether improvements in brain and cognition are associated with Kuvan treatment.

### 3100/F/Poster Board #1032

**Overexpression of Arginase in neurons as a potential protective model against nitric oxide mediated neurotoxicity.** *B. Keller[1], T. Bertin[1], B. Lanpher[2], O. Shchelochkov[1], B. Lee[1,3].* 1) Baylor College of Medicine, Molecular and Human Genetics, Houston, Texas, United States; 2) Vanderbilt University School of Medicine, Nashville, Tennessee, United States; 3) Howard Hughes Medical Institute, Houston, Texas, United States.

Nitric oxide (NO) is an important messenger molecule. In the brain it plays an important role in synaptic plasticity and has a role in the regulation of the neurophysiological phenomenon underlying memory and depression. NO has a pivotal role in neuronal development; low levels have been described to be protective in neurons degeneration but high levels of NO cause neuronal destruction. NO is synthesized from aginine by the nitric oxide synthases (NOS) enzymes. However; arginine is also the substrate for arginase to generate ornithine, the last metabolite in the urea cycle. In mammals, there are two isoforms of arginase; the cytoplasmatic isoform, arginase I, functions predominantly in the liver to detoxify the body from harmful ammonia. Arginase II regulates arginine/ornithine concentrations in the cell. The later isoform is located in mitochondria of the kidney and the prostate and at lower levels in mammary glands, macrophages, as well as the brain. Both isoforms compete with the nitric oxide synthases for their rate limiting substrate arginine, leading to decreased formation of nitric oxide. We hypothesize that overexpression of arginase in the brain will be a protective model for nitric oxide mediated neurotoxicity. We generated a transgenic mouse model over expressing arginase I specifically in neurons under the control of the Thy-1 promoter. Founders show an up to 30 fold over expression of arginase I with comparable enzyme activity. The mice survive, have normal growth, are fertile with offspring born in mendelian ratio. H&E Staining and neuron specific Nissl staining show no abnormalities compared to wild type mice. This model will be a valuable tool to further test whether genetic inhibition of nitric oxide production will decrease neurotoxicity in neurologic diseases such as traumatic brain injury (TBI) and amyotrophic lateral sclerosis (ALS).

### 3101/F/Poster Board #1033

**Potential applications of fluorescence-labeled α-L-iduronidase.** *B. Tippin, S. Kan, L. Troitskaya, P. Dickson.* Los Angeles Biomedical Research Institute at Harbor-UCLA Medical Center, 1124 West Carson St, Torrance, CA 90502.

Mucopolysaccharidosis I (MPS I) is an inherited, lysosomal storage disease caused by lack or low level of α-L-iduronidase (IDU), resulting in progressive accumulation of glycosaminoglycan (GAG) in lysosomes of different tissues including the brain. Some clinical improvement in patients has been observed by enzyme replacement therapy (ERT) with recombinant human IDU (rhIDU; laronidase, Aldurazyme), but the treatment of central nervous system (CNS) involvement is limited due to the difficulty of rhIDU to penetrate through the blood-brain barrier. Thus, cerebrospinal fluid (CSF) delivery is being investigated to apply rhIDU to CNS directly. While rhIDU distributes widely in MPS I dogs at 48 hours following intra-CSF injection, earlier and more precise time estimates of CSF delivery are hampered by the need for serial measurements at different locations. Fluorescent-labeled rhIDU will allow us to study CSF distribution *in vivo* in small animal models, and *ex vivo* using confocal microscopy.

rhIDU was labeled with Alexa Fluor 680 dye (Molecular Probes) to DOL = 3.50 (degree of labeling: moles dye per mole protein). Purified, labeled-rhIDU retained its activity towards the artificial substrate 4MUI *in vitro* when compared to non-labeled rhIDU. Uptake kinetics of labeled-rhIDU into human MPS I fibroblasts ($k_{uptake}$ of 0.72 nM ) matched previously reported values for unlabeled rhIDU ($k_{uptake}$ of 0.7 nM) (Kakkis E. *et al.* 1994 Protein Expr Purif. **5**: 225-32). Furthermore, the labeled-rhIDU was directly detected in MPS I fibroblasts by confocal microscopy, and its subcellular localization was verified within lysosomes by Lysotracker® and antibody against rhIDU. These results suggest that the label does not significantly interfere with the enzyme's ability to enter cells or disturb its active site.

This study demonstrates that fluorescent-labeled rhIDU will be a valuable tool to assess enzyme distribution in CSF and other tissues of interest, with potential for *in vivo* and *ex vivo* applications.

### 3102/F/Poster Board #1034

**Cause of Death in MPS I Registry Patients.** *C. Whitley[1], G. Cox[2], J. Wraith[3], P. Fernhoff[4].* 1) University of Minnesota, Minneapolis, MN; 2) Genzyme Corporation, Cambridge, MA; 3) Royal Manchester Children's Hospital, Manchester, UK; 4) Emory University, Atlanta, GA.

Background: The MPS I Registry is a global, voluntary, observational database that has collected anonymous, longitudinal data on over 700 patients since its inception in 2003. The Registry database is a unique resource to study the factors that impact the timing and cause of death in MPS I patients.

Methods: Registry data were collected prospectively and retrospectively (1979-2008). Two-thirds (67%) of deceased patients were posthumously enrolled. Data were categorized by phenotype, and cause of death. In 32 (22%) deceased patients, more than one cause of death was reported in multiple organ systems.

Results: Twenty percent (n=145) of Registry (N=729) patients were deceased. The majority (88%; 128/145) of deceased patients were clinically categorized with Hurler syndrome, the most severe phenotype of MPS I. Thirty-one percent of all Hurler patients (128/408) were deceased, compared to 8% of Hurler-Scheie (14/171) and 3% of Scheie (2/74) patients. Phenotype was undetermined for one deceased patient. The most common causes of death were respiratory and/or cardiac (46%), unknown (24%), and complications related to hematopoietic stem cell transplantation (HSCT) (13%). In 27 MPS I patients with a known respiratory cause of death, death was attributed to pneumonia (n=7), respiratory failure (n=8), pulmonary hemorrhage and/or edema (n=4), and other respiratory causes (n=8). In the 21 MPS I patients with a known cardiac cause of death, cardiac arrest (n=10) and cardiac failure (n=6) were the most frequently reported causes of death. Cardio/respiratory causes of death in 19 patients included cardiopulmonary failure (n=13), cardiopulmonary arrest (n=5), and severe heart abnormalities/pulmonary edema (n=1).

Conclusions: The most common causes of death in MPS I Registry patients were pulmonary and/or cardiac. Monitoring disease progression in these organ systems may provide important insight into the impact of treatment on morbidity and mortality.

### 3103/F/Poster Board #1035

**Principal components factor analysis of the insulin-like growth factor I (IGF-I) axis reveals a quantitative trait locus on chromosome 16p that is longitudinally associated with insulin and is mediated by IGF binding protein 3 and tumor necrosis factor-α.** *P.B. Higgins, V.P. Diego, S.A. Cole, T.D. Dyer, J.E. Curran, M.P. Johnson, E.K. Moses, L. Almasy, H.H.H. Göring, A.G. Comuzzie, J.W. MacCluer, M.C. Mahaney, J. Blangero.* Dept Genetics, SW Foundation Biomed Res, San Antonio, TX.

The insulin-like growth factor I (IGF-I) axis exerts important influences on insulin metabolism. Recently, the IGF binding proteins (IGFBPs), which are critical components of the IGF-I axis, have been found to exhibit influences on insulin metabolism that could be divided into IGF-I-dependent and -independent mechanisms. We hypothesized that a principal components factor analysis (PCFA) approach would be ideally suited to studying this system because of its ability to extract from the data factors that are correlated within but that are mutually orthogonal. To this end, we performed PCFA on the IGF-I axis, which is represented in our data by IGF-I, IGFBP1, IGFBP3, and the molar ratios of IGF-I to IGFBP1 and to IGFBP3, herein named ratioBP1 and ratioBP3. The latter variables are understood to be rough measures of free IGF-I. While the number of variables is quite small for a usual PCFA, the method is being used for its ability to extract mutually orthogonal factors, which speaks to mechanism in the present case. We found 3 factors, an axis factor comprised of IGF-I, ratioBP1, and ratioBP3, an IGFBP1 factor comprised of IGFBP1 and ratioBP1, and an IGFBP3 factor comprised of IGFBP3 and ratioBP3, which accounted for 45%, 29%, and 22% of the variance, respectively. Using a maximum likelihood variance components (VC) approach, we performed multipoint genome-wide scans of these 3 factors. For the IGFBP3 factor, we found a LOD score of 3.6 on chromosome 16 at the p-terminus, which is the location of the acid-labile subunit (*IGFALS*) gene. This is a significant finding because the vast majority of IGF-I is bound up in the blood stream by a complex comprised of IGFBP3 and IGFALS. Moreover, loss of function mutations in the *IGFALS* gene in humans and animal models are associated with dysregulated insulin metabolism. Bivariate VC analyses of the IGFBP3 factor with a gene expression measure (mRNA levels) of tumor necrosis factor-α (TNF-α) and with fasting insulin (FI) measured 5 years later from when the IGF-I axis variables were measured revealed LOD scores of 3.55 and 3, respectively, again at the p-terminus of chromosome 16. The IGFBP3 factor was significantly positively correlated with TNF-α, and significantly negatively correlated with FI. Together, these results may mean that IGFBP3 and TNF-α act to influence FI, and are pleiotropically regulated by the same locus, which is potentially the *IGFALS* gene.

**Accelerated neutrophil apoptosis in a congenital neutropenia syndrome, glucose-6-phosphatase-beta deficiency, is mediated by the mitochondrial stress pathway.** *H.S. Jun, Y.Y. Cheung, J.Y. Chou.* SCD, PDEGEN, NICHD, NIH, Bethesda, MD.

Accelerated neutrophil apoptosis in a congenital neutropenia syndrome, glucose-6-phosphatase-beta deficiency, is mediated by the mitochondrial stress pathway Hyun Sik Jun, Yuk Yin Cheung, and Janice Y. Chou, Section on Cellular Differentiation, Program on Developmental Endocrinology and Genetics, National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, MD 20892 Neutrophils, the first line of defense against bacterial or fungal infections, differentiate and mature in the bone marrow (BM). We have previously shown that G6pc3-/- mice lacking glucose-6-phosphatase-β (G6Pase-β or G6PC3) manifest neutropenia and that activated G6pc3-/- neutrophils, isolated from peritoneal exudates, exhibit dysfunction, increased production of endoplasmic reticulum (ER) chaperones, and enhanced apoptosis. Using a negative immunomagnetic depletion system to isolate resting neutrophils from the BM, we now show that G6pc3-/- BM is neutropenic, prior to extravasation, and that the resting neutrophils exhibit impaired respiratory burst, chemotactic, and calcium flux activities. Moreover, G6pc3-/- BM neutrophils exhibit ER stress, oxidative stress, and ultrastructural alterations of the ER. Activation of the protein kinase-like ER kinase (PERK) along with increased expression of phosphorylated eukaryotic translation initiation factor 2α, activating transcription factor 4, and C/EBP-homologous protein demonstrate the involvement of the PERK-mediated ER stress signaling pathway. G6pc3-/- BM neutrophils exhibit increased Annexin V binding and caspase-3 activation, consistent with an increased rate of apoptosis. Bax activation, mitochondrial release of pro-apoptotic effectors and caspase-9 activation demonstrate the involvement of the intrinsic mitochondrial apoptotic pathway. Taken together, the results demonstrate a critical role for G6Pase-β in ER homeostasis and normal neutrophil functions. This research is supported by the Intramural Research Programs of the NICHD, NIH.

### 3105/F/Poster Board #1037

**Enzyme replacement therapy given from birth may prevent brain GAG accumulation in MPS I dogs.** *S. Le[1], N.M. Ellinwood[2], A. Dierenfeld[2], J. Jens[2], E. Snella[2], C. Vogler[3], M. Passage[1], P. Dickson[1].* 1) Los Angeles Biomedical Research Institute at Harbor-UCLA Medical Center, 1124 West Carson St, Torrance, CA 90502; 2) Department of Animal Science, Iowa State University, 2356D Kildee Hall, Ames, IA 50011; 3) Department of Pathology, Saint Louis University School of Medicine, 1402 South Grand Blvd, St. Louis, MO 63104.

Intrathecal (IT) enzyme replacement therapy (ERT) has been studied in mucopolysaccharidosis I (MPS I) dogs as a way to reduce glycosaminoglycan (GAG) storage in brain. IT ERT in adult MPS I dogs showed reduction in brain GAG to normal levels, while intravenous (IV) ERT alone in adult MPS I dogs showed no significant changes in brain GAG storage to untreated MPS I. We tested IV ERT with recombinant human α-L-iduronidase in MPS I dogs 3-24 days old to determine whether GAG accumulation in the brain could be prevented. 4 MPS I dogs received weekly IV ERT at 0.58 mg/kg/wk, and 4 MPS I dogs received weekly IV ERT at 1.57 mg/kg/wk. 4 MPS I dogs received weekly IV ERT at 0.58 mg/kg/wk with quarterly (every three month) IT ERT at 0.059 mg/kg. Dogs were treated for 56-81 weeks, and were 13-19 mos. old at end-study. 6 age-matched MPS I dogs and 9 normal dogs were used as untreated controls. Whole brain GAG measured by alcian blue binding method in MPS I dogs treated from birth was 5.74 ± 0.160 μg GAG/mg dry weight (0.58 mg/kg IV ERT group, $p = 0.0013$ versus untreated), 4.43 ± 0.269 (1.57 mg/kg IV ERT group, $p = 0.0001$ vs. untreated), and 3.87 ± 0.312 (IT + IV group, $p = 0.0001$ vs. untreated). Brain GAG in MPS I untreated controls was 8.19 ± 0.984, and in normal controls was 5.40 ± 1.82. Tissue pathology by light and electron microscopy is pending. MPS I dogs treated from birth with clinically-used 0.58 mg/kg IV ERT, higher 1.57 mg/kg IV ERT, and IT + IV ERT show brain GAG storage comparable to normal levels. ERT from birth may be an effective strategy to prevent brain GAG accumulation in MPS I disease.

**Immune tolerance induction in enzyme replacement therapy for Pompe disease by anti-CD3 antibody and oral enzyme administration.** *T. Ohashi[1,2,3], S. Ilzuka[2], Y. Eto[3], H. Ida[1,2,3].* 1) Dep of Pediatrics, The Jikei Univ Sch of Medicine, Minatoku Tokyo, Japan; 2) Inst DNA Mecicine, The Jikei Univ Sch of Medicine, Minatoku Tokyo, Japan; 3) Dep of Genetic Diseases, The Jikei Univ Sch of Medicine, Minatoku Tokyo, Japan.

Enzyme replacement therapies (ERT) for 6 lysosomal storage diseases including Gaucher disease, Fabry disease, Pompe disease, mucoplysaccharidosis type I, II and VI, are approved in developed countries. Although their efficacy was proven in many clinical trials, a couple of limitations were turned out. Among them, negative impact of neutralizing antibody to enzyme was one of major limitation in ERT. In fact, we and others already reported negative impact of antibody for therapeutic efficacy of ERT in lysosomal storage diseases. To overcome these obstacles, we tried to induce immune tolerance to infused enzyme. Among 6, lysosomal diseasaes, antibody formation clearly affect the clinical outcome in infantile onset Pompe disease. Because of reason stated above, we choose alpha-Glucosidase (GAA) which is used for Pompe ERT as a model. In this study, we tried two methods to induce immune tolerance. Fist, we administered anti-CD3 antibody. Anti-CD 3 antibody was reported to induce immune tolerance to infused coagulation factor VIII in hemophilia and approved for rejection of renal transplantation in human. We intravenously injected low and high dose of anti-CD3 antibody to Balb/c mice followed by GAA immunization. Low dose anti-CD 3 successfully induced immune tolerance to enzyme but high dose of anti-CD 3 antibody did not. Although anti-CD 3 antibody induced immune tolerance, there are some side effect such as fever and chilling. Ideally, tolerance induction in ERT for lysosomal diseases should be long lasting and antigen specific. So, we tried oral tolerance induction, which might be safe and antigen specific. We orally administrated low and high dose of GAA to Balb/c mice and C57BL/6 mice, followed by GAA immunization. Both orally administered high dose and low dose of GAA successfully induced immune tolerance in both mouse strains. But the stronger immune tolerance was achieved in C57BL/6 mice by high dose oral GAA administration. We currently tested how long immune tolerance persists. In conclusion, parenteral administration of anti-CD 3 antibody and oral administration of GAA might be translated to clinics to induce immune tolerance ERT for lysosomal storage diseases.

### 3107/F/Poster Board #1039

**Proteinase-Activated Receptor (PAR1) Polymorphic variant correlates with thrombocytopenia in Gaucher Disease.** *D. Elstein[1], O. Seror-Burkis[1], A. Zimran[1], G. Altarescu[2].* 1) Gaucher Clinic, Shaare Zedek Medical Ctr, Jerusalem, Israel; 2) Medical Genetics Institute, Shaare Zedek Medical Ctr, Jerusalem, Israel.

Background: Enzyme replacement therapy (ERT) for Gaucher disease is safe and effectively corrects hepatosplenomegaly and hypersplenism. However, thrombocytopenia, not necessarily in severely affected patients nor correlated with splenomegaly, may not normalize. Platelets are involved in (acute and chronic) inflammation and thrombogenesis; both of these functions are mediated by Proteinase-Activated Receptors (PARs). PAR1 expression is down-regulated during systemic thrombin formation induced by inflammation with decreased responsiveness by PAR1 receptors after repeated stimulation. Accumulation of undegraded lipids in macrophages in Gaucher disease induce a chronic state of inflammation. Therefore, the purpose of this study was to describe PAR1 polymorphic genotypes in patients with Gaucher disease and ascertain whether these are correlated with platelet counts. Methods: Blood samples were taken from 80 patients with non-neuronopathic disease, some on ERT, and from 44 healthy controls. PAR1 polymorphisms IVS-14(A/T), -506(I/D) and -1426(C/T) were analyzed by standard methods. Clinical data was collected from the files. Associations between PAR1 and categorical variables were analyzed by chi-square and Fisher's exact tests; assessment of associations with quantitative variables used ANOVA and Scheffe post-hoc for multiple pair-wise comparisons. Non-parametric Kruskal-Wallis ANOVA was used when one category was small. All tests were 2-tailed; p values<0.05 was considered statistically significant. Results: There was a statistically significant difference (p=0.015) between patients and controls for [-1426] genotype but no significant correlations for -1426 with disease severity, need for ERT, need for splenectomy, or presence of bone disease; rather, a significant correlation between lower platelet counts (p=0.0003) and the[-1426TT genotype and a trend for correlation with inflammation markers (p=0.079). There was a statistically significant correlation for -506 genotype with femoral neck bone density (p=0.034). All patients' carried the Wild Type for IVS-14. Conclusion: Since genotype-1426 is the functional variant for PAR1, these provocative findings may suggest a role for PAR1 as an independently-sorting modifier of thrombocytopenia in Gaucher disease, and may have management implications as well such as with newer PAR1 antagonists and/or recombinant aprotinin variants entering clinical development.

**Study on dietary effect on plasma lipid changes and feto-placenta outcomes in preeclampsia-like ApoE -/- mouse model.** *M. Sun, R. Ma, Z. Yang, Corresponding author: Zi Yang, zi_yang@email.com.* Dept Ob & Gyn, Peking University Third Hospital, Beijing, China.

Objective: To investigate the effects of dietary factors on the preeclampsia-like development in mouse with lipid metabolism deficiency. Methods:Preeclampsia-like model were established in C57 apoE-/- and wild-type (WT) pregnant mice at early, mid and late gestational stages by injecting nitric oxide synthase (NOS) inhibitor L-arginine methyl ester (L-NAME) subcutaneously. Control groups matched each L-NAME group were received normal saline (NS) simultaneously. Each group was subdivided into standard chow groups (SC) and high-fat diet groups (HF). From day 1 of pregnancy, HF groups were fed a high-fat diet (21% fat, 0.15% cholesterol), and the other group was fed standard chow. All groups were measured blood pressure from day 2 to day 14 and 18 when the fetuses and placentas were removed under anesthesia. Blood pressure and urine protein were measured for identification of mice model, plasma lipid levels were measured, fetal outcomes were compared, liver and placenta histological changes were analyzed among groups. Data were analyzed statistically. Results: In apoE-/- and WT L-NAME groups, blood pressure and urine protein were significantly higher than those in all gestational age matched apoE-/- and WT NS groups ($p<0.05$). In early and mid HF+L-NAME subgroups, plasma concentration of total cholesterol, triglyceride and free fatty acid were all increased, and was the highest in early HF+L-NAME subgroup in apoE-/- mice ($p<0.05$). Morphological examination of placenta showed varying degrees of fibrinoid necrosis and villi interstitial edema in early and mid L-NAME subgroups both in ApoE-/- and WT mice with HF or SC compared to NS controls ($P<0.05$). But there was no significant difference between HF and SC subgroups. Remarkable lipid storage droplets in placenta and liver fatty infiltration were found by Oil Red O staining in early and mid HF+L-NAME subgroups in apoE-/- mice compared to other groups ($P<0.05$). Compared with SC+L-NAME subgroups, fetal weights and placenta weights were significantly decreased in early and mid HF+L-NAME ones ($p<0.05$). Changes in early HF+L-NAME subgroup in apoE-/- mice were striking ($p<0.05$). Conclusion: This study showed that high-fat dietary affected L-NAME preeclampsia-like development on plasma lipid levels and placenta and liver histological changes. High-fat dietary could aggravate the impact of L-NAME preeclampsia-like on pregnant outcomes at early gestational stage especially in ApoE-/- mice.

**Development of a Mucopolysaccharidosis IVA (MPS IVA; Morquio A Syndrome) Cell Model.** *M.M. Dvorak-Ewell[1], D. Crippen[2], C. Hague[1], M. Vellard[1].* 1) BioMarin Pharmaceutical Inc., Novato, CA; 2) The Buck Institute for Age Research, Novato, CA.

Mucopolysaccharidosis IVA (MPS IVA; Morquio A syndrome) is an autosomal-recessive lysosomal storage disorder caused by deficiency of N-acetylgalactosamine-6-sulfatase (GALNS), an enzyme that degrades keratan sulfate (KS). Clinical manifestations occur primarily in connective tissues rich in proteoglycans, including cartilage, heart valve and cornea, where the endogenously expressed KS accumulates. We produced recombinant human GALNS (rhGALNS) for a potential enzyme replacement therapy, and demonstrated its successful delivery to clinically relevant tissues, including growth plate cartilage and heart valve in the wild-type mice, in vivo. We then established an in vitro model of MPS IVA, using chondrocytes isolated from iliac crest biopsies of two MPS IVA patients (MQCH cells). To induce chondrogenic differentiation and KS production and accumulation, the cells were cultured in alginate beads for 6 - 15 weeks. We confirmed the absence of GALNS activity in MQCH cells by GALNS capture activity ELISA, and observed a resultant 5-10-fold increase in KS accumulation by capillary electrophoresis, in comparison to normal human chondrocytes. Upon treatment with 10nM rhGALNS, we observed lysosomal uptake and restoration of enzyme activity, as well as a decrease in keratan sulfate accumulation in MQCH cells. In an attempt to identify molecular pathways associated with MPS IVA pathophysiology, we used quantitative real-time RT-PCR to profile the chondrogenic gene expression by MQCH cells in comparison to normal human chondrocytes and MQCH cells treated with rhGALNS. We observed aberrant expression of collagens (e.g. 50 - 270-fold increase in collagen I, 10 - 350-fold increase in collagen X) indicating that the cartilaginous extracellular matrix is affected in MPS IVA. Furthermore, expression levels of molecules associated with osteoarthritis and inflammation are also altered (e.g. 22-1700-fold increase in matrix metalloprotease 13, 3-12-fold increase in cathepsin K). rhGALNS treatment attenuated the majority of gene expression changes. As primary human chondrocytes have a limited proliferative capacity in culture, we established immortalized MPS IVA chondrocyte cell lines by stably transfecting MQCH cells with the SV40 viral genome. These cell lines will be used for further characterization of MPS IVA pathophysiology and identification of treatment biomarkers.

***In vitro* characterization of a NAGLU lysine mutant for potential treatment of Sanfilippo B syndrome.** *S. Kan, L. Troitskaya, S. Dosovitz, K. Haitz, M. Passage, B.L. Tippin.* Los Angeles Biomedical Research Institute at Harbor-UCLA Medical Center, 1124 West Carson St, Torrance, CA 90502.

Mucopolysaccharidosis IIIB (MPS IIIB, Sanfilippo B syndrome) is an inherited lysosomal storage disease caused by deficiency in the enzyme, α-N-acetyl-glucosaminidase (NAGLU). There is currently no treatment for this disease. Early attempts to produce human recombinant NAGLU (rhNAGLU) enzyme for use as enzyme replacement therapy (ERT) for MPS IIIB failed due to lack of mannose-6-phosphate (M6P) tag addition to the recombinantly produced enzyme. Without the M6P tag, rhNAGLU cannot target and enter the appropiate cells of the body. GlcNAc1 phosphotransferase catalyzes the first step in generating M6P tags during post-translational processing in the Golgi apparatus by recognizing lysine patches on target proteins.

To overcome the lack of MP6 addition, we created a modified rhNAGLU with multiple lysine substitutions (rhLysNAGLU) using site-directed mutagenesis. The sites were chosen by comparative alignment of *NAGLU* genes among different species to maintain conservation of function, while providing a more lysine-rich target for GlcNAc1 phosphotransferase. rhLysNAGLU was expressed in Chinese hamster ovary cells (CHO) using the pCIneo vector (Promega) and the best expressing stable clone was selected for scaled up growth in roller bottles. We purified and characterized the rhLysNAGLU mutant for enzyme activity, stability, pH optimum, cellular uptake, lysosomal targeting, and glycosaminoglycan storage reduction capabilities in Sanfilippo B fibroblasts and compared it to purified rhNAGLU *in vitro*. These pre-clinical studies assess the enhancement and potential therapeutic use of the modified enzyme in ERT for Sanfilippo B syndrome.

**Enzyme Replacement Therapy in Patients with Hurler Syndrome in Japan.** *M. Kosuga[1], T. Tanaka[2], E. Oda[1], H. Fujita[2], R. Kosaki[2], T. Okuyama[1].* 1) Department of Clinical Laboratory Medicine, National Center for Child Health and Development, Setagaya-ku, Tokyo, Japan; 2) Department of Clinical Genetics and Molecular Medicine, National Center for Child Health and Development, Setagaya-ku, Tokyo, Japan.

BACKGROUND: Mucopolysaccharidosis type I (MPS I, Hurler syndrome) is a lysosomal storage disease caused by a deficiency of lysosomal enzyme, α-L-iduronidase. Recombinant human α-L-iduronidase (laronidase) has been available for patients with MPS I in Japan since 2006. Just about 20 MPS I patients are treated with enzyme replacement therapy (ERT) with laronidase. Because of a small number of treated MPS I patients and the shortness of observing period in ERT, it is important to evaluate the effect and safety of ERT carefully and periodically in MPS I patients. OBJECTIVE: This study aimed to assess the effect and safety of ERT with laronidase in Japanese patients with MPS I. PATIENTS: One male (age 5, Hurler) and two female (age 6 and 11, Hurler and Hurler-Scheie) were followed-up for a mean period of 40 months while undergoing ERT with laronidase. All patients received 0.58mg/kg laronidase i.v. weekly and were examined by means of physical examination, computed tomography of the abdomen, magnetic resonance imaging of the brain, range of motion measurements and measurements of urinary glycosaminoglycans (GAGs) excretion, anti-iduronidase IgG antibodies before ERT and every 6 months after starting ERT. RESULTS: There was clear improvement in the size of liver and reduction in urine GAGs in all patients. The range of motion in all joints was improved in one patient. Two of three patients had a decrease in the number of sleep apnea during ERT. But one patient desaturation index increased gradually and was considered to need continuous positive airway pressure at night and/or adenoidectomy. All patients were positive for antibodies to a-L-iduronidase within 2 months of initiating ERT. However, IgG antibodies were not observed in two of them at 5 months and 2 years post ERT respectively and gradually decreased with time in one patient. Infusion-related reactions consisted of urticaria and wheezing appeared in one patient. The reactions responded to reducing the rate of infusion and antihistamines. The extent of corneal clouding and cardiac function did not change in all patients. CONCLUSIONS: ERT with laronidase was effective significantly in reducing the size of liver and urine GAGs in all patient and ameliorating some clinical symptoms in Japanese patients with MPS type I. There were no critical infusion-related reactions and all patients continue to be treated with laronidase.

## 3112/F/Poster Board #1044

**UNFOLDED PROTEIN RESPONSE (UPR) IS NOT A MEDIATOR OF APOPTOSIS IN PERIPHERAL BLOOD MONONUCLEAR CELLS (PBMC) FROM FABRY DISEASE PATIENTS.** *P. Rozenfeld, N. De Francesco, C. Fossati.* LISIN, Facultad de Ciencias Exactas, Universidad Nacional de La Plata. Argentina.

The pathophysiology of lysosomal storage diseases (LSD) is not well understood, and it is not solely explained by the burden of storage material. Increased apoptosis has been detected in different LSDs. ER stress/UPR was shown to be a common mediator of apoptosis both in neurodegenerative and non-neurodegenerative LSDs. However, a recent work in neuronopathic Gaucher disease could not demonstrate the involvement of UPR. The aim of this work is to analyze if ER stress/UPR is activated and related to apoptosis in PBMC from Fabry disease patients. We analyzed levels of caspases related to ER stress by western-blotting and expression of genes associated to UPR by quantitative PCR in PBMC from Fabry disease patients. We neither found differences in the levels of ER stress-related caspases, caspase 4 and caspase 12 nor changes in expression of genes CHOP, GADD34, BiP, XBP1, EDEM1, HSP90B1. We conclude that ER stress/UPR is not activated in PBMC from Fabry disease patients, and is not a mediator of apoptosis.

## 3113/F/Poster Board #1045

**Life course analysis of the effects of FTO on BMI in the Northern Finland Birth Cohort 1966 using structural equation modelling.** *M. Jarvelin[1], M. Kaakinen[2], U. Sovio[1], A. Pouta[3], A-L. Hartikainen[2], A. Taanila[2], A. Bennett[4], M.I. McCarthy[4], E. Laara[2], ENGAGE project, HEALTH-F4-2007-201413.* 1) Epidemiology & Public Health, Imperial Collage London, London, United Kingdom; 2) University of Oulu, Biocenter Oulu, Finland; 3) National Institute for Health and Welfare, Oulu, Finland; 4) University of Oxford, UK.

Many studies have shown an association between FTO, the fat-mass and obesity associated gene, and adulthood body-mass index (BMI). More thorough analyses utilising phenotypic data from several time points during the life course may deepen our understanding of the interplay between genetic and environmental factors associated with BMI. We used structural equation modelling (SEM) technique to explore the network of variables associated with BMI from prenatal period until the age of 31 years in 4435 subjects from the Northern Finland Birth Cohort 1966. The association between the FTO rs9939609 risk allele and BMI at 31 years remained robust despite controlling for several relevant factors during the life course (total effect 1.41% difference in BMI levels per allele change corresponding to 0.35 kg/m2 in the mean level, $p<0.0001$). In addition to the association with adult BMI, evidence for associations in the same direction with maternal BMI (0.60%, $p=0.02$), birth BMI (0.30%, $p=0.12$) and BMI at 14 years (0.60%, $p=0.04$) were observed. The total effect of FTO, which takes into account direct and indirect effects through other factors was notably higher than pure direct effect of FTO on adult BMI. However, all the indirect effects came through earlier measurements of BMI and not through environmental exposures, such as diet, physical activity, drinking or smoking. This confirms the previous findings that BMI begins affecting well before adulthood and also suggests that FTO has a pure causal effect on BMI. SEM proved to be an efficient analysis method in estimating complex relationships jointly. The analyses with missing values were easy to incorporate via EM algorithm, allowing us to use the whole potential of the data. SEM could be more utilised in the joint analyses of genetic and environmental exposures.

## 3114/F/Poster Board #1046

**Genome-Wide Linkage Scan for Metabolic Syndrome Related Quantitative Traits in Dominican Families.** *C. Dong[1], A. Beecham[2], S. Blanton[2], S. Slifer[2], T. Rundek[1], R. Sacco[1].* 1) Department of Neurology, University of Miami Miller School of Medicine, Miami, FL; 2) Miami Institute of Human Genetics, University of Miami Miller School of Medicine, Miami, FL.

The metabolic syndrome (MetS) poses a major problem for public health and is characterized by the clustering of multiple correlated metabolic abnormalities. Studies have suggested that the components of MetS may share genetic and environmental determinants. To identify genetic loci for MetS in Hispanics, we performed autosomal genome linkage analyses of 1390 subjects from 100 Dominican families on multiple MetS-related traits: body mass index (BMI), weight, waist circumference (WC), waist-to-hip ratio (WHR), abdominal skinfold, average triceps skinfold thickness, diastolic and systolic blood pressure (DBP, SBP), triglyceride (TG), cholesterol, high-density lipoprotein (HDL), low-density lipoprotein (LDL) and fasting glucose. A composite factor for MetS was also derived from factor analysis with a high factor loading >0.4 for all traits except HDL. Multipoint variance component analyses were conducted for all traits by adjusting for demographic and lifestyle factors and medication history if applicable. Two regions were identified on chromosome 16 with the most significant or overlapping linkage signals: one is at 16q23 with the highest LOD score of 3.62 ($p<0.00005$) for cholesterol as well as suggestive linkage signals for LDL (LOD=2.65) and average triceps skinfold (LOD=2.32); another is at 16p12 with suggestive linkage signals for cholesterol (1.81), weight (2.26), BMI (2.27), TG (1.84) and MetS composite factor (2.55). Several regions were also found to have overlapping linkage signals of LOD score ≥1.5: chromosome 1 at 9-15 cM for WHR (1.80) and average triceps skinfold (1.88) as well as at 263-268 cM for BMI (2.03) and weight (2.45); chromosome 4 at 32-38 cM for abdominal skinfold (1.94) and fasting glucose (2.43); chromosome 9 at 112-164 cM for abdominal skinfold (1.85), HDL (2.20) and LDL (1.63); chromosome 12 at 125-145 cM for HDL (1.93) and fasting glucose (1.56); chromosome 14 at 84-113 cM for abdominal skinfold (2.17), TG (1.82) and LDL(1.82); chromosome 15 at 77-115 cM for TG (2.60) and WC (1.77); and chromosome 19 at 52 cM for LDL(2.67) and cholesterol (2.15). In addition, other regions with linkage signal of LOD score ≥2.0 for single trait were observed on chromosome 3 (2.33 for SBP at 221 cM), 5 (2.54 for fasting glucose at 114 cM) and 7 (2.56 for fasting glucose at 58 cM). Our results suggest that multiple loci, particularly 16p12 region, may contribute to the development of MetS and the related quantitative traits in Caribbean Hispanics.

## 3115/F/Poster Board #1047

**Desmosterolosis - clinical presentation, neuroradiologic findings, molecular evolution and novel therapeutic considerations.** *C.P. Schaaf[1], P. Katsonis[1], L. Kratz[2], J. Koster[3], R.I. Kelley[2], H.R. Waterham[3], O. Lichtarge[1], M. Shinawi[1].* 1) Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Genetics Laboratories, Kennedy Krieger Institute, Baltimore, MD; 3) Clinical Chemistry & Paediatrics, University of Amsterdam, Amsterdam, The Netherlands.

A sufficient supply of cholesterol is essential for proper development of the human brain. Neuronal differentiation, in particular synaptogenesis, occurs as a cholesterol-dependent process. Cholesterol is a precursor in the synthesis of steroids and other sterols, and it influences the Sonic Hedgehog pathway, an important signaling cascade for brain growth, patterning, and morphogenesis. Several disorders of cholesterol biosynthesis have been associated with structural brain abnormalities.

Desmosterolosis, a rare disorder of cholesterol biosynthesis, is caused by mutations in the enzyme 3β-hydroxysterol-Δ24reductase (DHCR24), a FAD-dependent oxidoreductase. To date, desmosterolosis has been described in only two patients. Here we report a third patient with desmosterolosis who presented with congenital hydrocephalus, mild arthrogryposis, and dysmorphic facial features. Brain MRI confirmed congenital hydrocephalus and revealed thickening of the tectum and the massa indermedia, dysplastic cerebrum with pachygyria, marked underopercularization, and a thin corpus callosum.

The diagnosis of desmosterolosis was established by detection of a significant elevation of plasma desmosterol of 284 μg/ml [nl: 0.82+/- 0.46 μg/mL], and enzyme activity studies in lymphoblasts confirmed the deficiency of DHCR24. The patient was found to be compound heterozygous for a c.281G>A (R94H) and a c.1438G>A (E480K) mutation. We performed structural and phylogenetic analyses of the respective mutations by mapping the DHCR24 sequence on the structure of 2exr (cytokinin oxidase/dehydrogenase from arabidopsis thaliana) and determined that the R94H mutation affects the FAD-binding domain, which is evolutionarily important to the enzyme, as its variations correlate with phylogenetic branching. The E480K mutation occurs in nature, but is accompanied with charge changes in the local protein environment.

We compare the presentation in our patient with the clinical findings of the previously reported cases of desmosterolosis, and propose a list of clinical findings that should instigate a diagnostic evaluation for desmosterolosis. Based on biochemical considerations and previous in vitro studies of mutant DHCR24 in yeast, an experimental therapeutic approach for patients with desmosterolosis is suggested.

## 3116/F/Poster Board #1048

**A *YARS2* mutation is a novel cause of mitochondrial myopathy characterized by lactic acidosis and sideroblastic anemia.** *L. Riley[1], P.F. Hickey[2,3], S. Cooper[4,5], M. McKenzie[6], M. Ryan[6], A. Compton[7], D. Thorburn[7], J. Rudinger-Thirion[8], E. de Leon[1], M. Bahlo[2], J. Christodoulou[1,5].* 1) Genetic Metabolic Disorders Research Unit, Children's Hospital at Westmead, Sydney, Australia; 2) Bioinformatics Division, The Walter & Eliza Hall Institute of Medical Research, Melbourne, Australia; 3) Department of Mathematics & Statistics, University of Melbourne, Melbourne, Australia; 4) Neurogenetics Research Unit, Children's Hospital at Westmead, Sydney, Australia; 5) Discipline of Paediatrics & Child Health, University of Sydney, Sydney, Australia; 6) Department of Biochemistry, LaTrobe University, Melbourne, Australia; 7) Murdoch Children's Research Institute, Royal Children's Hospital, Melbourne, Australia; 8) Unité Propre de Recherche du CNRS, Institut de Biologie Moléculaire et Cellulaire.

Mitochondrial respiratory chain disorders are a heterogeneous group of disorders due to mutations in either mitochondrial or nuclear encoded genes. Identification of causative mutations is important not only for diagnosis but also to understand the pathogenesis of these disorders. We have studied a family where consanguineous parents have had two affected children with persistent lactic acidemia, progressive skeletal myopathy, transfusion-dependent sideroblastic anaemia and deficiencies in complex I & IV activity (MLASA). We undertook multipoint autozygosity mapping of this family using the 250K *Nsp*I Affymetrix Human GeneChip Array to localise the mutated gene. Six regions of interest with a peak LOD score of 2.0 or higher were identified. These candidate regions were subjected to *in silico* analysis using the MitoCarta database which revealed 28 genes encoding proteins with mitochondrial functions. DNA sequencing revealed a missense mutation in one of the candidate genes, *YARS2*, which encodes mitochondrial tyrosyl-tRNA synthetase (mt-TyrRS). Another unrelated patient from the same ethnic group with MLASA was also found to be homozygous for this mutation. This sequence variation was not found in 160 chromosomes from control subjects. The missense mutation leads to a substitution of leucine at residue 52 for phenylalanine (p.F52L). Phe52 lies within the first β-strand of mitochondrial tyrosyl-tRNA synthetase and is highly conserved between species. mt-TyrRS is responsible for attaching Tyr to its cognate tRNA for incorporation into mitochondrial proteins, however the function of the region harbouring the mutation is unknown. Studies were undertaken to determine the expression level, stability and functionality of the mutant protein and its effect on mitochondrial protein synthesis. Preliminary Western blotting results indicate that mutant mt-TyrRS protein is expressed in patient samples, although levels of mt-TyrRS appeared to be lower compared to controls. A mitochondrial protein synthesis assay revealed defects in translation of some mitochondrial proteins. A recombinant form of the mutant protein has been produced to determine the catalytic rate of the enzyme. These functional studies should lead to a greater understanding of the role of the *YARS2* mutation in the pathogenesis of this mitochondrial respiratory chain disorder.

**Novel Mutations in CYP11B1 Gene and its protein modeling in a Patient with 11β-Hydroxylase Deficiency in Iran.** *M. Abbaszadegan[1], S. Hassani[1], R. Vakili[2], M. Saberi[3], A. Baraderan-Heravi[1], A. A'rabi[1], M. Hasemipour[4], M. Razzaghi-Azar[5], A. Baratian[5].* 1) Division of Human Genetics, Immunology Research Center, Avicenna Research Institute, Mashhad University of Medical Sciences (MUMS), Mashhad, Iran; 2) Departmant of Pediatrics, Imam Reza Hospital, MUMS, Mashhad, Iran; 3) Medicinal Chemistry Department, School of Pharmacy, Mashhad University of Medical Sciences, Mashhad, IRAN; 4) Esfahan Endocrine & Metabolic Research Center, Esfahan University of Medical Sciences, Esfahan, Iran; 5) Departmant of Pediatrics, H. Ali Asghar Hospital, Iran University of Medical Science (IUMS), Tehran, Iran.

Background: Mutations in the gene encoding 11β-Hydroxylase (CYP11B1) is the second most common cause of congenital adrenal hyperplasia (CAH), an autosomal recessive disorder characterized by adrenal insufficiency, virilization of female external genitalia, and hypertension with or without hypokalemic alkalosis in about two thirds of patients. Objective: Molecular analysis of CYP11B1 gene in CAH patients with 11β-hydroxylase deficiency. Patients and Methods: DNA analysis was performed in 5 unrelated Iranian families with at least one 11-β hydroxylase deficient child who was presented with precocious pseudopuberty in all male patients. All the patients were detected to have hypertension at the time of diagnosis or later which was controlled by Glucocorticoid treatment except one of them with uncontrolled hypertension and recurrent CVA attacks in spite of both Glucocorticoid and anti-hypertensive regimen and an unsuccessful adrenalectomy procedure. Cycle sequencing of 9 exons in CYP11B1 was performed. To inspect the effects of new mutation on protein structure and function, Three D models for the normal and mutant proteins was developed and their affinity to a previously found effective compound was examined. Models were investigated in SPDBViewer and ViewerLite programs checking amino acids making clashes, Phi-Psi angles, and secondary structure matching the secondary structure prediction. Results: Analysis of the CYP11B1 gene revealed two novel mutations, one as a small insertion in exon 7 (InsAG393) and the other as a single nucleotide deletion in exon 2 (Del G766). In addition to these novel mutations, 3 known mutations in 3 other patients were detected including a T318M, Q356X and R427H in homozygous state. The parents of the patients are consanguineous and heterozygous for the same mutations. Prediction of clinical severity, based on molecular modelling and sequence conservation, correlates well with the clinical diagnosis of the patients carrying these mutations. Conclusion: The novel mutations, Ins AG 393 and Del G766, have not been previously described in the CYP11B1 gene. These mutations predicted to drastically impair enzyme activity resulting in severe classic CAH. The study increases our knowledge of CAH due to 11β-OH deficiency and its various presentations. Prenatal diagnosis for these families is possible utilizing these molecular results.

## 3118/F/Poster Board #1050

**Orthopedic management in the mucopolysaccharidoses.** *K.K. White[1], R. Lachman[2], P. Harmatz[3], S. Turbeville[4].* 1) Children's Hospital and Regional Medical Center, Department of Orthopedic Surgery Seattle, WA, University of Washington Department of Orthopedics and Sports Medicine Seattle, WA; 2) Department of Pediatrics, International Skeletal Dysplasia Registry, UCLA School of Medicine, Radiological Services; 3) Oakland Children's Hospital and Research Center; 4) BioMarin Pharmaceutical, Inc.

The mucopolysaccharidoses (MPS) constitute a family of lysosomal storage diseases resulting from inborn errors of metabolism with subsequent abnormal accumulation of cellular glycosaminoglycans. The musculoskeletal manifestations in MPS range from mild platyspondyly and/or epiphyseal dysplasia to severe life threatening spinal problems and crippling hip deformities. Both joint stiffness and ligamentous laxity are associated with MPS disorders, compounding the problems associated with the skeletal deformities. Dysostosis multiplex, the radiographic constellation of skeletal abnormalities classically seen in MPS, results from defective endochondral growth throughout the skeletal system, including the hips, knees and spine. The molecular physiology of this problem is yet to be understood. Familiarity with these musculoskeletal findings is critical for recognition and diagnosis of these potentially devastating diseases, as well as for determining appropriate treatment options such as surgical procedures of the spine, hips, knees and hands to promote optimal function and gait. Enzyme replacement therapy (ERT) may be beneficial in reducing the burden of skeletal disease when treatment is initiated early. It is has also been shown to improve joint range of motion. While hematopoietic stem cell transplant (HSCT) may be potentially life saving for some MPS diseases, it does not usually alter the course of progressive skeletal disease, although some normalization of articular cartilage, joint range of motion and linear growth may occur. Surgical intervention is often still required in patients with MPS, and early intervention is critical in order to optimize long term function and quality of life. We review the current clinical knowledge-base of musculoskeletal disease in MPS including the impact of newer orthopedic treatment options.

### 3119/F/Poster Board #1051

**'Missing' enzymes and metabolic pathways: Redefining metabolic pathways with special reference to *Pseudomonas* species.** *D. Perumal[1,2], C.S Lim[1,2], M.K Sakharkar[1,2]*. 1) Advanced Design and Modeling Lab (ADaM),School of MAE, Nanyang Technological University, Singapore; 2) Bio Medical Engineering Research Center(BMERC), Research Techno Plaza,Nanyang Technological University, Singapore.

Comparative metabolic pathway analyses reveal that several pathways in the *Pseudomonas* species show high plasticity and versatility. Computational predictions from multiple sources of information, though useful, may sometimes be inconsistent and further confound the issue of annotation of genes. In such cases, experimental validations may become essential to resolve and reconcile the apparent inconsistencies. We present combined computational experimental analyses on eight completely sequenced *Pseudomonas* species. Potential bypasses in 11 metabolic pathways were identified. Our results for the first time confirm the presence of DNA sequence encoding the enzyme O-acetyl homoserine (thiol) lyase (EC: 2.5.1.49) in *Pseudomonas syringae pv. tomato* which reveals inconsistent annotations in KEGG and the recently published SYSTOMONAS database. These analyses connect and integrate systematic data generation, computational data interpretation, and experimental validation and represent a synergistic and powerful means for conducting biological research. Continued experimental investigation of the metabolic biochemistry of an organism is of importance in (1) to assign pertinent biochemical reactions to the enzymes found in the genome; (2) to validate and scrutinize information already found in the genome; and (3) determination of the presence of reactions or pathways not indicated by current genomic data. Through the comparison of metabolic pathways, intricate and complex relationships between genes that encode enzymes can be studied, and more sophisticated strategies for diagnosis and treatment of complex diseases may become feasible.

## 3120/F/Poster Board #1052

**Murine bone marrow eGFP- mesenchymal stem cells (bMSC): myogenic potential in dystrophic muscle.** *M. Vainzof, D. Ayub-Guerrieri, P.C.G. Onofre-Oliveira, V.F. Lopes, P.C.M. Martins.* Genetics/Hum Genome Res Ctr, IB-Univ Sao Paulo, Sao Paulo, Brazil.

Muscular dystrophies (MD) are heterogeneous genetic muscle disorders, still devoid of efficient treatment, and the mouse models for these diseases are an important tool for testing putative therapies. With a view to developing treatments for muscular dystrophy, we are testing the myogenic potential of murine bone marrow mesenchymal stem cells (bMSC) following transplantation into dystrophic mice. The bMSC were isolated from transgenic mice carrying a gene expressing enhanced green fluorescent protein (bMSC-eGFP), which constitutes a good marker for tracking them in the injected organism. In our previous studies, we observed that after 30 days post-injection of these cells, treated muscles from mdx mice showed no sign of muscle regeneration, nor any evidence of dystrophin expression. In contrast, non-GFP murine embryonic stem cells were retained. Additionally, human MSCs from adipose tissue were also retained after injection into SJL mouse muscles. To verify if eGFP expressing cells are less tolerated by the dystrophic muscle, a single dose of about $10^6$ bMSC-eGFP cells was injected intra-muscularly into mdx and normal C57Bl animals, and tracked through PCR using primers for the DNA sequence related to the eGFP gene. We detected the presence of eGFP up to 2 days post-injection, in both affected and normal animals. After this time, no traces of the eGFP DNA from transplanted cells were detected, suggesting that the cells had been effectively eliminated from the muscles. These results suggest that, in addition to a possibly adverse environment offered by the dystrophic muscle for the homing and maintenance of injected bMSC stem cells, cells expressing eGFP are poorly tolerated, and rapidly eliminated. Comparative studies of the potential of different stem cells injected into different animal models are important to improve the effectiveness of stem cells in neuromuscular therapies. Funding: FAPESP,CNPq-INCT,FINEP, ABDIM.

## 3121/F/Poster Board #1053

**Low plasma iduronate-2-sulfatase activity and elevated urinary glycosaminoglycans in brothers following stem cell transplantation (HSCT) for mucopolysaccharidosis type II.** *A. Paras[1,2], B.K. Burton[1,2].* 1) Dept Genetics, Children's Memorial Hospital, Chicago, IL; 2) Northwestern University Feinberg School of Medicine, Chicago IL.

The use of HSCT for the treatment of mucopolysaccharidosis type II has been controversial. Its efficacy has been difficult to gauge given the variability of the condition and paucity of data, and HSCT has not been routinely recommended. HSCT has resulted in improvement or stabilization of some aspects of the disease in selected patients, including resolution of hepatosplenomegaly, stabilization of cardiovascular disease, improvement of rhinorrhea and upper airway obstruction, and improvement in joint stiffness. Cognitive outcomes in published cases have been variable, with very limited data on patients transplanted at an early age (<1 year) who would be predicted to have severe CNS involvement based on family history. Intravenous enzyme replacement therapy with Elaprase improves many somatic symptoms including hepatosplenomegaly, joint stiffness, and pulmonary function. ERT is not expected to ameliorate the course of neurocognitive decline. A clear dilemma arises with regard to determining the best treatment strategy. Without clear documented benefits of HSCT for CNS disease, treatment with enzyme replacement therapy appears to provide comparable somatic benefits without the risk of morbidity and mortality associated with HSCT. However, if the diagnosis of MPS II is made in a very young child, the hope remains that HSCT may provide some protection from cognitive decline, as well documented in MPS I (Hurler syndrome). We present two brothers with MPS II who underwent successful unrelated umbilical cord blood stem cell transplantation at ages 11 months and 3y 11m. Assessments of plasma iduronate-2-sulfatase (I2S) have been low in both siblings (approximately 5% and 7% of control) and urinary glycosaminoglycans levels continue to be elevated 9 months post transplant, although a significant decline from baseline was documented in one of the brothers. The biochemical findings are difficult to interpret, and their clinical significance is unclear. The enzymatic findings suggest that plasma I2S is derived from a tissue not fully corrected by HSCT.

## 3122/F/Poster Board #1054

**The difference in effectiveness of herbal medicine between genetic and non-genetic spinocerebellar ataxia.** *T. Okabe.* Dept Integrated Trad Med, Univ Tokoy, Tokyo, Japan.

The spinocerebellar ataxias (SCAs) are clinically and genetically a heterogeneous group of neurodegenerative disorders. At present,we have no effective therapeutic tools. Previous studies have shown for the first time, the successful treatment by medicinal herbs of 2 Japanese patients with genetic spinocerebellar ataxia 6 (SCA6). Recently, we have succeeded in remission induction by the herbal medicine of an another case with CSA6. Ataxia of gait and stance disappeared and the total ataxia score was improved from 26 to 12 on a 100-point semiquantitative International Cooperative Ataxia Rating Scales(ICARS). The results suggest that the herbal therapy would be effective for this genetic spinocerebellar ataxia. In this study, we have examined the effect of the herbal therapy against sporadic spinocerebellar ataxia. Multiple system atrophy (MSA) is a sporadic progressive neurodegenerative disorder characterized by prominent cerebellar and extrapyramidal signs, dysarthria, and dysphagia and symptoms of autonomic nervous system failure (such as urinary incontinence or incomplete bladder emptying, orthostatic hypotension, constipation, erectile failure in men. Three Japanese patients with MSA were treated with the medicinal herbs, to see whether the herbal therapy would be effective against the sporadic spinocerebellar ataxia. Among these symptoms, cerebellar ataxias such as light-headedeness, ataxic gait and swallowing difficulty were slightly improved after the herbal therapy. However, autonomic nervous system failures were not ameliorated by the therapy. The formula used for these cases consisted of different types of herbs such as sedative, anticonvulsive, neuroprotective, neurorefgulatory and DNA binding herbs. Together with the successful treatment of SCA6, the results imply therapeutic potential of the herbal medicine especially for genetic cerebellar ataxia. Extensive studies are required for elucidation of the mechanisms by which medicinal herbs exert their therapeutic activities on this genetic disease of CAG repeat expansion mutation,.

## 3123/F/Poster Board #1055

**A KFC-based approach for rational drug design to treat genetic diseases.** *M. Tang[1], K. Wierenga[2], L. Elsas[1], K. Lai[1,3].* 1) Biochemistry and Mol. Biology, University of Miami Miller School of Medicine, Miami, FL; 2) Pediatrics, University of Oklahoma Health Sciences Center, Oklahoma City, OK; 3) Pediatrics, University of Utah School of Medicine, Salt Lake City, UT.

Traditional drug discoveries rely on experimental, knowledge-based high-throughput screens (HTS) to identify compounds that interact with chosen targets. Advances in high-precision computer modeling software not only allow the accurate docking of the selected compounds from the HTS screens to the targets, but also led to development of virtual fragment-based screens. We propose here that we can combine the results of both the **K**nowledge-based and **F**ragment-based screens with existing **C**rystallographic data of the target to identify more effective compounds to treat genetic disorders. To test our hypothesis, we focused on the potentially lethal genetic disorder called Classic Galactosemia (MIM 230400). Despite improvements in care, mental retardation, premature ovarian failure and other neurological deficits remain common sequelae of this disease. Various lines of evidence indicated that elevated level of galactose-1-phosphate (gal-1P), the product of galactokinase (GALK), is a major, if not sole, pathogenic mechanism in Classic Galactosemia. We hypothesize that elimination of gal-1P production in GALT-deficient cells by inhibiting GALK will significantly relieve them from galactose toxicity. To test this hypothesis, we have screened different chemical libraries composed of over 300,000 small molecules with diverse structural scaffolds for inhibitory properties against activity of purified human GALK. We have identified more than 200 small molecule compounds that inhibit human GALK activity in vitro of at least 86.5 percent. Characterization of selected compounds revealed good potency and considerable efficacy to lower gal-1P in patient cells in culture. However, significant toxicity due to off-target effects was also seen. To improve the potency and selectivity of the compounds, we performed structural studies of GALK-inhibitors using high-precision computer docking programs to establish enzyme-inhibitor interactions. We found that many inhibitors interact with amino acid residues known to be implicated in causing GALK deficiency in humans, and identified new "hotspots" of the GALK protein crucial for catalysis. Additionally, we conducted virtual fragment-based screenings to identify new chemical structures that can bind to the active site of GALK. Using the proposed KFC-based approach, we have generated novel hybrid molecules aimed to surpass the potency and selectivity of either parent compounds identified by the separate screens.

## 3124/F/Poster Board #1056

**Optic Neuritis and Accommodative Loss after Intravenous Pamidronate in a Child with COL1A1 Variant Osteogenesis Imperfecta and Juvenile Osteoporosis.** *S.C. Benes[1,4], J. Mahan[2], M.E. Nunes[3].* 1) Neuro-Ophthalmology, Nationwide Children's Hospital, Columbus, OH; 2) Nephrology, Nationwide Children's Hospital, Columbus, OH; 3) Genetics, Kaiser Permanente, San Diego, CA; 4) Neuro-Ophthalmology, The Eye Center of Columbus, Columbus, OH.

Case Report: A healthy 11 year old girl (60 inches, 97 pounds) had multiple fractures with sports. She was flexible at several joints and her bone density was consistent with osteoporosis. She underwent 4 intravenous disodium pamidronate infusions every 3 months with the expected headache and flu-like feelings for the 2 days following each of those 3-day infusions, treated with Motrin and rest. A repeat bone density was in the lower limit of normal for age. Following the fifth IV pamidronate infusion, at age 12, her headaches and generalized malaise were more intense than with the prior 4 infusions; on day 3 she had blurred vision in both eyes, pain on eye movement OD, loss of color vision OD, and reported a grey area in her central vision OD. The clinical diagnosis of right retrobulbar optic neuritis was made. She had reduced accommodative amplitude OU. Visual fields, OCT, B-scan ultrasound, visually evoked potentials and MRI testing showed no central nervous system pathology. We suspected this was a toxicity of pamidronate. Blood work was normal except for a low B2 and a single allele mutation COL 1A1 on chromosome 17, exon 8. Her asymptomatic mother shared this mutation. A literature review found only 3 cases of optic neuritis after bisphosphonate therapy in older adult women with osteoporosis. Most common visual complications with bisphosphonates were nonspecific blurred vision, conjunctivitis, episcleritis, scleritis, orbital inflammation, and intraocular inflammation (uveitis). Concerns include: (1) Will her vision fully recover? (2) When bone density normalizes, should the therapy continue? At what dose? Should the children return to sports? (3) Since bisphosphonates as a class have the most consistent rechallenge data on ocular inflammation, is there a safe alternative drug or reduced dose for her in future therapy? (4) Will orthodontia be complicated by excess immobility or mobility, or even osteonecrosis? (5) Are we missing optic neuropathies/ocular inflammations in juvenile pamidronate users due to infrequent questions about vision? (6) What end-points do we "treat to" in patients with juvenile osteoporosis and repeated fractures? (7) Regarding the variant of the COL1A1 allele substitution 613C>G with Pro27 Ala in the triple helix, is there a unique cross-over finding of osteogenesis imperfecta with collagen connective tissue defects (variants of Ehlers-Danlos) and joint hypermobility or a unique sensitivity to bisphosphonates?

## 3125/F/Poster Board #1057

**Enzyme Replacement Therapy for Hypophosphatasia Mouse.** *S. Tomatsu, H. Oikawa, A.M. Montano.* Dept Pediatrics, St Louis Univ Doisy Res Ctr, St Louis, MO.

Background: Hypophosphatasia (HPP) is an inborn error of metabolism caused by deficiency of the tissue-nonspecific alkaline phosphatase (TNSALP), resulting in a defect of bone mineralization. Natural substrates for this ectoenzyme accumulate extracellulary including inorganic pyrophosphate (PPi), an inhibitor of mineralization, and pyridoxal 5-phosphate (PLP), a co-factor form of vitamin B6. Enzyme replacement therapy (ERT) on HPP patients with partially purified plasma enzyme was attempted but with little clinical improvement. TNALP-null mouse model (Akp2-/-) has an infantile form of HPP with a severe hypomineralization and bone deformities. The affected mice die of vitamin B6-dependent seizures within 21 days without vitamin B6 treatment. Attaining clinical effectiveness with ERT for HPP requires delivering functional TNSALP enzyme to bone. There is no established medical treatment approved. Materials and Methods: The C-terminal-anchorless human recombinant TNSALP (hrTNSALP) enzyme derived from Chinese hamster ovary cell lines was purified. TNALP-null mice (Akp2-/-), an excellent model for infantile HPP, were treated from birth using hrTNALP. Long-term efficacy studies (six months) by ERT consisted of every 3 days subcutaneous injections till 28 days old (dose 10 U/g) and subsequently every 3 days intravenous injections for 5 months (dose 20 U/g). We assessed survival and growth rates as well as skeletal manifestations using radiography. Mice were fed with vitamin B6 containing diet. Results: Akp2-/- mice treated grew normally till 2 months and appeared well with a minimum skeletal disease and normal growth as well as absence of epilepsy compared to untreated mice which died by 3 weeks old. Moreover, both male and female treated mice of both genders were fertile. Even if both parents were affected, they provided pups without any complications. Although the treated mice kept active without seizure, after six months of treatment, we noticed moderate skeletal or dental disease with hypomineralization. Conclusions: 1. Enzyme replacement using recombinant form of human TNALP prevents infantile HPP in Akp2-/- mice and improves substantial clinical manifestations with prolonged survival period. 2. Long term efficacy should be carefully reviewed on treated mice. 3. In spite of the fact that treatment started from birth, it may be still challenge to have a complete remission in bone lesions. ERT will be a potential therapy for HPP.

## 3126/F/Poster Board #1058

**Pharmacological intervention for Rett Syndrome.** *J.C. Roux[1,2], E. Dura[1,2], N. Panayotis[1,2], A. Borges-Correia[1,2], A. Spiga[1,2], J. Mancini[3], L. Villard[1,2].* 1) INSERM, U910, Marseille, France; 2) Aix-Marseille University, La Timone Medical School, Marseille, France; 3) Marseille University Hospital, La Timone Children's Hospital, Marseille, France.

Rett syndrome is a severe neurological disorder caused by mutations in the MECP2 gene. Recent breakthrough experiments demonstrated that the reactivation of the Mecp2 gene in the mouse model of Rett syndrome could reverse the symptoms of the disease, thereby providing an exceptional pre-clinical proof of concept to support gene therapy approaches for Rett syndrome. Unfortunately, these approaches are currently out of reach for most genetic diseases and they will be even more complicated to provide to Rett syndrome patients because 1- the brain will be the organ to treat and 2- young children will have to be treated. While several groups have focused their efforts onto the development of these promising approaches, others are trying to develop pharmacological interventions to alleviate part of the symptoms. Using a Mecp2-deficient mouse, we have previously shown that breathing disturbances was associated to noradrenergic deficits at the brainstem level and we demonstrated a significant decrease in the number of noradrenergic neurons in two nuclei involved in the cardio-respiratory control. We subsequently showed that catecholaminergic neurons located in the peripheral nervous system are also affected by the lack of Mecp2 protein. We now have extended our analysis to the locus coeruleus, the main noradrenergic cluster in the brain, where we identified additional noradrenergic deficits, namely a decrease of tyrosine hydroxylase mRNA and protein and a decrease in the number of tyrosine hydroxylase expressing neurones. These catecholaminergic deficits could collectively explain the autonomic dysfunctions observed in the disease and open new perspectives to better understand the consequences of Mecp2 dysfunction. They also strenghten our approach based on pharmacological intervention to stimulate biogenic amine metabolism. We initially validated a pharmacological treatment in the mouse using desipramine, a noradrenergic reuptake inhibitor, and have initiated a phase II clinical trial. We are now testing additional candidate drugs to alleviate the autonomic and motor symptoms of Rett Syndrome using the Mecp2-deficient mouse as a pre-clinical model.

## 3127/F/Poster Board #1059

**Effect of laronidase therapy on myocardial function in a patient with MPS I assessed by two-dimensional ultrasound speckle tracking imaging.** *H. Harada, M. Nakamura, S. Ohno, H. Morita, A. Katoh, H. Ikeda.* Department of Cardiology, Kurume University Medical Center, Kurume, Fukuoka pref., Japan.

Purpose: We assessed whether laronidase, which is recombinant human $\alpha$-L-iduronidase, replacement therapy (LRT) is effective on left ventricular myocardial function in a patient with Sheie phenotype of MPS I. Methods and subject: We assessed left ventricular myocardial function using two-dimensional ultrasound speckle tracking imaging method in a 49-year-old woman with Sheie syndrome. Results: At 6 months after Laronidase ERT, the concentrations of urinary uronic acid gradually decreased (reduction ratio, 78.8%). Simultaneously, hepatosplenomegaly reduced and left ventricular weight decreased from 189 to 152g. These findings suggested that ERT was effective on MPS I. Left ventricular ejection fraction assessed by two-dimensional echocardiogram did not change after ERT. Next, we assessed myocardial function focused on longitudinal and radial strains and torsion obtained from two-dimensional speckle tracking imaging. In the myocardial longitudinal strain (shortening ratio), the mean shortening ratio changed from -13.2 to -17.4%. In the myocardial radial strain (thickening ratio), the mean thickening ratio changed from 26.6 to 83.4%. In the myocardial torsion, left ventricular torsion changed from +6 to +18 degrees. Summary: These indices of myocardial function were improved within normal limits after ERT. Thus, our findings were a first report that ERT had a beneficial effect on left ventricular myocardial function in a patient with MPS I.

## 3128/F/Poster Board #1060

**Home Therapy with Idursulfase for Hunter Syndrome: The Hunter Outcome Survey Experience.** *B.K. Burton[1], S.A. Jones[2].* 1) Dept Gen,Birth Def, Metab, Children's Memorial Hosp, Chicago, IL; 2) Specialist Registrar in Paediatric Metabolic Medicine, Willink Biochemical Genetics Unit, Royal Manchester Children's Hospital, Pendlebury, Manchester, United Kingdom.

Hunter syndrome is an X-linked metabolic disease caused by a deficiency in the lysosomal enzyme iduronate-2-sulfatase (I2S). Enzyme replacement therapy (ERT) with recombinant human I2S (Elaprase®, idursulfase, Shire HGT) for Hunter syndrome has been available since 2006. Idursulfase is administered weekly by an intravenous infusion that can last 3 to 4 hours. Because of the prolonged infusion time, patients are often forced to miss school or work on the day that they receive their dose. Home infusion offers an alternative, more convenient setting for these weekly infusions. Here we present observations about home infusion from the Hunter Outcome Survey (HOS). HOS is a global, multicenter, long-term observation survey designed to acquire data from Hunter syndrome patients in their normal medical care environment. As of April 16, 2009, 541 prospective patients (ie, alive at HOS entry) from 98 clinics in 23 countries have enrolled in HOS. Of the 367 patients in HOS receiving ERT, 82 (22%) were being treated at home, with most of these patients residing in the United States (n=33 from 13 clinics) or the United Kingdom (n=35 from 3 clinics), with 4 patients each in the Netherlands and Germany, 2 patients each in France and Sweden, and 1 patient each in Canada and Denmark. Their median age at the initiation of ERT was 8.6 years with a median age at transitioning to home therapy of 9.7 years. The median duration of ERT before transitioning to home therapy was 10.9 months (10th-90th percentile: 3.0-38.3 months). In the 65 patients who had not participated in clinical trials of idursulfase, the median age at initiation of ERT was 7.9 years and the median interval before beginning home therapy was 7.8 months (10th-90th percentile: 2.8-17.4 months). Three patients have experienced a total of 7 infusion-related reactions (IRR) after the onset of home therapy. These IRRs were mild-to-moderate in severity and involved fever and rash. In all cases these reactions were successfully managed by slowing or stopping the infusion and/or administration of an antihistamine. Overall, 2 of 28 patients (7%) with at least 12 months of home therapy have reported an IRR. Conclusions: Data from HOS indicate home therapy is feasible and is not associated with a higher incidence of adverse events or IRRs. Thus home therapy is well tolerated and accepted by these families, patients, their physicians, and importantly, by payers and medical insurers.

## 3129/F/Poster Board #1061

**Correction of PKU in the *Pah*$^{enu2}$ mouse by Phenylalanine Ammonium Lyase: Maternal, Biochemical, and Behavioral Studies.** *P. Laipis[1], W. Zeile[1], J. Embury[1], M. Lewis[2], R. Zori[3], D. Musson[4], B. Zhao[4], C. Santamaria[4], S. Bell[4], A. Cheng[4], C. O'Neill[4], L. Tsuruda[4].* 1) Dept Biochem & Molecular Biol, Univ Florida, Gainesville, FL; 2) Dept Psychiatry, Univ Florida, Gainesville, FL; 3) Dept Pediatrics, Univ Florida, Gainesville, FL; 4) BioMarin Pharmaceuticals, Inc. Novato, CA.

Phenylketonuria (PKU) is the most frequent disorder of amino acid metabolism (~1 in $10^4$ births) in populations of European origin. PKU patients accumulate phenylalanine (Phe) to abnormally high concentrations due to a low or absent phenylalanine hydroxylase (PAH), the first enzymatic step in Phe degradation. High Phe results in symptoms ranging from mild cognitive impairment to severe mental retardation. Although deleterious effects can be minimized by a Phe-restricted diet instituted at birth, the diet is demanding and most adult PKU patients are poorly compliant, leading to cognitive and behavioral deficits. Alternate therapies would be valuable, especially for treatment of Maternal PKU Syndrome. We have previously reported that a recombinant phenylalanine ammonium lyase derived from *Anabaena variabilis*, modified by multiple PEGylations (rAvPAL-PEG), is being developed as an investigational enzyme substitution therapy for PKU. Treatment of male BTBR *Pah*$^{enu2}$ mice, an animal model of PKU, with rAvPAL-PEG resulted in long-term correction of Phe levels (> 6 months). Mice were healthy, showed increased body weight and exhibited no adverse effects. Female mice also responded to rAvPAL-PEG, albeit at higher doses than males. Treated female mice showed a correction of the Maternal PKU Syndrome and produced viable pups. We have previously reported histological abnormalities in brains of both male and female PKU mice (Brain Res. 1127:136-50, 2007); rAvPAL-PEG treatment resulted in correction of these abnormalities and subsequent termination of rAvPAL-PEG treatment led to a slow return of these findings. Biochemical analysis showed that tyrosine levels, which are depressed in untreated PKU mice and human patients (Mol Genet Metab 69: 286-294, 2000), remain depressed in rAvPAL-PEG treated PKU mice with physiological Phe levels. This data suggests that not only is the PAH pathway an important input into tyrosine homoeostasis but also that impaired amino acid uptake may not be responsible for the tyrosine depression observed in untreated PKU patients. Based on this observation tyrosine dietary supplementation might be a useful adjunct to rAvPAL-PEG therapy for PKU. Finally, behavioral studies of treated mice show improvements in both activity levels and specific behavior patterns. These results suggest that rAvPAL-PEG therapy may be a viable alternative to the medical diet for PKU patients.

## 3130/F/Poster Board #1062

**Does Enzyme Replacement Therapy (ERT) Reduce the Frequency of Infectious Illnesses in Patients with Hunter Syndrome (MPS II)?** *R.H. Katz[1], B.K. Burton[1,2].* 1) Genetics, Children's Memorial Hospital, Chicago, IL; 2) Northwestern University Feinberg School of Medicine, Chicago, IL.

Individuals with Mucopolysaccharidosis type II (MPS II, Hunter syndrome) display a wide range of symptoms as a result of glycosaminoglycan (GAG) accumulation in tissues. These symptoms include chronic nasal congestion, chronic otitis media, and respiratory distress. Prior to 2006, there was no treatment for Hunter syndrome aside from symptomatic care. Idursulfase (Elaprase®, Shire HGT), an enzyme replacement therapy (ERT), was approved by the FDA and became commercially available in the US in August 2006. Between late August 2006 and January 2007, 6 patients with MPS II, ages 6-13, were started on Elaprase® therapy at Children's Memorial Hospital. Two of these patients have an attenuated phenotype without central nervous system (CNS) involvement, one patient has an intermediate phenotype with mild CNS involvement, and three patients have a severe phenotype with CNS involvement. We examined the medical records of these 6 patients for the two years prior to the initiation of ERT and two years post ERT. We tabulated the number of infectious illnesses diagnosed by their treating physicians, the number of emergency room visits, and the number of hospital admissions during this period of time. In total there were 38 pre-ERT infectious illnesses (14 otitis media, 4 viral infections, 17 upper respiratory infections, and 3 streptococcal pharyngitis), 18 post-ERT illnesses (6 otitis media, 2 viral infections, and10 upper respiratory infections), 2 pre-ERT emergency room visits (both for respiratory distress), 5 post-ERT emergency room visits (all for respiratory distress), 1 pre-ERT hospital admission (pneumonia), and 0 post-ERT hospital admissions. This preliminary data suggests that ERT may reduce the frequency of infectious illness in patients with Hunter syndrome. Further study in a larger number of patients will be needed to confirm these findings.

## 3131/F/Poster Board #1063

**Genz-112638 for Gaucher Disease Type 1: Phase 2 Clinical Trial Results after One Year of Treatment.** *J. Peterschmitt[1], E. Lukina[2], N. Watman[3], E. Avila Arreguin[4], M. Banikazemi[5], G. Pastores[6], M. Iastrebner[7], M. Dragosky[7], H. Rosenbaum[8], M. Phillips[9], M. Kaper[1], S.E. Smith[1], A.C. Puga[1].* 1) Genzyme Corporation, Cambridge, MA; 2) Russian Academy of Medical Sciences, Moscow, Russia; 3) Hospital Ramos Mejia, Buenos Aires, Argentina; 4) Instituto Mexicano del Seguro Social Hospital de Especialidades, Col. La Raza, Mexico; 5) Columbia University Medical Center, New York, NY; 6) New York University School of Medicine, New York, NY; 7) Instituto Argentino de Diagnostico y Tratamiento, Buenos Aires, Argentina; 8) Rambam Medical Center, Haifa, Israel; 9) Sha'are Zedek Medical Center, Jerusalem, Israel.

**Introduction:** Genz-112638, a novel oral small molecule inhibitor of glucosylceramide synthase, is under development for the treatment of Gaucher disease type 1 (GD1). An open-label, multicenter Phase 2 clinical trial to evaluate the efficacy, safety, and pharmacokinetics of Genz-112638 in patients with GD1 is ongoing. Results after 52 weeks of treatment are available. **Methods:** This trial of Genz-112638, given 50 or 100mg twice per day orally, treated 26 adults with GD1 (16F:10M; mean age 34 years, range 18-60; all Caucasian) at 7 sites in 5 countries. Inclusion criteria included splenomegaly (vol.≥10x normal) and either thrombocytopenia (platelets 45,000-100,000/$mm^3$) or anemia (hemoglobin 8-10 g/dL [F] or 8-11 g/dL [M]) and no enzyme replacement or substrate reduction therapy in the prior 12 months. The primary efficacy endpoint was a composite of 52-week improvements in ≥ 2 of 3 parameters: spleen volume (-15%), hemoglobin level (+0.5 g/dL) or platelet count (+15%). Bone status was evaluated by central review of MRI, DXA and X-ray. Long-term treatment and monitoring is ongoing. **Results:** 22 patients completed 52 weeks; 4 withdrew. The primary endpoint was met by 77% (20/26) of all patients and by 91% of 22 patients completing 52 weeks. Mean hemoglobin improved by 1.6±1.4 g/dL and platelet count by 40±37%. Mean spleen volume decreased by 39±11% and mean liver volume by 17±10%. Chitotriosidase and CCL-18 had median decreases of 52% and 55%. Plasma glucosylceramide levels normalized in all patients. No bone crises or reductions in mobility were reported. Femur MRI showed improved dark marrow signal in 7 patients and stable findings in the remaining 13 patients with data. There were no new lytic lesions or infarcts; one pre-existing infarct progressed. Lumbar spine bone mineral density (DXA Z-score) was -1.32±1.02 at baseline and improved by a mean of 0.31±0.48 (p=0.0146; n=18). Genz-112638 was well tolerated with an acceptable safety profile. In all, 91% of AEs were unrelated to drug treatment and most were mild in severity. The most common AEs overall were urinary tract infection and GI symptoms; no single AE occurred in more than 3 patients. Seven drug-related AEs occurred in 6 patients early in treatment and were mild and transient. **Conclusion:** Genz-112638 improved hematologic, visceral and bone manifestations in GD1 and was well tolerated in this Phase 2 study. Phase 3 studies of untreated and Cerezyme-stabilized patients will begin in mid-2009.

**Inflammation in the mucopolysaccharidoses and the use of anti-TNF-α therapy.** *C. Simonaro[1], Y. Ge[1], E. Eliyahu[1], K. Jepsen[2], E. Schuchman[1].*
1) Dept Genetics & Genomic Sci, Mount Sinai Sch Medicine, New York, NY; 2) Dept. of Orthopedics, Mount Sinai Sch Medicine, New York, NY.

Enzyme replacement therapy (ERT) is available for three MPS disorders, but has limited effects in the bones and joints. We have investigated the involvement of the toll-like receptor 4 (TLR4) signaling pathway in the pathogenesis of MPS bone and joint disease, and the use of anti-inflammatory agents for the treatment of these diseases. TLR4 knockout (KO) mice were bred to mice with MPS type VII. Double KO animals grew substantially better than MPS VII mice alone, and had longer and thinner faces. The levels of several inflammatory cytokines, including TNF-α, also were substantially reduced in the double KO mice, leading us to evaluate the effects of the FDA-approved anti-TNF-α drug, Remicade, in rats with MPS VI. When initiated pre-symptomatically (1 month of age), intravenous (2x per week for 24 weeks; 3 mg/Kg) Remicade treatment prevented the elevation of TNF-α and other inflammatory molecules in the blood. Importantly, the levels of these markers also were markedly reduced in chondrocytes and synovial fibroblasts from the treated animals. Although the overall growth of these animals was not improved by Remicade treatment, the number of apoptotic chondrocytes were reduced by ~50%, as was the infiltration of synovial tissue into the underlying bone. These results indicated positive effects of Remicade treatment at the sites of pathology. Remicade treatment also reversed the established inflammatory disease in older animals. Thus, these studies reveal the important role of TLR4 signaling in the pathogenesis of MPS bone and joint disease, and suggest that targeting a downstream mediator of this pathway, TNF-α, can have positive effects. **Resveratrol or SIRT1 activators: new candidate drugs for correction of inborn mitochondrial FAO or RC disorders?** *J. Bastin, F. Aubey, F. Fjouadi.* CNRS FRE 3210, Faculté Necker Enfants Malades, Paris, France.

Resveratrol (RSV) is a natural polyphenol compound found in red grapes and other plants, with potential anti-cancer and cardioprotective effects. RSV acts in part as an antioxidant to reduce cellular oxidative stress, but was also recently proposed to up-regulate mitochondrial oxidative metabolism, through an activation cascade involving SIRT1, a member of the NAD-dependant histone deacetylase sirtuin family, and PPAR Gamma Co-activator 1-alpha (PGC-1α), a key regulator of mitochondrial energy metabolism. This led us to test RSV effects on oxidative stress and residual metabolic capacities in fibroblasts from patients with inborn fatty acid β-oxidation (FAO) or respiratory chain (RC) deficiency. Addition of RSV stimulated residual FAO capacities (3H-palmitate oxidation) in a dose- (20μM to 80μM) and time-dependant manner in cultured patient fibroblasts with the mild form of Carnitine Palmitoyl Transferase 2 (CPT2) or Very Long Chain AcylCoA Dehydrogenase (VLCAD) deficiency. Furthermore, correction of FAO was achieved in cell lines with different CPT2-deficient or VLCAD-deficient genotypes, after treatment by RSV at 80μM for 48h. Quantitative PCR revealed a +30 to +60% CPT2 and VLCAD mRNA increase in response to RSV while western-blot indicated a marked RSV-induced up-regulation of CPT2 or VLCAD protein in the treated patient cells. Studies with DCFH-DA fluorescent probe showed that RSV treatment could also normalize the production of Reactive Oxygen Species (ROS) in FAO-deficient fibroblasts. Exposure of fibroblasts to a SIRT1 activator (CAY10591, Cayman chemicals) could mimic the stimulatory effects of RSV in FAO-deficient fibroblasts, whereas addition of SIRT1 inhibitor Sirtinol prevented the RSV-induced increase in FAO. In parallel, patient cells treated with siRNA directed against PGC-1α exhibited a markedly blunted response to RSV in FAO studies. Finally, preliminary western-blot data indicate that RSV could enhance the expression of subunits or ancillary proteins of all RC Complexes in control fibroblasts, and could increase mutated protein levels in CI- or CIV-deficient cells. Altogether, these initial studies -suggest a potential of natural or synthetic SIRT1 activators for correction of FAO or RC deficiencies due to partial loss-of-function mutations, which are often encountered in these genetic diseases - indicate that the SIRT1/PGC-1α cascade represents a highly relevant new therapeutic target in these disorders.

**Curcumin partially mitigated the phenotype of Pelizaeus-Merzbacher disease caused by *PLP1* point mutations in mouse.** *K. Inoue[1], L-H. Yu[1], T. Morimura[1], H. Iwashita[1], R. Yamamoto[1], K. Deguchi[1,2], B. Antalfy[2], N. Inoue[1], H. Osaka[3], M. Itoh[1], Y. Goto[1].* 1) Dept MR & BD Res, Natl Inst Neurosci, NCNP, Kodaira, Japan; 2) Dept of Pathology, Texas Children's Hospital, Houston, US; 3) Neurology, Clinical Research Institute, Kanagawa Childeren's Medical Center, Yokohama, Japan.

Natural compounds have great advantage in rapid and safe clinical application if therapeutic effects against genetic diseases, especially in pediatric patients, can be established. Pelizaeus-Merzbacher disease (PMD) is a devastating X-linked inherited neurodevelopmental disease characterized by a failure of myelination in the central nervous system (CNS). PMD is caused by *PLP1* mutations, including genomic duplication, deletion, and point mutations, each of which lead to CNS dysmyelination through different molecular mechanisms. Nevertheless, no effective therapy for PMD is available to date. *PLP1* point mutations, mainly leading to amino acid substitutions, cause improper protein folding and accumulation in the endoplasmic reticulum (ER), resulting in disruption of ER proteostasis and apoptosis of oligodendrocytes. A natural compound curcumin has been reported to mitigate manifestations of some protein-misfolding-diseases, such as cystic fibrosis and demyelinating peripheral neuropathy, in mice. Here we examined if curcumin can also alleviate phenotype of *msd*, a mouse model of PMD. We treated *msd* mice with oral administration of curcumin (180mg/kg/day) dissolved in milk and found that curcumin significantly extended the life span of *msd* mice. Curcumin also inhibited apoptosis of oligodendrocytes in the *msd* brains. In contrast, no improvement in mylin formation or myelin-protein expression was observed. Although the exact molecular mechanism for curcumin in reducing the cellular toxicity caused by misfolded mutant protein still remains to be resolved, our data suggest that curcumin can be a good candidate for the treatment of PMD patients with *PLP1* point mutations.

### 3135/F/Poster Board #1067

**Pharmacological antagonism of TGFβ signaling improves skeletal muscle repair in mice with sarcopenia.** *T.N. Burks, E. Andres-Mateos, J.L. Simmers, E.M. MacDonald, C. van Erp, R. Rattner, R.D. Cohn.* McKusick-Nathans Institute of Genetic Medicine, Department of Pediatrics and Neurology, Johns Hopkins University School of Medicine, Baltimore, Maryland.

We have previously demonstrated that increased TGFβ signaling causes abnormal muscle repair and regeneration in various inherited myopathies. Moreover, antagonism of TGFβ in dystrophin-deficient mdx mice and fibrillin-1 deficient Marfan syndrome mice attenuated myopathic disease progression and improved muscle regeneration and repair. Critical loss of muscle mass is observed in various systemic conditions as well as in the physiological process of aging (sarcopenia). This often not only increases morbidity and mortality, but also increases the incidence of pathologic fractures, functional deterioration and institutionalization. The molecular mechanisms underlying sarcopenia are only poorly understood, but it has recently been demonstrated that an increase in TGFβ signaling contributes to impaired satellite cell function and muscle repair in old skeletal muscle. We therefore evaluated whether antagonism of TGFβ signaling via administration of TGFβ-neutralizing antibody (TGFBNab) or the angiotensin II type1 receptor blocker, losartan, has any beneficial impact on the muscle repair process of aged mice in vivo. To assess muscle regeneration capacity, muscle injury was induced by administration of the snake venom cardiotoxin and skeletal muscles of aged mice were analyzed at 4 and 18 days after injury induction. We find that systemic TGFβ antagonism via TGFBNab or losartan significantly improves the muscle regeneration process in response to injury. Aged mice demonstrate an increase in regenerating muscle fibers at 4 days after injury induction. Furthermore, after 18 days, mice treated with TGFBNab or losartan exhibit significantly less of fibrotic tissue formation and an overall more homogeneous appearance of regenerated skeletal muscle. Thus, pharmacological antagonism of TGFβ signaling may be an interesting target for the management of age-related loss of muscle mass. Further studies of long-term administration of losartan in aged mice over a prolonged period of time are currently in process in order to establish whether a beneficial impact on steady-state architecture and muscle function can be determined.

**New approaches to the therapy of keratinisation disorders: 3D skin model with a disturbed epidermal barrier function.** *K.M. Eckl[1,2], G. Weindl[3], K. Ackermann[3], M. Schäfer-Korting[3], H.C. Hennies[1,4].* 1) Dermatogenetics, Cologne Center for Genomics, University of Cologne, Germany; 2) Institute of Neurophysiology, University of Cologne, Cologne, Germany; 3) Div. for Pharmacology, Institute for Pharmacy, Freie Universität Berlin, Berlin, Germany; 4) Center for Molecular Medicine, University of Cologne, Cologne, Germany.

Hereditary keratinisation disorders are a clinically and genetically heterogeneous group of skin diseases. They are characterised by abnormalities in terminal keratinocyte differentiation. Clinical features may include marked keratosis, more or less intense scaling of the skin and mild to extensive erythema. A disturbed epidermal barrier function is often seen, which leads to secondary symptoms such as increased trans-epidermal water loss, imbalances in nutrition but also often severe eczema and allergies. To investigate the epidermal barrier function and to assess specifically designed therapeutics we have developed a 3D skin model which mimics congenital ichthyosis, a rare and severe keratinisation disorder. The model consists of an underlying dermal equivalent and a fully stratified perfectly organised epidermal part, with a well established basement membrane zone in the dermal-epidermal junction area. For model preparation we use keratinocytes which have been specifically knocked down for single disease related genes. The model has been validated following OECD guidelines for artificial skin using reference substances and is now being used to investigate the ability, effects, and toxicity of the application of new drugs for therapeutic approaches, e.g. gene products and metabolites that are missing in the patient epidermis. To improve our model we are investigating the effects of long time cultivation and media components as well as the effects of melanocytes and Langerhans cells (dentritic cells) in the patient epidermis mimicking model. To improve cultivation duration the knock down process is now being changed from transient to lentiviral mediated. Our model is the first human artificial skin model showing an epidermal barrier functional defect, which is highly similar to biopsy samples from patients suffering from congenital ichthyosis. The models can be routinely manufactured, used for drug and cosmetic screening, is easily established and shows a high reproducibility from batch to batch. The European patent application for this model has just been filed.

## 3137/F/Poster Board #1069

**Management of ADHD in a population of Children with Genetic Learning Disability.** *A.D. Rasalam[1], J.C. Dean[2].* 1) Learning Disability Team, Royal Aberdeen Childrens Hospital, Aberdeen, United Kingdom; 2) Department of Clinical Genetics, Aberdeen Royal Infirmary, Foresterhill, Aberdeen, United Kingdom.

In North East Scotland (Population : 500,000; Estimated population with learning disability : 15,000), any child of school going age who has a recognised learning disability has their education provided through a special school or through a Special Needs Base within a mainstream school. The psychiatric and psychological needs of all these children are provided through the Learning Disability Team at the Royal Aberdeen Children's Hospital. All children referred to the team are offered genetic testing including Karyotype, Fragile X and Telomere MLPA to evaluate an underlying cause for their learning difficulties. Children are also offered an appointment with the geneticist as appropriate or when clinical suspicion of particular disorders exists. Among the children seen by the team 56 fulfilled the diagnostic criteria for Attention Deficit (Hyperactivity) Disorder. The diagnosis was made based on the presence of hyperactivity, impulsivity or problems of attention that is significantly in excess of that expected for developmental stage and evident in multiple settings. These children and their families are then offered psychological, behavioural and pharmacological interventions. Among these 56, an underlying genetic disorder which was identified in eleven (3 girls, 8 boys). The disorders diagnosed include Fragile X Syndrome, Neurofibromatosis Type 1, Myotonic Dystrophy, Hyperprolinemia, Incontinentia Pigmenti, Telomere deletion or duplication and one child with an apparently balanced reciprocal translocation. The balanced translocation involved chromosomes 9 and 10 and segregated with behaviour disturbance in the family. There were 3 Telomere duplications and one telomere deletion. One child had inherited 16q duplication from a parent who also has clinical features of attention deficit and impulsivity and had attended special school. The other patients had an 11q duplication, 12q duplication and 12q deletion. All the children had a beneficial response to treatment and are on either Methylphenidate or Atomoxetine or a combination of the two. Four patients responded to Methylphenidate, three to Atomoxetine, three to a combination of the two, while one family chose to try behavioural methods. The families and schools of these children have noticed a significant improvement in quality of life and academic progress in these children. Standard therapy including drug treatment appears to be of value in patients with ADHD due to an underlying genetic cause.

## 3138/F/Poster Board #1070

**Dose-dependent improvements of the hypophosphatasia phenotype in *Akp2$^{-/-}$* mice following the administration of ENB-0040.** *H. Landy[1], I. Lemire[2], L. Blond[3], T.P. Loisel[2], G. Boileau[4], J.L. Millan[5], P. Leonard[2], P. Crine[2].* 1) Enobia Pharma, Cambridge, MA; 2) Enobia Pharma, Montreal, Canada; 3) University of Montreal, Dept. of Clinical Sciences, Montreal, Canada; 4) University of Montreal, Dept. of Biochemistry, Montreal, Canada; 5) Burnham Institute for Medical Research, La Jolla, CA.

Hypophosphatasia (HPP) is a rare inherited form of rickets or osteomalacia caused by inactivating mutations in the gene encoding tissue nonspecific isozyme of alkaline phosphatase (TNSALP). The prevalence of the disease is about 1:100,000 for the severe form. Severity is inversely related to the age at symptom onset. Since no established medical therapy for HPP is presently available, we have designed a soluble recombinant form of TNSALP (ENB-0040) for enzyme replacement therapy. ENB-0040 comprises the catalytic domain of the human TNSALP, human immunoglobulin Fc region and a deca-aspartate peptide to target the enzyme directly to bone. We have used the *Akp2$^{-/-}$* mouse model to evaluate the effect of systemic administration of ENB-0040 on skeletal defects and survival of HPP mice. We have previously shown that daily subcutaneous (SC) administration of ENB-0040 prevents bone mineralization defects of the feet in *Akp2$^{-/-}$* mice. We have now evaluated the dose response relationship of ENB-0040 SC administration on survival and bone mineralization defects of the feet, rib cages and pelvic limbs. Newborn *Akp2$^{-/-}$* mice received daily SC injection of ENB-0040 at 0.5, 2.0 and 8.2 mg/kg for 43 days. The primary endpoint was extent of mineralization defects; secondary endpoints included mortality, body weight and femur and tibia length. Bone mineralization defects were evaluated by radiographs and classified in a blinded fashion by a qualified veterinarian radiologist. Animals were classified as Normal or Abnormal. Abnormal individuals have at least one missing bone structure including secondary ossification center. There is a clear relationship between administered daily dose of ENB-0040 and improvement of mineralization defects of feet, rib cages and pelvic limbs with $r^2$=0.993, 0.986 and 0.999, respectively. According to the dose response model, the ED50 was 0.9, 0.8 and 0.5 mg/kg/day for feet, rib cages and pelvic limbs. Long bones seem to respond to lower daily doses of ENB-0040. There was also a clear relationship between dose and survival with $r^2$=0.989. Median survival was improved from 19 days in Vehicle-treated *Akp2$^{-/-}$* mice to 24, 31 and >44 days with increasing doses of ENB-0040. Body weight and bone length were also improved in a dose dependent manner. These dose response relationships strongly support the pharmacological activity of ENB-0040 and provide support for the estimation of the range of human effective doses.

## 3139/F/Poster Board #1071

**Hydroxycobalamin dose escalation optimizes metabolic control in cblC.** *N. Carrillo-Carrasco[1], J. Sloan[1], D. Valle[2], A. Hamosh[2], C.P. Venditti[1].* 1) NHGRI, National Institutes of Health, Bethesda, MD; 2) Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD.

Cobalamin C (cblC), a form of combined methylmalonic acidemia and hyperhomocysteinemia, is recognized as the most frequent inborn error of intracellular cobalamin metabolism. This condition is detected by expanded newborn screening and although the phenotype is variable, many patients have an acute neonatal presentation that is life-threatening if not suspected and treated promptly. Intramuscular hydroxycobalamin (OH-Cbl) is the main treatment for patients with cblC, but formal dosing guidelines do not exist. Clinical improvement and a decrease of plasma methylmalonic acid (MMA) and total homocysteine (tHcy) levels, and an increase in methionine are typically observed soon after its initiation. However, despite treatment, long-term complications such as developmental delay and progressive visual loss may develop. We describe the biochemical response of a 13-year-old male with cblC and worsening metabolic parameters despite strict adherence to a conventional treatment regimen. He is homozygous for c.271dupA mutation, the most common disease-causing allele. He was diagnosed at 3 weeks of life, responded appropriately to conventional treatment with IM OH-Cbl 1 mg/day, betaine, folic acid and carnitine. At the time of assessment at 13 years of age, he had normal growth, pigmentary retinopathy with severely constricted visual fields, and mild developmental delay. tHcy was 112 $\mu$M (normal 0-13 $\mu$M), plasma MMA 25 $\mu$M (normal <0.27 $\mu$M), propionylcarnitine 3.92 nM (normal <0.8 nM), methionine 17 $\mu$M (normal: 7-47 $\mu$M). We progressively increased the OH-Cbl dose from 1 to 20 mg per day with no other modifications in his regimen. We observed a dose-dependent response with an 80% reduction of plasma MMA (25 to 5.14 $\mu$M) a 55% reduction of tHcy (112 to 50 $\mu$M) and a greater than two-fold elevation of methionine (17 to 36 $\mu$M). This was accompanied by a reduction in the levels of propionylcarnitine, 2-methylcitrate and cystathionine. Our observations show that higher OH-Cbl doses might be required to achieve an optimal biochemical response in cblC patients. Whether this intervention may slow or eliminate other complications in cblC is unknown. The safety of parenteral administration of much higher doses of OH-Cbl has been previously established. Future clinical trials to determine the benefits of this intervention in patients with cblC and other disorders of intracellular cobalamin metabolism should be planned.

### 3140/F/Poster Board #1072

**Simvastatin and brain cholesterol turnover in children with Smith-Lemli-Opitz syndrome (SLOS).** *L.S. Merkens[1], J.B. Roullet[1], A.E. DeBarber[2], A.S. Pappu[2], D. Lütjohann[3], J.A. Penfield[1], J.M. Jordan[4], W.E. Connor[5], R.D. Steiner[1,6].* 1) Dept Pediatrics, Oregon Health & Science Univ., Portland, OR; 2) Dept Physiology and Pharmacology, Oregon Health & Science Univ., Portland, OR; 3) Dept of Clinical Pharmacology, Univ. of Bonn, Bonn, Germany; 4) Oregon Clinical and Translational Research Institute, Oregon Health & Science Univ., Portland, OR; 5) Dept of Medicine, Oregon Health & Science Univ., Portland, OR; 6) Dept Molecular and Medical Genetics, Oregon Health & Science Univ., Portland, OR.

Smith-Lemli-Opitz syndrome is an autosomal recessive disorder caused by a defect in the final step in cholesterol (CH) synthesis. Mental retardation is one nearly universal feature. Cholesterol deficiency and accumulation of cholesterol precursors may be causative. One treatment objective is to raise plasma CH and lower precursors such as 7-dehydrocholesterol (7DHC). Dietary CH is widely used as potential treatment, but since it does not cross the blood brain barrier (BBB), it is unlikely to impact development in affected children. Statins inhibit HMG-CoA reductase, a key proximal enzyme in cholesterol synthesis. Lipophilic statins (e.g. simvastatin; simv) cross the BBB and may be therapeutic by reducing 7DHC while increasing brain CH synthesis (Hum Mol Genet: 15:839). 24S-hydroxycholesterol (24S) is formed in the brain from CH and crosses the BBB into the circulation where it serves as a marker of brain cholesterol turnover. Thus simv treatment may increase 24S in SLOS. We measured plasma (pl)-24S in 6 SLOS children (simv group, age: 1.3-12.5 yr) on high cholesterol diet before and after treatment with simv (mean treatment duration: 1.4.yr; dose 0.1-0.4 mg/kg) and in 6 SLOS children on a high cholesterol diet (control group; age 0.3-14.4 yr) at two visits separated by 1.9 yr on average (approximately the same as the simv treatment period). Sterols were measured by GC and 24S by GCMS or LCMS. The two groups had similar initial parameters: pl-CH and 7DHC concentrations (mg/dl) were respectively $115 \pm 17$ and $7.8 \pm 3.1$ (simv) and $91 \pm 23$ and $6.3 \pm 2.3$ (control) (mean ± SE). 24S changes were expressed as the ratio of 24S to pl-CH (ng/mg; PNAS 93:9799). This ratio decreased similarly in the two groups, by 22% on average (before and after treatment) in the simv group and by 30% in the control, cholesterol only group (change between the two visits; NS). We confirmed the effect of age on the 24S-to-CH ratio ($p < 0.02$) but did not find any significant relationship between this ratio and either the severity scores, pl-CH, or 7DHC concentrations. We conclude that since simv did not change 24S from treatment with dietary cholesterol alone, simv treatment does not alter brain CH turnover in SLOS and is therefore unlikely to be therapeutic under the current experimental conditions. Studies with a larger number of subjects and/or studies with optimal dosing of simv will be necessary to further establish the potential benefit of statin therapy in SLOS.

### 3141/F/Poster Board #1073

**Familial Dysautonomia: Therapeutic efficacy of kinetin and luminescence-based splicing assay.** *R.S. Shetty[1, 2], Y.T. Chen[1, 2], J. Mull[1, 2], M.M. Hims[1, 2], L. Liu[1, 2], M. Leyne[1, 2], J. Pickel[3], S.A. Slaugenhaupt[1, 2].* 1) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA; 2) Harvard Medical School, Boston, MA; 3) National Institute of Mental Health, National Institutes of Health, Bethesda, MD.

Familial dysautonomia (FD), a congenital sensory neuropathy having widespread sensory and autonomic dysfunction, is caused by aberrant splicing of *IKBKAP* gene. All FD patients carry an intronic splice site mutation (IVS20+6T>C) in the *IKBKAP* gene, which results in tissue-specific partial skipping of exon 20 and subsequent reduced production of IKAP protein. Although FD is a recessive disease, homozygous mutant cells express wild-type *IKBKAP* transcripts, and produce normal IKAP protein. We are targeting the plasticity of the splicing machinery for the development of therapeutics for FD that would improve the production of the wild-type *IKBKAP* transcript and potentially lead to dramatic phenotypic improvements. We have previously identified kinetin, a plant cytokinin, as a modulator of *IKBKAP* mRNA splicing in FD lymphoblast cell lines. Recently, we tested the ability of kinetin to alter *IKBKAP* splicing in humanized FD *IKBKAP* transgenic mouse models, which carry the intronic *IKBKAP* (IVS20+6T>C) splice mutation and exhibit similar tissue-specific aberrant splicing pattern as FD patients. Treatment with kinetin modifies *IKBKAP* splicing in all major tissues assayed in the transgenic mice. The wild-type *IKBKAP* mRNA and IKAP protein levels were also significantly higher in the kinetin-treated mice suggesting that dietary supplementation of kinetin holds great promise as a potential therapeutic for FD. In parallel, we are developing new luminescence-based *IKBKAP* splicing assays using our previously designed *IKBKAP* minigene constructs to measure levels of wild-type *IKBKAP* transcripts in cells. These assays will be useful for high-throughput screening for drugs that can be used for treatment of FD, and perhaps even other human genetic diseases caused by splicing disorders.

### 3142/F/Poster Board #1074

**Drug Development for Rare and Neglected Diseases.** *P. Terry[1], K. Zonno[1,2], S. Terry[2].* 1) GRAND Therapeutics Foundation, Washington, DC; 2) Genetic Alliance, Washington, DC.

Rare and neglected diseases suffer not only the burden of the condition, but a lack of adequate incentives to develop therapies. At present, there is clear evidence of the insurmountable difficulties associated with the complex technical, scientific, and business aspects of successfully delivering treatments for over 7,000 genetic diseases. A recent IOM report declared: "... drug sponsors can spend over 13 years studying the benefits and risks of a new compound, and several hundred millions of dollars completing studies before seeking FDA's approval. About 1 out of 10,000 chemical compounds initially tested for their potential as new medicines is found safe/effective, and approved by FDA..." This sobering assessment is reflective of the active drug development enterprise for common disease, and doesn't consider the more severe failure rates for rare disease. There appear to be four major barriers, or 'walls', blocking routine drug development: assay development, preclinical/medicinal chemistry, natural history studies/clinical cohort development and regulatory approval. A public-private partnership has been created to advance creative solutions to navigate through these four walls. The effort is focused on helping organize and fund applied research, technology development, intellectual property management, and product development for rare and neglected diseases. The activities will focus on genetic disease mechanisms and directly assist in the develop of screening assays, secondary functional assays, screening compounds, re-purposing approved drugs, and creating mechanisms to get treatments into patients through the early clinical trial phases. Multiple entry points for various diseases will be created to allow each stakeholder group to capitalize on their ability to contribute based on expertise, state of the science, and possible serendipity from discoveries in industry, academia, and federal activities across the drug development continuum. An analysis and outline of the current rare and neglected disease product development opportunities will be presented on this initiative.

### 3143/F/Poster Board #1075

**Correcting SMN2 splicing with tailed antisense oligoribonucleotides: a potential therapeutic strategy for Spinal Muscular Atrophy.** *N. Owen[1], H. Zhou[2], F. Muntoni[2], I. Eperon[1].* 1) Biochemistry, University of Leicester, Leicester, United Kingdom; 2) Dubowitz Neuromuscular Unit, Hammersmith Hospital, Imperial College, London, United Kingdom.

Childhood onset Spinal Muscular Atrophy (SMA) is caused by homozygous deleted or mutation of the survival of motor neuron (SMN1) gene in over 95% of cases. A nearly identical copy gene, SMN2, lies in the same chromosomal location but is only found in humans. A single coding nucleotide difference between the genes (C to T; +6 position of exon 7) causes predominant exclusion of exon 7, resulting in a less stable truncated protein product. SMN2 cannot wholly compensate for the loss of SMN1, but is able to modulate the disease phenotype through the low amount of full length protein produced. Two models have been proposed for the loss of exon 7 in SMN2 transcripts; loss of an Exonic Splicing Enhancer (ESE) or gain of an Exonic Splicing Silencer (ESS) sequence. With the first model the loss of an ESE would result in the loss of interaction of the SR protein SF2/ASF and the skipping of exon 7. As a potential therapy we have developed bifunctional oligonucleotides consisting of an RNA antisense moiety, able to base-pair with the SMN transcript, and a tail sequence with consensus motifs that bind SF2/ASF. Such Targeted Oligonucleotide Enhancers of Splicing (TOES) increase the inclusion of exon 7 both in vitro and in SMA patient derived cell lines. We have investigated the effect of chemical modification along with tail length to improve both efficacy and to minimise toxicity. The most effective TOES oligonucleotide to date comprises of LNA (locked nucleic acid) and 2'O-methyl RNA demonstrating low toxicity and increased inclusion of exon 7. In addition, we have tested alternative target annealing sites in exon 7 to determine whether the tail is sufficient to result in inclusion of the exon independent of exonic enhancer sequences. The results show that the most conserved exonic enhancer is required in addition to the TOES oligo. Further work is being directed to making self-sufficient trans-enhancers.

**Human Rhodopsin(P23H)-GFP: a Mouse Model to Examine Gene Therapy Strategies to Treat Autosomal Dominant Retinitis Pigmentosa.** *B.A. Price[1,2], T.G. Wensel[2], J.H. Wilson[1,2].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Verna and Marrs McLean Department of Biochemistry and Molecular Biology, Baylor College of Medicine, Houston, TX.

Retinitis pigmentosa (RP) is a disorder that is typified by progressive retinal degeneration affecting 1:4,000 people worldwide. Patients with RP experience night blindness early in the course of the disease, which suggests rod cell dysfunction. As the disease progresses, patients experience a loss of peripheral vision and ultimately become blind. Inheritance of RP is heterogeneous; patterns of autosomal dominant (AD), autosomal recessive (AR), and X-linked recessive have all been documented. Many genes are known to cause RP upon mutation, but the most commonly affected is rhodopsin. Over 100 different mutations within rhodopsin can cause either ADRP or ARRP, with ADRP being more prevalent. Mutations causing ADRP are found throughout the entire rhodopsin protein-coding region and primarily consist of missense and nonsense mutations. The most common in North America is a cytosine to adenosine transversion that occurs in codon 23 causing a change from proline to histidine (P23H). The exact mechanism of pathogenesis associated with this mutation remains ambiguous. Ultimately, we aim to treat this disorder using a gene knockout approach. We have engineered a mouse that expresses human Rhodopsin(P23H)-GFP (P23H-GFP) from the endogenous mouse locus. These mice express P23H-GFP at low levels to allow us to follow correction, but not necessarily high enough to cause retinal degeneration. Most autosomal dominant gene therapy strategies involve targeting a specific mutation, but due to the heterogeneous nature of ADRP this would be costly and time-consuming. Gene knockout could provide a strategy to treat multiple individuals with distinct mutations that cause ADRP.

**Therapeutic RNAi for Dominant Muscle Disease.** *J.R. Chamberlain, J. Wei, E.E. Finn.* Medical Genetics, Department of Medicine, University of Washington, Seattle, WA.

Developing therapies for dominant genetic disease requires approaches aimed at eliminating the toxic gene product, either protein or mRNA. We are developing methods based on the endogenous RNAi pathway to destroy expressed mRNAs that are involved in dominant muscle disease pathogenesis. Our goal is targeted knockdown of expression of either protein or mRNA expressed from microsatellite mutations that cause disease. To test the effectiveness of RNAi as a potential muscle therapy, we targeted *lac*Z mRNA that is constitutively expressed in tissues of the ROSA26 mouse. we expressed short-hairpin RNAs (shRNAs) from mU6 that targeted *lac*Z mRNA and delivered them to muscle via tail vein injections in the context of rAAV6. We observed a 50-fold and 30-fold reduction in β-gal activity from cardiac and skeletal muscle, respectively, that most likely reflects differing levels of transduction of the vector. Our original shRNA expression constructs led to toxicity in heart and liver tissues that was mitigated by shortening the recognition sequence from 21nt to 19nt. We have since redesigned our RNAi expression cassettes to express miR30-based hairpins from U6 or shRNAs from the muscle-specific creatine kinase promoters CK6 and CK7. The main focus for testing the therapeutic potential of RNAi *in vivo* is a mouse model of muscular dystrophy, the *HSA*$^{LR}$ model of myotonic dystrophy (DM). The pathogenic repeat-expanded mRNA responsible for DM is expressed in skeletal muscle from the human skeletal actin gene (HSA). We are using recombinant adeno-associated virus, serotype 6 (AAV6), for muscle delivery of the RNAi expression cassettes targeting the pathogenic repeat expanded DM mRNA. We have observed widespread transduction of the RNAi expression cassettes and concomitant changes in both splicing patterns associated with RNAi delivery *in vivo* and in electromyographic analyses of the mouse muscle that is different from the disease state that most likely reflective of phenotypic improvement due to RNAi. Therapeutic targets for facioscapulohumeral muscular dystrophy (FSHD), cause by macrosatellite repeat contraction, include *FRG1* and *DUX4*, both implicated in FSHD pathology. The ability to decrease β-gal activity in the ROSA26 mouse and to affect dominant disease in a mouse model of muscular dystrophy suggests that rAAV6 vectors delivering siRNAs could be used for treatment of dominantly inherited diseases of muscle.

### 3146/F/Poster Board #1078

**Lethal Murine Model of Methylmalonic Acidemia Rescued in Excess of 12 Months by Gene Therapy.** *R.J. Chandler[1,2], C.P. Venditti[1].* 1) National Human Genome Research Institute, National Institutes of Health, Bethesda, Maryland, USA; 2) Institute for Biomedical Sciences The George Washington University, Washington, District of Colombia, USA.

Methylmalonic acidemia (MMA) is a genetic disorder caused by deficient activity of methylmalonyl-CoA mutase (MUT). MMA patients exhibit increased methylmalonic acid levels in the plasma and urine. Clinical complications of this disease include lethal metabolic decompensation, growth retardation, renal failure, metabolic strokes and neurological complications. These clinical problems occur even when the patients are being properly managed and treated. Because of the high mortality and poor long-term prognosis associated with MMA, new therapies are needed. To investigate the efficacy of gene therapy for MMA, a recombinant adeno-associated virus serotype 8 carrying the murine *Mut* cDNA (rAAV8-m*Mut*) was injected directly into the liver of newborn *Mut*$^{-/-}$ mice. Greater than 95% of the 27 *Mut*$^{-/-}$ mice injected with 1 or 2x10$^{11}$GC of rAAV8-m*Mut* have survived for over 1 year. All the untreated (n=58) and rAAV8-*GFP* treated (n=18) *Mut*$^{-/-}$ mice perished before day of life 72 with most of these mice dying in the first few days of life. Hepatic *Mut* RNA levels decreased from 37-72% at 90 days post-injection to 10-15% at one year post-treatment. Significant levels of *Mut* RNA were also detected in the skeletal muscle, brain and heart. Protein was detectable in the liver and skeletal at 90 days. Plasma methylmalonic acid levels in the treated *Mut*$^{-/-}$ mice were significantly reduced at 24 and 60 days after treatment and remained stable one-year post-treatment, indicating that substantial MUT enzymatic activity was restored and maintained. Whole body MUT enzymatic activity, indirectly measured by *in vivo* conversion of 1-$^{13}$C-sodium propionate into $^{13}CO_2$, was detectable in *Mut*$^{-/-}$ mice one-year post-treatment. To more accurately simulate a treatment scenario in humans, three untreated *Mut*$^{-/-}$ mice that survived 20 days were treated with an intraperitoneal injection of rAAV8-m*Mut*. At the time of treatment, these *Mut*$^{-/-}$ mice were growth deficient, lethargic and exhibited plasma methylmalonic acid levels of 1,100+/-118 μM. Following treatment the mice *Mut*$^{-/-}$ exhibited a rapid increase in activity, growth, reduction of plasma methylmalonic acid levels to 361+/-38 μM and an increase in MUT activity. These experiments provide the first evidence that gene therapy has clinical utility in the long term and acute treatment for methylmalonic acidemia and provide proof of principle evidence to support the development of gene therapy for other organic acidemias.

## 3147/F/Poster Board #1079

**Complete genetic correction of induced pluripotent stem cells from Duchenne muscular dystrophy using a human artificial chromosome.**
*Y. Kazuki[1], M. Hiratsuka[2], M. Takiguchi[1], M. Osaki[1], H. Hoshiya[1], K. Hiramatsu[1], N. Kajitani[1], T. Yoshino[3], K. Kazuki[1], N. Uno[1], M. Nakagawa[4], K. Takahashi[4], S. Yamanaka[4], M. Oshimura[1].* 1) Department of Biomedical Science, Institute of Regenerative Medicine and Biofunction, Graduate School of Medical Science, Tottori University, Tottori, Japan; 2) Department of Molecular and Cellular Biology, School of Life Sciences, Faculty of Medicine, Tottori University, Tottori, Japan; 3) Division of Functional Genomis, Research Center for Bioscience and Technology, Tottori University, Tottori, Japan; 4) Department of Stem Cell Biology, Institute for Frontier Medical Sciences, Kyoto University, Japan.

Induced pluripotent stem (iPS) cells made with defined factors have great potential for gene therapy, as such cells can be generated from an individual's tissues, and when re-introduced can contribute to the specialised function of any tissue. Homologous recombination has been used for the gene restoration of various genetic defects in embryonic stem (ES) or iPS cells. However, gene defects with unknown sites of mutation and those involving large deletions cannot be restored by homologous recombination. Duchenne muscular dystrophy (DMD) is caused by dysfunction of the dystrophin gene. Although several vectors have been developed for DMD gene therapy, no episomal vector containing the entire dystrophin genomic region has been reported, due to the extremely large size of this region (2.4 Mb). Human artificial chromosomes (HACs) offer several advantages as gene therapy vectors, including stable episomal maintenance that avoids insertional mutations and the ability to carry large gene inserts including regulatory elements. As a proof of concept, we herein report the correction of a genetic deficiency in iPS cells derived from DMD model (mdx) mice and human DMD patient, using a HAC with a entire genomic dystrophin (DYS-HAC) which we have recently developed (Hoshiya et al.,Mol. Ther.2009). The DYS-HAC was transferred to the mdx- or DMD patient-specific iPS cells via microcell-mediated chromosome transfer (MMCT). FISH analyses showed that the DYS-HAC was present as an individual chromosome in the iPS cells. Multiplex PCR and PCR analyses showed the transferred DYS-HAC corrected the deletion of dystrophin in the iPS cells. Next, the iPS cells containing the DYS-HAC were injected into SCID mice to assess the capacity of the differentiation and the expression in the teratoma. The transplanted DMD patient- and mdx-specific iPS cells with DYS-HAC gave rise to differentiate to three germ layers and the human dystrophin expression was detected in the tissues. Furthermore, chimeric mice from the mdx-iPS (DYS-HAC) were produced to assess the capacity of differentiation and human dystrophin expression in vivo. The DYS-HAC was detected in the all tissues examined and the dystrophin was detected in the sarcolemmal membrene of the chimeric muscle. Therefore, the combination of patient-specific iPS cells and HAC containing defective gene(s) provides a powerful tool for gene and cell therapies.

## 3148/F/Poster Board #1080

**Human FVIII expression using a HAC vector toward stem cell-mediated gene therapy for hemophilia A.**
*H. Kurosaki[1], M. Hiratsuka[2], N. Imaoka[1], Y. Iida[1], Y. Kazuki[1], C. Ishihara[3], N. Uno[1], H. Takeya[3], M. Oshimura[1].* 1) Department of Biomedical Science, Institute of Regenerative Medicine and Biofunction, Graduate School of Medical Science, Tottori University, Yonago, Japan; 2) Division of Human Genome Science, Department of Molecular and Cellular Biology, School of Life Sciences, Faculty of Medicine, Tottori University, Yonago, Japan; 3) Division of Pathological Biochemistry, Department of Biomedical Sciences, School of Life Sciences, Faculty of Medicine, Tottori University, Yonago, Japan.

Hemophilia A, an X-linked hemorrhagic disorder due to mutations in the gene that encodes Factor VIII (FVIII), affects 1 in 5000 males. Clinically, severe hemophilia is characterized by spontaneous and prolonged hemorrhage that can result in disability and death. Current therapies include fixed-dose FVIII prophylaxis, factor replacement therapies, and most recently, gene therapy using viral vectors. These therapies are limited by incomplete efficacy, high cost, restricted availability, and the possible tumorigenesis in treated patient. Human artificial chromosome (HAC) is stably maintained as an independent chromosome in host cells and should be free from the potential insertional mutagenesis problem of conventional transgenes. Therefore, HAC has been proposed as an alternative implement to cell-mediated gene therapy. In this study, we sought to elucidate the potential of HAC vector carrying the human FVIII cDNA for gene therapy of Hemophilia A. We have demonstrated the production and secretion of FVIII using the HAC vector carrying multi-copies of FVIII, and that HAC vector can be maintained as an independent mini-chromosome without integration into the host genome in CHO cells. We observed the expression level of FVIII depends on the copy number on the HAC in CHO cell. Next, the FVIII-HAC was transferred from the CHO hybrids into human immortalized (hi) MSC using the microcell-mediated chromosome transfer (MMCT) technique. We also observed that FVIII was expressed in hiMSC with the FVIII-HAC as a function of copy number, i.e., 4 copies < 16 copies. These results suggest that the HAC vector is useful for regulated expression of transgenes in stem cell-mediated gene therapy.

## 3149/F/Poster Board #1081

**A novel non-integrated human artificial chromosome vector carrying a conditional centromere.**
*Y. Iida[1], J. Ohzeki[2], Y. Kazuki[1], H. Hoshiya[1], M. Takiguchi[1], M. Hayashi[1], M. Nakano[2], H. Masumoto[2], W. Earnshaw[3], V. Larionov[4], M. Oshimura[1].* 1) Department of Biomedical Science, Institute of Regenerative Medicine and Biofunction, Graduate School of Medical Sciences, Tottori University, Yonago, Tottori, Japan; 2) Lab. of Cell Engineering, Dept. of Human Genome Research, Kazusa DNA Research Institute, Chiba, Japan; 3) Wellcome Trust Centre for Cell Biology, University of Edinburgh, scotland, United Kingdom; 4) Lab. of Biosystems and Cancer, National Cancer Institute, NIH, Bethesda, Maryland, United States.

**Background** Conventional gene transfer techniques using a viral vector, plasmid, P1 phage-derived artificial chromosome (PAC), bacterial artificial chromosome (BAC) and yeast artificial chromosome (YAC) integrate randomly into the host chromosome. Whenever the gene expression becomes unnecessary, it is difficult to remove the transgene because of insertion into host chromosomes. Conditional gene expression system without host chromosomal integration will be useful for physiological analysis. **Results** Human artificial chromosome containing tet-oprerator sequence in the centromeric region (tetO-HAC) had previously produced (Nakano et al., Dev. Cell 2008). The function of centromere can be controlled w/ or w/o doxycycline after introducing tet-repressor rtTA gene. To be useful for gene delivery, we inserted a loxP cassette into the tetO-HAC by homologous recombination. By using the Cre/loxP recombination, we introduced the EGFP gene into the tetO-HAC, resulting in stable expression at least 2 weeks. The tetO-EGFP-HAC was eliminated by introduction of rTA with high efficiency. This elimination system with the tetO-HAC could not affect host chromosome stability. **Conclusion** Here, we established a conditional gene expression system using a non-integrated human chromosome vector. Hence, a non-integrated artificial chromosome vector will be a useful tool for the conditional gene expression.

## 3150/F/Poster Board #1082

**Adeno-associated virus (AAV) type8 mediated systemic neonatal gene therapy for hypophosphatasia.**
*T. Matsumoto, S. Yamamoto, K. Miyke, N. Miyke, Y. Odagaki, H. Orimo, T. Shimada.* Department of Biochemistry and Molecular Biology, Nippon Medical School, 1-1-5 Sendagi Bunkyo-ku Tokyo, Japan.

Hypophosphatasia (HPP) is an inherited systemic skeletal disease caused by the deficiency of tissue-nonspecific alkaline phosphatase (TNALP). TNALP is attached to the outside plasma membrane via a GPI anchor and expressed in mainly liver, bone and kidney. Absence of TNALP activity results in extracellular accumulation of a natural substrate, inorganic pyrophosphate (PPi), which is a strong inhibitor for mineralization. HPP is clinically classified into four forms based on the age at onset and its severity. TNALP knock-out mice (Akp2-/-) phenotypically mimic to infantile HPP. They are born with a normally mineralized skeleton but develop apparent richets and die within 3 weeks, suffering severe skeletal hypomineralization and epileptic seizures. Recently, Millan et. al., demonstrated that Akp2-/- mice could be treated by daily subcutaneous injection of a bone-targeted form of TNALP in which a deca-aspartate (D10) sequence is linked to the C terminal end of soluble TNALP. We are currently trying to develop gene therapy approaches for HPP. In this experiment, we studied the feasibility of adeno associated virus (AAV) mediated systemic gene therapy of neonatal mice. We generated AAV vector expressing human soluble TNALP with a D10 sequence (AAV8-TNALPD10). In vitro experiments using culture cells showed that TNALP-D10 has high affinity to hydroxyapatite and enhances mineralization. Next, we injected AAV8-TNALPD10 (1x1012 vg/body) into the jugular vein of neonatal AKP2-/- mice at day 1. Sustained expression of TNALP activity in plasma (10.47 ± 4.3 U/ml) was detected in treated mice for at least 2 months. Mature bone mineralization was confirmed by X-ray analysis. Most significantly, treated HPP mice lived for more than 27 weeks with normal physical activity and healthy appearance, while non-treated mice died by 3 weeks. Ectopic calcification and abnormal calcium metabolism were not detected in treated mice. Furthermore, the mice treated with 1x1011 vg/body AAV8-TNALPD10 lived at least 9 weeks (n=5), while the mice treated with 1x1010 vg/body died within 3 weeks (n=7) as nontreated mice. These results suggest that AAV mediated systemic neonatal gene therapy is safe and effective to cure the infantile form of hypophosphatasia.

### 3151/F/Poster Board #1083

**Adeno associated virus (AAV)-mediated neonatal gene therapy of metachromatic leukodystrophy.** *N. Miyake, K. Miyake, M. Yamamoto, T. Shimada.* Dept of Biochemistry and Molecular Biology, Nippon Medical School, Tokyo, Japan.

Lysosomal storage diseases (LSDs) are important targets for enzyme replacement and gene therapy. The success of gene therapy for LSDs with neurological involvement such as metachromatic leukodystrophy (MLD) depends on the development of efficient delivery of lysosomal enzymes and/or vectors across the blood-brain barrier (BBB) to achieve wide distribution of enzyme throughout the brain. Since both the immune system and the BBB are developmentally immature during the perinatal period, neonatal gene transfer may be a highly promising strategy to treat genetic neurological disorders. In this experiment, we studied the feasibility of adeno associated virus (AAV) mediated systemic neonatal gene therapy of MLD mice. First, we examined biodistribution of serotype 8 AAV vector expressing GFP (AAV8/GFP) after injection into the jugular vein of neonatal mice (C57BL/6). Strong GFP expression was detected in the liver, muscle, and heart one month after injection. In addition, widespread transduction throughout the brain including the cortex, cerebellum, olfactory bulb, and brainstem was observed after neonatal injection, indicating that systemic neonatal injection of AAV is an effective strategy to cross the BBB for gene transfer into the central nervous system, which is tightly protected from virus infection in adult mice. To treat MLD mice, we generated serotype 8 AAV vector expressing human arylsulfatase A (AAV8/ASA) and IV injected into neonatal MLD mice. ELISA analysis showed that sustained expression of ASA was detected in the liver, muscle, heart and brain for more than one year. Furthermore, in the behavior test, AAV8/ASA treated mice showed a significant improvement in their ability to traverse narrow balance beams, as compared to non-treated MLD mice (Latency: $8.6 \pm 0.4$ vs. $13.0 \pm 1.3$ sec, $P<0.05$; Slips: $2.9 \pm 0.3$ vs. $4.3 \pm 0.4$ times, $P<0.05$). These data suggest that systemic neonatal injection of AAV is an effective strategy for treatment of genetic neurological diseases such as MLD and Krabbe disease.

### 3152/F/Poster Board #1084

**Adenoassociated virus-derived vector mediated correction of Mucopolysaccharidosis IVA.** *A.M. Montaño[1], C.J. Almeciga-Diaz[2], S. Tomatsu[1], L.A. Barrera[2].* 1) Dept Pediatrics, St Louis Univ, St Louis, MO, USA; 2) Instituto de Errores Innatos del Metabolismo, Pontificia Universidad Javeriana, Bogotá, Colombia.

Morquio A disease (MPS IVA) is an autosomal recessive disorder caused by the deficiency of N-acetylgalactosamine-6-sulfate sulfatase (GALNS), leading to accumulation of keratan sulfate and chondroitin-6-sulfate mainly in bone and cornea. The disease is characterized by generalized skeletal dysplasia and normal intelligence. So far there is no effective therapy available for Morquio A patients. In this study we have used adenoassociated virus-derived vectors (AAV) to mediate the gene transfer of the human GALNS gene in-vitro and in-vivo. We used three different promoters to drive GALNS gene expression, the human cytomegalovirus major immediate early promoter/enhancer (CMV), human alpha-antitrypsine (AAT) and elongation factor 1-alpha (EF1). In HEK293 cells, the eukaryotic promoters AAT and EF1 induced similar expression levels to those obtained with the CMV promoter. Transfection of human MPS IVA fibroblasts produced GALNS enzyme levels of 36, 54 and 15% compared to normal human fibroblasts, for CMV-GALNS, AAT-GALNS and EF1-GALNS vectors, respectively, while in murine MPS IVA chondrocytes values were around 40 and 70% of normal values. These enzyme activity levels were increased between 1.5 and 4.0-fold when cells were co-transfected with an AAV vector carrying the human Sulfatase Modifying Factor-1 (SUMF1) gene, and allowed to raise normal enzyme levels in MPS IVA fibroblasts. Seven to eight week-old MPS IVA mice were intravenously infused with AAT-GALNS and CMV-SUMF1 vectors for 12 weeks. GALNS activity in plasma and tissues was around 20 and 40%, respectively, of wild-type levels. These enzyme levels allowed a complete clearance of glycosaminoglycans (GAGs) in liver of MPS IVA treated animals. However, no difference in urinary GAG levels was observed between MPS IVA untreated, treated and wild-type animals, showing the need to use a different biomarker or quantification method. Finally, no silencing of CMV promoter was observed neither in-vitro nor in-vivo, pointing towards an effect of the vector type over this silencing mechanism. Altogether these results are the first evidence of the enzymatic correction in a murine model of MPS IVA by gene therapy and show the advantage of the co-expression with SUMF1 in order to obtain therapeutic levels of enzyme activity.

### 3153/F/Poster Board #1085

**Long-term expression of human Factor IX in rhesus macaque following catheter-based delivery of HDAd.** *P. Ng[1], P.M. Patel[2], N.C. Grove[1], D. Palmer[1], A. Beaudet[1], C. Mullins[2], N. Brunetti-Pierri[1].* 1) Dept Molecular & Human Genetics, Baylor Colllege of Medicine, Houston, TX; 2) Dept Pediatric Cardiology, Baylor College of Medicine, Houston, TX.

Helper-dependent adenoviral (HDAd) vectors result in long-term transgene expression without chronic toxicity and therefore, they hold tremendous potential for liver-directed gene delivery for the treatment of inborn errors of hepatocyte metabolism including hemophilias. The rhesus macaque is an excellent nonhuman primate animal model for preclinical testing of hemophilia B gene therapy. The administration of first generation adenoviral (FGAd) vectors in rhesus macaques resulted in short term human Factor IX (hFIX) expression and the induction of high-titer, neutralizing anti-hFIX antibodies. The formation of neutralizing anti-hFIX antibodies by FGAd is a serious concern for gene therapy applications and therefore it should be carefully evaluated in the preclinical studies for HDAd vectors. Towards this goal, we have administered an HDAd expressing hFIX to four rhesus macaques through a balloon catheter strategy that we have previously developed. In this approach a balloon catheter is percutaneously positioned in the inferior vena cava to occlude hepatic venous outflow and $1x10^{11}$ or $1x10^{12}$ vp/kg of an HDAd expressing hFIX was injected into the liver via a hepatic artery catheter. To date, all four animals have exhibited sustained, therapeutic levels of hFIX and absence of neutralizing anti-hFIX antibodies. These results suggest that in contrast to FGAd, HDAd vectors can drive long-term FIX expression and do not result in neutralizing anti-hFIX antibody formation. Therefore, HDAd are attractive vectors for hemophilia B gene therapy.

### 3154/F/Poster Board #1086

**Efficient dystrophin restoration in mdx mice skeletal muscles is induced by ZM2 nanoparticles-AON complexes.** *P. Rimessi[1], M. Fabris[1], E. Bassi[1], S. Falzarano[1], P. Sabatelli[1,2], G. Vattemi[3], D. Perrone[4], F. Gualandi[1], N.M. Maraldi[5], L. Merlini[1], K. Sparnacci[6], M. Laus[6], P. Bonaldo[7], P. Braghetta[7], A. Ferlini[1].* 1) Dept Medical Genetics, University of Ferrara, Ferrara, Italy; 2) IGM-CNR, Unit of Bologna c/o IOR, Bologna, Italy; 3) Department of Neurological Sciences and Vision, Section of Clinical Neurology, University of Verona, Verona, Italy; 4) Department of Biology and Evolution, University of Ferrara, Ferrara, Italy; 5) Department of Human Anatomical Sciences, University of Bologna and Laboratory of Cell Biology, IOR, Bologna, Italy; 6) Department of Environmental and Life Sciences INSTM, University of Piemonte Orientale, Alessandria, Italy; 7) Department of Histology, Microbiology, and Medical Biotechnology; University of Padova, Padova, Italy.

Therapeutic approaches for Duchenne muscular dystrophy (DMD) represent now a realistic hope. However, obstacles must be overcame as optimising the non-toxic effective doses, improving the delivery system, reaching all affected tissues, obtaining a sustainable therapeutic effect, finding an easy-handling way of administration in view of life-long treatment. In this study we describe novel core-shell nanoparticles (marked as ZM2) we designed and prepared. These cationic nanoparticles are made up of a core of N-isopropil-acrylamide+ (NIPAM), and surrounded by a shell bearing cationic groups. The adsorption of 2'-O-methyl full-length phosphorothioate (2OMePS) AON onto ZM2 nanospheres, resulted in a high loading value, corresponding to 90 μg of AON per mg of nanoparticles. We injected intraperitoneally the ZM2/AON compound (7.5 mg/Kg of AON) in mdx mice for 7 weeks (1/week), and 1 week after the last administration we performed tissues analysis. Since counting positive fibers is considered a fundamental parameter for evaluating the dystrophin restoration efficiency, we compared two independent methods, the first manual and the second represented by a novel semi-automated and semi-quantitative using a software we developed in cooperation with Nikon (NIS-Elements 3.0 AR imaging program, Nikon). The two different approaches gave quite similar results, with dystrophin positive fibers ranging from 40% and 35%.RT-PCR and exon specific Real time RT-PCR assays showed an exon 23 skipping percentage of 10% in skeletal muscles. Western blotting analysis showed the presence of high molecular weight dystrophin protein in ZM2-AON compound treated mdx mice. In conclusion, this novel ZM2-AON compound greatly enhances the dystrophin restoration in the skeletal muscles of the mdx mice, confirming that these NPs represent a very promising vehicle for systemic delivering of AONs. The combination of slow release and depot effects, together with the protection from degradation/sequestration and the high AON binding capacity of this novel ZM2 NPs could be responsible for the relevant efficacy and efficiency. ACKNOWLEDGMENTS The Telethon Italy grants GGP05115 and GUP07011 (both to A.F.). Thanks are also due to Prof. A. Medici (Dept of Chemistry, University of Ferrara) and to the Industria Chimica Emiliana (ICE Reggio Emilia) Grant (to AF), to TREAT-NMD Network of Excellence of EU FP7 n. 036825 (to LM and Telethon-Italy).

## 3155/F/Poster Board #1087

**Manipulating Gene Splicing to Rescue Common Mutations in Metabolic Disorders.** *L.M. Vincent, S.G. Ziegler, R. Hess, W. Westbroek, W.A. Gahl, M. Huizing.* Med Gen Br, NHGRI/NIH, Bethesda, MD.

Certain rare disorders, including the Hermansky-Pudlak (HPS), Griscelli (GS), and Chediak-Higashi syndromes (CHS), result from defects in the biogenesis of lysosome-related organelles (LROs), such as melanosomes in melanocytes, lytic granules in lymphocytes, and delta granules in platelets. Some clinical characteristics of LRO disorders include albinism, bleeding diathesis, infections, neurological impairment, and fatal pulmonary fibrosis. Directed therapy is difficult since little is known about the protein functions in LROs. In view of successful advances in therapeutic exon skipping (e.g., Duchene Muscular Dystrophy), we applied anti-sense morpholino oligonucleotides (MOs) to patients' cells to induce in-frame skipping of one or more exons carrying deleterious mutations that result in HPS type 1 (HPS-1) or CHS. RT-PCR analysis confirmed that all our MOs had at least 75% efficacy in removing their exon targets. Immunofluorescence (IF) staining against the melanosomal protein TYRP1 detected melanosome trafficking defects (lack of accumulation in dendritic tips) that are typical for HPS-1. MOs targeting *HPS1* exons 12 and 13 induced this phenotype in normal melanocytes and consequently failed to rescue the phenotype in patients' cells. Interestingly, an *HPS1* exon 15 MO, which targets the major 16bp duplication Puerto-Rican founder mutation, achieved partial rescue of the HPS-1 phenotype. Ongoing immunoblot assays against HPS1 and HPS4, which interact in the Biogenesis of Lysosome-related Organelles Complex (BLOC)-3, will further verify cellular functionality of these exon-skipped HPS1 isoforms. We also targeted CHS-causing mutations in the ARM/HEAT repeats of the gene *CHS1/LYST*. IF staining against lysosome associated membrane protein-3 (LAMP-3) of patients' fibroblasts detected the enlarged lysosomes typical for CHS. Removal of ~120kDa of CHS1, through concurrent skipping of exons 4, 5, and 6, induced a severe CHS phenotype in normal fibroblasts indicating significant loss of CHS1 function, while skipping of exons 11 and 12 only induced a mild loss of CHS1 function. Ongoing studies will determine if the skipping of exons 11 and 12 can rescue patients' fibroblasts. The transition from normal to defective HPS1 or CHS1 function can be followed using MOs and cell biological techniques to investigate the basic defect in these diseases. Thus, MO-induced exon skipping has the potential for determining the mechanism of action and treatment of genetic disorders.

## 3156/F/Poster Board #1088

**Antisense RNA/ethylene-bridged nucleic acids chimera induces exon skipping and restores dystrophin expression in myocytes of Duchenne muscular dystrophy.** *M. Yagi, Y. Yamauchi, H. Awano, Y. Takeshima, M. Matsuo.* Dept Pediatrics, Kobe Univ Graduate Sch Med, Kobe, Japan.

Duchenne muscular dystrophy (DMD) is a progressive muscle wasting disease, succumbing at twenties and caused by mutations in the dystrophin gene. Nearly two thirds of DMD cases are found to have exon deletion mutations in the dystrophin gene and shift the reading frame of dystrophin mRNA, thereby creating a stop codon. As a result, dystrophin is deficient in their muscle. On the other hand, mild Becker muscular dystrophy (BMD) is shown to have in-frame deletion mutation is the dystrophin gene, enabling truncated dystrophin production. It is supposed that transformation of an out-of-frame mutation into an in-frame mutation is a way of DMD treatment. We have long proposed that induction of exon skipping by antisense oligonucleotides is the most plausible therapy for DMD. Previous studies have demonstrated antisense phospholothioate oligonucleotides induced exon 19 [Pramono et al. 1996] and artificial induction of exon 19 skipping led to muscle dystrophin expression in vitro and in vivo [Takeshima et al. 2001][Takeshima et al. 2006]. Taken it into consideration that a 2'-O, 4'-C-ethlene-bridged nucleic acid (ENA) is highly nuclease-resistant and thermodynamically stable, we reported that an antisense RNA/ENA chimera was 40 times as effective as corresponding conventional phosphorotioate oligonucleotides in inducing exon 19 skipping [Yagi et al., 2004]. To develop the broad therapeutic applicability of this exon skipping strategy, it is necessary to identify the specific antisense oligonucleotides that can accurately and efficiently skip exons located in the deletion hot spots in the dystrophin gene. We focus to induce skipping of exon 45 that is located in one of the deletion hot spots. We designed many antisense RNA/ENA chimeras against exon 45 and examined their ability to induce exon skipping. The best antisense RNA/ENA chimera could induce exon 45 skipping in cultured myotubes from DMD patients with different types of deletions mutations neighboring exon 45. Remarkably, 100% of the dystrophin mRNA obtained from cultured myotubes with the antisense oligonucleotides treatment lacked exon 45. The production of dystrophin in treated myotubes was also confirmed. Our results make dystrophin expression possible in a broader spectrum of DMD cases.

**Evaluation of gene therapy for Hereditary Inclusion Body Myopathy (HIBM) using GNE-Lipoplex.** *T. Yardeni[1,4], C. Ciccone[1], J. Poling[1], L.M. Vincent[1], K. Patzel[1], I. Manoli[1], S. Hoogstraten-Miller[2], T. Ferrine[2], D. Darvish[3], Y. Anikster[4], J. Nemunaitis[5], P. Maples[5], C. Jay[5], W.A. Gahl[1], M. Huizing[1].* 1) Medical Genetics Branch, NHGRI/ NIH, Bethesda, MD; 2) OLAM, NHGRI, NIH, Bethesda, MD; 3) HIBM Research group, Encino, CA; 4) Tel-Aviv University, Sackler Faculty of Mdicine, ISRAEL; 5) Gradalis Inc., Dallas, TX.

HIBM is an adult-onset, progressive neuromuscular disorder, caused by *GNE* mutations. *GNE* encodes the ubiquitously expressed, key enzyme in sialic acid (SA) synthesis, UDP-GlcNAc 2-epimerase/ManNAc kinase. We created an HIBM mouse model, mimicking the Persian-Jewish founder mutation M712T. Mutant mice unexpectedly died before day 3 of life (P3) from severe glomerulopathy due to hyposialylation. Administration of the SA precursor ManNAc led to improved glomerular sialylation and survival of mutant pups beyond P3. We are pursuing a therapeutic trial for HIBM using ManNAc, which has yet to be approved by regulatory authorities. In addition to this proposal to manipulate compounds in the SA pathway, delivery of an intact *GNE* gene may be a feasible treatment option. We created a human non-viral GNE-plasmid embedded in cationic liposomes (*h*GNE-lipoplex), which was administered via intramuscular injection (biceps and extensor carpi radialis longus) to one HIBM patient. The patient showed no adverse effects and her arm muscle strength improved moderately. To proceed with *h*GNE-lipoplex intravenous (IV) or intrahepatic (the major organ of SA synthesis) injections in patients, we tested these treatments in our HIBM mice. *h*GNE-lipoplex was injected IV (retro-orbitally) and intra-hepatically in litters at age P1. Survival beyond P3 was the initial outcome parameter. The major tissues of treated mice were assessed at P5 for *h*GNE expression, glomerular disease, sialylation, and histology. Intrahepatic treatment yielded survival of all wild type (+/+) and heterozygous (+/-) pups, but just one of 8 mutants survived beyond P3; that pup had increased sialylation of the glomerular glycoprotein podocalyxin at P5. IV injections resulted in no surviving mutants beyond P3; however, some +/- pups died as well, indicating possible lethality of the injection method. Surviving +/+ showed *h*GNE expression in liver and kidney at P5, indicating no toxicity of *h*GNE-lipoplex and effective gene delivery to these tissues. It is possible that *h*GNE-lipoplex treatment at P1 (untreated mice die at P3) may not allow enough time for *h*GNE protein to be expressed and to produce enough SA, whereas the ManNAc treatment immediately delivers the substrate, bypassing the critical GNE processing step, allowing for faster production of SA. Further animal studies are planned to elucidate the timing and efficacy of GNE-lipoplex therapy.

**AAV2/8-Mediated Gene Therapy Provides Prolonged Protection Against Biochemical Induction of Acute Attacks and Improves Motor Function in Acute Intermittent Porphyria Mice.** *M. Yasuda[1], D.F. Bishop[1], M.E. Fowkes[2], S.H. Cheng[3], L. Gan[1], R.J. Desnick[1].* 1) Gen & Genomic Sci, Mount Sinai Sch Med, New York, NY; 2) Pathology, Mount Sinai School of Medicine, New York, NY; 3) Genzyme Corporation, Framingham, MA.

Acute Intermittent Porphyria (AIP) is an autosomal dominant inborn error of hepatic heme biosynthesis due to the half-normal activity of hydroxymethylbilane synthase (HMB-synthase). Patients with AIP are prone to life-threatening acute neurological attacks that are precipitated by various factors (e.g., fasting, cytochrome P450 inducing drugs, menstruation, alcohol, etc.) that induce hepatic heme biosynthesis and result in increased plasma and urinary $\delta$-aminolevulinic acid (ALA) and porphobilinogen (PBG). The acute attacks are currently treated with intravenous hematin, but a more continuous therapy is needed, particularly for patients experiencing frequent attacks. Thus, a recombinant AAV8-based serotype vector expressing murine HMB-synthase driven by the liver-specific $\alpha$1-microglobin enhancer and $\alpha$1-antitrypsin promoter was generated, and its effectiveness to prevent the biochemical induction of an acute attack was evaluated in an AIP mouse model with ~30% residual HMB-synthase activity. Intraperitoneal administration of the AAV vector resulted in a rapid and dose-dependent increase of HMB-synthase activity, most marked in the liver. Administration of 7.6 x $10^{11}$ viral particles achieved wild-type or greater levels of HMB-synthase activity that were stably sustained for over 40 weeks. Treated mice were resistant to the characteristic accumulation of urinary ALA and PBG when periodically challenged with intraperitoneal injections of phenobarbital, a potent inducer of hepatic heme biosynthesis, thus indicating that the expressed enzyme was functional *in vivo*. Notably, the treated mice performed significantly better on rotarod and footprint analyses compared to untreated controls at 32 weeks of treatment, although AAV therapy did not prevent the development of peripheral motor neuropathy. In conclusion, these studies demonstrated successful long-term correction of the hepatic metabolic abnormalities and improvement of motor function, and thus provide the rationale for the development of AAV-mediated therapy for patients with recurrent AIP attacks.

**Development of Functionalized Mesoporous Silica Nanoparticles as Potential Hepatic Theranostic Agents.** *Y.H. Zhang[1], B.L. Huang[1], M. Liong[2], N. Henderson-MacLennan[1], J. Zink[2,3], E.R.B. McCabe[1,3,4].* 1) Dept Pediatrics, UCLA Sch Medicine, Los Angeles, CA; 2) Dept Chemistry and Biochemistry, UCLA, Los Angeles, CA; 3) California NanoSystems Institute, UCLA, Los Angeles, CA; 4) Department of Human Genetics and Bioengineering, UCLA, Los Angeles, CA.

Mesoporous silica nanoparticles (MSNPs), functionalized with tissue-specific ligands, iron oxide cores and therapeutic drugs, have been used for targeting, imaging and drug therapy in culture (Liong et al. ACS Nano 2:889-896, 2008). Lactobionic acid (LA) is galactose chemically linked to gluconic acid, and is reported to be a specific ligand for the hepatocyte-specific asialoglycoprotein receptor (ASGPR). LA-conjugated particles have been used in culture and in vivo (Kamruzzaman Selim et al. Biomaterials 28:710-716, 2007), but not with MSNPs. Our goal is to develop a hepatocyte-specific delivery system for improved diagnostics (e.g. enhanced MRI) and therapeutics (e.g. small molecules, DNAs and proteins), referred to as "theranostics." We coupled MSNPs with LA (LA-MSNPs) and tested intracellular uptake and toxicity. Preliminary cell culture experiments showed that LA-MSNPs were internalized into HepG2 cells. We are evaluating the uptake of LA-MSNPs into HepG2 cells compared with MCF7 (breast adenocarcinoma) cells. We are also comparing the uptake of LA-MSNPs with uptake of unmodified MSNPs. The preliminary experiments indicated that the LD50 for LA-MSNPs, as a measure of cytotoxicity, was 2000ug/ml despite substantial, receptor-mediated association with HepG2 cells. These data suggest relatively low toxicity. We are testing the LA-MSNPs in cell lines before testing these in vivo to optimize the functionalized MSNPs before investing the time and money on whole animal experiments. We speculate that theranostic nanoparticles will gain broad application in the diagnosis and treatment of genetic diseases.

## 3160/F/Poster Board #1092

**Clinical phenotype of Becker muscular dystrophy patients with deletions generated by exon 51 skipping.** *A.T.J.M. Helderman-van den Enden[1], C.S.M. Straathof[2], A. Aartsma-Rus[1], J.T. den Dunnen[1], B.M. Verbist[3], E. Bakker[1], J.J.G.M. Verschuuren[2], H.B. Ginjaar[1].* 1) Center for Human and Clinical Genetics Leiden University Medical Center, Leiden, Netherlands; 2) Department of Neurology of the Leiden University Medical Center; 3) Department of Radiology of the Leiden University Medical Center.

Mutations in the dystrophin-encoding DMD gene on the X chromosome result generally in Duchenne muscular dystrophy (DMD) if the mutation is out-of-frame and in Becker muscular dystrophy (BMD) if the mutation preserves the reading frame. Consequently, in BMD patients an altered form of dystrophin is present that is partially functional, whereas in DMD patients dystrophin is virtually absent in muscle fibers. DMD patients may benefit from antisense-mediated skipping of exon 51 to restore the reading frame, which would result in the production of a shortened, Becker-like dystrophin protein. The course and prognosis of DMD patients could then be converted into that of BMD, if these antisense oligonucleotides (AON) can be successfully delivered to all skeletal muscles. Local intramuscular treatment with AON was successful in a DMD patient with an exon 50 deletion. Systemic antisense-mediated exon skipping is currently tested in phase I/II clinical trials. We describe the clinical features in two adult Becker patients with a deletion of exons 45-51 and in one schoolboy with a deletion of exons 50-51 of the DMD gene. They all had minimal complaints and no restrictions in daily life. The sharp contrast in clinical features between the severe exon 50 related DMD phenotype and the mild exon 50-51 BMD phenotype suggests that early AON treatment of DMD patients could have a major impact on clinical outcome.

## 3161/F/Poster Board #1093

**Novel approaches for characterizing molecular networks involved in the maintenance of skeletal muscle mass.** *E. Andres-Mateos[1], T.N. Burks[1], R. Marx[1], J.L. Simmers[1], E.M. MacDonald[1], T.G. Marr[3], D.K. Vaughan[4], R.D. Cohn[1,2].* 1) Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Department of Pediatrics and Neurology, Johns Hopkins University School of Medicine, Baltimore, MD; 3) Hiberna Corporation, Boulder, CO; 4) Department of Biology and Microbiology, University of Wisconsin Oshkosh, Oshkosh, WI.

A plethora of genetic disorders is associated with significantly decreased skeletal muscle mass and concomitant muscle weakness and atrophy. These conditions include, but are not limited to, primary skeletal muscle disorders such as muscular dystrophies, structural myopathies and metabolic myopathies. Loss of skeletal muscle mass can also be observed in a variety of peripheral and/or central nervous system disorders such as the mitochondriopathies, spinal muscular atrophy and amyotrophic lateral sclerosis. The underlying pathogenetic phenomena can vary but are generally thought to be the net result of perturbed satellite cell function accompanied by increased muscle proteolysis and decreased protein synthesis. In stark contrast, hibernating mammals have evolved to survive prolonged periods of immobilization without any significant loss of muscle mass. The molecular mechanisms underlying this phenomenon are poorly understood, and we therefore explored the molecular pathways involved in the maintenance of muscle mass in the hibernating 13-lined ground squirrel (Spermophilus tridecemlineatus). Comparative analysis of various skeletal muscles from hibernating and non-hibernating squirrels reveals no significant differences in the morphology or size of the muscle fibers, but in hibernating animals, we do observe a switch from fast-type muscle fibers to slow-type fibers, which are more resistant to injury. Further molecular analysis during hibernation demonstrates a downregulation of muscle atrophy pathways that involve FOXO3a, independent of the activation of Akt. Interestingly, we also observe an up-regulation of AMPK and an increased expression of PGC-1$\alpha$. Moreover, we find an increased expression of anti-apoptotic proteins during hibernation. In summary, our results demonstrate for the first time that a remarkable pattern of decreased proteolysis is accompanied by increased mitochondrial metabolism and protection against apoptosis,in a physiological animal model of prolonged immobilization. Thus, our data provide new insights into the molecular pathways involved in maintenance of muscle mass and protection against atrophy. This approach will enable us to identify the key regulatory molecules responsible for these pathway alterations, opening new avenues for therapeutic interventions in patients with a variety of inherited and acquired forms of skeletal muscle atrophy and degeneration.

## 3162/F/Poster Board #1094

**Use of intravenous ketamine in pain management in NF1-associated glomus tumors: A case report.** *S. Coombes[1], A. Mannes[2], D. Stewart[1].* 1) NHGRI, Bethesda, MD; 2) NIH Clinical Center, Bethesda, MD.

Glomus tumors are small, benign tumors that arise from the glomus body, a thermoregulatory shunt concentrated in the fingertips. Glomus tumors are associated with the monogenic tumor-predisposition disorder neurofibromatosis type 1 (NF1). Glomus tumors often present with a triad of tenderness, cold insensitivity and paroxysmal pain. In our experience with 4 adults with NF1, surgical excision is often, but not always, curative. Pain recurrence could not always be attributed to identifiable recurrent tumor burden. We present a case report of a 37-year-old Hispanic female with NF1and multiple glomus tumors of the fingers. At the time of her presentation, she had a 5-year history of severe pain in the 3rd, 4th and 5th digits of both hands that left her unable to work. Her symptoms and imaging of the hands were consistent with glomus tumors and the complex regional pain syndrome (CRPS). Over a period of 2 years, she underwent three surgeries (including glomus tumor excision and neurectomy) on her fingers, however, after a short period of relief, her pain would return. Conventional treatment strategies, including gabapentin, pregabaline, local blocks, topical lidocaine, hydromorphone and methadone did not provide adequate relief. Multiple stellate ganglion blocks provided only temporary relief. Given the intractability of her pain, we administered low-dose (10 $\mu$g/kg/hr) intravenous ketamine over three days. She also received serial bupivacaine blocks of the left fourth digit. Prior to treatment, she reported 10/10 pain, especially in the fourth finger of the left hand. She also had hyperesthesia, allodynia, and flushing of the left hand. The fingertip of the left fourth finger was visibly swollen. After 3 days of intravenous ketamine, she reported 3/10 pain in the left fourth digit. The swelling of the left fourth digit had resolved. At eight weeks of follow-up, she reports that her fingers remain essentially pain-free. She also reports that her frequent migraine headaches and sciatica symptoms have also resolved since the ketamine infusion. Treatment with intravenous ketamine appears to be successfully controlling this patient's severe, refractory pain secondary to CRPS.

**Landscape analysis of biobanks and registries as a tool to enhance translational research systems.** *S.F. Terry, J. Bialick, K. Zonno, L. Horn.* Genetic Alliance, Washington, DC.

Clinical data registries and biospecimen repositories are crucial for enabling translational research by providing samples for gene discovery, study of disease biology and pathways, and development of new tests and targeted therapies. Redundant repositories and registries for specific diseases are abundant and new registries and biobanks are proliferating around institutions, communities and states. The registry and biobank landscape is highly variable, both in purpose and process. In an attempt to understand the variability and discern best practices, we undertook a landscape analysis in May 2009 to examine registries' and biorepositories' structures and processes. A comprehensive survey regarding the following aspects of registries and biobanks was sent out within the field: collection and storage of clinical data and specimens, confidentiality, privacy, and security of data and samples, regulatory compliance, as well governance, management and finances. Using the listserv of the professional society of biobank directors, as well as direct contact with many biobank directors, we were able to survey them. Results showed a wide variety of methods for data collection and storage, highly variable consenting processes, generally poor privacy protections, very little donor-centric focus and disparate regulatory compliance. Furthermore, none of the biobanks surveyed indicated that they had any ability to collect patient data from an EMR/PHR system despite the fact that nearly half stored their information in a secure online server. Of great concern in a general lack of interoperability, and little attention to standardized language. The data gathered led to registry and biobank best practices and recommendations. These are useful to both the registry and biobanking industry and also to policy makers as these repositories become more ubiquitous.

## 3164/F/Poster Board #1096

**Brain delivery of recombinant acid sphingomyelinase by ICAM-1-targeted nanocarriers.** *C. Garnacho[1], R. Dhami[2], E. Schuchman[2], S. Muro[1,3].* 1) Center for Biosystems Research, U. Maryland Biotechnology Institute, College Park, MD; 2) Dept. of Genetics and Genomics Sciences, Mount Sinai School of Medicine, New York, NY; 3) Fischell Dept. of Bioengineering, U.Maryland College Park, College Park, MD.

Genetic deficiency of acid sphingomyelinase (ASM) causes types A and B Niemann-Pick disease (NPD), leading to aberrant lysosomal accumulation of sphingomyelin and cholesterol, multi-organ dysfunction, and premature mortality, which in Type A NPD is due to neurological defects. Enzyme replacement therapy (ERT) by intravenous infusion of recombinant ASM shows promising therapeutic potential, yet this strategy is suboptimal for enzyme delivery to the brain. As an example to overcome this obstacle, we coupled ASM to polymer nanocarriers targeted to intercellular adhesion molecule-1 (ICAM-1), a surface protein abundantly expressed in diseased brain endothelium, as well as neuronal and glial cells. ASM was absorbed on 180 nm poly(lactic-co-glycolic acid) nanocarriers coated with anti-ICAM (anti-ICAM/ASM NCs). C57Bl/6 and ASM knockout mice were injected with anti-ICAM/125I-ASM NCs vs naked 125I-ASM, and the isotope content was determined from blood and brain 30 min post-injection. Data were calculated as percent of the injected dose (% ID) and brain/blood localization ratio (LR, %ID per gram of tissue / %ID per gram of blood). Brain targeting was also visualized by fluorescence microscopy using polystyrene anti-ICAM/ASM NCs or control IgG/ASM NCs. Although naked 125I-ASM was detected in the brain (0.32±0.06 %ID), a high fraction of the enzyme was in circulation 125I-ASM at that time (32.7±5.9 %ID). Hence, the brain/blood localization ratio for 125I-ASM was 0.04±0.01. In contrast, anti-ICAM/125I-ASM NCs were detected in the brain (0.3±0.02 %ID) but the fraction of carriers in circulation was significantly lower (12.2±0.06 %ID), and the brain/blood localization ratio was 0.12±0.01. Therefore, brain-tissue targeting of anti-ICAM/125I-ASM/NCs was ~3 fold over that of the naked enzyme. Fluorescence microscopy confirmed specific targeting of anti-ICAM/ASM NCs in the brain. Anti-ICAM/ASM NCs had a different distribution pattern at 5-15 min versus 30-60 min post-injection. At earlier time points anti-ICAM/ASM NCs looked scattered on the brain vasculature, whereas the carriers formed ring-like structures at the later time points, suggesting endocytic transport to perinuclear lysosomes. Therefore, ICAM-1-targeted nanocarriers hold promise to enhance brain targeting of enzyme replacement for NPD and, likely, other lysosomal disorders.

## 3165/F/Poster Board #1097

**Improved delivery of alpha-galactosidase to Fabry disease endothelial cells by ICAM-1-targeted nanocarriers.** *J. Hsu[1], D. Serrano[2], C. Garnacho[3], S. Muro[1,3].* 1) Fischell Dept. of Bioengineering, U. Maryland College Park, College Park, MD; 2) Cell Biology and Molecular Genetics, U. Maryland College Park, College Park, MD; 3) Center for Biosystems Research, U. Maryland Biotechnology Institute, College Park, MD.

Fabry disease is a lysosomal storage disorder (LSD) characterized by genetic deficiency of $\alpha$-Galactosidase A ($\alpha$-Gal), which causes aberrant intracellular storage of globotriaosylceramide (Gb3). It mainly affects vascular endothelial cells (ECs), resulting in vascular lesions, myocardial ischemia, hypertension, cerebrovascular damage, thrombosis, and premature death. Enzyme replacement therapy (ERT) by infusing recombinant $\alpha$-Gal in circulation is an available treatment for Fabry disease. However, lack of specific affinity of this enzyme to ECs results in rapid clearance from the bloodstream. To overcome this obstacle, we propose to target $\alpha$-Gal to intercellular adhesion molecule 1 (ICAM-1), an EC surface molecule highly expressed in diseased endothelium. To evaluate this strategy we coupled model coffee bean $\alpha$-Gal and anti-ICAM to the surface of 100 nm, FITC-labeled polystyrene prototypes or biodegradable PLGA nanocarriers (anti-ICAM/$\alpha$-Gal NCs), and tested their binding, endocytosis, lysosomal transport, and Gb3 degradation (vs that of naked $\alpha$-Gal) by fluorescence microscopy in macro- and micro-vascular ECs, either control or treated with deoxygalactonojirimycin and TNF$\alpha$ to mimic Gb3 accumulation and inflammation in Fabry disease. Anti-ICAM NCs bound specifically to both EC types, validating the adequacy of this strategy for targeting these two distinct vascular beds. Targeting was similar for control cells and the Fabry model, and was not compromised by coating $\alpha$-Gal along with anti-ICAM on the carrier surface. ECs internalized >80% anti-ICAM/$\alpha$-Gal NCs within 1 h, which was mediated via amiloride-sensitive ICAM-mediated endocytosis, distinct from the clathrin mechanism utilized for classical Fabry disease ERT. Anti-ICAM/$\alpha$-Gal NCs were transported to Texas red dextran-labeled lysosomes and co-localized with intracellular Gb3 by 3-5 h after their uptake by ECs. Finally, incubation of cells with chloroquine (to neutralize the lysosomal pH and inhibit endogenous lysosomal enzymes while permitting activity of the coffee bean $\alpha$-Gal) and anti-ICAM/$\alpha$-Gal NCs resulted in the reduction of Gb3 accumulation to control values in Fabry EC models, vs naked Gb3 which only partially attenuated Gb3 accumulation. These results indicate that ERT assisted by ICAM-1-targeted nanocarriers has the potential to evolve into a new ERT for Fabry disease and, perhaps, other LSDs.

## 3166/F/Poster Board #1098

**Enhanced delivery of lysosomal enzyme replacement therapies by targeting ICAM-1 versus receptors of clathrin and caveolar endocytic pathways.** *M. Meng[1], C. Garnacho[2], S. Muro[2,3].* 1) Dept. of Pharmacology, University of Pennsylvania School of Medicine, Philadelphia, PA; 2) Center for Biosystems Research, U. Maryland Biotechnology Institute, College Park, MD; 3) Fischell Dept. of Bioengineering, U. Maryland College Park, College Park, MD.

Genetic deficiency of acid sphingomyelinase (ASM) causes Niemann-Pick disease (NPD), leading to excess lysosomal storage of sphingomyelin and cholesterol, neurologic and pulmonary pathology. Enzyme replacement therapy (ERT) by infusion of recombinant ASM is based on the presence of mannose-6-phosphate on this enzyme, which target ASM to cell receptors mediating lysosomal delivery via clathrin pits. However, the efficacy of this strategy is suboptimal. Targeting ASM to the cell adhesion molecule ICAM-1, by coupling ASM to anti-ICAM nanocarriers, switched the uptake pathway from clathrin pits to non-classical cell adhesion molecule (CAM) endocytosis and improved ASM delivery in vitro and in vivo. To define parameters which provide such an enhanced delivery, we compared the accessibility of ICAM-1 to that of receptors of classical endocytosis, and explored how NPD lipid storage affects classical vs CAM endocytosis required for intracellular ASM delivery. Isotope tracing in mice showed that antibodies to transferrin receptor and PV1 (the protein of caveolae diaphragm), associated to clathrin- and caveolar- pathways, only accessed their targets from the circulation when administered as free counterparts (12.5±3.5 and 17.4±0.3 % injected dose, ID, in lungs) but not when coupled to carriers (0.8±0.02 and 3.5±0.4 %ID in lungs). Contrary, ICAM-1 was accessible to both free anti-ICAM (6.5±0.2 %ID in lungs vs 1.2±0.2 % for IgG) and anti-ICAM nanocarriers (25.5±1.6 %ID in lungs vs 1.3±0.3 % for IgG nanocarriers). In cell culture, fluorescence tracing showed that clathrin-mediated uptake of transferrin was decreased in NPD fibroblasts (71±3 % of control), which also displayed altered clathrin recruitment to transferrin binding sites (17±2% co-localization in NPD cells vs. 69±9% in normal cells). Disease cells also showed decreased caveolar-mediated uptake of cholera toxin (70±9 % of normal cells) and abnormal recruitment of caveolin-1 to cholera toxin binding sites (7±2% co-localization in NPD cells vs. 83±3% in normal cells). Contrary, CAM-mediated endocytosis of anti-ICAM nanocarriers was not affected in NPD fibroblasts (102±7% of control). Hence, both high accessibility of ICAM-1 to anti-ICAM nanocarriers and efficient CAM endocytosis, as opposed to determinants and pathways of classical endocytosis, support enhanced ASM delivery by anti-ICAM nanocarriers and may represent a valuable means to improve ERT for NPD and, likely, other lysosomal storage disorders.

## 3167/F/Poster Board #1099

**Disabling autophagy in skeletal muscle permits fully effective enzyme replacement therapy in a lysosomal storage disease, Pompe Disease.** *N. Raben, C. Schreiner, R. Baum, S. Takikita, P. Plotz.* NIAMS, ARB, NIH, Bethesda, MD.

Autophagy, a major pathway for delivery of proteins and organelles to lysosomes, has been implicated in many cellular and developmental processes and in several human diseases, including Pompe disease, a lysosomal storage disorder caused by deficiency of acid alpha-glucosidase (GAA). The enzyme is responsible for the breakdown of glycogen within the lysosomes. Clinically the disease manifests as a profound cardiac and skeletal muscle myopathy. The current enzyme replacement therapy (ERT) with recombinant GAA (Myozyme, Genzyme Corp.) clears glycogen effectively in the heart, but substantially less so in skeletal muscle. In our GAA KO model and in patients with Pompe disease, we have observed an upregulation of autophagy and large pools of autophagic debris in skeletal muscle cells. In the Pompe mice, the autophagic buildup and the resistance to therapy are linked and limited to fast fibers. Since autophagy is a presumed mechanism of glycogen delivery to the lysosomes we tried to reduce both the amount of lysosomal glycogen and the autophagic accumulation by knocking out either Atg5 or Atg7, two critical autophagic genes, in the skeletal muscle of Pompe mice. Suppression of autophagy alone resulted in a somewhat diminished glycogen load. Following ERT, however, the skeletal muscle glycogen was reduced to normal or near normal levels. This successful clearance of lysosomal glycogen has never been observed in Pompe mice with genetically intact autophagy. Furthermore, following ERT, these glycogen-free lysosomes became functionally competent, as evidenced by a dramatic reduction in the level of ubiquitinated proteins. Because this therapeutic approach leaves muscle cells deficient in autophagy, we analyzed muscle-specific autophagy-deficient wild type mice. We have found that disabling autophagy in skeletal muscles of wild type mice has no significant effect on their apparent strength, mobility, weight, or lifespan. We are currently exploring the feasibility of autophagy suppression in skeletal muscle on a temporary basis as a therapeutic approach. It has recently become clear that the upregulation of autophagy is a common feature in a variety of lysosomal storage disorders; therefore, the suppression of autophagy may have a broad application to these and other classes of diseases with autophagic dysfunction.

## 3168/F/Poster Board #1100

**Cystine Depletion of Cystinotic Fibroblasts by Cystinosin.** *J. Thoene, M. Witcher.* Pediatrics, D5420 MPB0718, Univ Michigan, Ann Arbor, MI.

Cystinosis results from defective lysosomal cystine transport, leading to lysosomal cystine storage. Cystinosin, encoded by CTNS, at 17p13.3, functions to move cystine from the lysosome. To determine if cystinosin administration to cultured cystinotic fibroblasts could correct cystine storage, the human cystinosin gene was subcloned into pFastBacHTA vector and the resulting construct transformed into E.coli DH10Bac to generate recombinant Bacmid. Positive colonies were selected by Gm, Tet and Kan, followed by PCR identification. The recombinant Bacmid was extracted and then transfected into Sf9 cells to generate the baculovirus, P1 viruses were amplified, and the target protein identified by Western blot using a recombinant antibody to an added 6-His tag on the protein N-terminus. Reactivity was found to remain mainly in the cell pellet, and not seen in the medium.This portion of the work performed under contract by GenScript Corporation. Removal of medium after 5 days incubation on transfected Sf9 cells, dialysis into Ham's F12 and addition of this dialyzed medium (Cys) to cystinotic fibroblasts produced a 63% cystine loss over 4 days compared to negligible loss induced by media from outside the dialysis membrane(Contr).See table. Results are per cent of initial values for two experiments in cell line GM 00008 and 1 in GM 00046. Initial cystine content was 4.56 and 3.48 nmol cystine /mg cell protein for GM00008, and 2.99 in GM 00046. We speculate that cystinosin in the medium is either too dilute, or modified such as not to be seen on Western.

## 3169/F/Poster Board #1101

**Down syndrome, Ts65Dn, mice benefit from neural progenitor cell treatment.** *K.B. Bjugstad[1], S.K. Cornelius[1], E.Y. Snyer[2], K.N. Maclean[1].* 1) Pediatrics, University of Colorado Denver, Aurora, CO; 2) Stem Cells & Regenerative Medicine, The Burnham Institute for Medical Research, La Jolla, CA.

Down syndrome (DS) is the most common cause of genetic mental retardation. It results from the triplication of human chromosome 21. The genes found at 21q21-21q22.3 are associated with the cognitive deficits of DS and may reveal the etiology of Alzheimer's disease (AD). All DS brains examined have amyloid plaques, neurofibrillary tangles, and neuronal loss, decades before the general population. The genes carried on chromosome 21 that might be involved in AD include the amyloid precursor protein, superoxide dismutase 1, and carbonyl reductase. The Ts65Dn mouse is a model of DS /AD, and carries a partial triplication of mouse chromosome 16, the portion that is analogous to 21q21-21q22.3. The triplication of these genes produces a mouse that has many of the cognitive deficits associated with pediatric development and later AD. The trisomic mouse was used to determine if disomic neural precursor cells (NPC) could attenuate cognitive dysfunction and preserve the neuronal population during aging. Young (2m) and aged (10m) trisomic and disomic littermates were implanted bilaterally into the hippocampus with murine-derived NPC (C17.2 line). Three months post-transplant, mice underwent cognitive behavior testing. Young (now 5m) and Aged (now 13m) mice were tested in conditioned taste avoidance (CTA) where learning is determined by the avoidance of a novel flavor. Aged mice were further tested in the Morris water maze (MWM), a task of spatial learning. At the end of behavior testing, brains were examined for preservation of host hippocampal neurons using immunohistochemistry against microtubule associated protein 2(MAP2). Trisomic mice were impaired in the CTA, final MWM latencies, and increased MWM search perseveration. The implantation of NPC improved groups' CTA performance and shortened the trisomic group's final MWM latencies, but had no effect on perseveration. Trisomic mice had fewer CA1 and CA3 neurons than disomic littermates. Aging potentiated neuronal loss in CA3 and dentate gyrus (DG) of trisomic mice. The implantation of NPC increased cell numbers in all aged mice but in the DG, only the trisomic mice benefited. CA1 appeared unaffected by NPC presence. While trisomic mice suffered from various cognitive deficits and possessed fewer hippocampal neurons, implantation of NPC rescued some cognition and preserved neurons in CA3 and DG. These NPC induced effects in both young and aged models of DS, support their potential use as a treatment for DS/AD.

Progressive muscular dystrophies (PMD) are a group of disorders characterized by progressive degeneration of skeletal muscle caused by the absence or defective muscular proteins. The possibility to restore the faulty muscle protein and improve muscular performance by cell therapy is a promising approach for the treatment of PMD. Different animal models are available for pre-clinical studies; however the only animal model that reproduces the full spectrum of human Duchenne Muscular Dystrophy pathology is the Golden Retriever Muscular Dystrophy (GRMD) dog. Affected animals carry a splice site mutation in intron 6 of the dystrophin gene. This mutation predicts a premature termination codon in exon 8 and a peptide that is 5% the size of normal dystrophin. These dogs present clinical signs within the first weeks of life involving the limbs as well as masticatory muscles. Diaphragmatic and intercostal muscles impairment leads to progressive respiratory failure. Death occurs from bronchopneumonia and cardiac arrest, usually before 2 years of age. Here we have injected human adipose-derived stem cells (hADSC) intravenously, without immunosupression, into 2-months old GRMD male dogs. These animals received 5 . $10^7$ cells . kg-1 for six months, weekly in the first month and then monthly. This methodoly was used aiming to compare the results with our previous observed data in the SJL mice model, using the same protocol. We are currently evaluating their ability to: engraft into recipient dystrophic muscle after systemic delivery; form chimeric human/canine muscle fibers; express human muscle proteins in the dystrophic host and improve muscular performance. The results may have important applications for future therapies in patients with different forms of muscular dystrophies. SUPPORTED by FAPESP, INCT, CNPQ and FINEP.
